In this chapter we will look at ADO and *dbGo*. (This set of Delphi components was called ADOExpress but has been renamed dbGo in Delphi 6, because Microsoft has objected to the use of the term *ADO* in product names.) It is possible to use ADO in Delphi without using dbGo. By importing the ADO type library, you can gain direct access to the ADO interfaces; this is, indeed, how Delphi programmers used ADO before the release of Delphi 5. However, this path bypasses Delphi's database infrastructure and ensures that you are unable to make use of other Delphi technologies such as DataSnap. Alternatively, you can turn to Delphi's active third-party market for other ADO component suites such as Adonis, AdoSolutio, Diamond ADO, and Kamiak.

This chapter uses dbGo for all of its examples, not only because it is readily available and supported but also because it is a very viable solution. Regardless of your final choice, you will find the information here useful.

Microsoft Data Access Components (MDAC)

ADO is part of a bigger picture called Microsoft Data Access Components (MDAC). MDAC is an umbrella for Microsoft's database technologies and includes ADO, OLE DB, ODBC, and RDS (Remote Data Services). Often you will hear people use the terms MDAC and ADO interchangeably (but incorrectly) because their version numbers and releases are now aligned. As ADO is only distributed as part of MDAC, we talk in terms of MDAC releases. The major releases of MDAC have been versions 1.5, 2.0, 2.1, 2.5, and 2.6. Microsoft releases MDAC independently and makes it available for free download and virtually free distribution (there are distribution requirements, but almost all Delphi developers will not have trouble meeting these requirements). MDAC is also distributed with most Microsoft products that have some kind of database content. This includes Windows 98, Windows 2000, Windows Millennium Edition, Microsoft Office, Internet Explorer, and SQL Server. In addition, Delphi 6 Enterprise ships with MDAC 2.5, and Delphi 5 Enterprise ships with MDAC 2.1.

There are two consequences of this level of availability. First, it is highly likely that your users will already have MDAC installed on their machines. Second, whatever version your users have, or you upgrade them to, it is also virtually certain that someone, either you, your users, or other application software, will upgrade their existing MDAC to whatever the current release of MDAC is. There is no way you will be able to prevent this, as MDAC is installed with such commonly used software as Internet Explorer. Add to this the fact that Microsoft supports only the current release of MDAC and the release before it, and you are forced to arrive at a conclusion:

> Your applications must be designed to work with the current release of MDAC or the release before it.

If you chart the releases of MDAC, you can expect to see a new version of MDAC every 10 months on average (Delphi itself has a new release every 14 months on average).

As an ADO developer, you should regularly check the MDAC pages on Microsoft's site at `www.microsoft.com/data`. From there you can download the latest version of MDAC for free. At the time of writing, this is MDAC 2.6, which you can download from `www.microsoft.com/data/download_260rtm.htm` (5.2 MB), but you should check for a more recent version first.

While you are on this Web site, you should take the opportunity to download the MDAC SDK (13 MB) if you do not already have it or the Platform SDK (the MDAC SDK is part of the Platform SDK). The MDAC SDK is your bible. Download it and consult it regularly and use it to answer your ADO questions. You should treat this as your first port of call when you need MDAC information. Beyond this, you should read the README files that come with MDAC. Look in `\Program Files\Common Files\System\ADO` for all of the files ending `README.TXT`.

Finally, in getting ready for using ADO in your Delphi applications, you should check for dbGo/ADOExpress updates on Borland's excellent community site (`http://community.borland.com`). Informal patches are released here that are often a must-have. For example, there is a show-stopping problem when using MDAC 2.6 and Delphi 5's ADOExpress, which requires a patch.

OLE DB Providers

OLE DB providers enable access to a source of data. They are ADO's equivalent to the BDE's drivers. However, although the BDE's Driver SDK has been available for many years, there are no third-party BDE drivers. This is not the case for OLE DB providers. MDAC includes many providers that I'll discuss, but many more are available from Microsoft and, more prolifically, the third-party market. It is no longer possible to reliably list all available OLE DB providers, because the list is so large and ever-changing, but here are some of the main vendors of these drivers:

Company	Web Site	OLE DB Provider
B2 Systems	`www.b2systems.com`	SQL Server, Oracle, Sybase, Informix, RDB, DB2, flat files
ISG	`www.isgsoft.com`	ISG Navigator (ISAM, DB2, IMS, Informix, Jasmine, Open Ingres, Oracle, SQL Server, Sybase, Adabas, RDB, RMS, VSAM)
Merant	`www.merant.com`	DB2, Informix, Lotus Notes, SQL Server, Ingres, Oracle, Sybase

You should add to this list almost all database vendors, as the majority now supply their own OLE DB providers. For example, Oracle supplies the ORAOLEDB provider. Notable omissions include InterBase; at the time of writing, Borland doesn't plan to write an OLE DB provider for InterBase. Your only solutions are to access InterBase either using the ODBC Driver, or through Jason Wharton's InterBase provider (`www.ibobjects.com`, although this is still in development) or Dmitry Kovalenko's IBProvider (`www.lcpi.lipetsk.ru/prog/eng/index.html`).

TIP Jason Wharton's OLE DB Provider is additionally interesting because it is written using Binh Ly's OLE DB Provider Development Toolkit (`www.techvanguards.com/products/optk/install.htm`). If you want to write your own OLE DB provider, this is an easier way than most.

MDAC OLE DB Providers

When you install MDAC, you automatically install the OLE DB providers shown in Table 16.1:

TABLE 16.1: OLE DB Providers Included with MDAC

Driver	Provider	Description
MSDASQL	ODBC Drivers	ODBC drivers (default)
Microsoft.Jet.OLEDB.3.5	Jet 3.5	MS Access 97 databases only
Microsoft.Jet.OLEDB.4.0	Jet 4.0	MS Access databases et al.
SQLOLEDB	SQL Server	MS SQL Server databases
MSDAORA	Oracle	Oracle databases
MSOLAP	OLAP Services	Online Analytical Processing
SampProv	Sample provider	Example of an OLE DB provider for CSV files
MSDAOSP	Simple provider	For creating your own providers for simple text data

If you do not specify which OLE DB provider you are using, OLE DB defaults to the ODBC OLE DB Provider, which is used for backward compatibility with ODBC. As you learn more about ADO, you will discover the limitations of this provider. It's probable that you will eventually tire of these limitations, and I recommend that you look from the beginning for an OLE DB provider that is specific to your database rather than struggle with the ODBC OLE DB Provider.

The Jet OLE DB Providers support MS Access and other "desktop" databases. We will return to these providers later.

The SQL Server Provider supports SQL Server 7, SQL Server 2000, and Microsoft Database Engine (MSDE). MSDE is worth taking a moment's thought over. MSDE is SQL Server with most of the tools removed and some code added to deliberately degrade performance when there are more than 5 active connections. MSDE is important for two reasons. First, it is free. You can download it from Microsoft's Web site and, with very few restrictions, distribute it with your application. Second, MSDE is SQL Server. Of course you don't get the

SQL Server tools, and it does deliberately degrade performance, but it is SQL Server. This means that it is perfect for use with low numbers of users. When the number of users increases and performance starts to suffer, your upgrade path to SQL Server is just a question of paying for SQL Server. Compatibility is virtually assured. You use the same OLE DB provider, and you use it in exactly the same way with exactly the same names and parameters. This is because MSDE is SQL Server. Because of these reasons and because Microsoft is moving their emphasis away from Access, MSDE is worth considering for future developments.

The OLE DB Provider For OLAP can be used directly but is more often used by ADO Multi-Dimensional (ADOMD). ADOMD is an additional ADO technology designed to provide Online Analytical Processing (OLAP). If you have used Delphi's Decision Cube, or Excel's Pivot Tables, or Access's Cross Tabs, then you have used some form of OLAP.

In addition to these MDAC OLE DB providers, Microsoft supplies other OLE DB providers with other products or with downloadable SDKs. The Active Directory Services OLE DB Provider is included with the ADSI SDK; the AS/400 And VSAM OLE DB Provider is included with SNA Server; and the Exchange OLE DB Provider is included with Microsoft Exchange 2000.

The OLE DB Provider For Indexing Service provides access to (and is part of) Microsoft Indexing Service, a Windows NT and 2000 mechanism that speeds up file searches by building catalogs of file information. Indexing Service is integrated into IIS and, consequently, is often used for indexing Web sites. Microsoft Indexing Service is also available for Windows NT 4 as part of the NT 4 Option Pack.

The OLE DB Provider For Internet Publishing is included with Internet Explorer 5, Windows 2000, and Office 2000 and allows developers to manipulate directories and files using HTTP. This is useful for maintaining Web sites that support either FrontPage Web Extender (WEC) or Web Distributed Authoring and Versioning (WebDAV).

Still more OLE DB providers come in the form of *service providers*. As their name implies, OLE DB service providers provide a service to other OLE DB providers. Often these service providers will go unnoticed because they are invoked automatically as needed without programmer intervention. The Cursor Service, for example, is invoked when you create a client-side cursor, and the Persisted Recordset provider is invoked to save data locally.

dbGo

The set of components that make up dbGo (Table 16.2) should be easily recognizable by programmers familiar with the BDE, dbExpress, or IBExpress.

TABLE 16.2: dbGo Components

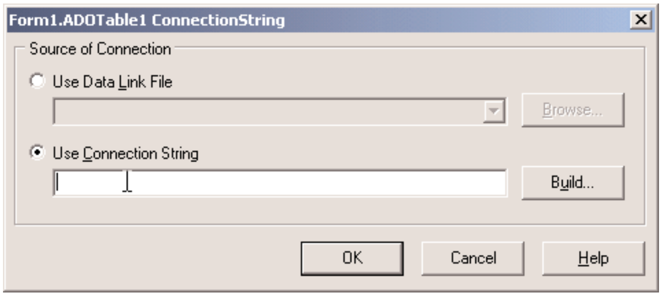
dbGo Component	Description	BDE Equivalent Component
TADOConnection	Connection to a database	TDatabase
TADOCommand	Executes an action SQL command	No equivalent
TADODataSet	All-purpose TDataSet	No equivalent
TADOTable	Encapsulation of a table	TTable
TADOQuery	Encapsulation of SQL SELECT	TQuery
TADOStoredProc	Encapsulation of a stored procedure	TStoredProc
TRDSConnection	Remote Data Services connection	No equivalent

The four dataset components (TADODataSet, TADOTable, TADOQuery, TADOStoredProc) are implemented almost entirely by their immediate ancestor TCustomADODataSet. This component provides the majority of dataset functionality, and its descendants are mostly thin wrappers that expose different features of the same component. As such, the components have a lot in common. In general, however, TADOTable, TADOQuery, and TADOStoredProc are viewed as "compatibility" components and are used to aid the transition of knowledge and code from their BDE counterparts. Be warned, though: These compatibility components are similar to their counterparts but not exactly the same. You will find differences in any application except the most trivial. TADODataSet is the component of choice partly because of its versatility but also because it is closer in appearance to the ADO Recordset interface upon which it is based. Throughout this chapter, we will use all of the TDataSet components to give you the experience of using each.

Enough theory. Let's see some action. Drop a TADOTable onto a form. Look in the Object Inspector and you will not see any `DatabaseName` or `AliasName` properties. ADO doesn't use aliases, so there are no alias-related properties. Instead ADO runs on *connection strings*. Connection strings are the lifeblood of ADO, and you should take time out to master this subject. You can type in a connection string by hand if you know what you are doing, but only programmers who think that VI is a great editor of our time enjoy doing this. For the rest of us, there is the connection string editor. In the Object Inspector, click the ellipses in the `ConnectionString` property. This invokes Delphi's connection string editor (Figure 16.1).

FIGURE 16.1:

Delphi's connection string editor



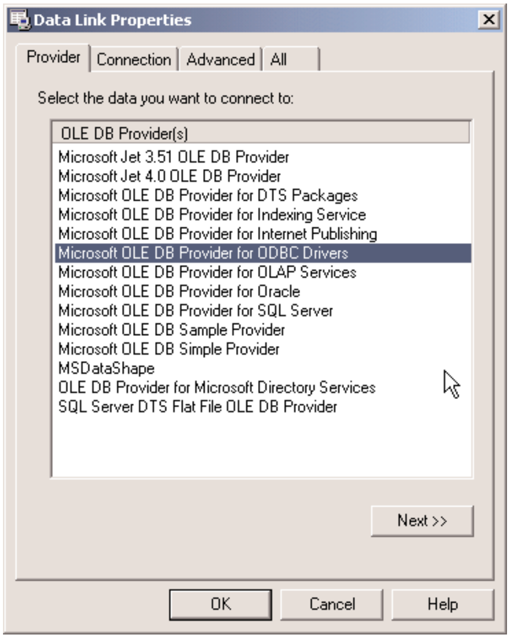
○ Use Data Link File

● Use Connection String

This editor adds little value to the process of entering a connection string, so you can click Build to go straight to Microsoft's connection string editor (Figure 16.2).

FIGURE 16.2:

Microsoft's connection string editor



Select the data you want to connect to:

OLE DB Provider(s)

Microsoft Jet 3.51 OLE DB Provider
Microsoft Jet 4.0 OLE DB Provider
Microsoft OLE DB Provider for DTS Packages
Microsoft OLE DB Provider for Indexing Service
Microsoft OLE DB Provider for Internet Publishing
Microsoft OLE DB Provider for ODBC Drivers
Microsoft OLE DB Provider for OLAP Services
Microsoft OLE DB Provider for Oracle
Microsoft OLE DB Provider for SQL Server
Microsoft OLE DB Sample Provider
Microsoft OLE DB Simple Provider
MSDataShape
OLE DB Provider for Microsoft Directory Services
SQL Server DTS Flat File OLE DB Provider

This is a tool you will come to know and love—or maybe just to know. The first tab shows the OLE DB providers and service providers installed on your computer. The list will vary according to the version of MDAC and other software installed on your computer. You can see that the OLE DB Provider for ODBC Drivers is selected by default. In our first example, we will open the infamous MS Access Northwind database using the Jet 4.0 OLE DB Provider. Northwind is the Microsoft equivalent of DBDEMOS; it is the test data used in many examples on ADO because it is so widely available. The exact location of Northwind and its name are not fixed, but you should search your hard disk for `Northwind.mdb` or `NWind.mdb`. Microsoft SQL Server comes with a very similar version of the same database, also called Northwind.

Double-click the Jet 4.0 OLE DB Provider and you will be presented with the Connection tab. This page varies according to the provider you select, but for Jet it simply asks you for the name of the database and your login details. If you have Microsoft Office installed on your computer, then the database name will probably be

```
c:\program files\microsoft office\office\samples\northwind.mdb
```

Click the Test Connection button to test the validity of your selections.

The Advanced tab handles access control to the database, and this is where you would specify exclusive or read-only access to the database.

The All tab lists all the parameters in the connection string. The list is specific to the OLE DB provider you selected on the first page. You should make a mental note of this page, because it contains many parameters that are the answers to many problems. Click OK to close the Microsoft connection string editor, click OK again to close the Borland connection string editor, and the value will be returned to the `ConnectionString` property, which will now be set to

```
Provider=Microsoft.Jet.OLEDB.4.0;Data Source=c:\program files\microsoft office\
  office\samples\northwind.mdb;Persist Security Info=False
```

So connection strings are just a string with many parameters delimited by semicolons. If you want to add, edit, or delete any of these parameter values programmatically, you must write your own routines to find the parameter in the list and amend it appropriately.

Now that we have set the connection string, we can select a table. Drop down the list of tables using the `TableName` property in the Object Inspector. Select the Customers table and set `Active` to True. Add a TDataSource and a TDBGrid and connect them all together, and you are now using ADO.

Incidentally, if you are going to use dbGo on a permanent basis, you might benefit from a simple tip. If you followed along with the last example, you will have noticed that you had to flip back and forth between the Data Access page and the ADO page to drop a TDataSource component onto the form. If you use dbGo exclusively, then the TDataSource component is the only component you will ever need on the Data Access page. Delphi's IDE prevents you from adding the same component to multiple pages, but you can move components. To move the TDataSource component from the Data Access page to the ADO page, right-click the palette, select Properties, and drag TDataSource onto the ADO page. If, however, you use both ADO and another database technology such as the BDE, then you can simulate installing

TDataSource on multiple pages by creating a Component Template for a TDataSource and installing it on the ADO page. This is a more elegant solution than creating a TADODataSource descendant, because the component that is dropped onto the form is still a genuine TDataSource and not some other component.

TADOConnection

When a TADOTable component is used in this way, it creates its own connection component behind the scenes in the same way that the BDE components create their temporary TDatabase component. You do not have to accept the default connection it creates, and you should not accept it. Instead, you should create your own connection in the form of a TADOConnection component.

The TADOConnection component is used for many of the same purposes as the BDE's TDatabase component. It allows you to customize the login procedure, control transactions, execute action commands directly, and reduce the number of connections in an application. Using a TADOConnection is easy. Place one on a form and set its `ConnectionString` property in the same way as for the TADOTable. Alternatively, you can double-click a TADOConnection to invoke the connection string editor directly. With the `ConnectionString` set to `Northwind.mdb`, you can disable the login dialog box by setting `LoginPrompt` to False. To make use of the new connection, set `ADOTable1`'s `Connection` property to `ADOConnection1`. You will see `ADOTable1`'s `ConnectionString` property reset because `Connection` and `ConnectionString` are mutually exclusive. One of the benefits of using a TADOConnection is that the connection string is centralized instead of scattered throughout many components. Another, more important, benefit is that all of the components that share the TADOConnection share a single connection. Without your own TADOConnection, each ADO dataset uses its own connection.

Data Link Files

So a TADOConnection allows us to centralize the definition of a connection string within a form or data module. However, even though this is a worthwhile step forward from scattering the same connection string throughout all ADO datasets, it still suffers from a fundamental flaw: If you use a database engine that defines the database in terms of a filename, then the path to the database file(s) is hard-coded in the EXE. This makes for a very fragile application. The BDE uses aliases to overcome this problem; ADO uses Data Link files. A Data Link file is a connection string in an INI file. The following is an example of a Data Link file:

```
[oledb]
; Everything after this line is an OLE DB initstring
Provider=Microsoft.Jet.OLEDB.4.0;Data Source=c:\program files\microsoft office\
  office\samples\northwind.mdb;Persist Security Info=False
```

Although you can give a Data Link file any extension, the recommended extension is .UDL. You can create a Data Link using any text editor, or you can right-click Windows Explorer, select New, then Text Document, rename the file with a UDL extension, and then double-click the file to invoke the Microsoft connection string editor.

To use the Data Link file, set the TADOConnection's ConnectionString to:

```
File Name=TEST.UDL
```

assuming that the file is called TEST.UDL and it is in the same directory as the EXE. You can place your Data Link files anywhere on the hard disk, but if you are looking for a common, shared location, then you can use the DataLinkDir function in ADODB.PAS:

```
ShowMessage('The Data Link directory is ' + DataLinkDir);
```

If you haven't altered MDAC's defaults, DataLinkDir will return

```
C:\Program Files\Common Files\System\OLE DB\Data Links
```

Delphi 5's ADOExpress suffers from a flaw when using data link files, which is fixed in Delphi 6's dbGo. In 5, set the Connected property of the TADOConnection to True and watch the ConnectionString property. The ConnectionString becomes the actual connection string that is in use (i.e., the one from the data link file). The problem is that when the property is streamed to the form when the application is saved, it is the active connection string that is saved. The reference to the data link file is permanently forgotten. If you change the data link file, you will not see any change to your application.

If you want to use data link files and you don't want to suffer from this problem, use the following TADOConnectionX component instead of TADOConnection:

```
TADOConnectionX = class(TADOConnection)
private
  FUDLFile: string;
protected
  procedure DoConnect; override;
published
  property UDLFile: string read FUDLFile write FUDLFile;
end;
```

The component has a UDLFile property where the UDL filename is permanently stored (you must manually set this property yourself). The class has a single method, DoConnect, which ensures that the UDL file is always read each time the connection is opened:

```
procedure TADOConnectionX.DoConnect;
begin
  if FUDLFile <> '' then
    ConnectionString:= 'File Name=' + FUDLFile;
  inherited;
end;
```

Dynamic Properties

Imagine that you are responsible for designing a new database middleware architecture. You have to reconcile two opposing goals of a single API for all databases and access to database-specific features. You could take the approach of designing an interface that is the sum of all of the features of every database ever created. Each class would have every property and method imaginable, but it would only use the properties and methods it had support for. It doesn't take much discussion to realize that this isn't a good solution. ADO has to solve these apparently mutually exclusive goals, and it does so using *dynamic properties*. Almost all ADO interfaces, and their corresponding dbGo components, have a property called Properties that is a collection of database-specific properties. These properties can be accessed by their ordinal position, like this:

```
ShowMessage(ADOTable1.Properties[1].Value);
```

But they are more usually accessed by name like this:

```
ShowMessage(ADOConnection1.Properties['DBMS Name'].Value);
```

It would be tedious to list all of the different dynamic properties for all of the different classes for all of the different OLE DB providers for all of the situations in which they are used, but to give you an idea of their importance, a typical ADO Connection or Recordset has approximately 100 dynamic properties. As we will see throughout this chapter, the answers to many ADO questions lie in dynamic properties, so keep your eyes and ears open for the ones that solve your problems. An important event, `OnRecordsetCreate`, was planned to be added to TCustomADODataSet in Delphi 6, which you may need to be aware of when using dynamic properties. (This event was not yet included as this book went to press.) `OnRecordsetCreate` is called immediately after the recordset has been created but has not been opened. This is useful when setting some dynamic properties as certain properties can only be set when the recordset is closed.

Getting Schema Information

One of the BDE components for which there is no apparent ADO alternative is TSession. TSession is used for several purposes, but a common use is to retrieve schema information (information about the structure of the database and its contents). In ADO this information can be retrieved using TADOConnection's `OpenSchema` method. This method accepts four parameters. The first, and most interesting, is the kind of data that `OpenSchema` should return. It is a `TSchemaInfo` value, which is a set of 40 values including those for retrieving a list of tables, indexes, columns, views, and stored procedures. The second parameter is a filter to place on the data before it is returned. We will see an example of this parameter in a moment.

The third parameter is a GUID for a provider-specific query and is only used if the first parameter is siProviderSpecific. The fourth and final parameter is a TADODataSet into which the data is returned. This last parameter illustrates a common theme in ADO: any method that needs to return more than a small amount of data will return its data as a Recordset, or in dbGo terms, a TADODataSet.

To use `TADOConnection.OpenSchema`, you need an open a TADOConnection. The following example retrieves a list of primary keys for every table into a TADODataSet:

```
ADOConnection1.OpenSchema(siPrimaryKeys, EmptyParam, EmptyParam, ADODataSet1);
```

Each field in a primary key has a single row in the result set. So a table with a composite key of two fields has two rows. The two `EmptyParam` values indicate that these parameters are given empty values and are ignored.

When `EmptyParam` is passed as the second parameter, the result set includes all information of the requested type for the entire database. For many kinds of information, you will want to filter the result set. You can, of course, apply a traditional Delphi filter to the result set using the `Filter` and `Filtered` properties or the `OnFilterRecord` event. However, this applies the filter on the client side in this example. Using the second parameter, we can apply a more efficient filter at the source of the schema information. The filter is specified as an array of values. Each element of the array has a specific meaning relevant to the kind of data being returned. For example, the filter array for primary keys has three elements: the first is the catalog (*catalog* is ANSI-speak for the database), the second is the schema, and the third is the table name. This example returns a list of primary keys for the Customers table:

```
var
  Filter: OLEVariant;
begin
  Filter := VarArrayCreate([0, 2], varVariant);
  Filter[2] := 'CUSTOMERS';
  ADOConnection1.OpenSchema(
  siPrimaryKeys, Filter, EmptyParam, ADODataSet1);
end;
```

You can retrieve the same information using ADOX, and this warrants a brief comparison between `OpenSchema` and ADOX. ADOX is an additional ADO technology that allows you to retrieve and update schema information. It is ADO's equivalent to SQL's Data Definition Language (DDL, i.e., CREATE, ALTER, DROP) and Data Control Language (DCL, i.e., GRANT, REVOKE). ADOX is not directly supported in dbGo, but you can easily import the ADOX type library and use it successfully in Delphi applications. Unfortunately, ADOX is not as universally implemented as `OpenSchema`, so there are greater gaps. If you just want to retrieve information and not to update it, then `OpenSchema` is usually a better choice.

Using the Jet Engine

Now that you have some of the MDAC and ADO basics under your belt, we can take a moment out to look at the Jet engine. This engine is of great interest to some and of no interest to others. If you're interested in Access, Paradox, dBase, text, Excel, Lotus 1-2-3, or HTML, then this section is for you. If you have no interest in any of these formats, you can safely skip this section.

The Jet database engine is usually associated with Microsoft Access databases, and this is, indeed, its forte. However, the Jet engine is also an all-purpose desktop database engine, and this lesser-known attribute is where much of its strength lies. Since using the Jet engine with Access is its default mode and is straightforward, this section mostly covers use of non-Access formats, which are not so obvious.

Before we look at these formats, we should discuss the availability of the Jet engine. It was included with MDAC from v1.5c until, and including, v2.5. From MDAC v2.6, the Jet engine was dropped from MDAC (which accounts for the reduction in download size from 7.5 MB to 5.2 MB). You can download a distributable version of the Jet engine from `www.microsoft.com/data/download.htm`. Of course, if you have installed MDAC prior to v2.6, or Microsoft Access, Office, Excel, Visual Basic, or Visual C++ on your user's machine, then your user will already have the Jet engine.

There are two Jet OLE DB providers: the Jet 3.51 OLE DB Provider and the Jet 4.0 OLE DB Provider. The Jet 3.51 OLE DB Provider uses the Jet 3.51 engine and supports Access 97 databases only. If you intend to use Access 97 and not Access 2000, then you will get better performance using this OLE DB provider in most situations than using the Jet 4.0 OLE DB Provider. The Jet 4.0 OLE DB Provider supports Access 97, Access 2000, and Installable Indexed Sequential Access Method (IISAM) drivers. Installable ISAM drivers are those written specifically for the Jet engine to support access to ISAM formats such as Paradox, dBase, and text, and it is this facility that makes the Jet engine so useful and versatile. The complete list of ISAM drivers installed on your machine depends on what software you have installed on your machine. You can find this list by looking in the registry at

```
HKEY_LOCAL_MACHINE\Software\Microsoft\Jet\4.0\ISAM Formats
```

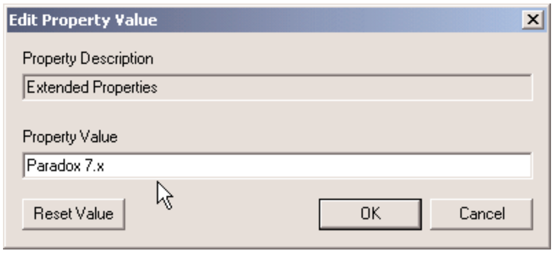
However, the Jet engine includes drivers for Paradox, dBase, Excel, text, and HTML.

Paradox

The Jet engine, naturally, expects to be used with Access databases. To use it with any database other than Access, you need to tell it which IISAM driver to use. This is a painless process that involves setting the Extended Properties connection string argument in the connection string editor. We'll do a quick example. Add a TADOTable to a form and invoke the connection string editor. Select the Jet 4.0 OLE DB Provider. Select the All page, locate the Extended Properties property, and double-click it to show the dialog box illustrated in Figure 16.3.

FIGURE 16.3:

Setting Extended Properties



Edit Property Value

Property Description: Extended Properties

Property Value: Paradox 7.x

Enter **Paradox 7.x** in the Property Value as shown and click OK. Now go back to the Connection tab and enter the name of the directory containing the Paradox tables. For example you can enter

```
c:\program files\common files\borland shared\data
```

which contains Delphi's DBDEMOS Paradox tables. Unfortunately, the Browse button showing the ellipses does not react to the Extended Properties value and always expects to select a file and not a directory, and so it has little value when used with Paradox databases. Click OK on both dialog boxes and select a table in the TADOTable's `TableName`. Set `Active` to True and you are now using Paradox through ADO.

Sadly, I have some bad news for Paradox users. Under certain circumstances, you will need to install the BDE in addition to the Jet engine. It is bizarre that in a chapter dedicated to ADO we are talking about the need to install the BDE in addition to MDAC, but depending on your application this may be true. Jet 4.0 requires the BDE in order to be able to update Paradox tables, but it doesn't require the BDE just to read them. The same is true for most releases of the Paradox ODBC Driver. As disastrous as this sounds, all is not lost. Microsoft has received justified criticism on this point and has made a new Paradox IISAM available that does not require the BDE. You can get these updated drivers from Microsoft Technical Support.

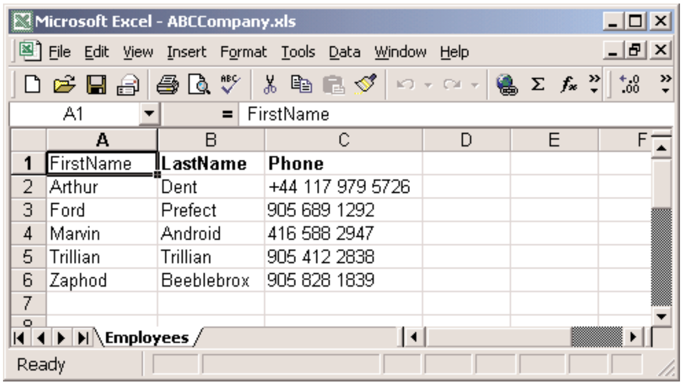
NOTE As you learn more and more about ADO, you will discover how much of ADO depends on the OLE DB provider and the DBMS (database management system) in question. You will see how the desktop databases such as Paradox and dBase have more restrictions and fewer functional features. If you are using Paradox simply because it is free, then you would be well advised to use another free database such as Access or MSDE. Alternatively, if leaving Paradox is not an option, then you should closely compare the BDE's support for Paradox with ADO's support for Paradox. In some cases, you will find the BDE's support better.

Excel

Excel is easily accessed using the Jet OLE DB Provider. Once again, we use the Extended Properties property and set it to Excel 8.0. Assume that we have an Excel spreadsheet called `ABCCompany.xls` that, in Excel, looks like Figure 16.4.

FIGURE 16.4:

ABCCompany.xls in Excel



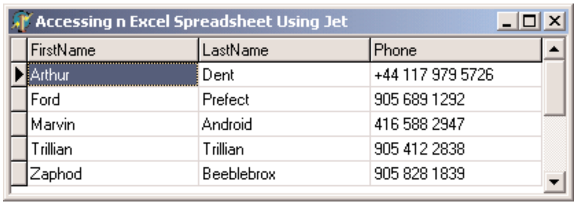
Microsoft Excel - ABCCompany.xls
File Edit View Insert Format Tools Data Window Help
A1
= FirstName
Employees
Ready

	A	B	C	D	E	F
1	FirstName	**LastName**	**Phone**			
2	Arthur	Dent	+44 117 979 5726			
3	Ford	Prefect	905 689 1292			
4	Marvin	Android	416 588 2947			
5	Trillian	Trillian	905 412 2838			
6	Zaphod	Beeblebrox	905 828 1839			
7						

Notice that the sheet is called Employees. Our mission is to open and read this file using Delphi. You can, of course, solve this problem by automating Excel with only a small knowledge of COM. However, the ADO solution is considerably easier to implement.

Ensure that your spreadsheet is not open in Excel. Add a TADODataSet to a form. Set `ConnectionString` to use the Jet 4.0 OLE DB Provider and set Extended Properties to Excel 8.0. In the Connection tab, set the database name to the full file and path specification of the Excel spreadsheet. Close the connection string editor. The TADODataSet component works by opening or executing a value in its `CommandText` property. This value might be the name of a table or an SQL statement or a stored procedure or the name of a file. You specify how this value is interpreted by setting the `CommandType` property. Set `CommandType` to cmdTableDirect to indicate that the value in `CommandText` is the name of a table and that all columns should be returned from this table. Select `CommandText` in the Object Inspector and you will see a drop-down arrow. Drop down the arrow and a single "table" will be displayed: Employees$. (Excel workbooks are suffixed with a $.) Set `Active` to True, add a TDataSource and a TDBGrid and connect them altogether, and you will see the Excel spreadsheet. It will be a little difficult to view in the grid because each column has a width of 255 characters. You can change this either by adding columns to the grid and changing their `Width` properties, or by adding persistent fields and changing their `Size` or `DisplayWidth` properties. After a little rearranging, you should see something like Figure 16.5.

FIGURE 16.5:
ABCCompany.xls in Delphi



FirstName	LastName	Phone
Arthur	Dent	+44 117 979 5726
Ford	Prefect	905 689 1292
Marvin	Android	416 588 2947
Trillian	Trillian	905 412 2838
Zaphod	Beeblebrox	905 828 1839

Now save your application. If you run it from the IDE, you will discover the first of the limitations of the Excel IISAM: the XLS file is opened exclusively. To run the application, you will first need to close the application that is open in the IDE and then run it from Windows Explorer. When you run the program, you will notice another limitation of this IISAM driver: you can add new rows and edit existing rows, but you cannot delete rows.

Incidentally, you could have used either TADOTable or TADOQuery, instead of TADODataSet, but you need to be aware of how ADO treats symbols in things like table names and field names. If you were to use a TADOTable and drop down the list of tables, you would see the Employees$ table as you would expect. Unfortunately if you attempt to open the table, you will receive an error. The same is true for `SELECT * FROM Employees$` in a `TADOQuery`. The problem lies with the dollar sign in the table name. If you use characters such as dollars, dots, or, more importantly, spaces in table names or field names, then you must enclose the name in square brackets (e.g., `[Employees$]`).

Text Files

One of the very useful IISAM drivers that comes with the Jet engine is the Text IISAM. This driver allows you to read and update text files of almost any structured format. We will start with a simple text file to get up and running and then cover the variations later. Assume we have a simple text file called `NightShift.TXT` that contains the following text:

```
CrewPerson ,HomeTown
Neo        ,Cincinnati
Trinity    ,London
Morpheus   ,Milan
```

Add a TADOTable to a form, set its `ConnectionString` to use the Jet 4.0 OLE DB Provider, and set Extended Properties to Text. The Text IISAM considers a directory a database, so you need to enter the directory that contains the `NightShift.TXT` file as the database name. Back in the Object Inspector, drop down the list of tables in the `TableName` property. The "database" consists of all of the text files in this directory. You will notice that the dot in the filename has been converted to a hash, as in `NightShift#TXT`. Set `Active` to True, add a TDataSource and a TDBGrid and connect them altogether, and you will see the contents of the text file in a grid.

If your computer's settings are such that the decimal separator is a comma instead of a period (so that 1,000.00 is displayed as 1.000,00), then you will need to either change your Regional Settings (Start ➢ Settings ➢ Control Panel ➢ Regional Settings ➢ Numbers) or take advantage of SCHEMA.INI, described shortly.

Of course, the grid indicates that the widths of the columns are 255 characters. You can change these just as we did in Excel by adding persistent fields or columns to the grid and then setting the relevant width property. Alternatively you can define the structure of the text file more specifically using SCHEMA.INI.

Text files come in all shapes and sizes. Often you do not need to worry about the format of a text file because the Text IISAM takes a peek at the first 25 rows to see whether it can determine the format for itself. It uses this information and some additional information in the Registry to decide how to interpret the file and how to behave. If you have a file that doesn't match a regular format the Text IISAM can determine, then you can provide this information in the shape of SCHEMA.INI. SCHEMA.INI is an INI file located in the same directory as the text files to which it refers. It contains *schema* information, also called metadata, about any or all of the text files in the same directory. Each text file is given its own section, identified by the name of the text file, such as [NightShift.TXT].

Thereafter you can specify the format of the file, the names, types, and sizes of columns, any special character sets to use, and any special column formats (e.g., date/time, currency). Let's assume that we change our NightShift.TXT file to the following format:

```
Neo        |Cincinnati
Trinity    |London
Morpheus   |Milan
```

In this example, the column names are not included in the text file and the delimiter is a vertical bar. An associated SCHEMA.INI file might look something like the following:

```
[NightShift.TXT]
Format=Delimited(|)
ColNameHeader=False
Col1=CrewPerson Char Width 10
Col2=HomeTown Char Width 30
```

Regardless of whether or not you use a SCHEMA.INI file, you will encounter two limitations of the Text IISAM: rows cannot be deleted, and rows cannot be edited.

Importing and Exporting

The Jet engine is particularly adept at importing and exporting data. The process of exporting data is the same for each export format and consists of executing a SELECT statement with a special syntax. Let's start with an example of exporting data from the Northwind

Access database to a Paradox table. You will need an active TADOConnection, called ADOConnection1 in our example, that uses the Jet 4.0 OLE DB Provider to open the Northwind.mdb Access database. The following code exports the Customers table to a Paradox Customers.db file:

```
ADOConnection1.Execute('SELECT * INTO Customers ' +
   'IN "C:\Temp" "Paradox 7.x;" FROM CUSTOMERS');
```

Let's look at the pieces of this SELECT statement. The INTO clause specifies the new table that will be created by the SELECT statement; this table must not already exist. The IN clause specifies the database to which the new table is added; in Paradox, this is a directory that already exists. The clause immediately following the database is the name of the IISAM driver to be used to perform the export. *You must include the trailing semicolon at the end of the driver name*. The FROM clause is a regular part of any SELECT statement.

All export statements follow these same basic clauses, but you will find that some IISAM drivers have differing interpretations of what a database is. I'll do another couple of examples to demonstrate the differences. Here, we export the same data to Excel:

```
ADOConnection1.Execute('SELECT * INTO Customers ' +
   'IN "Northwind.xls" "Excel 8.0;" FROM CUSTOMERS');
```

A new Excel file called Northwind.xls is created in the application's current directory. A workbook called Customers is added, containing all of the data of the Customers table in Northwind.mdb. You can also export data to Excel by automating Excel, but if you have ever done this you will know that this ADO solution is simpler by far.

This next example exports the same data to HTML:

```
ADOConnection1.Execute('SELECT * INTO [Customers.htm] ' +
   'IN "C:\Temp" "HTML Export;" FROM CUSTOMERS');
```

In this example, the database is the directory, as it was for Paradox but not for Excel. The table name must include the .htm extension and, therefore, it must be enclosed in square brackets. Notice that the name of the IISAM driver is "HTML Export", not just "HTML", because this driver can only be used for exporting to HTML.

The last IISAM driver we'll look at in this investigation of the Jet engine is the sister to HTML Export: HTML Import. Add a TADOTable to a form, set its ConnectionString to use the Jet 4.0 OLE DB Provider and Extended Properties to HTML Import. Set the database name to the name of the HTML file created by the export a few moments ago—that is, C:\Temp\Customers.htm. Close the connection string editors and set the TableName to Customers. Open the table and you have just imported the HTML file! Bear in mind, though, that the name of this IISAM driver is "HTML Import", not just "HTML". If you attempt to update the data in any way, you'll receive an error because this driver is intended for import only. Finally, if you create your own HTML files containing tables and want to open these tables using this driver, then remember that the name of the table is the value of the CAPTION tag of the HTML TABLE.

Cursor Locations and Cursor Types

There are two properties of ADO datasets that have a fundamental impact on your application and are inextricably linked with each other: `CursorLocation` and `CursorType`. The key to a successful application and to understanding your dataset's behavior and capabilities and the performance of your application lies in understanding these two properties.

The `CursorLocation`, of type `TCursorLocation`, allows you to specify what is in control of the retrieval and update of your data. You have two choices: client (`clUseClient`) or server (`clUseServer`). Your choice affects your dataset's functionality, performance, and scalability.

A client cursor is managed by the ADO Cursor Engine. This engine is an excellent example of an OLE DB service provider: it provides a service to other OLE DB providers. The ADO Cursor Engine manages the data from the client side of the application. All data in the result set is retrieved from the server to the client when the dataset is opened. Thereafter, the data is held in memory and updates and manipulation are managed by the ADO Cursor Engine. One benefit is that manipulation of the data, after the initial retrieval, is considerably faster. Furthermore, as the manipulation is performed in memory, the ADO Cursor Engine is more versatile than most server-side cursors and offers facilities that cannot be reproduced by server-side cursors. I'll examine these benefits later, as well as other technologies that depend on client-side cursors such as disconnected and persistent recordsets.

A server-side cursor is managed by the DBMS. In a client/server database such as SQL Server, Oracle, or InterBase, this means that the cursor is managed physically on the server. In a desktop database such as Access or Paradox, the "server" location is simply a logical location, as the database is running on the desktop. Server-side cursors are often faster to load than client-side cursors because not all of the data is transferred to the client when the dataset is opened. This also makes them more suitable for very large result sets where the client has insufficient memory to hold the entire result set in memory. Often you can determine what kinds of features will be available to you with each cursor location by thinking through how the cursor works. A good example of how features determine cursor type is locking, which I will cover in more detail later. To place a lock on a record requires a server-side cursor, because there must be a conversation between the application and the DBMS.

Another issue that will affect your choice of cursor location is scalability. Server-side cursors are managed by the DBMS; in a client/server database, this will be located on the server. As more and more users use your application, the load on the server increases with each server-side cursor. A greater workload on the server means that the DBMS becomes a bottleneck faster, so the application is less scalable. You can achieve better scalability by using client-side cursors. The initial hit on opening the cursor is often heavier, because all the data is transferred to the client, but the maintenance of the open cursor can be lower. As you can see, many conflicting issues are involved in choosing the correct cursor location for your datasets.

Your choice of cursor location directly affects your choice of cursor type. To all intents and purposes there are four cursor types, but I will digress for a moment to explain why there is one unused value. There is a cursor type that means "unspecified." Many values in ADO signify an unspecified value, and I will cover them all here and explain why you won't have much to do with them. They exist in Delphi because they exist in ADO. ADO was mostly designed for Visual Basic and C programmers. In these languages, you use the objects directly without any of the assistance that dbGo provides. As such, you can create and open *recordsets*, as they are called in ADO-speak, without having to specify every value for every property. The properties for which a value has not been specified have an unspecified value. However, in dbGo we use components. These components have constructors, and these constructors initialize the properties of the components. So from the moment you create a dbGo component, it will usually have a value for each and every property. The consequence is that we have little need for the unspecified values in many enumerated types.

Back to the cursor types. Cursor types, of type `TCursorType`, affect how your data is read and updated. There are four choices: forward-only, static, keyset, and dynamic. Before we get too involved in all of the permutations of cursor locations and cursor types, you should be aware that there is only one cursor type available for client-side cursors: the static cursor. All other cursor types are only available to server-side cursors. I'll return to the subject of cursor type availability after we have looked at the various cursor types, in increasing order of expensiveness.

The least expensive cursor type, and therefore the type with the best possible performance, is the forward-only cursor, which, as the name implies, will let you navigate forward. The cursor reads the number of records specified by `CacheSize` (default of 1) and each time it runs out of records, it reads another `CacheSize` set. Any attempt to navigate backward through the result set beyond the number of records in the cache will result in an error.

Knowing how a forward-only cursor works should help you to understand why they do not support bookmarks. A bookmark normally allows your dataset to navigate by jumping to a selected row. Because you can only travel forward through a forward-only cursor and any bookmark placed will be behind the current cursor position, bookmarks are not supported. As such a forward-only cursor is not suitable for use in the user interface where the user can control the direction through the result set. However, it is eminently suitable for batch operations and reports, because these situations start at the top of the result set and work progressively toward the end, then the result set is closed.

A static cursor works by reading the complete result set and providing a window of CacheSize records into the result set. As the complete result set has been retrieved by the server, you can navigate both forward and backward through the result set. However, in exchange for this facility, the data is static—that is, updates, insertions, and deletions made by other users cannot be seen because the cursor's data has already been read.

A keyset cursor is best understood by breaking *keyset* down into its two words *key* and *set*. Key, in this context, refers to an identifier for each row. Often this will be a primary key. A keyset cursor, therefore, is a set of keys. When the result set is opened, the complete list of keys for the result set is read. If, for example, the dataset was a query like SELECT * FROM CUSTOMERS, then the list of keys would be built from SELECT CUSTID FROM CUSTOMERS. This set of keys is held until the cursor is closed. When the application requests data, the OLE DB provider reads the rows using the keys in the set of keys. Consequently, the data is always up to date. If another user changes a row in the result set, then the changes will be seen when the data is reread. However, the set of keys, itself, is static; it is read only when the result set is first opened. So if another user adds new records, these additions will not be seen. Deleted records become inaccessible, and changes to primary keys (you don't let your users change primary keys, do you?) are also inaccessible.

The last, and most expensive, cursor type is dynamic. A dynamic cursor is almost identical to a keyset cursor. The sole difference is that the set of keys is reread when the application requests data that is not in the cache. As the default for TADODataSet.CacheSize is 1, this is very frequent. You can imagine the additional load this places on the DBMS and the network and why this is the most expensive cursor. However, the result set can see and respond to the additions and deletions made by other users.

Ask and Ye Shall Not Receive

Now that we know all about cursor locations and cursor types, a word of warning: not all combinations of cursor location and cursor type are possible. Usually, this is a limitation imposed by the DBMS and/or the OLE DB provider as a result of the functionality and architecture of the DBMS. For example, client cursors always force the cursor type to static. You can see this for yourself. Add a TADODataSet to a form, set its ConnectionString to any database, set ClientLocation to clUseCursor and CursorType to ctDynamic. Now set Active to True and keep your eye on the CursorType; it changes to ctStatic. We learn an important lesson from this example:

> What you ask for is not necessarily what you get.

Always check your properties after opening a dataset for what you think you "know" is true.

Each OLE DB provider will make different changes according to different requests and circumstances, but to give you a rough idea of what you can expect here are a few examples. The Jet 4.0 OLE DB Provider changes most cursor types to keyset. The SQL Server OLE DB Provider often changes keyset and static to dynamic. The Oracle OLE DB Provider changes all cursor types to forward-only. The ODBC OLE DB Provider makes various changes according to the ODBC driver in use.

RecordCount = –1

Armed with all of this knowledge about cursors, we can explain why ADO datasets sometimes return –1 for their `RecordCount`. A forward-only cursor cannot know how many records are in the result set until it reaches the end, so it returns –1 for the `RecordCount`. A static cursor always knows how many records are in the result set, because it reads the entire set when it is opened, so it returns the number of records in its result set. A keyset cursor also knows how many records are in the result set, because it has to retrieve a fixed set of keys when the result set is opened, so it also returns a useful value for `RecordCount`. A dynamic cursor does not reliably know how many records are in the result set, because it is regularly rereading the set of keys, so it returns –1. You could, of course, avoid using `RecordCount` altogether and execute `SELECT COUNT(*) FROM tablename`, but this will be an accurate reflection of the number of records in the database, which is not necessarily the same as the number of records in the dataset.

Client Indexes

One of the many benefits of client-side cursors is the ability to create local, or *client*, indexes. You can try this out for yourself. Assuming that you have an ADO client-side dataset for the Northwind's Customer table, which has a grid attached to it, set the dataset's `IndexFieldNames` property to CompanyName. Immediately the grid will show that the data is in CompanyName order. There is an important point to make here: In order to index the data, ADO did not have to reread the data from its source. The index was created from the data in memory. This means not only is the creation of the index just about as fast as it could possibly be, but the network and the DBMS are not overloaded with transferring the same data over and over in different orders. The `IndexFieldNames` property has more potential. Set it to `Country;CompanyName` and you will see the data ordered first by country and then, within country, in company name order. Now set `IndexFieldNames` to `CompanyName DESC`. Be sure to write DESC in capitals and not "desc" or "Desc". I'm sure you won't be surprised to see that the data is now sorted in descending order.

This simple but powerful feature allows us to solve one of the great bugbears of database developers. From time to time users seem to ask the inevitable, and quite reasonable, question, "Can I click the columns of the grid to sort my data?" There are three traditional answers to this question:

- "Yes. I can replace all of my grids with non–data-aware controls such as `TListView` that have the sorting built into the control. Of course, I lose all of the benefits of data-aware controls with this solution."
- "Yes. I can trap the TDBGrid's `OnTitleClick` event and rebuild the SQL SELECT statement to include an appropriate ORDER BY clause and then reissue the SELECT statement. Of course, this will mean requerying exactly the same data as I already have just to get it in a different order, but the user is always right."
- "No. I admit that this would be a cool feature, but the extra load on the DBMS and the network is antisocial to other users."

Sadly, none of the above are acceptable answers. Client indexes to the rescue! Add the following `OnTitleClick` event to the grid:

```
procedure TForm1.DBGrid1TitleClick(Column: TColumn);
begin
  if ADODataSet1.IndexFieldNames = Column.Field.FieldName then
    ADODataSet1.IndexFieldNames := Column.Field.FieldName + ' DESC'
  else
    ADODataSet1.IndexFieldNames := Column.Field.FieldName
end;
```

This simple event checks to see whether the current index is built on the same field as the column. If it is, then a new index is built on the column but in descending order. If not, then a new index is built on the column. When the user clicks the column for the first time, it is sorted in ascending order, and when it is clicked for the second time, it is sorted in descending order. You could extend this to allow the user to Ctrl-click several column titles to build up more complicated indexes. Of course, all of this can be achieved using TClientDataSet, but that solution is not as elegant for two reasons: descending indexes must be built from scratch (because TClientDataSet does not support the DESC keyword) and existing ascending indexes cannot be changed to descending indexes (they must be deleted and rebuilt).

Cloning

ADO is crammed full of features. You can argue that "feature-rich" can translate into "footprint-rich," but it also translates into more powerful and reliable applications. One such powerful feature is cloning. A cloned recordset is a new recordset that has all of the same properties as the original from which it is cloned. First, I'll explain how you can create and use a clone, and then I'll explain why they are so useful.

You can clone a recordset, or, in dbGo-speak, a dataset, using the `Clone` method. You can clone any ADO dataset, but we will use TADOTable in this example. Add a TADOTable to a form and set its `ConnectionString` to use any OLE DB provider that returns rectangular data (e.g., the Jet or SQL Server OLE DB providers). Set its `TableName` to any table and open the table. Add a TDataSource and a TDBGrid to allow you to view the table. Now add a second TADOTable and a button with the following code:

```
ADOTable2.Clone(ADOTable1);
```

This line clones `ADOTable1` and assigns the clone to `ADOTable2`. If you add another TDataSource and TDBGrid to show `ADOTable2`, you will see a second view of the data. The two datasets have their own record pointers and other status information, so the clone does not interfere with its original copy.

This behavior makes them ideal for *black box programming*. This term comes from an old story, in which you could ask the black box any question at all and it would guarantee to provide an answer. You couldn't see inside the black box and you didn't know how it worked, just that it did. The black box did what it was supposed to and no more. It is this last part that is so essential to programming: functions and procedures do *no more than they are supposed to*. Sometimes this is also referred to as having "zero side effects." So in this example, the `CountSelected` function attempts to count all of the rows where the `Selected` field is True:

```
function CountSelected(
ADODataSet: TCustomADODataSet): integer;
var
  Bookmark: TBookmark;
begin
  Result := 0;
  Bookmark := ADODataSet.GetBookmark;
  try
    ADODataSet.First;
    while not ADODataSet.EOF do
    begin
      if ADODataSet.FieldByName('Selected').AsBoolean then
        Inc(Result);
      ADODataSet.Next;
    end;
    ADODataSet.GoToBookmark(Bookmark);
  finally
    ADODataSet.FreeBookmark(Bookmark);
  end;
end;
```

At first sight, this function appears to be a black box function. It dutifully saves the current row position of the dataset using a bookmark and restores the position before returning, so that the net effect of moving the row position is zero. This is a standard approach to black box programming: if you change something in your routine that you are not supposed to change, then you must restore it again afterward.

Sadly, this routine is not black box. The movement of the row pointer will be observed by any data-aware controls, and the user interface will be updated by every row movement. A better solution to this problem is to use cloning:

```
function CountSelected(ADODataSet: TCustomADODataSet): integer;
var
  Clone: TADODataSet;
begin
  Result := 0;
  Clone := TADODataSet.Create(nil);
  try
    Clone.Clone(ADODataSet);
    Clone.First;
    while not Clone.EOF do
    begin
      if Clone.FieldByName('Selected').AsBoolean then
        Inc(Result);
      Clone.Next;
    end;
    Clone.Close;
  finally
    Clone.Free;
  end;
end;
```

The new clone will not interfere with its original in any way, making it ideal for black box programming. In particular, note that the closing of the clone does not close the original or other clones. In fact, not even the closing of the original closes its clones. I will use cloning later in this chapter, but before we close this subject, there are two points worth mentioning.

WARNING A recordset must support bookmarks in order to be cloned, so forward-only and dynamic cursors cannot be cloned. You can determine whether a recordset supports bookmarks using the `Supports` method (e.g., `ADOTable1.Supports([coBookMark])`).

TIP One of the useful side effects of clones is that the bookmarks created by one clone are usable by all other clones.

Transaction Processing

Transaction processing allows developers to group together individual updates to a database into a single logical unit of work. The benefit is that a database engine can be told to accept or reject the complete unit of work as a single entity. The facility is present in nearly all of today's DBMSs, because it's essential for maintaining the integrity of the database. The classic example used to illustrate the need for transaction processing is the transfer of money to and from a bank account. The movement of money from one account into another consists of two steps: the removal of money from one account and the addition of the same money into another account. The entire transaction must either wholly succeed or wholly fail in order for integrity to be maintained. If only one half of the transaction succeeds, the money will either have been created (by adding money to one account while failing to remove it from the other) or destroyed (by removing money from one account while failing to add it to the other). Database programming is full of examples that require transaction processing, and in this section we will see how ADO handles this subject.

ADO's transaction processing support is controlled using a TADOConnection. The following list summarizes the relevant methods:

TADOConnection Method	Description	TDatabase Equivalent
`BeginTrans`	Begins a transaction	`StartTransaction`
`CommitTrans`	Commits a transaction	`Commit`
`RollbackTrans`	Rolls back a transaction	`Rollback`

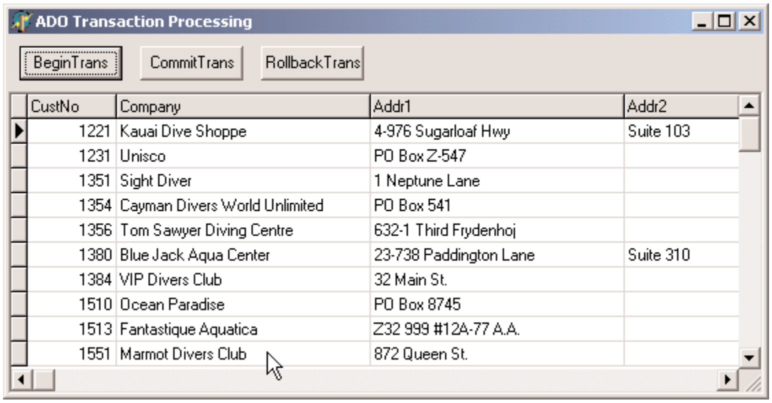
To investigate ADO's transaction processing support, we will build a simple test program. We will use this test program to investigate the different levels of transaction processing support offered by different OLE DB providers and different databases.

Create a new application and add a TADOConnection. Set the `ConnectionString` to use the ODBC OLE DB Provider and the DBDEMOS Paradox data supplied with Delphi. You might find it easier to first create an ODBC Data Source, say DBDEMOS, and refer to that. Set the `LoginPrompt` to False and `Connected` to True. Add a TADOTable, set `Connection` to ADOConnection1, `TableName` to Customers, and `Active` to True. Add a TDataSource and a TDBGrid and connect them so that the Customers table is shown in the grid. Add three buttons to the top of the form to execute each of the following commands:

```
ADOConnection1.BeginTrans;
ADOConnection1.CommitTrans;
ADOConnection1.RollbackTrans;
```

The running application should look something like Figure 16.6.

FIGURE 16.6:
ADO transaction processing



CustNo	Company	Addr1	Addr2
1221	Kauai Dive Shoppe	4-976 Sugarloaf Hwy	Suite 103
1231	Unisco	PO Box Z-547	
1351	Sight Diver	1 Neptune Lane	
1354	Cayman Divers World Unlimited	PO Box 541	
1356	Tom Sawyer Diving Centre	632-1 Third Frydenhoj	
1380	Blue Jack Aqua Center	23-738 Paddington Lane	Suite 310
1384	VIP Divers Club	32 Main St.	
1510	Ocean Paradise	PO Box 8745	
1513	Fantastique Aquatica	Z32 999 #12A-77 A.A.	
1551	Marmot Divers Club	872 Queen St.	

Click the BeginTrans button and you will receive an error indicating that the DBMS or the OLE DB provider is not capable of beginning a transaction. The problem lies with the Paradox ODBC Driver, which simply doesn't support transaction processing. You can find out what level of transaction processing support you have using the connection's Transaction DDL dynamic property—for example,

```
if ADOConnection1.Properties['Transaction DDL'].Value > DBPROPVAL_TC_NONE then
  ADOConnection1.BeginTrans;
```

The DBPROPVAL_TC_NONE constant comes from OLEDB.PAS along with several others like it. The related constants indicate that transaction support is available for Data Manipulation Language (DML) statements, meaning that SQL UPDATE, INSERT, and DELETE statements will all be included in transactions. ADO updates databases using SQL, so all of the dbGo components' DML methods (e.g., Append, Post, Delete) are also included in this list. The difference between the DBPROPVAL_TC constants is the level of support for Data Definition Language (DDL) commands included in a transaction. DDL is the set of SQL commands that alter the structure of the database and allow developers to perform actions such as adding and deleting columns and adding new tables. Given the nature of these commands, it is unlikely that you would want to mix DDL commands in a transaction with DML commands, so your interest in the Transaction DDL dynamic property might not extend beyond the DBPROPVAL_TC_NONE constant. If you do intend to include DDL commands in a transaction, you should check the other constants to see how the DDL will be treated by the DBMS. Some DBMSs will ignore the DDL, some will generate an exception if it is included in a transaction, some will cause certain DDL commands to lock a table, and others will automatically commit a transaction when the DDL is executed.

Let's get back to our test application. Change the TADOConnection's ConnectionString to use the Jet 4.0 OLE DB Provider and set its Extended Properties (in the All tab) to

Paradox 7.x. Set the database name to Delphi's DBDEMOS directory (`c:\program files\common files\borland shared\data`). Save the connection string and reopen the TADOTable. You should see no difference from the previous example. Now run the application and click the BeginTrans button. Success? Unfortunately, no. This is a cruel, cruel trick on the part of the Jet 4.0 OLE DB Provider. Make a few changes and click the RollbackTrans button; close the application down and restart it. You will see that the changes that you made were permanent and your act of rolling them back made no difference at all. As I said, it is a cruel trick, because transactions on a Paradox database cannot be rolled back, and this makes them rather useless. If you read through the section in this chapter on the Jet engine and, in particular, the section on Paradox, you will recall that I mentioned that the support for Paradox is lower than most developers would like. Transaction processing is one such example.

Now let's look at how Access handles transaction processing. Create an ODBC System Data Source Name using the ODBC Manager. Call it Northwind DSN, use the Microsoft Access ODBC driver, and set the database to `Northwind.mdb`. In Delphi, change the TADOConnection to use the ODBC OLE DB Provider and the new Northwind DSN. Now save the connection string, change the `TADOTable`'s `TableName` from Customer to Customers, and open it. Run the application and click the BeginTrans button. At last, transaction processing that works. You can make changes to the Northwind database and roll back the changes, and they will be rolled back! However, something you cannot do is start a transaction within a transaction. Try clicking the BeginTrans button twice and you get a "Cannot start more transactions on this session" error. This is a limitation of ODBC and not the Jet engine and is a useful example of why you should always try to locate an OLE DB provider for your DBMS instead of an ODBC driver.

Nested Transactions

If you try the same test again but use the Jet 4.0 OLE DB Provider, you will see that you can click the BeginTrans button five times before receiving an error on the sixth attempt. Jet supports *nested transactions*, which are transactions that exist within the context of another transaction. The nested or *inner* transaction can be committed or rolled back without affecting the outcome of the *outer* transaction. Let's work through a sequence of steps to be sure of how this works:

1. Begin a transaction.
2. Change the `ContactName` of the Around The Horn record from Thomas Hardy to Dick Solomon.
3. Begin a nested transaction.

4. Change the ContactName of the Bottom-Dollar Markets record from Elizabeth Lincoln to Sally Solomon.
5. Roll back the inner transaction.
6. Commit the outermost transaction.

The net effect is that only the change to the Around The Horn record is permanent. If, however, the inner transaction had been committed and the outer transaction rolled back, then the net effect would be that *none* of the changes were permanent (even the changes in the inner transaction). Although we are using Access to illustrate this behavior, the behavior is the same for all OLE DB providers that support nested transactions. This, of course, leads us to an ongoing theme in our ADO exploration: The ADO documentation simply states how any given feature is supposed to work when it is fully implemented by the OLE DB provider and the DBMS, but it does not necessarily follow that it *is* implemented for all OLE DB providers and all DBMSs. In the example of nested transactions, we have seen that ODBC does not support them and that the Jet OLE DB Provider supports up to five levels of nested transactions. The SQL Server OLE DB Provider does not support nesting.
In SQL Server 7.0 and 2000, full nested transaction support
is provided. In SQL Server 6.5, only "fake nesting" is supported, where all inner-transaction instructions are ignored. You can commit and roll back inner transactions without any effect. It is only the outermost transaction that decides whether the complete sum of all of the work is committed or rolled back.

There is another issue that you should consider if you intend to use nested transactions. TADOConnection has a property called Attributes, which determines how the connection should behave when a transaction is committed or rolled back. It is a set of TXActAttributes that, by default, is empty. There are only two values in TXActAttributes: xaCommitRetaining and xaAbortRetaining (this value is often mistakenly written as xaRollbackRetaining because this would have been a more logical name for it). When xaCommitRetaining is included in Attributes and a transaction is committed, a new transaction is automatically started. When xaAbortRetaining is included in Attributes and a transaction is rolled back, a new transaction is automatically started. This means that if you include these values in Attributes, a transaction will always be in progress, because when you end one transaction another will always be started. Most programmers prefer to be in greater control of their transactions than allowing them to be automatically started, so these values are not commonly used. However, they have a special relevance to nested transactions. If you nest a transaction and set `Attributes` to `[xaCommitRetaining, xaAbortRetaining]`, then the outermost transaction can never be ended. Consider the sequence of events:

1. An outer transaction is started.
2. An inner transaction is started.
3. The inner transaction is committed or rolled back.
4. A new inner transaction is automatically started as a consequence of the `Attributes` property.

The outermost transaction can never be ended because a new inner transaction will also be started when one ends. The conclusion is that the use of the `Attributes` property and the use of nested transactions should be considered mutually exclusive.

Lock Types

ADO supports four different approaches to locking your data for update. In this section I will provide an overview of the four approaches, and in subsequent sections we will take a closer look. The four approaches are made available to you through the dataset's `LockType` property, of type `TLockType`, and can be ltReadOnly, ltPessimistic, ltOptimistic, or ltBatchOptimistic (there is, of course, an ltUnspecified but, for the reasons mentioned earlier, we are ignoring "unspecified" values).

The ltReadOnly value specifies that the data is read-only and cannot be updated. As such, there is effectively no locking control required because the data cannot be updated.

The ltPessimistic and ltOptimistic values offer the same "pessimistic" and "optimistic" locking control that the BDE offers. One important benefit that ADO offers over the BDE in this respect is that the choice of locking control remains yours. If you use the BDE, the decision to use pessimistic or optimistic locking is made for you by the BDE driver you use. If you use a desktop database such as dBase or Paradox, then the BDE driver uses pessimistic locking; if you use a client/server database such as InterBase, SQL Server, or Oracle, the BDE driver uses optimistic locking.

Pessimistic Locking

The words *pessimistic* and *optimistic* in this context refer to the developer's expectations of conflict between user updates. Pessimistic locking assumes that there is a high probability that users will attempt to update the same records at the same time and that a conflict is likely. In order to prevent such a conflict, the record is locked when the edit begins. The record lock is maintained until the update is completed or cancelled. A second user who attempts to edit the same record at the same time will fail in their attempt to place their record lock and will receive a “Could not update; currently locked” exception.

This approach to locking will be familiar to developers who have worked with desktop databases such as dBase and Paradox. The benefit is that the user knows that if they can begin editing a record, then they will succeed in saving their update. The disadvantage of pessimistic locking is that the user is in control of when the lock is placed and when it is removed. If the user is skilled with the application, then this could be as short as a couple of seconds. However, in database terms a couple of seconds is an eternity. At the worst end of the scale, the user can begin an edit and go to lunch, and the record could be locked until the user returns. As a consequence of this, most proponents of pessimistic locking guard against this eventuality by using a TTimer or other such device to time out any locks after a certain amount of keyboard and mouse inactivity.

Another problem with pessimistic locking is that it requires a server-side cursor. Earlier we looked at cursor locations and saw that they have an impact on the availability of the different cursor types. Now we can see that cursor locations also have an impact on locking types. Later in this chapter we will see more benefits of client-side cursors, and if you choose to take advantage of these benefits, then you’ll be unable to use pessimistic locking.

Pessimistic locking is one of the areas of ADOExpress/dbGo that changed in Delphi 6. This section describes the way pessimistic locking works in version 6 (which is now the same as for ADO). Create a new application and add a TADODataSet. Set its `ConnectionString` to use either the Jet or SQL Server Northwind database. Set its `CommandType` to cmdTable and `CommandText` to Customers. As we will be using pessimistic locking, we must set the `CursorLocation` to clUseServer and `LockType` to ltPessimistic. Finally, set `Active` to True. Add a TDataSource and a TDBGrid, connect them altogether, and ensure that the grid is aligned to client.

Now for the test. Run the application and begin editing a record. Using Windows Explorer, run a second copy of the same application and attempt to edit the same record; you will fail because the record is locked by another user.

If you were using ADOExpress in Delphi 5, the attempt to edit the same record at the same time would have succeeded, because ADOExpress in version 5 did not lock the record at the beginning of the edit. The work-around for this problem in Delphi 5 involved creating a clone of the original recordset and forcing a record lock in the clone before an edit, and releasing the record lock before the actual post or when the edit was cancelled.

Jet Page and Row Locking

This section demystifies some of the issues surrounding locking in Microsoft's Jet engine. If you have no interest in Access as a database, you can safely skip over this section.

The Jet 4.0 OLE DB Provider, which you will recall is used primarily for Access 2000 databases although it can also be used with Access 97 databases, supports both page-level and row-level locking. The Jet 3.5 OLE DB Provider, which is used solely for Access 97 databases, supports page-level locking only. A *page* is a length of data. The page in question completely contains the record for which the lock is required. In Jet 3.5, a page is 2 KB in length, and in Jet 4.0 it is 4 KB. It is unlikely that a record is exactly 2 KB or 4 KB, so the locking of a single record usually includes the locking of one or more subsequent records. Clearly this locks additional records unnecessarily, which is a disadvantage of page locking and is the main reason why Jet 4.0 offers a choice of page or row locking.

Row locking, sometimes referred to as Alcatraz in the Jet engine, allows a single row to be locked individually with no additional space locked. As such, this solution provides the least lock contention. The path to understanding locking in Jet lies in Jet's dynamic properties. Most of your control over Jet locking is provided by the ADO Connection object's dynamic properties. The first and most important dynamic property is Jet OLEDB:Database Locking Mode, which can be revealed in a TADOConnection as follows:

```
ShowMessage(ADOConnection1.Properties[
  'Jet OLEDB:Database Locking Mode'].Value);
```

By default this value is 1, which means that the connection will allow recordsets to choose between row locking and page locking. The only alternative value is 0, which forces page locking. However, in order to ensure that all users use the same locking mechanism, the first user who opens the database dictates the locking mode used by all users. This mode remains in force until all users have disconnected from the database.

The second part of the locking jigsaw is the recordset. The recordset itself can specify its locking mode, using the Jet OLEDB:Locking Granularity dynamic property. By default this value is 2, which indicates that it should use row-level locking. Setting this value to 1 indicates that the recordset should use page locking. The Jet OLEDB:Locking Granularity dynamic property is ignored if the connection's Jet OLEDB:Database Locking Mode is not 1. You will have to use the `OnRecordsetCreate` event added in Delphi 6 to set the dynamic property, because it can only be set when the recordset is created but closed. (`OnRecordsetCreate` was not yet functional as this book went to press. Also, if you are using ADOExpress in Delphi 5, you will have to modify the source code of `TCustomADODataSet.OpenCursor` to add in your own `OnRecordsetCreate` event immediately after the recordset is created.) Thus, so far, Jet 4.0 uses row-level locking by default. This is true but there is an extra twist to add to this tale.

Row-level locking is only the default for recordsets. It is not the default for SQL you execute directly, or what BDE developers refer to as “non-passthrough SQL.” For SQL statements you write yourself and execute directly, the default locking mode is still page locking, even using Jet 4.0.

Having gone through these trials and tribulations you will be pleased to learn that Jet provides a significant level of control over its locking facilities. Once again, this control is offered by dynamic properties and is available through TADOConnection. The following list shows the relevant dynamic properties:

Property	Description
Jet OLEDB:Lock Delay	Milliseconds to wait before attempting to reacquire a lock (default is 0)
Jet OLEDB:Lock Retry	Number of times to retry a failed lock (default is 0)
Jet OLEDB:Max Locks Per File	Maximum number of locks that Jet can place on a database (default is 9500)
Jet OLEDB:Page Locks To Table	Number of page locks before Jet promotes to a table lock (default is 0)

Updating JOINs

One of the reasons why people used to turn to cached updates in the BDE and, more recently, TClientDataSet, is to make an SQL JOIN updatable. Consider the following SQL equi-join:

```
SELECT * FROM Products, Suppliers
WHERE Products.SupplierID=Suppliers.SupplierID
```

This statement provides a list of products and the details of the suppliers of those products. The BDE considers any SQL JOIN to be read-only because inserting, updating, and deleting rows in a join is ambiguous. For example, should the insert of a row into the above join result in a new product and also a new supplier or just a new product?

The BDE supports cached updates, which allow the developer to resolve this ambiguity by specifying exactly what the developer wants to happen. Although the BDE’s cached updates implementation is often flawed, and cached updates are now discouraged in favor of the more reliable TClientDataSet, the concept is sound.

ADO supports an equivalent to cached updates, called batch updates, which are very similar. In the next section we will take a closer look at ADO’s batch updates, what they can offer you, and why they are so important. However, in this section they will not be needed to solve the problem of updating a join for a very simple reason: in ADO, joins are naturally updatable. Place a TADOQuery on a form and set its connection string to use a Northwind database. Enter the SQL join above in its SQL property and set `Active` to True. Add a TDataSource and a TDBGrid and connect them altogether and run the program. Now edit one of the Product's fields and save the changes (by moving off the record). No error occurs because the update has been applied successfully. ADO has taken a more practical approach to the problem: it has made some intelligent guesses. In an ADO join, each field object knows which underlying table it belongs to. If you update a field of the Products table and post the change, then a SQL UPDATE statement is generated to update the field in the Products table. If you change a field in the Products table and a field in the Suppliers table, then two SQL UPDATE statements are generated, one for each table.

The inserting of a row into a join follows a similar behavior. If you insert a row and enter values for the Products table only, then a SQL INSERT statement is generated for the Products table. If you enter values for both tables, two SQL INSERT statements are generated, one for each table. The order in which the statements are executed is important, because the new product might relate to the new supplier, so the new supplier is inserted first.

The biggest problem with ADO's solution can be seen when a row in a join is deleted. The deletion attempt will appear to fail. The exact message you see depends on the version of ADO you are using and the DBMS, but it will be along the lines that you cannot delete the row because other records relate to it. The error message can be confusing. In our scenario, the error message implies that a product cannot be deleted because there are records that relate to the product. The error occurs whether the product has any related records or not. The explanation can be found by following through the same logic for deletions as for insertions. Two SQL DELETE statements are generated: one for the Suppliers table and then another for the Products table. Contrary to appearances, the DELETE statement for the Product table succeeds. It is the DELETE statement for the Suppliers table that fails, because the Supplier cannot be deleted while it still has dependent records.

If you are curious about the SQL statements that get generated and you use SQL Server, you can see these statements using SQL Server Profiler.

Despite understanding how this works, a better way of looking at this problem is through the user's eyes. From their point of view, when they delete a row in the grid, do they intend to delete just the product or both the product and the supplier? I would wager that 99% of users expect the former and not the latter. Fortunately you can achieve exactly this with our old friend, the dynamic property—in this case, the Unique Table dynamic property. You can specify that deletes refer to just the Products table and not to Suppliers using the following line of code:

```
ADOQuery1.Properties['Unique Table'].Value := 'Products';
```

As this value cannot be assigned at design time, the next best alternative is to place this line in the form's OnCreate event.

For me, updatable joins are just one of many examples of how the designers of ADO have replaced traditional problems with elegant solutions.

Batch Updates

Batch updates are ADO's equivalent to the BDE's cached updates; they are similar in functionality, syntax, and, to some extent, implementation, with the all-important difference being that their implementation is not fundamentally flawed. The idea is the same for both database technologies: By using batch/cached updates, any changes you make to your records can be made in memory and then later the entire "batch" of changes can be submitted as one operation. There are some performance benefits to this approach, but there are more practical reasons why this technology is a necessity: the user might not be connected to the database at the time they make their updates. This would be the case in the infamous "briefcase" application, which we will return to later, but this can also be the case in Web applications that use another ADO technology, Remote Data Services (RDS).

You can enable batch updates in any ADO dataset by setting LockType to ltBatchOptimistic before the dataset is opened. In addition, you will need to set the CursorLocation to clUseClient, as batch updates are managed by ADO's cursor engine. Hereafter, changes are all made to a "delta" (i.e., a list of changes). The dataset looks to all intents and purposes as if the data has changed, but the changes have only been made in memory; they have not been applied to the database. To make the changes permanent, use UpdateBatch (equivalent to cached updates' ApplyUpdates):

```
ADODataSet1.UpdateBatch;
```

(Fortunately, there is no equivalent to the cached update's CommitUpdates method, because the successful changes are automatically removed from the batch.) To reject the entire batch of updates, use either CancelBatch or CancelUpdates. There are many similarities in method and property names between ADO's batch updates and BDE's cached updates and TClientDataSet. UpdateStatus, for example, can be used in exactly the same way as for cached updates to identify records according to whether they have been inserted, updated, deleted, or unmodified. This is particularly useful for highlighting records in different colors in a grid or showing their status on a status bar. Some differences between the syntaxes are slight, such as changing RevertRecord to CancelBatch(arCurrent). Others require more effort.

One useful cached update feature that is not present in ADO batch updates is the dataset's UpdatesPending property. This property is true if changes have been made but not yet applied. This is particularly useful in a form's OnCloseQuery event:

```
procedure TForm1.FormCloseQuery(
Sender: TObject; var CanClose: Boolean);
begin
  CanClose := True;
  if ADODataSet1.UpdatesPending then
    CanClose := (MessageDlg('Updates are still pending' #13 +
      'Close anyway?', mtConfirmation, [mbYes, mbNo], 0) = mrYes);
end;
```

However, with a little knowledge and a little ingenuity we can implement a suitable ADOUpdatesPending function. The little knowledge is that ADO datasets have a property called FilterGroup, which is a kind of filter. Unlike a dataset's Filter property, which filters the data based on a comparison of the data against a condition, FilterGroup filters based on the status of the record. One such status is fgPendingRecords, which includes all records that have been modified but not yet applied. So to allow the user to look through all of the changes they have made so far, you need only execute two lines:

```
ADODataSet1.FilterGroup := fgPendingRecords;
ADODataSet1.Filtered := True;
```

Naturally, the result set will now include the records that have been deleted. If you try this yourself, the effect that you will see will depend on the version of dbGo you have and the patches you have applied to it. In early versions of ADOExpress, the deleted record showed the fields of the previous record. This either was confusing (if there was a previous record) or resulted in a fatal error (if there wasn't). In later versions, the fields are just left blank, which also is not very helpful because you don't know what record has been deleted.

Back to the UpdatesPending problem. The "little ingenuity" is the knowledge of clones, discussed earlier. The idea of the ADOUpdatesPending function is that it will set the FilterGroup to restrict the dataset to only those changes that have not yet been applied. All we need to do is to see whether there are any records in the dataset once the FilterGroup has been applied. If there are, then some updates are pending. However, if we do this with the actual dataset, then the setting of the FilterGroup will move the record pointer and the user interface will be updated. The best solution is to use a clone.

```
function ADOUpdatesPending(ADODataSet: TCustomADODataSet): boolean;
var
  Clone: TADODataSet;
begin
  Clone := TADODataSet.Create(nil);
  try
    Clone.Clone(ADODataSet);
```

```
      Clone.FilterGroup := fgPendingRecords;
      Clone.Filtered    := True;
      Result := not (Clone.BOF and Clone.EOF);
      Clone.Close;
    finally
      Clone.Free;
    end;
  end;
```

In this function we clone the original dataset, set the FilterGroup, and check to see whether the dataset is at both beginning of file and also end of file. If it is, then no records are pending.

Optimistic Locking

Earlier we looked at the LockType property and saw how pessimistic locking worked. In this section, we'll look at optimistic locking, not only because it is the preferred locking type for medium- to high-throughput transactions but also because it is the locking scheme employed by batch updates.

Optimistic locking assumes that there is a low probability that users will attempt to update the same records at the same time and that a conflict is unlikely. As such, the attitude is that all users can edit any record at any time, and we deal with the consequences of conflicts between different users' updates to the same records when the changes are saved. Thus, conflicts are considered an exception to the rule. This means that there are no controls to prevent two users from editing the same record at the same time. The first user to save their changes will succeed. The second user's attempt to update the same record might fail. This behavior is essential for briefcase applications and Web applications, where there is no permanent connection to the database and, therefore, no way to implement pessimistic locking. In contrast with pessimistic locking, optimistic locking has the additional considerable benefit that resources are consumed only momentarily and, therefore, the average resource usage is much lower, making the database more scalable.

Let's consider an example. Assume that we have a TADODataSet connected to the Customers table of Northwind, that LockType is set to ltBatchOptimistic, and the contents are displayed in a grid. Assume that we also have a button to call UpdateBatch. Run the program twice and begin editing a record in the first copy of the program. Although for the sake of simplicity we will be demonstrating a conflict using just a single machine, the scenario and subsequent events are unchanged when using multiple machines. In this example I will choose the Bottom-Dollar Markets company in Canada and change the name to Bottom-Franc Markets. Save the change, move off the record to post it, and click the button to update the batch. Now, in the second copy of the program, locate the same record and change the company name to Bottom-Pound Markets. Move off the record and click the button to update the batch. It will fail. As with many ADO error messages, the exact message you receive will depend not only on the version of ADO you are using but also on how closely you followed the example. In ADO 2.6, the error message is “Row cannot be located for updating. Some values may have been changed since it was last read.” This is the nature of optimistic locking. The update to the record is performed by executing the following SQL statement:

```
UPDATE CUSTOMERS SET CompanyName="Bottom-Pound Markets"
WHERE CustomerID="BOTTM" AND CompanyName="Bottom-Dollar Markets"
```

The number of records affected by this update statement is expected to be 1, because it locates the original record using the primary key and the contents of the `CompanyName` field as it was when the record was first read. In our example, however, the number of records affected by the UPDATE statement is 0. This can only occur if the record has been deleted, or the record’s primary key has changed, or the field that we are changing was changed by someone else. Hence, the update fails.

If our “second user” had changed the `ContactName` field and not the `CompanyName` field, then the UPDATE statement would have looked like this:

```
UPDATE CUSTOMERS SET ContactName="Liz Lincoln"
WHERE CustomerID="BOTTM" AND ContactName="Elizabeth Lincoln"
```

In our scenario, this statement would have succeeded because the other user didn’t change the primary key or the contact name.

This behavior differs from the BDE’s behavior in the same scenario. In this example, using the BDE the attempt to update the contact name would have failed because, by default, the BDE includes every field in the WHERE clause. The consequence of this is that any change to the record will fail if any other user has already changed any field, regardless of whether the changed fields are the same fields or different fields. Fortunately, both the BDE and ADO allow you to specify how you want to locate the original record: in the BDE you use the `UpdateMode` property, and in ADO the Update Criteria dynamic property of a dataset. The following list shows the possible values that can be assigned to this dynamic property:

Constant	**Locate Records By**
adCriteriaKey	Primary key columns only
adCriteriaAllCols	All columns
adCriteriaUpdCols	Primary key columns and changed columns only
adCriteriaTimeStamp	Primary key columns and a timestamp column only

The reason why the BDE and ADO differ in their behavior is that their defaults differ. The BDE’s default behavior is equivalent to ADO’s adCriteriaAllCols, whereas ADO’s default is adCriteriaUpdCols. Don’t fall into the trap of thinking that one of these settings is better than another for your whole application. In practice, your choice of setting will be influenced by the contents of each table. Say that the Customers table has just CustomerID, Name, and City fields. In this case, the update of any one of these fields is logically not mutually exclusive with the update of any of the other fields, so a good choice for this table would be adCriteriaUpdCols (i.e., the default). If, however, the Customers table included a PostalCode field, then the update of a PostalCode field would be mutually exclusive with the update of the City field by another user (because if the city changes, then surely so should the postal code, and possibly vice versa). In this case, you could argue that adCriteriaAllCols would be a safer solution.

Another issue to be aware of is how ADO deals with errors during the update of multiple records. Using the BDE's cached updates and TClientDataSet, you can use the OnUpdateError event to handle each update error as the error occurs and resolve the problem before moving on to the next record. In ADO, you cannot establish such a dialog. You can monitor the progress and success or failure of the updating of the batch using the dataset's OnWillChangeRecord and OnRecordChangeComplete, but you cannot revise the record and resubmit it during this process as you can with the BDE and TClientDataSet. There's more: if an error occurs during the update process, the updating does not stop. It continues to the end until all updates have been applied or have failed. This can produce a rather unhelpful and blatantly incorrect error message. If more than one record cannot be updated, or the single record that failed is not the last record to be applied, then the error message in ADO 2.6 is "Multiple-step OLE DB operation generated errors. Check each OLE DB status value, if available. No work was done." The last sentence is the problem; it states that "No work was done," but this is incorrect. It is true that no work was done on the record that failed, but other records were successfully applied and their updates stand.

Resolving Update Conflicts

As a consequence of the nature of applying updates, the approach that you need to take to update the batch is to update the batch, let the individual records fail, and then deal with the failed records once the process is over. You can determine which records have failed by setting the dataset's FilterGroup to fgConflictingRecords:

```
ADODataSet1.FilterGroup := fgConflictingRecords;
ADODataSet1.Filtered := True;
ADODataset1.Recordset.Resync(adAffectGroup, adResyncUnderlyingValues);
```

For each failed record, you can inform the user of three critical pieces of information about each field using the following TField properties:

Property	Description
NewValue	The value this user changed it to
CurValue	The new value from the database
OldValue	The value when first read from the database

Users of TClientDataSet will be aware of the very handy `TReconcileErrorForm` dialog, which wraps up the process of showing the user the old and new records and allows them to specify what action to take. Unfortunately, there is no ADO equivalent to this form, and `TReconcileErrorForm` has been written with TClientDataSet so much in mind that it is difficult to convert it for use with ADO datasets.

One last gotcha to point out when using these `TField` properties: They are taken straight from the underlying ADO Field objects to which they refer. This means, as is common in ADO, that you are at the mercy of your chosen OLE DB provider to support the features you hope to use. All is well for most providers, but the Jet OLE DB Provider returns the same value for `CurValue` as it does for `OldValue`. In other words, if you use Jet, you cannot determine what the other user changed the field to unless you resort to your own measures.

Disconnected Recordsets

All this knowledge of batch updates allows us to take advantage of our next ADO feature: disconnected recordsets. A disconnected recordset is a recordset that has been disconnected from its connection. What is impressive about this feature is that the user cannot tell the difference between a regular recordset and a disconnected one; their feature sets and behavior are almost identical. To disconnect a recordset from its connection, the `CursorType` must be set to clUseClient and the `LockType` must be set to ltBatchOptimistic. You then simply tell the dataset that it no longer has a connection:

```
ADODataSet1.Connection := nil;
```

Hereafter, the recordset will continue to contain the same data, support the same navigational features, and allow records to be added, edited, and deleted. The only relevant difference is that you cannot update the batch because you need to be connected to the server to update the server. To reconnect the connection (and use `UpdateBatch`):

```
ADODataSet1.Connection := ADOConnection1;
```

This same feature is available to the BDE and other database technologies by switching over to TClientDataSets, but the beauty of the ADO solution is that you can build your entire application using dbGo dataset components and be unaware of disconnected recordsets. At the point that you discover this feature and want to take advantage of it, you can continue to use the same components that you always used.

So why would you want to disconnect your recordsets? For two reasons:

- To keep the total number of connections lower
- To create a briefcase application

I'll cover keeping down the number of connections here and return to briefcase applications later. Most regular client/server business applications open tables and maintain a permanent connection to their database while the table is open. However, there are usually only two reasons why you want to be connected to the database: to retrieve data and to update data. If you change your regular client/server application so that, after the table is opened and the data retrieved, then the dataset is disconnected from the connection and the connection dropped, your user will be none the wiser and the application will not need to maintain an open database connection. The following code shows the two steps:

```
ADODataSet1.Connection := nil;
ADOConnection1.Connected := False;
```

The only other point at which a connection is required is when the batch of updates needs to be applied, so the update code would look like this:

```
ADOConnection1.Connected := True;
ADODataSet1.Connection := ADOConnection1;
try
  ADODataSet1.UpdateBatch;
finally
  ADODataSet1.Connection := nil;
  ADOConnection1.Connected := False;
end;
```

If this approach were followed throughout the application, the average number of open connections at any one time would be minimal because the connections would only be open for the small amount of time that they are required. The consequence of this change is scalability; The application will be able to cope with significantly more simultaneous users than one that maintains an open connection. The downside, of course, is that the reopening of the connection can be a lengthy process on some, but not all, database engines, so the application will be slower to update the batch.

Connection Pooling

All of this talk of dropping connections and reopening them brings us to the subject of connection pooling. Connection pooling, not to be confused with session pooling, allows connections to a database to be reused once they have been finished with. This happens automatically and, if your OLE DB provider supports it and it is enabled, you need take no action to take advantage of connection pooling. There is a single reason why you would want to pool your connections: performance. The problem with database connections is that it can take time to establish a connection. In a desktop database such as Access, this is typically a small amount of time. In a client/server database such as Oracle used on a network, this time could be measured in seconds. Given such an expensive (in performance terms) resource, it makes sense to promote its reuse. With ADO's connection pooling enabled, ADO Connection objects are placed in a pool when the application "destroys" them. Subsequent attempts to create an ADO connection will automatically search the connection pool for a connection with the same connection string. If a suitable connection is found, it is reused; otherwise, a new connection is created. The connections themselves stay in the pool until they are reused, the application closes, or they time out. By default, connections will time out after 60 seconds, but from MDAC 2.5 onward you can set this using the `HKEY_CLASSES_ROOT\CLSID\<ProviderCLSID>\SPTimeout` registry key. The connection pooling process occurs seamlessly, without the intervention or knowledge of the developer. This process is similar to the BDE's database pooling under Microsoft Transaction Server (MTS) and COM+, with the important exception that ADO performs its own connection pooling without the aid of MTS or COM+.

By default, connection pooling is enabled on all of the MDAC OLE DB providers for relational databases (including SQL Server and Oracle) with the notable exception of the Jet OLE DB Provider. If you use ODBC you should choose between ODBC's connection pooling and ADO's connection pooling, but you should not use both. From MDAC 2.1 on, ADO's connection pooling is enabled and ODBC's is disabled.

NOTE Connection pooling does not occur on Windows 95 regardless of the OLE DB provider.

To be truly comfortable with connection pooling, you will need to see the connections getting pooled and timed out. Unfortunately, there are no adequate ADO connection pool spying tools available at the time of writing, so we will use SQL Server's Performance Monitor as it can accurately spy on SQL Server database connections. Figure 16.7 is a look at SQL Server's Performance Monitor with all of the "counters" deleted except User Connections. This allows us to concentrate of the subject of connection pooling.

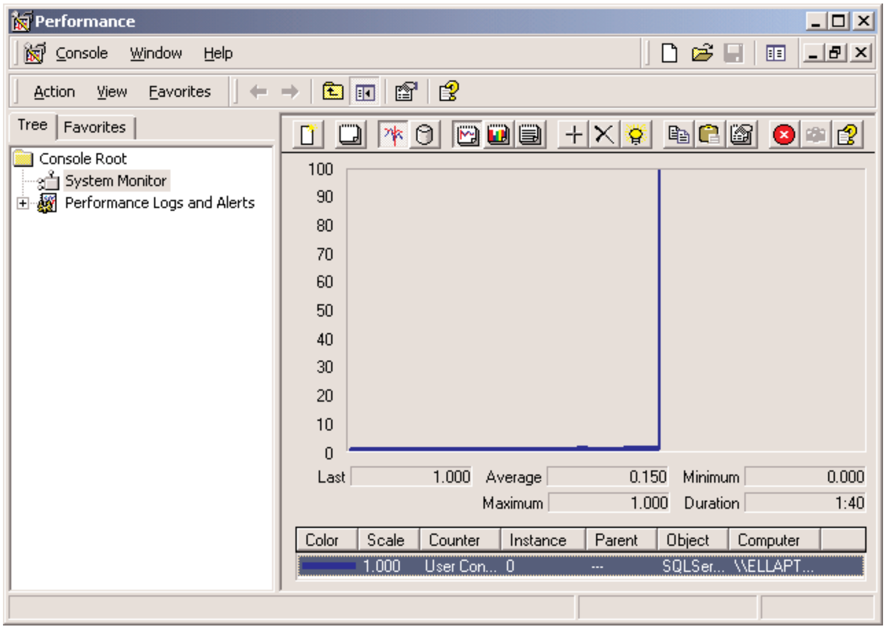
The Last field under the graph shows us the number of active connections to the database.

To see how connection pooling works, you can set up a very simple test. Create a new application and add a TADOConnection to the form. Set the `ConnectionString` to use the SQL Server OLE DB Provider and the Northwind database but leave `Connected` as False. Now add a check box with the following `OnClick` event:

```
procedure TForm1.CheckBox1Click(Sender: TObject);
begin
  ADOConnection1.Connected := CheckBox1.Checked;
end;
```

FIGURE 16.7:

SQL Server's Performance Monitor



Last 1.000 Average 0.150 Minimum 0.000
Maximum 1.000 Duration 1:40

Color	Scale	Counter	Instance	Parent	Object	Computer
▬	1.000	User Con...	0	---	SQLSer...	\\ELLAPT...

Run the program and make sure that you can see the Performance Monitor at the same time. Now click the check box to open the connection. In the Performance Monitor, you will see the connection count increase by one. Now close the application and the count immediately decreases by one, because the connection pool is destroyed with the application. Now rerun the program, check the check box, and check it a second time to close the connection. You will see that the connection count does not decrease by one. Observe Performance Monitor for a further 60 seconds, and the connection count will then decrease by one when the pooled connection times out.

You can enable or disable connection pooling either in the Registry or in the connection string. The key in the Registry is `OLEDB_SERVICES` and can be found at `HKEY_CLASSES_ROOT\CLSID\<ProviderCLSID>`. It is a bit array that allows you to disable several OLE DB services, including connection pooling, transaction enlistment, and the cursor engine. To disable connection pooling using the connection string, include `";OLE DB Services=-2"` at the end of the connection string. To enable connection pooling for the Jet OLE DB Provider, you can include `";OLE DB Services=-1"` at the end of the connection string, which enables all OLE DB services.

Persistent Recordsets

One of the very useful features that contributes to the briefcase model is persistent recordsets. These allow you to save the contents of any recordset to a local file, which can be loaded later. Apart from aiding with the briefcase model, this feature allows developers to create true single-tier applications. It means that you can deploy a database application without having to deploy a database. This makes for a very small footprint on your client's machine.

You can "persist" your datasets using the SaveToFile method:

```
ADODataSet1.SaveToFile('Local.ADTG');
```

This will save the data and its delta in a file on your hard disk. You can reload this file using the LoadFromFile method, which accepts a single parameter indicating the file to load. The format of the file is Advanced Data Table Gram (ADTG), which is a proprietary Microsoft format. It does, however, have the advantage of being very efficient. If you prefer, you can save the file as XML by passing a second parameter to SaveToFile:

```
ADODataSet1.SaveToFile('Local.XML', pfXML);
```

However, ADO does not have its own built-in XML parser (as TClientDataSet does), so it must use the MSXML parser. Your user must either install Internet Explorer 5 or later or download the MSXML parser from the Microsoft Web site. If you intend to persist your files locally in XML format, be aware of a few disadvantages. First, the saving and loading of XML files is slower than the saving and loading of ADTG files. Second, ADO's XML files (and XML files in general) are significantly larger than their ADTG counterparts (XML files are typically twice as large as their ADTG counterparts). Third, ADO's XML format is specific to Microsoft, as most companies' XML implementations are. This means that the XML generated in ADO is not readable by Borland's TClientDataSet and vice versa. In fact, it's worse than that, because the XML generated in ADO 2.1 is incompatible with the XML in ADO 2.5. Fortunately this last problem can be overcome using Delphi 6's new TXMLTransform component, which can be used to translate between different XML structures.

If you intend to use these features solely for single-tier applications and not as part of the briefcase model, then you can save yourself a little effort by using a TADODataSet and setting its CommandType to cmdFile and its CommandText to the name of the file. This will save you the effort of having to call LoadFromFile manually. You will, however, still have to call SaveToFile. In a briefcase application, however, this approach is too limiting, as the dataset can be used in two different modes.

The Briefcase Model

Our new-found knowledge of batch updates, disconnected recordsets, and persistent recordsets allows us to take advantage of the "briefcase model." The idea behind the briefcase model is that your users want to be able to use your application while they are out on the road. They want to take the same application that they use on the desktops in the office and use it on their laptops while on their clients' sites. The problem with this scenario traditionally is that when your users are at their clients' sites, they are not connected to their database server, because their database server is running on their network back at their office. Consequently, there is no data on their laptop, and the data cannot be updated anyway.

This is where that new-found knowledge comes in. Assume that the application has already been written; the user has requested this new briefcase enhancement, and you have to retrofit it into your existing application. You need to add a new option for your users to allow them to "prepare" the briefcase application. This simply consists of executing `SaveToFile` for each and every table in the database. The result is a collection of ADTG or XML files that mirror the contents of the database. These files are then copied to the laptop where a copy of the application has previously been installed.

The application needs to be sensitive to whether it is running locally or connected to the network. You can decide this either by attempting to connect to the database and seeing whether it fails, by detecting the presence of a local "briefcase" file, or by creating some flag of your own design. If the application decides it is running in briefcase mode, then it needs to use `LoadFromFile` for each table instead of setting `Connected` to True for the TADOConnections and `Active` to True for the ADO datasets. Thereafter, the briefcase application needs to use `SaveToFile` instead of `UpdateBatch` whenever data is saved. Upon return to the office, there needs to be an update process where each table is loaded from its local file, the dataset is connected to the database, and the changes are applied using `UpdateBatch`. Voilà, the briefcase model.

Deploying MDAC

MDAC, and therefore ADO, can be almost freely distributed. There are some conditions on its distribution, but these are to protect Microsoft from unreasonable behavior and it is unlikely that regular application developers will fall afoul of them. To distribute MDAC, you distribute and execute `MDAC_TYP.EXE`. You may not distribute and install MDAC components individually. If you use InstallShield Express For Delphi, then you will have to run `MDAC_TYP.EXE` separately from your regular InstallShield Setup program, because InstallShield Express For Delphi cannot shell out to an external program—i.e., `MDAC_TYP.EXE`. If you use an installation program that can shell out to another program, you might want to be aware of some of the parameters you can pass to MDAC_TYP.EXE. The various parameters affect whether the user has to specifically accept the end user license, whether the file copy dialog is shown, whether there is an automatic reboot on completion (or the user decides to reboot or there is no reboot), and, finally, whether MDACSET.LOG is a summary log file or a full log file. The /Q parameter is a quiet, but not completely silent, setup. A truly silent setup can be achieved with /Q:A /C:"setup /QNT" parameters. See the Platform SDK for a complete list of setup parameters. Although I have not tested installing every version of MDAC on top of every other version of MDAC, my experience is that, despite the progress bar indicating the successful progress of the installation, an earlier version of MDAC does not overwrite a later version of MDAC.

In addition to installing MDAC, you will also need to install DCOM if the target is Windows 95.

One invaluable tool that you should add to your toolbox is Component Checker. This is available for free download from www.microsoft.com/data/download.htm. Component Checker is the most accurate method of determining which version of MDAC is installed on a machine. It scans for all ADO, OLE DB, and ODBC files and gets their version numbers. It can compare all of these version numbers against its own internal database of correct version numbers for each release of MDAC. At the end of its analysis, it reveals the version of MDAC that most closely matches the files installed on a machine. It is also useful as a kind of "REGEDIT For MDAC," as it reports on all of the MDAC registry information using a considerably more relevant user interface than REGEDIT. Finally, it is the only safe way of removing MDAC from a machine.

ADO.NET

ADO.NET is part of Microsoft's new dotNet (or ".NET") architecture—their redesign of application development tools to better suit the needs of Web development. At the time of writing, Visual Studio.NET was in beta, so this section has been included solely as a means to give you an idea of where ADO is heading.

ADO.NET is a revolution of ADO. It looks at the problems of Web development and addresses shortcomings of ADO's solution. The problem with ADO's solution is that it is based on COM. For one- and two-tier applications, COM imposes few problems, but in the world of Web development it is unacceptable as a transport mechanism. COM suffers from three main problems for use in Web development: it (mostly) runs only on Windows; the transmission of recordsets from one process requires COM marshalling; and COM calls cannot penetrate corporate firewalls. ADO.NET's solution to all of these problems is to use XML.

Continued on next page

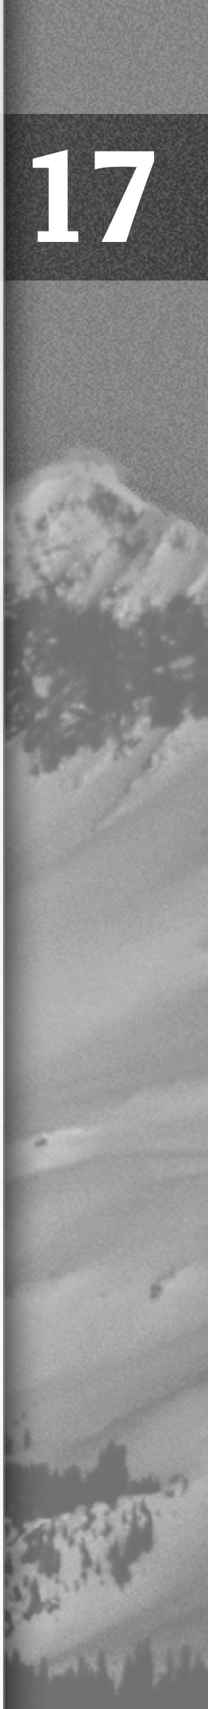
Some other redesign issues focus around breaking up the ADO recordset into separate classes. The resulting classes are adept at solving a single problem instead of multiple problems. For example, the ADO.NET class currently called `DataSetReader` is very similar to a read-only, forward-only server-side recordset and, as such, is best suited to reading a result set very quickly. A `DataTable` is most like a disconnected, client-side recordset. A `DataRelation` has similarities with the MSDataShape OLE DB Provider. So you can see that your knowledge of how ADO works is of great benefit in understanding the basic principles of ADO.NET.

If you wish to experiment with ADO.NET in Delphi before direct support is added to Delphi, then you will need to give Delphi access to the ADO.NET classes, which are called "managed" classes and are based on a new run-time environment called the Common Language Runtime (CLR). These classes are not COM classes and, as such, Delphi cannot normally access them. However, Visual Studio.NET includes a utility called `REGASM.EXE`, which takes any "assembly" (library of managed classes) and creates a COM type library interface to the managed classes. As Delphi can easily access COM classes, simply import the resulting type library into Delphi and use the classes as if they were COM classes.

What's Next?

This chapter described ActiveX Data Objects (ADO) and dbGo, the set of Delphi components for accessing the ADO interfaces. You've seen how to take advantage of Microsoft Data Access Components (MDAC) and various server engines, and I've described some of the benefits and hurdles you'll encounter in using ADO.

The next chapter will take you into the world of Delphi's DataSnap architecture, for developing custom client and server applications in a three-tier environment.



CHAPTER 17

Multitier Database Applications with DataSnap

- Logical three-tier architecture
- The technical foundation of DataSnap
- The connection protocols and the data packets
- Delphi's support components (client-side and server-side)
- The connections broker and other new Delphi 6 features

Large companies often have broader needs than applications using local database and SQL servers can meet. In the past few years, Borland Software Corporation has been addressing the needs of large corporations, and it even temporarily changed its own name to Inprise to underline this new enterprise focus. The name was changed back to Borland, but the focus on enterprise development remains.

Delphi is targeting many different technologies: three-tier architectures based on Windows NT and DCOM, CORBA architectures based on NT and Unix servers, TCP/IP and socket applications, and—most of all—SOAP- and XML-based Web services. This chapter focuses on database-oriented multitier architectures, while XML-oriented solutions will be discussed in Chapter 23, "XML and SOAP."

Even though I haven't yet discussed COM and sockets (covered in Chapters 19 to 21), in this chapter we'll build multitier architectures based on those technologies. As we'll use high-level Delphi support, not knowing the details of some of the foundations should not create any problem. I'll concentrate more on the programming aspects of these architectures than on installation and configuration (the latter aspects are subject to change across different operating systems and are too complex to cover thoroughly).

Before proceeding, I should emphasize two important elements. First, the tools to support this kind of development are available only in the Enterprise version of Delphi; and second, you'll have to pay a license fee to Borland in order to deploy the necessary server-side software for DataSnap. This second requirement makes this architecture cost-effective mainly for large systems (that is, servers connected to dozens or even hundreds of clients). The license fee is only required for deployment of the server application and is a flat fee for each server you deploy to (regardless of the number of clients that will connect). The license fee is not required for development or evaluation purposes.

NOTE You spend money on the DataSnap license, but you might save on the SQL server client licenses. When SQL server licenses were based on the number of connections, companies have saved tens of thousands of dollars in those licenses by connecting the hundreds of clients to a few instances of the DataSnap server, using few connections with the SQL server. Nowadays, the licenses for most SQL servers are based on the number of users who connect to the database, not the number of connections active at each time, so this kind of savings doesn't always apply.

One, Two, Three Levels

Initially, database PC applications were client-only solutions: the program and the database files were on the same computer. From there, adventuresome programmers moved the database files onto a network file server. The client computers still hosted the application software and the entire database engine, but the database files were now accessible to several users at the same time. You can still use this type of configuration with a Delphi application and Paradox files (or, of course, Paradox itself), but the approach was much more widespread just few years ago.

The next big transition was to client/server development, embraced by Delphi since its first version. In the client/server world, the client computer requests the data from a server computer, which hosts both the database files and a database engine to access them. This architecture downplays the role of the client, but it also reduces its requirements for processing power on the client machine. Depending on how the programmers implement client/server, the server can do most (if not all) of the data processing. In this way, a powerful server can provide data services to several less powerful clients.

Naturally, there are many other reasons for using centralized database servers, such as the concern for data security and integrity, simpler backup strategies, central management of data constraints, and so on. The database server is often called a SQL server, because SQL is the language most commonly used for making queries into the data, but it may also be called a DBMS (database management system), reflecting the fact that the server provides tools for managing the data, such as support for backup and replication.

Of course, some applications you build may not need the benefits of a full DBMS, so a simple client-only solution might be sufficient. On the other hand, you might need some of the robustness of a DBMS system, but on a single, isolated computer. In this case, you can use a local version of a SQL server, such as InterBase. Traditional client/server development is done with a two-tier architecture. However, if the DBMS is primarily performing data storage instead of data- and number-crunching, the client might contain both user interface code (formatting the output and input with customized reports, data-entry forms, query screens, and so on) and code related to managing the data (also known as *business rules*). In this case, it's generally a good idea to try to separate these two sections of the program and build a logical three-tier architecture. The term *logical* here means that there are still just two computers (that is, two physical tiers), but we've now partitioned the application into three distinct elements.

Delphi 2 introduced support for a logical three-tier architecture with data modules. As you'll recall, a *data module* is a nonvisual container for the data access components of an application, but it often includes several handlers for database-related events. You can share a single data module among several different forms and provide different user interfaces for the same data; there might be one or more data-input forms, reports, master/detail forms, and various charting or dynamic output forms.

The logical three-tier approach solves many problems, but it also has a few drawbacks. First, you must replicate the data-management portion of the program on different client computers, which might hamper performance, but a bigger issue is the complexity this adds to code maintenance. Second, when multiple clients modify the same data, there's no simple way to handle the resulting update conflicts. Finally, for logical three-tier Delphi applications, you must install and configure the database engine (if any) and SQL server client library on every client computer.

The next logical step up from client/server is to move the data-module portion of the application to a separate server computer and design all the client programs to interact with it. This is exactly the purpose of remote data modules, which were introduced in Delphi 3. Remote data modules run on a server computer—generally called the application server. The application server in turn communicates with the DBMS (which can run on the application server or on another dedicated computer). Therefore, the client machines don't connect to the SQL server directly, but indirectly via the application server.

At this point there is a fundamental question: Do we still need to install the database access software? The traditional Delphi client/server architecture (even with three logical tiers) requires you to install the database access on each client, something quite troublesome when you must configure and maintain hundreds of machines. In the physical three-tier architecture, you need to install and configure the database access only on the application server, not on the client computers. Since the client programs have only user interface code and are extremely simple to install, they now fall into the category of so-called *thin clients*. To use marketing-speak, we might even call this a *zero-configuration thin-client architecture*. But let us focus on technical issues instead of marketing terminology.

The Technical Foundation of DataSnap

When Borland introduced this physical multitier architecture in Delphi, it was called MIDAS (Middle-tier Distributed Application Services). For example, Delphi 5 included the third version of this technology, MIDAS 3. Now Delphi 6 renames this technology as *DataSnap* and extends its capabilities.

DataSnap requires the installation of specific libraries on the server (actually the middle-tier computer), which provides your client computers with the data extracted from the SQL server database or other data sources. DataSnap does not require a SQL server for data storage. DataSnap can serve up data from a wide variety of sources, including SQL, CORBA, other DataSnap servers, or just data computed on the fly.

As you would expect, the client side of DataSnap is extremely thin and easy to deploy. The only file you need is `Midas.dll`, a small (260 KB) DLL that implements the `ClientDataSet` and `RemoteServer` components and provides the connection to the application server. As we've seen in Chapter 14, "Client/Server Programming," this DLL is basically a small, stand-alone database engine. It caches data from a remote data module and enforces the rules requested by the Constraint Broker.

The application server uses the same DLL to handle the datasets (called *deltas*) returned from the clients when they post updated or new records. However, the server also requires several other libraries, all of which are installed by DataSnap.

The *IAppServer* Interface

Starting with Delphi 5, the two sides of a DataSnap application communicate using the `IAppServer` interface.

NOTE In Delphi 5 (and 6), the `IAppServer` interface supersedes Delphi 4's `IProvider` interface. The main reason for this change was support for stateless objects. With `IProvider`, the server stored status information about the client program—for example, which records had already been passed to the client. This made it difficult to adapt the server-side objects to stateless connection layers, like CORBA message queues and MTS, and also to move toward HTTP and Web-based support. Other reasons for moving to this new architecture were to make the system more dynamic (providers are now exported by setting a property, not by changing the type library) and to reduce the number of calls, or *round-trips*, which can affect performance. DataSnap makes fewer calls but delivers more data each time.

The `IAppServer` interface has the following methods:

```
AS_ApplyUpdates
AS_GetRecords
AS_DataRequest
AS_GetProviderNames
AS_GetParams
AS_RowRequest
AS_Execute
```

You'll seldom need to call them directly, anyway, because there are Delphi components to be used on the client and server sides of the application that embed these calls, making them easier (and at times even hiding them completely). In practice, the server will make available to the client objects implementing this interface, possibly along with other custom interfaces.

NOTE A DataSnap server exposes an interface using a COM type library, a technology I'll discuss in Chapter 20, "Automation, ActiveX, and Other COM Technologies."

The Connection Protocol

DataSnap defines only the higher-level architecture and can use different technologies for moving the data from the middle tier to the client side. DataSnap supports most of the leading standards, including the following:

Distributed COM (DCOM) and Stateless COM (MTS or COM+) DCOM is directly available in Windows NT/2000 and 98/Me, and it requires no additional run-time applications on the server. You still have to install it on Windows 95 machines. DCOM is basically an extension of COM technology (discussed in Chapter 19, "COM Programming," and Chapter 20) that allows a client application to use server objects that exist and execute on a separate computer. The DCOM infrastructure allows you to use stateless COM objects, available in the COM+ and in the older MTS (Microsoft Transaction Server) architectures. Both COM+ and MTS provide features such as security, component management, and database transactions, and are available in Windows NT/2000 and in Windows 98/Me.

Due to the complexity of DCOM configuration and of its problems in passing through firewalls, even Microsoft is abandoning DCOM in favor of SOAP-based solutions.

TCP/IP sockets These are available on most systems. Using TCP/IP you might distribute clients over the Web, where DCOM cannot be taken for granted, and have many fewer configuration headaches. To use sockets, the middle-tier computer must run the `ScktSrvr.exe` application provided by Borland, a single program that can run either as an application or as a service. This program receives the client requests and forwards them to the remote data module (executing on the same server) using COM. Sockets provide no protection against failure on the client side, as the server is not informed and might not release resources when a client unexpectedly shuts down.

HTTP and SOAP The use of HTTP as a transport protocol over the Internet simplifies connections through firewalls or proxy servers (which generally don't like custom TCP/IP sockets). You need a specific Web server application, `httpsrvr.dll`, which accepts client requests and creates the proper remote data modules using COM. These Web connections can use SSL security but must register themselves by adding a call to `EnableWebTransport` in the `UpdateRegistry` method. Finally, Web connections based on HTTP transport can use DataSnap object-pooling support.

NOTE The DataSnap HTTP transport can use XML as the data packet format, enabling any platform or tool that can read XML to participate in a DataSnap architecture. This is an extension of the original DataSnap data packet format, which is also platform-independent. The use of XML over HTTP is also the foundation of SOAP. There's more on XML in Chapter 23.

CORBA Common Object Request Broker Architecture is an official standard for object management available on most operating systems. Compared to DCOM, the advantage is that your client and server applications can be also written with Java and other products. The Borland implementation of CORBA, VisiBroker, is available with Delphi Enterprise. CORBA provides many benefits, including location transparency, load balancing, and failover from the ORB run-time software. (An in-depth discussion of CORBA is certainly beyond the scope of this book, and in practice only a limited number of Delphi programmers use CORBA.)

Internet Express As an extension to this architecture, you can transform the data packets into XML and deliver them to a Web browser. In this case, you basically have one extra tier: the Web server gets the data from the middle tier and delivers it to the client. I'll discuss this new architecture, called Internet Express, in Chapter 23. The DLL can also be folded into the executable file by using the MidasLib unit.

Providing Data Packets

The entire Delphi multitier data-access architecture centers around the idea of *data packets*. In this context, a data packet is a block of data that moves from the application server to the client or from the client back to the server. Technically, a data packet is a sort of subset of a dataset. It describes the data it contains (usually a few records of data), and it lists the names and types of the data fields. Even more important, a data packet includes the constraints—that is, the rules to be applied to the dataset. You'll typically set these constraints in the application server, and the server sends them to the client applications along with the data.

All communication between the client and the server occurs by exchanging data packets. The provider component on the server manages the transmission of several data packets within a big dataset, with the goal of responding faster to the user. As the client receives a data packet, in a ClientDataSet component, the user can edit the records it contains. As mentioned earlier, during this process the client also receives and checks the constraints, which are applied during the editing operations.

When the client has updated the records and sends a data packet back, that packet is known as a *delta*. The delta packet tracks the difference between the original records and the updated ones, recording all the changes the client requested from the server. When the client asks to apply the updates to the server, it sends the delta to the server, and the server tries to apply each of the changes. I say *tries* because if a server is connected to several clients, the data might have changed already, and the update request might fail.

Since the delta packet includes the original data, the server can quickly determine if another client has already changed it. If so, the server fires an `OnReconcileError` event, which is one of the vital elements for thin-client applications. In other words, the three-tier architecture uses an update mechanism similar to the one Delphi uses for cached updates. As we have seen in Chapter 14, "Client/Server Programming Techniques," the `ClientDataSet` manages data in a memory cache, and it typically reads only a subset of the records available on the server side, loading more elements only as they're needed. When the client updates records or inserts new ones, it stores these pending changes in another local cache on the client, the *delta cache*.

The client can also save the data packets to disk and work off-line, thanks to the MyBase support discussed in Chapter 13, "Delphi's Database Architecture." Even error information and other data moves using the data packet protocol, so it is truly one of the foundation elements of this architecture.

NOTE It's important to remember that data packets are protocol-independent. A data packet is merely a sequence of bytes, so anywhere you can move a series of bytes, you can move a data packet. This was done to make the architecture suitable for multiple transport protocols (including DCOM, CORBA, HTTP, and TCP/IP) and for multiple platforms.

Delphi Support Components (Client-Side)

Now that we've examined the general foundations of Delphi's three-tier architecture, we can focus on the components that support it. For developing client applications, Delphi provides the ClientDataSet component, which provides all the standard dataset capabilities and embeds the client side of the `IAppServer` interface. In this case, the data is delivered through the remote connection.

The connection to the server application is made via another component you'll also need in the client application. You should use one of the four specific connection components (available in the DataSnap page):

- The DCOMConnection component can be used on the client side to connect to a DCOM and MTS server, located either on the current computer or in another one indicated by the `ComputerName` property. The connection is with a registered object having a given `ServerGUID` or `ServerName`.
- The CorbaConnection component can be used to hook with a CORBA server. You indicate the `HostName` (the name or IP address) to indicate the server computer, the `RepositoryID` to request a specific data module on the server, and optionally the `ObjectName` property if the data module exports multiple objects.
- The SocketConnection component can be used to connect to the server via a TCP/IP socket. You should indicate the IP address or the host name, and the GUID of the server object (in the `InterceptGUID` property). In Delphi 5, this connection component

has an extra property, SupportCallbacks, which you can disable if you are not using callbacks and want to deploy your program on Windows 95 computers that don't have Winsock 2 installed.

NOTE In the WebServices page, you can also find the SoapConnection component, which requires a specific type of server and will be discussed in Chapter 23.

- The WebConnection component is used to handle an HTTP connection that can easily get through a firewall. You should indicate the URL where your copy of httpsrvr.dll is located and the name or GUID of the remote object on the server.

Delphi 6 adds new client-side components to the DataSnap architecture, mainly for managing connections:

- The ConnectionBroker component can be used as an alias of an actual connection component, something useful when you have a single application with multiple client datasets. In fact, to change the physical connection of each of the datasets, you only need to change the Connection property of the ConnectionBroker. You can also use the events of this virtual connection component in place of those of the actual connections, so you don't have to change any code if you change the data transport technology. For the same reason, you can refer to the AppServer object of the ConnectionBroker instead of the corresponding property of a physical connection.
- The SharedConnection component can be used to connect to a secondary (or child) data module of a remote application, piggy-backing on an existing physical connection to the main data module. In other words, an application can connect to multiple data modules of the server with a single, shared connection.
- The LocalConnection component can be used to target a local dataset provider as the source of the data packet. The same effect can be obtained by hooking the ClientDataSet directory to the provider. However, using the LocalConnection, you can write a local application with the same code as a complete multitier application, using the IAppServer interface of the "fake" connection. This will make the program easier to scale up, compared to a program with a direct connection.

A few other components of the DataSnap page relate to the transformation of the DataSnap data packet into custom XML formats. These components (XMLTransform, XMLTransform-Provider, and XMLTransformClient) will be discussed in Chapter 23.

Delphi Support Components (Server-Side)

On the server side (or actually the middle tier), you'll need to create an application or a library that embeds a remote data module, a special version of the `TDataModule` class. There are actually specialized remote data modules for transactional COM and CORBA support. In the Multitier page of the New Items dialog box (obtained with the File ➢ New ➢ Others menu) are specific wizards to create remote data modules of each of these types.

The only specific component you need on the server side is the DataSetProvider. You need one of these components for every table or query you want to make available to the client applications, which will then use a separate ClientDataSet component for every exported dataset. The DataSetProvider was already introduced in Chapter 14.

NOTE The DataSetProvider component of Delphi 5 and 6 supersedes the stand-alone Provider component of Delphi 4 and the internal Provider object, which was embedded in the `TBDEDataSet` subclasses.

Building a Sample Application

Now we're ready to build a sample program. This will allow us to observe some of the components I've just described in action, and it will also allow us to focus on some other problems, shedding light on other pieces of the Delphi multitier puzzle. I'll build the client and application server portions of a three-tier application in two steps. The first step will simply test the technology using a bare minimum of elements. These programs will be very simple.

From that point, we'll add more power to the client and the application server. In each of the examples, we'll display data from local Paradox tables, and we'll set up everything to allow you to test the programs on a stand-alone computer. I won't cover the steps you have to follow to install the examples on multiple computers with various technologies—that would be the subject of at least one other book.

The First Application Server

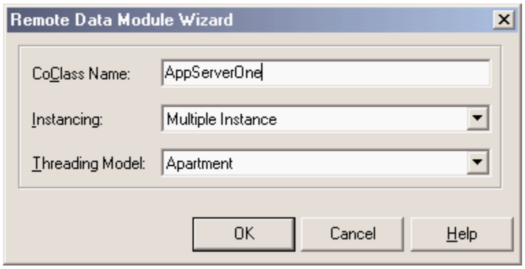
The server side of our basic example is very easy to build. Simply create a new application and add a remote data module to it using the corresponding icon in the Multitier page of the Object Repository. The simple Remote Data Module Wizard (see Figure 17.1) will ask you for a class name and the instancing style. As you enter a class name, such as AppServerOne, and click the OK button, Delphi will add a data module to the program. This data module will have the usual properties and events, but its class will have the following Pascal declaration:

```
type
  TAppServerOne = class(TRemoteDataModule, IAppServerOne)
  private
```

```
    { Private declarations }
  protected
    class procedure UpdateRegistry(Register: Boolean;
      const ClassID, ProgID: string); override;
  public
    { Public declarations }
  end;
```

FIGURE 17.1:

The simple Remote Data Module Wizard



Remote Data Module Wizard

CoClass Name: AppServerOne

Instancing: Multiple Instance

Threading Model: Apartment

In addition to inheriting from the TRemoteDataModule base class, this class implements the custom IAppServerOne interface, which derives from the standard DataSnap interface (IAppServer). The class also overrides the UpdateRegistry method to add the support for enabling the socket and Web transports, as you can see in the code generated by the wizard. At the end of the unit, you'll find the class factory declaration, which will become clear after reading Chapter 19:

```
initialization
  TComponentFactory.Create(ComServer, TAppServerOne,
    Class_AppServerOne, ciMultiInstance, tmApartment);
end.
```

Now you can add a dataset component to the data module (I've used the dbExpress SQLDataSet), connect it to a database and a table or query, activate it, and finally add a DataSetProvider and hook it to the dataset component. You'll obtain a DFM file like this:

```
object AppServerOne: TAppServerOne
  object SQLConnection1: TSQLConnection
    ConnectionName = 'IBLocal'
    LoginPrompt = False
  end
  object SQLDataSet1: TSQLDataSet
    SQLConnection = SQLConnection1
    CommandText = 'select * from EMPLOYEE'
  end
  object DataSetProvider1: TDataSetProvider
    DataSet = SQLDataSet1
    Constraints = True
    end
  end
```

What about the main form of this program? Well, it's almost useless, so we can simply add a label to it indicating that it's the form of the server application. When you've built the server, you should compile it and run it once. This operation will automatically register it as an Automation server on your system, making it available to client applications. Of course, you should register the server on the computer where you want it to run, either the client or the middle tier.

The First Thin Client

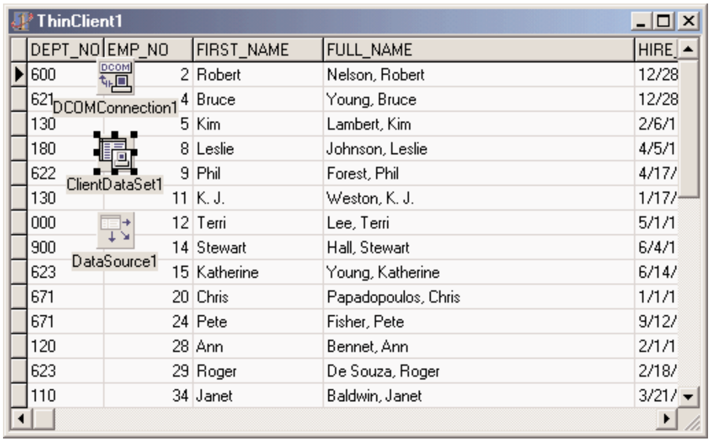
Now that we have a working server, we can build a client that will connect to it. We'll again start with a standard Delphi application and add a DCOMConnection component to it (or the proper component for the specific type of connection you want to test). This component defines a `ComputerName` property that you'll use to specify the computer that hosts the application server. If you want to test the client and application server from the same computer, you can leave this blank.

Once you've selected an application server computer, you can simply display the `ServerName` property's combo-box list to view the available DataSnap servers. This combo box shows the servers' registered names, by default the name of the executable file of the server followed by the name of the remote data module class, as in `AppServ1.AppServerOne`. Alternatively, you can type the GUID of the server object in the `ServerGUID` property. Delphi will automatically fill this property as you set the `ServerName` property, determining the GUID by looking it up in the Registry.

At this point, if you set the DCOMConnection component's `Connected` property to True, the server form will appear, indicating that the client has activated the server. You don't usually need to perform this operation, because the ClientDataSet component typically activates the RemoteServer component for you. I've suggested this simply to emphasize what's happening behind the scenes.

TIP You should generally leave the DCOMConnection component's `Connected` property set to False at design time, to be able to open the project in Delphi even on a computer where the DataSnap server is not already registered.

As you might expect, the next step is to add a ClientDataSet component to the form. You must connect the ClientDataSet to the `DCOMConnection1` component via the `RemoteServer` property, and thereby to one of the providers it exports. You can see the list of available providers in the `ProviderName` property, via the usual combo box. In this example, you'll be able to select only `DataSetProvider1`, as this is the only provider available in the server we've just built. This operation connects the dataset in the client's memory with the dbExpress dataset on the server. If you activate the client dataset and add a few data-aware controls (or a DBGrid), you'll immediately see the server data appear in them, as illustrated in Figure 17.2.



DEPT_NO	EMP_NO	FIRST_NAME	FULL_NAME	HIRE_

FIGURE 17.2: When you activate a ClientDataSet component connected to a remote data module at design time, the data from the server becomes visible as usual.

Here is the DFM file for our minimal client application, ThinCli1:

```
object Form1: TForm1
  Caption = 'ThinClient1'
  object DBGrid1: TDBGrid
    Align = alClient
    DataSource = DataSource1
  end
  object DCOMConnection1: TDCOMConnection
    ServerGUID = '{09E11D63-4A55-11D3-B9F1-00000100A27B}'
    ServerName = 'AppServ1.AppServerOne'
  end
  object ClientDataSet1: TClientDataSet
    Aggregates = <>
    Params = <>
    ProviderName = 'DataSetProvider1'
    RemoteServer = DCOMConnection1
  end
  object DataSource1: TDataSource
    DataSet = ClientDataSet1
  end
end
```

Obviously, the programs of our first three-tier application are quite simple, but they demonstrate how to create a dataset viewer that splits the work between two different executable files. At this point, our client is only a viewer. If you edit the data on the client, it won't be updated on the server. To accomplish this, you'll need to add some more code to the client. However, before we do that, let's add some features to the server.

Adding Constraints to the Server

When you write a traditional data module in Delphi, you can easily add some of the application logic, or business rules, by handling the dataset events, and by setting field object properties and handling their events. You should avoid doing this work on the client application; instead, write your business rules on the middle tier.

In the DataSnap architecture, you can send some constraints from the server to the client and let the client program impose those constraints during the user input. You can also send field properties (such as minimum and maximum values and the display and edit masks) to the client and (using some of the data access technologies) process updates through the dataset used to access the data (or a companion UpdateSql object).

Field and Table Constraints

When the provider interface creates data packets to send to the client, it includes the field definitions, the table and field constraints, and one or more records (as requested by the ClientDataSet component). This implies that you can customize the middle tier and build distributed application logic by using SQL-based constraints.

The constraints you create using SQL expressions can be assigned to an entire dataset or to specific fields. The provider sends the constraints to the client along with the data, and the client applies them before sending updates back to the server. This reduces network traffic, compared to having the client send updates back to the application server and eventually up to the SQL server, only to find that the data is invalid. Another advantage of coding the constraints on the server side is that if the business rules change, you need to update the single server application and not the many clients on multiple computers.

But how do you write constraints? There are several properties you can use:

- BDE datasets have a `Constraints` property, which is a collection of `TCheckConstraint` objects. Every object has a few properties, including the expression and the error message.
- Each field object defines the `CustomConstraint` and `ConstraintErroMessage` properties. There is also an `ImportedConstraint` property for constraints imported from the SQL server.
- Each field object has also a `DefaultExpression` property, which can be used locally or passed to the ClientDataSet. This is not an actual constraint, only a suggestion to the end user.

Our next example, AppServ2, adds a few constraints to a remote data module connected to the sample EMPLOYEE InterBase database. After connecting the table to the database and creating the field objects for it, you can set the following special properties:

```
object SQLDataSet1: TSQLDataSet
  ...
  object SQLDataSet1EMP_NO: TSmallintField
    CustomConstraint = 'x > 0 and x < 10000'
    ConstraintErrorMessage =
      'Employee number must be a positive integer below 10000'
    FieldName = 'EMP_NO'
  end
  object SQLDataSet1FIRST_NAME: TStringField
    CustomConstraint = 'x <> '#39#39
    ConstraintErrorMessage = 'The first name is required'
    FieldName = 'FIRST_NAME'
    Size = 15
  end
  object SQLDataSet1LAST_NAME: TStringField
    CustomConstraint = 'not x is null'
    ConstraintErrorMessage = 'The last name is required'
    FieldName = 'LAST_NAME'
  end
end
```

NOTE The expression `'x <> '#39#39` is the DFM transposition of the string `x <> ''`, indicating that we don't want to have an empty string. The final constraint, `not x is null`, instead allows empty strings but not null values.

Including Field Properties

You can control whether the properties of the field objects on the middle tier are sent to the ClientDataSet (and copied into the corresponding field objects of the client side), by using the `poIncFieldProps` value of the `Options` property of the DataSetProvider. This flag controls the download of the field properties `Alignment`, `DisplayLabel`, `DisplayWidth`, `Visible`, `DisplayFormat`, `EditFormat`, `MaxValue`, `MinValue`, `Currency`, `EditMask`, and `DisplayValues`, if they are available in the field. Here is an example of another field of the AppServ2 example with some custom properties:

```
object SQLDataSet1SALARY: TBCDField
  DefaultExpression = '10000'
  FieldName = 'SALARY'
  DisplayFormat = '#,###'
  EditFormat = '####'
  Precision = 15
  Size = 2
end
```

With this setting, you can simply write your middle tier the way you usually set the fields of a standard client/server application. This approach also makes it faster to move existing applications from a client/server to a multitier architecture. The main drawback of sending fields to the client is that transmitting all the extra information takes time. Turning off `poIncFieldProps` can dramatically improve network performance of datasets with many columns.

A server can generally filter the fields returned to the client; it does this by declaring persistent field objects with the Fields editor and omitting some of the fields. Because a field you're filtering out might be required to identify the record for future updates (if the field is part of the primary key), you can also use the field's `ProviderFlags` property on the server to send the field value to the client but make it unavailable to the ClientDataSet component (this provides some extra security, compared to sending the field to the client and hiding it there).

Field and Table Events

You can write middle-tier dataset and field event handlers as usual and let the dataset process the updates received by the client in the traditional way. This means that updates are considered to be operations on the dataset, exactly as when a user is directly editing, inserting, or deleting fields locally.

This is accomplished by setting the `ResolveToDataSet` property of the `TDatasetProvider` component, again connecting either the dataset used for input or a second one used for the updates. This approach is possible with datasets supporting editing operations. These includes BDE, ADO, and InterBase Express datasets, but not those of the new dbExpress architecture.

With this technique, the updates are performed by the dataset, which implies a lot of control (the standard events are being triggered) but generally slower performance. Flexibility is much greater, as you can use standard coding practices. Also, porting existing local or client/server database applications, which use dataset and field events, is much more straightforward with this model. However, keep in mind that the user of the client program will receive your error messages only when the local cache (the delta) is sent back to the middle tier. Saying to the user that some data prepared half an hour ago is not valid might be a little awkward. If you follow this approach, you'll probably need to apply the updates in the cache at every `AfterPost` event on the client side.

Finally, if you decide to let the dataset and not the provider do the updates, Delphi helps you a lot in handling possible exceptions. Any exceptions raised by the middle-tier update events (for example, `OnBeforePost`) are automatically transformed by Delphi into update errors, which activate the `OnReconcileError` event on the client side (more on this event later in this chapter). No exception is shown on the middle tier, but the error travels back to the client.

Adding Features to the Client

After adding some constraints and field properties to the server, we can now return our attention to the client application. The first version was very simple, but now there are several features we can add to it to make it work well. In the ThinCli2 example, I've embedded support for checking the record status and accessing the delta information (the updates to be sent back to the server), using some of the ClientDataSet techniques already discussed in Chapter 13. The program also handles reconcile errors and supports the briefcase model.

Keep in mind that while you're using this client to edit the data locally, you'll be reminded of any failure to match the business rules of the application, set up on the server side using constraints. The server will also provide us with a default value for the Salary field of a new record and pass along the value of its `DisplayFormat` property. In Figure 17.3 you can see one of the error messages this client application can display, which it receives from the server. This message is displayed while editing the data locally, not when you send it back to the server.

FIGURE 17.3:

The error message displayed by the ThinCli2 example when the employee ID is too large

usUnmodified	623	15	Katherine	6/14/1990
usUnmodified				

Employee number must be a positive integer below 10000.

The Update Sequence

This client program also includes a button to Apply the updates to the server and a standard reconcile dialog. Here is a summary of the complete sequence of operations related to an update request and the possible error events:

1. The client program calls the `ApplyUpdates` method of a ClientDataSet.
2. The delta is sent to the provider on the middle tier. The provider fires the `OnUpdateData` event, where you have a chance to look at the requested changes before they reach the

database server. At this point you can modify the delta, which is passed in a format compatible with the data of a ClientDataSet.

3. The provider (technically, a part of the provider called the "resolver") applies each row of the delta to the database server. Before applying each update, the provider receives a `BeforeUpdateRecord` event. If you've set the `ResolveToDataSet` flag, this update will eventually fire local events of the dataset in the middle tier.

4. In case of a server error, the provider fires the `OnUpdateError` event (on the middle tier) and the program has a chance of fixing the error at that level.

5. If the middle-tier program doesn't fix the error, the corresponding update request remains in the delta. The error is returned to the client side at this point or after a given number of errors have been collected, depending on the value of the `MaxErrors` parameter of the `ApplyUpdates` call.

6. Finally, the delta packet with the remaining updates is sent back to the client, firing the `OnReconcileError` event of the ClientDataSet for each remaining update. In this event handler, the client program can try to fix the problem (possibly prompting the user for help), modifying the update in the delta, and later reissuing it.

Refreshing Data

You can obtain an updated version of the data, which other users might have modified, by calling the `Refresh` method of the ClientDataSet. However, this operation can be done only if there are no pending update operations in the cache, as calling `Refresh` raises an exception when the change log is not empty:

```
if cds.ChangeCount = 0 then
  cds.Refresh;
```

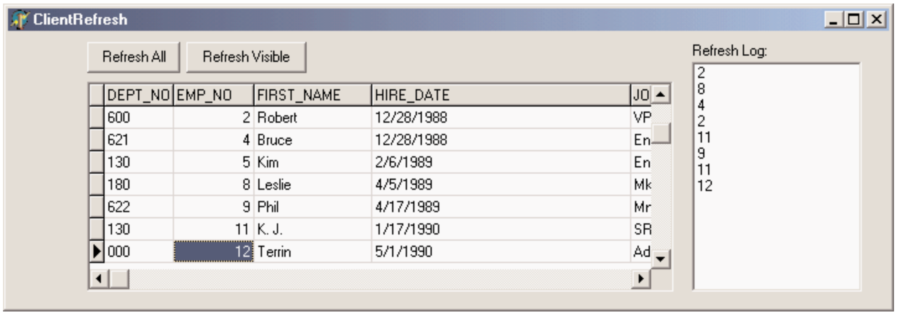
If only some records have been changed, you can refresh the others by calling `RefreshRecords`. This method refreshes only the current record, but it should be used only if the user hasn't modified the current record. In this case, in fact, `RefreshRecords` leaves the unapplied changes in the change log. As an example, you can refresh a record every time it becomes the active one, unless it has been modified and the changes have not yet been posted to the server:

```
procedure TForm1.cdsAfterScroll(DataSet: TDataSet);
begin
  if cds.UpdateStatus = usUnModified then
    cds.RefreshRecord;
end;
```

When the data is subject to frequent changes by many users and each user should see changes right away, you should generally apply any change immediately in the `AfterPost` and `AfterDelete` methods, and call `RefreshRecords` for the active record (as shown above) or each of the records visible inside a grid. This code is actually part of the ClientRefresh example, connected to the AppServ2 server. For debugging purposes, the program also logs the EMP_NO field for each record it refreshes, as you can see in Figure 17.4.

FIGURE 17.4:

The form of the ClientRefresh example, which automatically refreshes the active record and allows more extensive updates by pressing the buttons



DEPT_NO	EMP_NO	FIRST_NAME	HIRE_DATE	JO
600	2	Robert	12/28/1988	VP
621	4	Bruce	12/28/1988	En
130	5	Kim	2/6/1989	En
180	8	Leslie	4/5/1989	Mk
622	9	Phil	4/17/1989	Mr

000	12	Terrin	5/1/1990	Ad

```
2
8
4
2
11
9
11
12
```

I've done this by adding a button to the ClientRefresh example. The handler of this button moves from the current record to the first visible record of the grid and then to the last visible record. This is accomplished by noting that there are `RowCount - 1` rows visible, assuming that the first row is the fixed one hosting the field names. The program doesn't call `RefreshRecord` every time, as each movement will trigger an `AfterScroll` event with the code shown above. This is the code to refresh the visible rows, which might even be triggered by a timer:

```
var
  i: Integer;
  bm: TBookmarkStr;
begin
  // refresh visible rows
  cds.DisableControls;
  // start with the current row
  i := TMyGrid(DbGrid1).Row;
  bm := cds.Bookmark;
  try
    // get back to the first visible record
    while i > 1 do
    begin
      cds.Prior;
      Dec (i);
    end;
    // return to the current record
    i := TMyGrid(DbGrid1).Row;
    cds.Bookmark := bm;
    // go ahead until the grid is complete
    while i < TMyGrid(DbGrid1).RowCount do
    begin
      cds.Next;
      Inc (i);
    end;
  finally
    // set back everything and refresh
    cds.Bookmark := bm;
    cds.EnableControls;
  end;
```

This approach generates a huge amount of network traffic, so you might want to trigger updates only when there are actual changes. This can be implemented by adding a callback technology to the server, so that it can inform all connected clients that a given record has changed. The client can determine whether it is interested in the change and eventually trigger the update request.

Advanced DataSnap Features

There are many more features in DataSnap than I've covered up to now. Here is a quick tour of some of the more advanced features of the architecture, partially demonstrated by the AppSPlus and ThinPlus examples. Unfortunately, demonstrating every single idea would turn this chapter into an entire book (and not every Delphi programmer is interested in and can afford DataSnap), so I'll limit myself to an overview.

Besides the features discussed in the following sections, the AppSPlus and ThinPlus examples demonstrate the use of a socket connection, limited logging of events and updates on the server side, and direct fetching of a record on the client side. The last feature is accomplished with this call:

```
procedure TClientForm.ButtonFetchClick(Sender: TObject);
begin
  ButtonFetch.Caption := IntToStr (cds.GetNextPacket);
end;
```

This allows you to get more records than are actually required by the client user interface (the DBGrid). In other words, you can fetch records directly, without waiting for the user to scroll down in the grid. I suggest you study the details of these complex examples after reading the rest of this section.

ThinPlus example: This program requires Delphi's socket server (provided in Delphi's bin folder) to run. This is apparently not clear in the text. Without this program you'll see a socket error.

Parametric Queries

If you want to use parameters in a query or stored procedure, then instead of building a custom solution (with a custom method call to the server), you can let Delphi help you. First define the query on the middle tier with a parameter, such as:

```
select * from customer where Country = :Country
```

Use the `Params` property to set the type and default value of the parameter. On the client side, you can use the Fetch Params command of the ClientDataSet's shortcut menu, after connecting it to the proper provider. At run time, you can call the equivalent `FetchParams` method of the ClientDataSet component.

Now you can provide a local default value to the parameter by acting on the `Params` property. This will be sent to the middle tier when you fetch the data. The ThinPlus example refreshes the parameter with the following code:

```
procedure TFormQuery.btnParamClick(Sender: TObject);
begin
  cdsQuery.Close;
  cdsQuery.Params[0].AsString := EditParam.Text;
  cdsQuery.Open;
end;
```

You can see the secondary form of this example, which shows the result of the parametric query in a grid, in Figure 17.5. In the figure you can also see some custom data sent by the server, as explained in the section "Customizing the Data Packets."

FIGURE 17.5:

Custom Method Calls

Since the server has a normal COM interface, we can add more methods or properties to it and call them from the client. Simply open the type library editor of the server and use it as with any other COM server. In the AppSPlus example, I've added a custom `Login` method with the following implementation:

```
procedure TAppServerPlus.Login(const Name, Password: WideString);
begin
  // TODO: add actual login code...
  if Password <> Name then
    raise Exception.Create ('Wrong name/password combination received')
  else
    Query.Active := True;
  ServerForm.Add ('Login:' + Name + '/' + Password);
end;
```

The program makes a simple test, instead of checking the name/password combination against a list of authorizations as a real application should do. Also, disabling the `Query` doesn't really work, as it can be activated by the provider. Disabling the DataSetProvider is actually a more robust approach. The client has a simple way to access the server, the `AppServer` property of the remote connection component. Here is a sample call from the ThinPlus example, which takes place in the `AfterConnect` event of the connection component:

```
procedure TClientForm.ConnectionAfterConnect(Sender: TObject);
begin
  Connection.AppServer.Login (Edit2.Text, Edit3.Text);
end;
```

Note that you can call extra methods of the COM interface through DCOM and also using a socket-based or HTTP connection. Because the program uses the `safecall` calling convention, the exception raised on the server is automatically forwarded and displayed on the client side. This way, when a user selects the Connect check box, the event handler used to enable the client datasets is interrupted, and a user with the wrong password won't be able to see the data.

NOTE Besides direct method calls from the client to the server, you can also implement callbacks from the server to the client. This can be used, for example, to notify every client of specific events. COM events are one way to do this. As an alternative, you can add a new interface, implemented by the client, which passes the implementation object to the server. This way, the server can call the method on the client computer. Callbacks are not possible with HTTP connections, though.

Master/Detail Relations

If your middle-tier application exports multiple datasets, you can retrieve them using multiple ClientDataSet components on the client side and connect them locally to form a master/detail structure. This will create quite a few problems for the detail dataset unless you retrieve all of the records locally.

This solution also makes it quite complex to apply the updates; you cannot usually cancel a master record until all related detail records have been removed, and you cannot add detail records until the new master record is properly in place. (Actually, different servers handle this differently, but in most cases where a foreign key is used, this is the standard behavior.) What you can do to solve this problem is to write complex code on the client side to update the records of the two tables according to the specific rules.

A completely different approach is to retrieve a single dataset that already includes the detail as a dataset field, a field of type TDatasetField. To accomplish this, you need to set up the master/detail relation on the server application:

```
object TableCustomer: TTable
  DatabaseName = 'DBDEMOS'
  TableName = 'customer.db'
end
object TableOrders: TTable
  DatabaseName = 'DBDEMOS'
  MasterFields = 'CustNo'
  MasterSource = DataSourceCust
  TableName = 'ORDERS.DB'
end
object DataSourceCust: TDataSource
  DataSet = TableCustomer
end
object ProviderCustomer: TDataSetProvider
  DataSet = TableCustomer
end
```

On the client side, the detail table will show up as an extra field of the ClientDataSet, and the DBGrid control will display it as an extra column with an ellipsis button. Clicking the button will display a secondary form with a grid presenting the detail table (see Figure 17.6). If you need to build a flexible user interface on the client, you can then add a secondary ClientDataSet connected to the dataset field of the master dataset, using the DataSetField property. Simply create persistent fields for the main ClientDataSet and then hook up the property:

```
object cdsDet: TClientDataSet
  DataSetField = cdsTableOrders
end
```

With this setting you can show the detail dataset in a separate DBGrid placed as usual in the form (the bottom grid of Figure 17.6) or in any other way you like. Note that with this structure, the updates relate only to the master table, and the server should handle the proper update sequence even in complex situations.

FIGURE 17.6:

The ThinPlus example shows how a dataset field can either be displayed in a grid in a floating window or extracted by a ClientDataSet and displayed in a second form. You'll generally do one of the two things, not both!

Using the Connection Broker

I've already mentioned that the ConnectionBroker component can be helpful in case you might want to change the physical connection used by many ClientDataSet components of a single program. In fact, by hooking each ClientDataSet to the ConnectionBroker, you can change the physical connection of them all simply by updating the physical connection of the broker.

These are the settings used by the ThinPlus example:

```
object Connection: TSocketConnection
  ServerName = 'AppSPlus.AppServerPlus'
  AfterConnect = ConnectionAfterConnect
  Address = '127.0.0.1'
end
object ConnectionBroker1: TConnectionBroker
  Connection = Connection
end
```

```
object cds: TClientDataSet
  ConnectionBroker = ConnectionBroker1
end
// in the secondary form
object cdsQuery: TClientDataSet
  ConnectionBroker = ClientForm.ConnectionBroker1
end
```

That's basically all you have to do. To change the physical connection, drop a new DataSnap connection component to the main form and set the `Connection` property of the broker to it.

WARNING There are some glitches with the ConnectionBroker, even in the shipping version of Delphi 6. If you experience unusual errors in a program that uses this component, try removing it. Of course, this note applies only until Borland provides a patch to fix this behavior.

More Provider Options

I've already mentioned the `Options` property of the DataSetProvider component, noting that it can be used to add the field properties to the data packet. There are several other options you can use to customize the data packet and the behavior of the client program. Here is a short list:

- You can minimize downloading BLOB data with poFetchBlobsOnDemand option. In this case, the client application can download BLOBs by specifying the `FetchOnDemand` property of the ClientDataSet to True or by calling the `FetchBlobs` method for specific records. Similarly, you can disable the automatic downloading of detail records by setting the poFetchDetailsOnDemand option. Again, the client can use the `FetchOnDemand` property or call the `FetchDetails` method.
- When you are using a master/detail relation, you can control cascades with either of two options. The poCascadeDeletes flag controls whether the provider should delete detail records before deleting a master record. You can set this option if the database server performs cascaded deletes for you as part of its referential integrity support. Similarly, you can set the poCascadeUpdates option when the update of key values of a master/detail relation can be performed automatically by the server.
- You can limit the operations on the client side. The most restrictive option, poReadOnly, disables any update. If you want to give the user a limited editing capability, use poDisableInserts, poDisableEdits, or poDisableDeletes.
- You can resend to the client a copy of the records the client has modified with `poAutoRefresh`, which is useful in case other users have simultaneously made other, nonconflicting changes. You can also send back to the client changes done in the `BeforeUpdateRecord`

or AfterUpdateRecord event handlers by specifying the poPropogateChanges option. This option is also handy when you are using autoincrement fields, triggers, and other techniques that modify data on the server or middle tier beyond the changes requested from the client tier.

- Finally, if you want the client to drive the operations, you can enable the poAllowCommandText option. This lets you set the SQL query or table name of the middle tier from the client, using the GetRecords or Execute methods.

The Simple Object Broker

The SimpleObjectBroker component provides an easy way to locate a server application among several server computers. You simply provide a list of available computers, and the client will try each of them in order until it finds one that is available.

Moreover, if you enable the LoadBalanced property, the component will randomly choose one of the servers; when many clients use the same configuration, the connections will be automatically distributed among the multiple servers. If this seems like a "poor man's" object broker, consider that some highly expensive load-balancing systems don't actually offer much more than this.

Object Pooling

When multiple clients connect to your server at the same time, you have two options. The first is to create a remote data module object for each of them and let each request be processed in sequence (the default behavior for a COM server with the ciMultiInstance style). Alternatively, you can let the system create a different instance of the application for every client (ciSingleInstance). This requires more resources and more SQL server connections (and licenses), potentially overloading the BDE (as it cannot handle more than a set number of threads or processes).

An alternative approach is offered by the support in DataSnap for object pooling. All you need to do to request this feature is add a call to RegisterPooled in the overridden UpdateRegistry method. Combined with the stateless support built into this architecture, the pooling capability allows you to share some middle-tier objects among a much larger number of clients.

The users on the client computers will spend most of their time reading data and typing in updates, and they generally don't continue asking for data and sending updates. When the client is not calling a method of the middle-tier object, this can be used for another client. Being stateless, in fact, every request reaches the middle tier as a brand-new operation, even when a server is dedicated to a specific client.

Pooling mechanisms are built into MTS and CORBA, but DataSnap makes it available also for HTTP and socket-based connections, and for the Internet Express Web client.

Customizing the Data Packets

There are many ways to include custom information within the data packet handled by the `IAppServer` interface. The simplest is probably to handle the `OnGetDataSetProperties` event of the provider itself. This event has a `Sender` parameter, a dataset parameter indicating where the data is coming from, and an `OleVariant` array `Properties` parameter, in which you can place the extra information. You need to define one variant array for each extra property and include the name of the extra property, its value, and whether you want the data to return to the server along with the update delta (the `IncludeInDelta` parameter).

Of course, you can pass properties of the related dataset component, but you can also pass any other value (extra fake properties). In the AppSPlus example, I pass to the client the time the query was executed and its parameters:

```
procedure TAppServerPlus.ProviderQueryGetDataSetProperties(
  Sender: TObject; DataSet: TDataSet; out Properties: OleVariant);
begin
  Properties := VarArrayCreate([0,1], varVariant);
  Properties[0] := VarArrayOf(['Time', Now, True]);
  Properties[1] := VarArrayOf(['Param', Query.Params[0].AsString, False]);
end;
```

On the client side, the ClientDataSet component has a `GetOptionalParameter` method to retrieve the value of the extra property with the given name. The ClientDataSet also has the `SetOptionalParameter` method to add more properties to the dataset. These values will be saved to disk (in the briefcase model) and eventually sent back to the middle tier (by setting the `IncludeInDelta` member of the variant array to True). Here is a simple example of the retrieval of the dataset in the code above:

```
Caption := 'Data sent at ' + TimeToStr (TDateTime (
  cdsQuery.GetOptionalParam('Time')));
Label1.Caption := 'Param ' + cdsQuery.GetOptionalParam('Param');
```

The effect of this code was visible in Figure 17.5. An alternative and more powerful approach for customizing the data packet sent to the client is to handle the `OnGetData` event of the provider, which receives the outgoing data packet in the form of a client dataset. Using the methods of this client dataset, you can edit data before it is sent to the client. For example, you might encode some of the data or filter out sensitive records.

What's Next?

Borland originally introduced its multitier technology in Delphi 3 and has kept extending it from version to version. In addition to further updates and the change of the MIDAS name to DataSnap, Delphi 6 sees the introduction of XML and SOAP support, introducing an alternate and extended architecture for multitier applications. We'll fully explore this topic in Chapter 23.

For the moment, we'll continue with database programming, discussing data-aware controls and custom datasets. In the next part of the book we'll explore COM, sockets, and Internet programming, getting to XML and SOAP at the end of the book, after we've discussed a lot of foundation material.

CHAPTER 18

Writing Database Components

- Data-aware components: the data link
- Field-oriented data-aware controls
- Data-aware TrackBar and ProgressBar
- Record-oriented data-aware controls
- A record viewer
- Building custom datasets
- Saving a dataset to a local stream

In Chapter 11, “Creating Components,” we explored the development of Delphi components in depth. Now that I’ve discussed database programming, we can get back to the earlier topic and focus on the development of database-related components.

There are basically two families of such components. There are data-aware controls you can use to present the data of a field or an entire record to the users of a program. There are dataset components you can define to provide data to existing data-aware controls, reading it from a database or any other data source. In this chapter, I’ll cover both topics.

The Data Link

When you write a Delphi database program, you generally connect some data-aware controls to a DataSource component, and then connect the DataSource component to a dataset. The connection between the data-aware control to the DataSource is called a *data link* and is represented by an object of class `TDataLink`. The data-aware control creates and manages this object and represents its only connection to the data. From a more practical perspective, to make a component data-aware, you need to add a data link to it and surface some of the properties of this internal object, such as the `DataSource` and `DataField` properties.

Delphi uses the DataSource and DataLink objects for bidirectional communication. The dataset uses the connection to notify the data-aware controls that new data is available (because the dataset has been activated, or the current record has changed, and so on). Data-aware controls use the connection to ask for the current value of a field or to update it, notifying the dataset of this event.

The relations among all these components are complicated by the fact that some of the connections can be one-to-many. For example, you can connect multiple data sources to the same dataset, and you generally have multiple data links to the same data source, simply because you need one link for every data-aware component, and in most cases you connect multiple data-aware controls to each data source.

The *TDataLink* Class

We’ll work for much of this chapter with `TDataLink` and its derived classes, which are defined in the DB unit. This class has a set of protected virtual methods, which have a role similar to events. They are “almost-do-nothing” methods you can override in a specific subclass to intercept user operations and other data-source events. Here is a list, extracted from the source code of the class:

```
type
  TDataLink = class(TPersistent)
  protected
    procedure ActiveChanged; virtual;
    procedure CheckBrowseMode; virtual;
    procedure DataSetChanged; virtual;
    procedure DataSetScrolled(Distance: Integer); virtual;
    procedure FocusControl(Field: TFieldRef); virtual;
    procedure EditingChanged; virtual;
    procedure LayoutChanged; virtual;
    procedure RecordChanged(Field: TField); virtual;
    procedure UpdateData; virtual;
```

All of these virtual methods are called by the DataEvent private method, a sort of window procedure for a data source, a procedure triggered by several data events (see the TDataEvent enumeration). These events originate in the dataset, fields, or data source, and are generally applied to a dataset. The DataEvent method of the dataset component dispatches the events to the connected data sources. Each data source calls the NotifyDataLinks method to forward the event to each connected data link, and then the data source triggers either its own OnDataChange or OnUpdateData event.

Derived DataLink Classes

The TDataLink class is not technically an abstract class, but you'll seldom use it directly. When you need to create data-aware controls, you'll need to use one of its derived classes or derive a new one yourself. The most important class derived from TDataLink is the TFieldDataLink class, which is used by data-aware controls that relate to a single field of the dataset. Most data-aware controls fall into this category, and the TFieldDataLink class solves the most common problems of this type of component.

All of the table- or record-oriented data-aware controls define specific subclasses of TDataLink, as we'll do later on. The TFieldDataLink class has a list of events corresponding to the virtual methods of the base class it overrides. This makes the class simpler to customize, as you can use event handlers instead of having to inherit a new class from it. Here's an example of an overridden method, which fires the corresponding event, if available:

```
procedure TFieldDataLink.ActiveChanged;
begin
  UpdateField;
  if Assigned(FOnActiveChange) then FOnActiveChange(Self);
end;
```

The TFieldDataLink class contains also the Field and FieldName properties that let you connect the data-aware control to a specific field of the dataset. The link keeps also a reference to the current visual component, using the Control property.

Writing Field-Oriented Data-Aware Controls

Now that you understand the theory of how the data link classes work, I can start building some data-aware controls. The first two examples I'll build are data-aware versions of the ProgressBar and TrackBar common controls. We can use the first to display a numeric value, such as a percentage, in a visual way. We can use the second to allow a user to change the numeric value as well.

A Read-Only ProgressBar

A data-aware version of the ProgressBar control is a relatively simple case of a data-aware control, because it is a read-only control. This component is derived from the version that's not data-aware and adds a few properties of the data link object it encapsulates:

```
type
  TMdDbProgress = class(TProgressBar)
  private
    FDataLink: TFieldDataLink;
    function GetDataField: string;
    procedure SetDataField (Value: string);
    function GetDataSource: TDataSource;
    procedure SetDataSource (Value: TDataSource);
    function GetField: TField;
  protected
    // data link event handler
    procedure DataChange (Sender: TObject);
  public
    constructor Create (AOwner: TComponent); override;
    destructor Destroy; override;
    property Field: TField read GetField;
  published
    property DataField: string read GetDataField write SetDataField;
    property DataSource: TDataSource read GetDataSource write SetDataSource;
  end;
```

As with every data-aware component that connects to a single field, this control makes available the DataSource and DataField properties. There is very little code to write here; simply export the properties from the internal data link object, as follows:

```
function TMdDbProgress.GetDataField: string;
begin
  Result := FDataLink.FieldName;
end;

procedure TMdDbProgress.SetDataField (Value: string);
begin
```

```
  FDataLink.FieldName := Value;
end;

function TMdDbProgress.GetDataSource: TDataSource;
begin
  Result := FDataLink.DataSource;
end;

procedure TMdDbProgress.SetDataSource (Value: TDataSource);
begin
  FDataLink.DataSource := Value;
end;

function TMdDbProgress.GetField: TField;
begin
  Result := FDataLink.Field;
end;
```

Of course, to make this component work, you must create and destroy the data link when the component itself is created or destroyed:

```
constructor TMdDbProgress.Create (AOwner: TComponent);
begin
  inherited Create (AOwner);
  FDataLink := TFieldDataLink.Create;
  FDataLink.Control := self;
  FDataLink.OnDataChange := DataChange;
end;

destructor TMdDbProgress.Destroy;
begin
  FDataLink.Free;
  FDataLink := nil;
  inherited Destroy;
end;
```

In the preceding constructor, notice that the component installs one of its own methods as an event handler for the data link. This is where the most important code of the component resides. Every time the data changes, we modify the output of the progress bar to reflect the values of the current field:

```
procedure TMdDbProgress.DataChange (Sender: TObject);
begin
  if (FDataLink.Field <> nil) and (FDataLink.Field is TNumericField) then
    Position := FDataLink.Field.AsInteger
  else
    Position := Min;
end;
```

Following the convention of the VCL data-aware controls, if the field type is invalid, the component doesn't display an error message—it simply disables the output. Alternatively, you might want to check the field type when `SetDataField` method assigns it to the control.

In Figure 18.1 you can see an example of the DbProgr application's output, which uses both a label and a progress bar to display an order's quantity information. Thanks to this visual clue, you can step through the records and easily spot orders for many items. One obvious benefit to this component is that the application contains almost no code, since all the important code is in the component itself.

FIGURE 18.1: The data-aware ProgressBar in action in the DbProgr example

As you've seen, a read-only data-aware component is not too difficult to write. It gets extremely complex, on the other hand, to use such a component inside a DBCtrlGrid container.

NOTE If you remember the discussion of the `Notification` method in Chapter 11, you might wonder what happens if the data source referenced by the data-aware control is destroyed. The good news is that the data source has a destructor that removes itself from its own data links. So there is no need for a `Notification` method for data-aware controls, even though you'll see books and articles suggesting it, and VCL has plenty of this extra useless code.

Replicable Data-Aware Controls

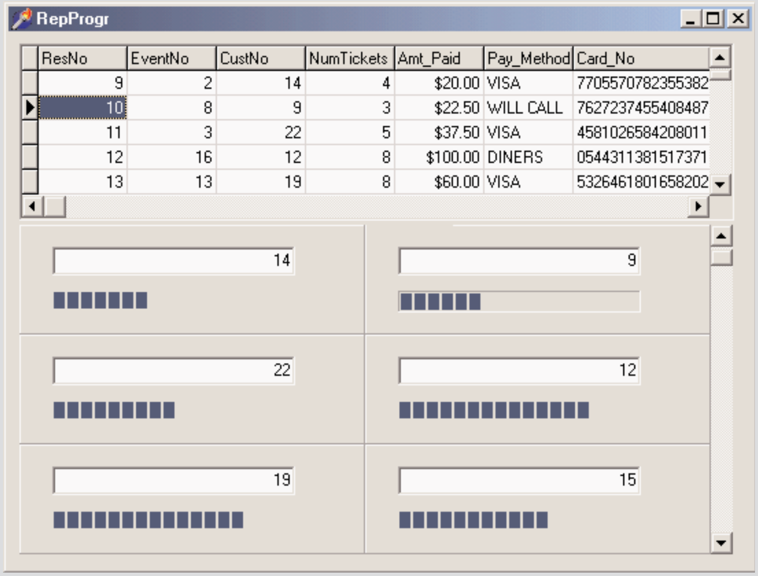
Extending a data-aware control to support its use inside a DBCtrlGrid component is rather complex and not well documented. You can find a complete "replicable" version of the progress bar in the MdDataPack package and an example of its use in the `RepProgr` folder, along with an HTML file describing its development. The DBCtrlGrid component has a peculiar behavior, as it displays on screen multiple versions of the same physical control, using some

Continued on next page

"smoke and mirrors." The grid can attach the control to a data buffer other than the current record and redirects the control paint operations to another portion of the monitor.

In short, to appear in the DBCtrlGrid, a component must have its csReplicatable control style set, a flag merely indicating that your component actually supports being hosted by a control grid. First, the component must respond to the `cm_GetDataLink` Delphi message and return a pointer to the data link, so that the control grid can use and change it. Second, it needs a custom `Paint` method to draw the output in the appropriate canvas object, which is provided in a parameter of the `wm_Paint` message in case the csPaintCopy flag of the `ControlState` property is set.

The actual code of the example is rather complex, and the DBCtrlGrid component is not heavily used, so I decided not to give you full details here, but you can find the full code and some more information in the source code on the companion CD. Here's the output of a test program that uses this component:



ResNo	EventNo	CustNo	NumTickets	Amt_Paid	Pay_Method	Card_No
9	2	14	4	$20.00	VISA	7705570782355382
10	8	9	3	$22.50	WILL CALL	7627237455408487
11	3	22	5	$37.50	VISA	4581026584208011
12	16	12	8	$100.00	DINERS	0544311381517371
13	13	19	8	$60.00	VISA	5326461801658202

A Read-Write TrackBar

The next step is to write a component that allows a user to modify the data in a database, not just browse it. The overall structure of this type of component isn't very different from the previous version, but there are a few extra elements. In particular, when the user starts interacting with the component, the code should put the dataset into edit mode and then notify the dataset that the data has changed. The dataset will then use an event handler of the FieldDataLink to ask for the updated value.

To demonstrate how you can create a data-aware component that modifies the data, I've decided to extend the TrackBar control. This probably isn't the simplest example, but it demonstrates several important techniques.

Here's the definition of the component's class:

```
type
  TMdDbTrack = class(TTrackBar)
  private
    FDataLink: TFieldDataLink;
    function GetDataField: string;
    procedure SetDataField (Value: string);
    function GetDataSource: TDataSource;
    procedure SetDataSource (Value: TDataSource);
    function GetField: TField;
    procedure CNHScroll(var Message: TWMHScroll); message CN_HSCROLL;
    procedure CNVScroll(var Message: TWMVScroll); message CN_VSCROLL;
    procedure CMExit(var Message: TCMExit); message CM_EXIT;
  protected
    // data link event handlers
    procedure DataChange (Sender: TObject);
    procedure UpdateData (Sender: TObject);
    procedure ActiveChange (Sender: TObject);
  public
    constructor Create (AOwner: TComponent); override;
    destructor Destroy; override;
    property Field: TField read GetField;
  published
    property DataField: string read GetDataField write SetDataField;
    property DataSource: TDataSource read GetDataSource write SetDataSource;
  end;
```

Compared to the read-only data-aware control built earlier, this class is a bit more complex, because it has three message handlers, including component notification handlers, and two new event handlers for the data link. The component installs these event handlers in the constructor, which also disables the component:

```
constructor TMdDbTrack.Create (AOwner: TComponent);
begin
  inherited Create (AOwner);
  FDataLink := TFieldDataLink.Create;
  FDataLink.Control := self;
  FDataLink.OnDataChange := DataChange;
  FDataLink.OnUpdateData := UpdateData;
  FDataLink.OnActiveChange := ActiveChange;
  Enabled := False;
end;
```

All of the get and set methods and the DataChange event handler are very similar to those in the TMdDbProgress component. The only difference is that whenever the data source or data field changes, the component checks the current status to see whether it should enable itself:

```
procedure TMdDbTrack.SetDataSource (Value: TDataSource);
begin
  FDataLink.DataSource := Value;
  Enabled := FDataLink.Active and (FDataLink.Field <> nil) and
    not FDataLink.Field.ReadOnly;
end;
```

This code tests three conditions: the data link should be active, the link should refer to an actual field, and the field shouldn't be read-only. When the user changes the field, the component should also consider that the field name might be invalid; to test for this condition, the component should rather use a try/finally block:

```
procedure TMdDbTrack.SetDataField (Value: string);
begin
  try
    FDataLink.FieldName := Value;
  finally
    Enabled := FDataLink.Active and (FDataLink.Field <> nil) and
      not FDataLink.Field.ReadOnly;
  end;
end;
```

The control executes the same test when the dataset is enabled or disabled:

```
procedure TMdDbTrack.ActiveChange (Sender: TObject);
begin
  Enabled := FDataLink.Active and (FDataLink.Field <> nil) and
    not FDataLink.Field.ReadOnly;
end;
```

The most interesting portion of this component's code is related to its user interface. When a user starts moving the scroll thumb, the component should do the following: put the dataset into edit mode, let the base class update the thumb position, and alert the data link (and therefore the data source) that the data has changed. Here's the code:

```
procedure TMdDbTrack.CNHScroll(var Message: TWMHScroll);
begin
  // enter edit mode
  FDataLink.Edit;
  // update data
  inherited;
  // let the system know
  FDataLink.Modified;
end;
```

```
procedure TMdDbTrack.CNVScroll(var Message: TWMVScroll);
begin
  // enter edit mode
  FDataLink.Edit;
  // update data
  inherited;
  // let the system know
  FDataLink.Modified;
end;
```

When the dataset needs new data—for example, to perform a `Post` operation—it simply requests it from the component via the `TFieldDataLink` class's `OnUpdateData` event:

```
procedure TMdDbTrack.UpdateData (Sender: TObject);
begin
  if (FDataLink.Field <> nil) and (FDataLink.Field is TNumericField) then
    FDataLink.Field.AsInteger := Position;
end;
```

If the proper conditions are met, the component simply updates the data in the proper table field. Finally, if the component loses the input focus, it should force a data update (if the data has changed) so that any other data-aware components showing the value of that field will display the correct value as soon as the user moves to a different field. If the data hasn't changed, the component won't bother updating the data in the table. This is the standard `CmExit` code for components used by VCL and borrowed for our component as well:

```
procedure TMdDbTrack.CmExit(var Message: TCmExit);
begin
  try
    FDataLink.UpdateRecord;
  except
    SetFocus;
    raise;
  end;
  inherited;
end;
```

Again, there is a demo program for testing this component; you can see its output in Figure 18.2. The DbTrack program contains a check box to enable and disable the table, the visual components, and a couple of buttons you can use to detach the vertical TrackBar component from the field it relates to. Again, I placed these on the form to test enabling and disabling the track bar.

☑ Table Active

FIGURE 18.2: The DbTrack example has a couple of track bars you can use to enter data in a database table. The check box and buttons are used to test the enabled status of the components.

Creating Custom Data Links

The data-aware controls I've built up to this point all referred to specific fields of the dataset, so I was able to use a `TFieldDataLink` object to establish the connection with a data source. Now I want to build a data-aware component that works with a dataset as a whole, a simple record viewer.

Delphi's database grid shows the value of several fields and several records simultaneously. In my record viewer component, I want to list all the fields of the current record, using a customized grid. This example will show you how to build a customized grid control, and a custom data link to go with it.

A Record Viewer Component

In Delphi there are no data-aware components that manipulate multiple fields of a single record, without displaying other records. In fact, the only component that displays multiple fields from the same table is the DBGrid, which displays multiple fields and multiple records.

The record viewer component I'm going to describe in this section is based on a two-column grid; the first column displays the table's field names, while the second column displays the corresponding field values. The number of rows in the grid will correspond to the number of fields, with a vertical scroll bar in case they can't fit in the visible area.

The data link we need in order to build this component is a simple class, connected only to the record viewer component, and declared directly in the implementation portion of its unit. This is the same approach used by VCL for some specific data links. Here's the definition of the new class:

```
type
  TMdRecordLink = class (TDataLink)
  private
    RView: TMdRecordView;
  public
    constructor Create (View: TMdRecordView);
    procedure ActiveChanged; override;
    procedure RecordChanged (Field: TField); override;
  end;
```

As you can see, the class overrides the methods related to the principal event, in this case simply the activation and data (or record) change. Alternatively, I could have exported some events and then let the component handle them. That's what the TFieldDataLink does, but the approach I've taken makes more sense for a data link class, because you'll want to use it with different data-aware components. The constructor requires the associated component as its only parameter:

```
constructor TMdRecordLink.Create (View: TMdRecordView);
begin
  inherited Create;
  RView := View;
end;
```

After storing a reference to the associated component, the other methods can operate on it directly:

```
procedure TMdRecordLink.ActiveChanged;
var
  I: Integer;
begin
  // set number of rows
  RView.RowCount := DataSet.FieldCount;
  // repaint all...
  RView.Invalidate;
end;

procedure TMdRecordLink.RecordChanged;
begin
  inherited;
  // repaint all...
  RView.Invalidate;
end;
```

As you've seen, the record link code is very simple. Most of the difficulties in building this example depend on the use of a grid. To avoid dealing with useless properties, I've derived the record viewer grid from the TCustomGrid class. This class incorporates much of the code for grids, but most of its properties, events, and methods are protected. For this reason, the class declaration is quite long, because it needs to publish many existing properties. Here is an excerpt (excluding the base class properties):

```
type
  TMdRecordView = class(TCustomGrid)
  private
    // data-aware support
    FDataLink: TDataLink;
    function GetDataSource: TDataSource;
    procedure SetDataSource (Value: TDataSource);
  protected
    // redefined TCustomGrid methods
    procedure DrawCell (ACol, ARow: Longint; ARect: TRect;
      AState: TGridDrawState); override;
    procedure ColWidthsChanged; override;
    procedure RowHeightsChanged; override;
  public
    constructor Create (AOwner: TComponent); override;
    destructor Destroy; override;
    procedure SetBounds (ALeft, ATop, AWidth, AHeight: Integer); override;
    procedure DefineProperties (Filer: TFiler); override;
    // public parent properties (omitted...)
  published
    // data-aware properties
    property DataSource: TDataSource read GetDataSource write SetDataSource;
    // published parent properties (omitted...)
  end;
```

Besides redeclaring the properties to publish them, the component defines a data link object and the `DataSource` property. There's no `DataField` property for this component, because it refers to an entire record. The component's constructor is very important. It sets the values of many unpublished properties, including the grid options:

```
constructor TMdRecordView.Create (AOwner: TComponent);
begin
  inherited Create (AOwner);
  FDataLink := TMdRecordLink.Create (self);
  // set numbers of cells and fixed cells
  RowCount := 2; // default
  ColCount := 2;
  FixedCols := 1;
  FixedRows := 0;
  Options := [goFixedVertLine, goFixedHorzLine,
    goVertLine, goHorzLine, goRowSizing];
  DefaultDrawing := False;
  ScrollBars := ssVertical;
  FSaveCellExtents := False;
end;
```

The grid has two columns, one of them fixed, and no fixed rows. The fixed column is used for resizing each row of the grid. Unfortunately, a user cannot drag the fixed row to resize the columns, because you can't resize fixed elements, and the grid already has a fixed column.

NOTE An alternative approach could be to have an extra empty column, as the DBGrid control does. You'd be able to resize the two other columns after adding a fixed row. Overall, though, I prefer my implementation.

I've used an alternative approach to resize the columns. The first column (holding the field names) can be resized either using programming code or visually at design time, and the second column (holding the values of the fields) will be resized to use the remaining area of the component, leaving space for the borders, lines, and vertical scrollbar:

```
procedure TMdRecordView.SetBounds (ALeft, ATop, AWidth, AHeight: Integer);
begin
  inherited;
  ColWidths [1] := Width - ColWidths [0] - GridLineWidth * 3 -
    GetSystemMetrics (sm_CXVScroll) - 2; // border
end;
```

This takes place when the component size changes and when either of the columns change. With this code, the `DefaultColWidth` property of the component becomes, in practice, the fixed width of the first column.

After everything has been set up, the key method of the component is the overridden `DrawCell` method, detailed in Listing 18.1. This is where the control displays the information about the fields and their values. There are three things it needs to draw. If the data link is not connected to a data source, the grid displays an "empty element" sign (*[]*). When drawing the first column, the record viewer shows the `DisplayName` of the field, which is the same value used by the DBGrid for the heading. When drawing the second column, the component accesses the textual representation of the field value, extracted with the `DisplayText` property (or with the `AsString` property for memo fields).

Listing 18.1: The `DrawCell` method of the custom RecordView component

```
procedure TMdRecordView.DrawCell(ACol, ARow: Longint; ARect: TRect;
  AState: TGridDrawState);
var
  Text: string;
  CurrField: TField;
  Bmp: TBitmap;
begin
  CurrField := nil;
  Text := '[]'; // default
  // paint background
```

```
    if (ACol = 0) then
      Canvas.Brush.Color := FixedColor
    else
      Canvas.Brush.Color := Color;
    Canvas.FillRect (ARect);
    // leave small border
    InflateRect (ARect, -2, -2);
    if (FDataLink.DataSource <> nil) and FDataLink.Active then
    begin
      CurrField := FDataLink.DataSet.Fields[ARow];
      if ACol = 0 then
        Text := CurrField.DisplayName
      else if CurrField is TMemoField then
        Text := TMemoField (CurrField).AsString
      else
        Text := CurrField.DisplayText;
    end;
    if (ACol = 1) and (CurrField is TGraphicField) then
    begin
      Bmp := TBitmap.Create;
      try
        Bmp.Assign (CurrField);
        Canvas.StretchDraw (ARect, Bmp);
      finally
        Bmp.Free;
      end;
    end
    else if (ACol = 1) and (CurrField is TMemoField) then
    begin
      DrawText (Canvas.Handle, PChar (Text), Length (Text), ARect,
        dt_WordBreak or dt_NoPrefix)
    end
    else // draw single line vertically centered
      DrawText (Canvas.Handle, PChar (Text), Length (Text), ARect,
        dt_vcenter or dt_SingleLine or dt_NoPrefix);
    if gdFocused in AState then
      Canvas.DrawFocusRect (ARect);
  end;
```

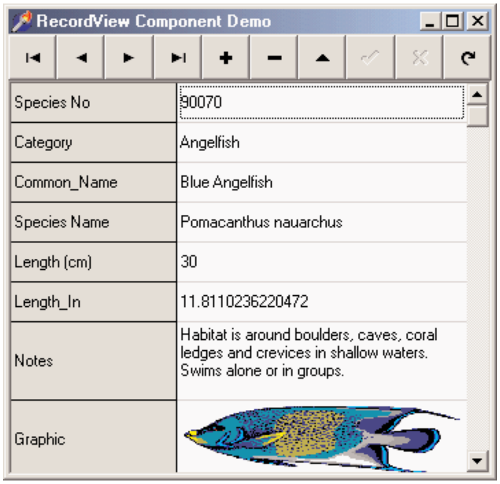
The final portion of the method is where the component considers memo and graphic fields. If the field is a TMemoField, the DrawText function call doesn't specify the dt_SingleLine flag, but uses dt_WordBreak flag to wrap the words when there's no more room. For a graphic field, of course, the component uses a completely different approach, assigning the field image to a temporary bitmap, and then stretching it to fill the surface of the cell.

Notice also that the component sets the DefaultDrawing property to False, so that it's also responsible for drawing the background and the focus rectangle, as it does in the DrawCell method. The component also calls the InflateRect API function to leave a small area between the cell border and the output text. The actual output is produced by calling another Windows API function, `DrawText`, which centers the text vertically in its cell.

This drawing code works both at run time, as you can see in Figure 18.3, and at design time. The output may not be perfect, but this component can certainly be very useful in many cases. If you want to display the data for a single record, instead of building a custom form with labels and data-aware controls, you can easily use this record viewer grid. Of course, it's important to remember that the record viewer is a read-only component: it's certainly possible to extend it to add editing capabilities (they're already part of the `TCustomGrid` class). However, instead of adding this support, we've decided to make the component more complete by adding support for displaying BLOB fields.

FIGURE 18.3:

The ViewGrid example demonstrates the output of the RecordView component, using Borland's sample BioLife database table.



Species No	90070
Category	Angelfish
Common_Name	Blue Angelfish
Species Name	Pomacanthus nauarchus
Length (cm)	30
Length_In	11.8110236220472
Notes	Habitat is around boulders, caves, coral ledges and crevices in shallow waters. Swims alone or in groups.
Graphic	

To improve the graphical output, the control makes the lines for those fields twice as high as those for plain text fields. This operation is accomplished when the dataset connected to the data-aware control is activated. The `ActiveChanged` method of the data link is triggered also by the `RowHeightsChanged` methods, connected to the `DefaultRowHeight` property of the base class:

```
procedure TMdRecordLink.ActiveChanged;
var
  I: Integer;
begin
  // set number of rows
  RView.RowCount := DataSet.FieldCount;
  // double the height of memo and graphics
  for I := 0 to DataSet.FieldCount - 1 do
    if DataSet.Fields [I] is TBlobField then
```

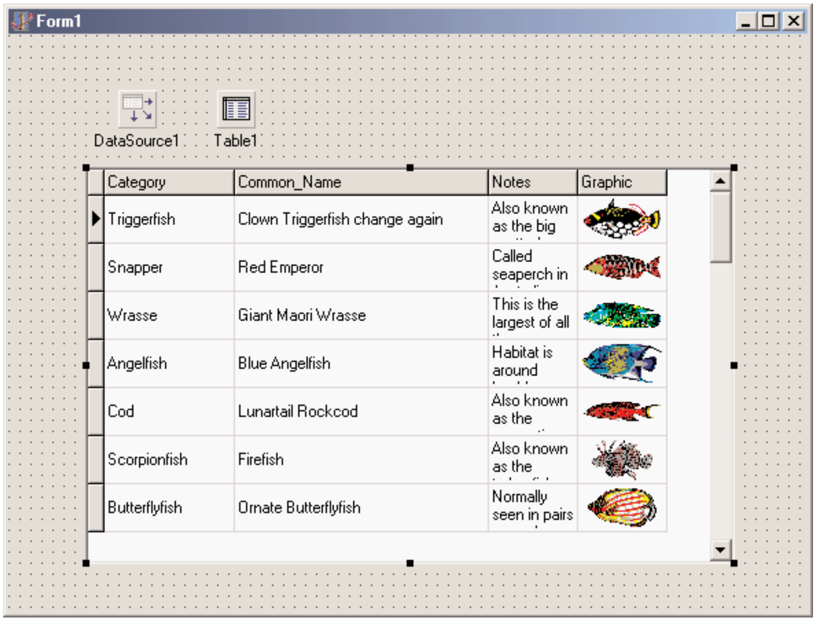
```
        RView.RowHeights [I] := RView.DefaultRowHeight * 2;
    // repaint all...
    RView.Invalidate;
  end;
```

At this point, we stumble into a minor problem. In the `DefineProperties` method, the `TCustomGrid` class saves the values of the `RowHeights` and `ColHeights` properties. We could disable this streaming by overriding the method and not calling `inherited` (which is generally a bad technique to use), but it is also possible to toggle the `FSaveCellExtents` protected field to disable this feature.

Customizing the DBGrid Component

Besides writing brand-new custom data-aware components, it's common for Delphi programmers to customize the DBGrid control. The goal for the next component is to enhance the DBGrid with the same kind of custom output I've used for the RecordView component, directly displaying graphic and memo fields. To do this, the grid needs to make the row height resizable, to allow space for a reasonable amount of text and big enough for graphics. You can see an example of this grid at design time in Figure 18.4.

FIGURE 18.4: An example of the MdDbGrid component at design time. Notice the output of the graphics and memo fields.



Category	Common_Name	Notes	Graphic
Triggerfish	Clown Triggerfish change again	Also known as the big	
Snapper	Red Emperor	Called seaperch in	
Wrasse	Giant Maori Wrasse	This is the largest of all	
Angelfish	Blue Angelfish	Habitat is around	
Cod	Lunartail Rockcod	Also known as the	
Scorpionfish	Firefish	Also known as the	
Butterflyfish	Ornate Butterflyfish	Normally seen in pairs	

While creating the output was a simple matter of adapting the code used in the record viewer component, setting the height of the grid cells ended up being a very difficult problem to solve. The lines of code you'll see for that operation may be few, but they cost me hours of work!

NOTE Unlike the generic grid we've used above, a DBGrid is a virtual view on the dataset—there is no relation between the number of rows shown on the screen and the number of rows of data in the dataset. When you scroll up and down through the data records of the dataset, you are not scrolling up and down through the rows of the DBGrid; the rows are stationary while the data moves from one row to the next to give the appearance of movement. For this reason, the program doesn't try to set the height of an individual row to suit its data, but it sets the height of all the data rows to a multiline height value.

This time the control doesn't have to create a custom data link, because it is deriving from a component that already has a complex connection with the data. The new class has a new property to specify the number of lines of text for each row and overrides a few virtual methods:

```
type
  TMdDbGrid = class(TDbGrid)
  private
    FLinesPerRow: Integer;
    procedure SetLinesPerRow (Value: Integer);
  protected
    procedure DrawColumnCell(const Rect: TRect; DataCol: Integer;
      Column: TColumn; State: TGridDrawState); override;
    procedure  LayoutChanged; override;
  public
    constructor Create (AOwner: TComponent); override;
  published
    property LinesPerRow: Integer
      read FLinesPerRow write SetLinesPerRow default 1;
  end;
```

The constructor simply sets the default value for the `FLinesPerRow` field. Here is the set method for the property:

```
procedure TMdDbGrid.SetLinesPerRow(Value: Integer);
begin
  if Value <> FLinesPerRow then
  begin
    FLinesPerRow := Value;
    LayoutChanged;
  end;
end;
```

The side effect of changing the number of lines is a call to the LayoutChanged virtual method. The system calls this method frequently when one of the many output parameters changes. In the code of this method, the component first calls the inherited version and then sets the height of each row. As a basis for this computation it uses the same formula of the TCustomDBGrid class: the text height is calculated using the sample word *Wg* in the current font (this text is used because it includes both a full-height uppercase character and a lowercase letter with a descender). Here's the code:

```
procedure TMdDbGrid.LayOutChanged;
var
  PixelsPerRow, PixelsTitle, I: Integer;
begin
  inherited LayOutChanged;

  Canvas.Font := Font;
  PixelsPerRow := Canvas.TextHeight('Wg') + 3;
  if dgRowLines in Options then
    Inc (PixelsPerRow, GridLineWidth);

  Canvas.Font := TitleFont;
  PixelsTitle := Canvas.TextHeight('Wg') + 4;
  if dgRowLines in Options then
    Inc (PixelsTitle, GridLineWidth);

  // set number of rows
  RowCount := 1 + (Height - PixelsTitle) div (PixelsPerRow * FLinesPerRow);

  // set the height of each row
  DefaultRowHeight := PixelsPerRow * FLinesPerRow;
  RowHeights [0] := PixelsTitle;
  for I := 1 to RowCount - 1 do
    RowHeights [I] := PixelsPerRow * FLinesPerRow;
end;
```

WARNING Font and TitleFont are the grid defaults that can be overridden by properties of the individual DBGrid column objects. This component would currently ignore those settings.

The difficult part here was to get the last four statements correct. You can simply set the DefaultRowHeight property, but in that case the title row will probably be too high. At first, I tried setting the DefaultRowHeight and then the height of the first row, but this complicated the code used to compute the number of visible rows in the grid (the read-only VisibleRowCount property). If you specify the number of rows (in order to avoid having rows hidden beneath the lower edge of the grid), the base class keeps recomputing them.

Finally, here's the code used to draw the data, ported from the RecordView component and adapted slightly for the grid:

```
procedure TMdDbGrid.DrawColumnCell (const Rect: TRect; DataCol: Integer;
  Column: TColumn; State: TGridDrawState);
var
  Bmp: TBitmap;
  OutRect: TRect;
begin
  if FLinesPerRow = 1 then
    inherited DrawColumnCell(Rect, DataCol, Column, State)
  else
  begin
    // clear area
    Canvas.FillRect (Rect);
    // copy the rectangle
    OutRect := Rect;
    // restrict output
    InflateRect (OutRect, -2, -2);
    // output field data
    if Column.Field is TGraphicField then
    begin
      Bmp := TBitmap.Create;
      try
        Bmp.Assign (Column.Field);
        Canvas.StretchDraw (OutRect, Bmp);
      finally
        Bmp.Free;
      end;
    end
    else if Column.Field is TMemoField then
    begin
      DrawText (Canvas.Handle, PChar (Column.Field.AsString),
        Length (Column.Field.AsString), OutRect, dt_WordBreak or dt_NoPrefix)
    end
    else // draw single line vertically centered
      DrawText (Canvas.Handle, PChar (Column.Field.DisplayText),
        Length (Column.Field.DisplayText), OutRect,
        dt_vcenter or dt_SingleLine or dt_NoPrefix);
  end;
end;
```

In the code above you can see that if the user displays just a single line, the grid uses the standard drawing technique with no output for memo and graphic fields. However, as soon as you increase the line count, you'll see a better output.

To see this code in action, run the GridDemo example. This program has two buttons you can use to increase or decrease the row height of the grid, and two more buttons to change the font. This is an important test because the height in pixels of each cell is the height of the font multiplied by the number of lines.

Building Custom Datasets

When discussing the TDataSet class and the alternative families of dataset components available in Delphi, in Chapter 13, "Delphi's Database Architecture," I mentioned the possibility of writing a custom dataset class. Now it's time to have a look at an actual example. The reasons for writing a custom dataset relate to the fact that you won't need to deploy a database engine but you'll still be able to take full advantage of Delphi's database architecture, including things like persistent database fields and data-aware controls.

Writing a custom dataset is one of the most complex task for a component developer, so this is one of the most advanced areas (as far as low-level coding practices, including tons of pointers) of the entire book. Moreover, Borland hasn't released any official documentation on writing custom datasets. If you are early in your experience with Delphi, you might want to skip the rest of this chapter and come back here later.

The TDataSet class is an abstract class, which declares several virtual abstract methods—23 to be precise. Every subclass of TDataSet must override all of those methods.

Before discussing the development of a custom dataset, we need to explore a few technical elements of the TDataSet class, in particular record buffering. The class maintains a list of buffers, which store the values of different records. These buffers store the actual data, but they also usually store further information for the dataset to use when managing the records. These buffers don't have a predefined structure, and each custom dataset must allocate the buffers, fill them, and destroy them. The custom dataset must also copy the data from the record buffers to the various fields of the dataset, and vice versa. In other words, the custom dataset is entirely responsible for handling these buffers.

In addition to managing the data buffers, the component is also responsible for navigating among the records, managing the bookmarks, defining the structure of the dataset, and creating the proper data fields. The TDataSet class is nothing more than a framework; you must fill it with the appropriate code. Fortunately, most of the code follows a standard structure, which the TDataSet-derived VCL classes use. Once you've grasped the key ideas, you'll be able to build multiple custom datasets borrowing quite a lot of code.

To simplify this type of reuse, I've collected the common features required by any custom dataset in a TMDCustomDataSet class. However, I'm not going to discuss the base class first and the specific implementation later, because that would probably be rather complex to understand. Instead, I'll detail the code required by a dataset, presenting methods of the generic and specific classes at the same time, according to a logical flow.

The Definition of the Classes

The starting point, as usual, is the declaration of the two classes discussed in this section, the generic custom dataset I've written and the specific component storing data in a stream. These declaration of these classes is available in Listing 18.2. Besides virtual methods, the classes contain a series of protected fields used to manage the buffers, track the current position and record count, and handle many other features. You should also notice another record declaration at the beginning, a structure used to store the extra data for every data record we place in a buffer. The dataset places this information in each record buffer, following the actual data.

Listing 18.2: The declaration of `TMdCustomDataSet` and `TMdDataSetStream`

```
// in the unit MdDsCustom
type
  EMdDataSetError = class (Exception);

  TMdRecInfo = record
    Bookmark: Longint;
    BookmarkFlag: TBookmarkFlag;
  end;
  PMdRecInfo = ^TMdRecInfo;

  TMdCustomDataSet = class(TDataSet)
  protected
    // status
    FIsTableOpen: Boolean;
    // record data
    FRecordSize,        // the size of the actual data
    FRecordBufferSize,  // data + housekeeping (TRecInfo)
    FCurrentRecord,     // current record (0 to FRecordCount - 1)
    BofCrack,           // before the first record (crack)
    EofCrack: Integer;  // after the last record (crack)
    // create, close, and so on
    procedure InternalOpen; override;
    procedure InternalClose; override;
    function IsCursorOpen: Boolean; override;
    // custom functions
    function InternalRecordCount: Integer; virtual; abstract;
    procedure InternalPreOpen; virtual;
    procedure InternalAfterOpen; virtual;
    procedure InternalLoadCurrentRecord(Buffer: PChar); virtual; abstract;
    // memory management
    function AllocRecordBuffer: PChar; override;
    procedure InternalInitRecord(Buffer: PChar); override;
    procedure FreeRecordBuffer(var Buffer: PChar); override;
    function GetRecordSize: Word; override;
    // movement and optional navigation (used by grids)
    function GetRecord(Buffer: PChar; GetMode: TGetMode; DoCheck: Boolean):
      TGetResult; override;
    procedure InternalFirst; override;
    procedure InternalLast; override;
    function GetRecNo: Longint; override;
    function GetRecordCount: Longint; override;
    procedure SetRecNo(Value: Integer); override;
    // bookmarks
    procedure InternalGotoBookmark(Bookmark: Pointer); override;
    procedure InternalSetToRecord(Buffer: PChar); override;
    procedure SetBookmarkData(Buffer: PChar; Data: Pointer); override;
    procedure GetBookmarkData(Buffer: PChar; Data: Pointer); override;
    procedure SetBookmarkFlag(Buffer: PChar; Value: TBookmarkFlag); override;
    function GetBookmarkFlag(Buffer: PChar): TBookmarkFlag; override;
    // editing (dummy vesions)
    procedure InternalDelete; override;
    procedure InternalAddRecord(Buffer: Pointer; Append: Boolean); override;
    procedure InternalPost; override;
    procedure InternalInsert; override;
    // other
    procedure InternalHandleException; override;
  published
    // redeclared dataset properties
    property Active;
    property BeforeOpen;
    property AfterOpen;
    property BeforeClose;
    property AfterClose;
    property BeforeInsert;
    property AfterInsert;
    property BeforeEdit;
    property AfterEdit;
    property BeforePost;
    property AfterPost;
    property BeforeCancel;
    property AfterCancel;
    property BeforeDelete;
    property AfterDelete;
    property BeforeScroll;
    property AfterScroll;
    property OnCalcFields;
    property OnDeleteError;
    property OnEditError;
    property OnFilterRecord;
    property OnNewRecord;
    property OnPostError;
  end;

// in the unit MdDsStream
type
  TMdDataFileHeader = record
    VersionNumber: Integer;
    RecordSize: Integer;
    RecordCount: Integer;
  end;

  TMdDataSetStream = class(TMdCustomDataSet)
  private
    procedure SetTableName(const Value: string);
  protected
    FDataFileHeader: TMdDataFileHeader;
    FDataFileHeaderSize,    // optional file header size
    FRecordCount: Integer;  // current number of records
    FStream: TStream;       // the physical table
    FTableName: string;     // table path and file name
    FFieldOffset: TList;    // field offsets in the buffer
  protected
    // open and close
    procedure InternalPreOpen; override;
    procedure InternalAfterOpen; override;
    procedure InternalClose; override;
    procedure InternalInitFieldDefs; override;
    // edit support
    procedure InternalAddRecord(Buffer: Pointer; Append: Boolean); override;
    procedure InternalPost; override;
    procedure InternalInsert; override;
    // fields
    procedure SetFieldData(Field: TField; Buffer: Pointer); override;
    // custom dataset virutal methods
    function InternalRecordCount: Integer; override;
    procedure InternalLoadCurrentRecord(Buffer: PChar); override;
  public
    procedure CreateTable;
    function GetFieldData(Field: TField; Buffer: Pointer): Boolean; override;
  published
    property TableName: string read FTableName write SetTableName;
  end;
```

In dividing the methods into sections (as you can see by looking at the source code files), I've marked each one with a roman number. You'll see those numbers in a comment describing the method, so that while browsing this long listing you'll immediately know which of the three sections you are in.

Section I: Initialization, Opening, and Closing

The first methods I'll examine are responsible for initializing the dataset, and for opening and closing the file stream we'll use to store the data. In addition to initializing the component's internal data, these methods are responsible for initializing and connecting the proper TFields objects to the dataset component. To make this work, all we need to do is to initialize the FieldsDef property with the definitions of the fields for our dataset, then call a few standard methods to generate and bind the TField objects. This is the general InternalOpen method:

```
procedure TMDCustomDataSet.InternalOpen;
begin
  InternalPreOpen; // custom method for subclasses

  // initialize the field definitions
  InternalInitFieldDefs;

  // if there are no persistent field objects, create the fields dynamically
  if DefaultFields then
    CreateFields;
  // connect the TField objects with the actual fields
  BindFields (True);

  InternalAfterOpen; // custom method for subclasses

  // sets cracks and record position and size
  BofCrack := -1;
  EofCrack := InternalRecordCount;
  FCurrentRecord := BofCrack;
  FRecordBufferSize := FRecordSize + sizeof (TMdRecInfo);
  BookmarkSize := sizeOf (Integer);

  // everything OK: table is now open
  FIsTableOpen := True;
end;
```

You'll notice that the method sets most of the local fields of the class, and also the BookmarkSize field of the base TDataSet class. Within this method, I call two custom methods I introduced in my custom dataset hierarchy: InternalPreOpen and InternalAfterOpen. The first, InternalPreOpen, is used for operations required at the very beginning, such as checking whether the dataset can actually be opened and reading the header information from the file. The code checks an internal version number for consistency with the value saved when the table is first created, as you'll see later on. By raising an exception in this method, we can eventually stop the open operation.

Here is the code for the to methods in the derived stream-based dataset:

```
const
  HeaderVersion = 10;

procedure TMdDataSetStream.InternalPreOpen;
begin
  // the size of the header
  FDataFileHeaderSize := sizeOf (TMdDataFileHeader);

  // check if the file exists
  if not FileExists (FTableName) then
    raise EMdDataSetError.Create ('Open: Table file not found');

  // create a stream for the file
  FStream := TFileStream.Create (FTableName, fmOpenReadWrite);

  // initialize local data (loading the header)
  FStream.ReadBuffer (FDataFileHeader, FDataFileHeaderSize);
  if FDataFileHeader.VersionNumber <> HeaderVersion then
    raise EMdDataSetError.Create ('Illegal File Version');
  // let's read this, double check later
  FRecordCount := FDataFileHeader.RecordCount;
end;

procedure TMdDataSetStream.InternalAfterOpen;
begin
  // check the record size
  if FDataFileHeader.RecordSize <> FRecordSize then
    raise EMdDataSetError.Create ('File record size mismatch');
  // check the number of records against the file size
 if (FDataFileHeaderSize + FRecordCount * FRecordSize) <> FStream.Size then
    raise EMdDataSetError.Create ('InternalOpen: Invalid Record Size');
end;
```

The second method, `InternalAfterOpen`, is used for operations required after the field definitions have been set and is followed by code that compares the record size read from the file against the value computed in the `InternalInitFieldDefs` method. The code checks also that the number of records read from the header is compatible with the actual size of the file. This test might fail if the dataset wasn't closed properly: you might want to modify this code to let the dataset refresh the record size in the header anyway.

The `InternalOpen` method of the custom dataset class is specifically responsible for calling `InternalInitFieldDefs`, which determines the field definitions (at either design time or run time). For this example, I've decided to base the field definitions on an external file, a simple INI file that provides a section for every field. Each section contains the name and data type of the field, as well as its size if it is string data. Listing 18.3 is the Contrib.INI file that we'll use in the component's demo application:

Listing 18.3: The Contrib.INI file for the demo application

```
[Fields]
Number = 6

[Field1]
Type = ftString
Name = Name
Size = 30

[Field2]
Type = ftInteger
Name = Level

[Field3]
Type = ftDate
Name = BirthDate

[Field4]
Type = ftCurrency
Name = Stipend

[Field5]
Type = ftString
Name = Email
Size = 50

[Field6]
Type = ftBoolean
Name = Editor
```

This file, or a similar one, must use the same name as the table file and must be in the same directory. The InternalInitFieldDefs method (shown in Listing 18.4) will read it, using the values it finds to set up the field definitions and determine the size of each record. The method also initializes an internal TList object that stores the offset of every field inside the record. We'll use this TList to access fields' data within the record buffer, as you can see in the code listing.

Listing 18.4: The InternalInitFieldDefs method of the stream-based dataset

```
procedure TMdDataSetStream.InternalInitFieldDefs;
var
  IniFileName, FieldName: string;
  IniFile: TIniFile;
```

```
    nFields, I, TmpFieldOffset, nSize: Integer;
    FieldType: TFieldType;
  begin
    FFieldOffset := TList.Create;
    FieldDefs.Clear;
    TmpFieldOffset := 0;
    IniFilename := ChangeFileExt(FTableName, '.ini');
    Inifile := TIniFile.Create (IniFilename);
    // protect INI file
    try
      nFields := IniFile.ReadInteger (' Fields', 'Number', 0);
      if nFields = 0 then
        raise EDataSetOneError.Create (' InitFieldsDefs: 0 fields?');
      for I := 1 to nFields do
      begin
        // create the field
        FieldType := TFieldType (GetEnumValue (TypeInfo (TFieldType),
          IniFile.ReadString ('Field' + IntToStr (I), 'Type', '')));
        FieldName := IniFile.ReadString ('Field' + IntToStr (I), 'Name', '');
        if FieldName = ''  then
          raise EDataSetOneError.Create (
            'InitFieldsDefs: No name for field ' + IntToStr (I));
        nSize := IniFile.ReadInteger ('Field' + IntToStr (I), 'Size', 0);
        FieldDefs.Add (FieldName, FieldType, nSize, False);
        // save offset and compute size
        FFieldOffset.Add (Pointer (TmpFieldOffset));
        case FieldType of
          ftString:                     Inc (TmpFieldOffset, nSize + 1);
          ftBoolean, ftSmallInt, ftWord:    Inc (TmpFieldOffset, 2);
          ftInteger, ftDate, ftTime:        Inc (TmpFieldOffset, 4);
          ftFloat, ftCurrency, ftDateTime:  Inc (TmpFieldOffset, 8);
        else
          raise EDataSetOneError.Create (
             'InitFieldsDefs: Unsupported field type');
        end;
      end; // for
    finally
      IniFile.Free;
    end;
    FRecordSize := TmpFieldOffset;
  end;
```

Closing the table is simply a matter of disconnecting the fields (using some standard calls). Each class must dispose the data it allocated and update the file header, the first time records are added and each time the record count has changed:

```
  procedure TMDCustomDataSet.InternalClose;
  begin
    // disconnect field objects
    BindFields (False);
    // destroy field object (if not persistent)
    if DefaultFields then
      DestroyFields;
    // close the file
    FIsTableOpen := False;
  end;

  procedure TMdDataSetStream.InternalClose;
  begin
    // if required, save updated header
    if (FDataFileHeader.RecordCount <> FRecordCount) or
      (FDataFileHeader.RecordSize = 0) then
    begin
      FDataFileHeader.RecordSize := FRecordSize;
      FDataFileHeader.RecordCount := FRecordCount;
      if Assigned (FStream) then
      begin
        FStream.Seek (0, soFromBeginning);
        FStream.WriteBuffer (FDataFileHeader, FDataFileHeaderSize);
      end;
    end;
    // free the internal list field offsets and the stream
    FFieldOffset.Free;
    FStream.Free;
    inherited InternalClose;
  end;
```

Another related function is used to test whether the dataset is open, something we can solve using the corresponding local field:

```
  function TMDCustomDataSet.IsCursorOpen: Boolean;
  begin
    Result := FIsTableOpen;
  end;
```

These are the opening and closing methods you need to implement in any custom dataset. However, most of the time, you'll also add a method to create the table. In this example, the `CreateTable` method creates an empty file and inserts information in the header: a fixed version number, a dummy record size (we don't know the size until we initialize the fields), and the record count (which is zero to start):

```
  procedure TMdDataSetStream.CreateTable;
  begin
    CheckInactive;
    InternalInitFieldDefs;

    // create the new file
    if FileExists (FTableName) then
```

```
      raise EMdDataSetError.Create ('File ' + FTableName + ' already exists');
    FStream := TFileStream.Create (FTableName, fmCreate or fmShareExclusive);
    try
      // save the header
      FDataFileHeader.VersionNumber := HeaderVersion;
      FDataFileHeader.RecordSize := 0;    // used later
      FDataFileHeader.RecordCount := 0;   // empty
      FStream.WriteBuffer (FDataFileHeader, FDataFileHeaderSize);
    finally
      // close the file
      FStream.Free;
    end;
  end;
```

Section II: Movement and Bookmark Management

As mentioned earlier, one of the things every dataset must implement is *bookmark management*, which is necessary for navigating through the dataset. Logically, a bookmark is a reference to a specific record of the dataset, something that uniquely identifies the record so that a dataset can access it and compare it to other records. Technically, bookmarks are pointers. You can implement them as pointers to specific data structures that store record information, or you can implement them as simple record numbers. For simplicity, I'll use the latter approach.

Given a bookmark, you should be able to find the corresponding record, but given a record buffer, you should also be able to retrieve the corresponding bookmark. This is the reason for appending the TMdRecInfo structure to the record data in each record buffer. This data structure stores the bookmark for the record in the buffer, as well as some bookmark flags defined as:

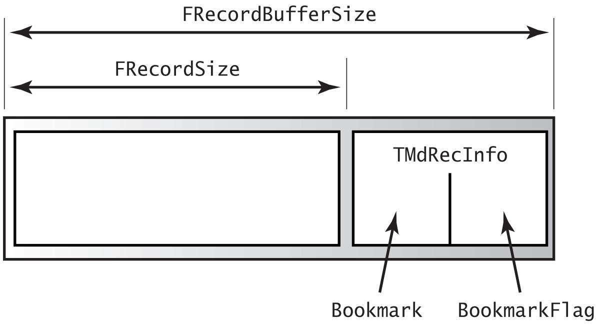
```
type
  TBookmarkFlag = (bfCurrent, bfBOF, bfEOF, bfInserted);
```

The system will request us to store these flags in each record buffer, and will later ask us to retrieve the flags for a given record buffer.

To summarize, the structure of a record buffer stores the data of the record, the bookmark, and the bookmark flags, as you can see in Figure 18.5.

FIGURE 18.5:

The structure of each buffer of the custom dataset, along with the various local fields referring to its sub-portions



To access the bookmark and flags, we can simply use as an offset the size of the actual data, casting the value to the `PMdRecInfo` pointer type, and then access the proper field of the `TMdRecInfo` structure via the pointer. The two methods used to set and get the bookmark flags demonstrate this technique:

```
procedure TMDCustomDataSet.SetBookmarkFlag (Buffer: PChar;
  Value: TBookmarkFlag);
begin
  PMdRecInfo(Buffer + FRecordSize).BookmarkFlag := Value;
end;

function TMDCustomDataSet.GetBookmarkFlag (Buffer: PChar): TBookmarkFlag;
begin
  Result := PMdRecInfo(Buffer + FRecordSize).BookmarkFlag;
end;
```

The methods we use to set and get the current bookmark of a record are similar to the previous two, but they add some complexity because we receive a pointer to the bookmark in the `Data` parameter. Casting this pointer as an integer pointer (`PInteger`) and dereferencing it, we obtain the bookmark value:

```
procedure TMDCustomDataSet.GetBookmarkData (Buffer: PChar; Data: Pointer);
begin
  PInteger(Data)^ := PMdRecInfo(Buffer + FRecordSize).Bookmark;
end;

procedure TMDCustomDataSet.SetBookmarkData (Buffer: PChar; Data: Pointer);
begin
  PMdRecInfo(Buffer + FRecordSize).Bookmark := PInteger(Data)^;
end;
```

The key bookmark management method is `InternalGotoBookmark`, which your dataset uses to make a given record the current one. You'll notice that this isn't the standard navigation technique, since it's much more common to move to the next or previous record (something we can accomplish using the GetRecord method presented in the next section), or to move to the first or last record (something we'll accomplish using the InternalFirst and InternalLast methods described shortly).

Oddly enough, the InternalGotoBookmark method doesn't expect a bookmark parameter, but a pointer to a bookmark, so we must dereference it to determine the bookmark value. The following method, InternalSetToRecord, is what you use to jump to a given bookmark, but it must extract the bookmark from the record buffer passed as a parameter. Then, InternalSetToRecord calls InternalGotoBookmark. Here are the two methods:

```
procedure TMDCustomDataSet.InternalGotoBookmark (Bookmark: Pointer);
var
  ReqBookmark: Integer;
begin
  ReqBookmark := PInteger (Bookmark)^;
  if (ReqBookmark >= 0) and (ReqBookmark < InternalRecordCount) then
    FCurrentRecord := ReqBookmark
  else
    raise EMdDataSetError.Create ('Bookmark ' +
      IntToStr (ReqBookmark) + ' not found');
end;

procedure TMDCustomDataSet.InternalSetToRecord (Buffer: PChar);
var
  ReqBookmark: Integer;
begin
  ReqBookmark := PMdRecInfo(Buffer + FRecordSize).Bookmark;
  InternalGotoBookmark (@ReqBookmark);
end;
```

In addition to the bookmark management methods just described, there are several other navigation methods we use to move to specific positions within the dataset, such as the first or last record. Actually, these two methods don't move the current record pointer to the first or last record, but move it to one of two special locations before the first record and after the last one. These are not actual records; Borland calls them *cracks*. The beginning-of-file crack, or BofCrack, has the value –1 (set in the InternalOpen method), since the position of the first record is zero. The end-of-file crack, or EofCrack, has the value of the number of records, since the last record has the position FRecordCount - 1. We've used two local fields, called EofCrack and BofCrack, to make this code easier to read:

```
procedure TMDCustomDataSet.InternalFirst;
begin
  FCurrentRecord := BofCrack;
end;

procedure TMDCustomDataSet.InternalLast;
```

```
begin
  EofCrack := InternalRecordCount;
  FCurrentRecord := EofCrack;
end;
```

The `InternalRecordCount` method is a virtual method introduced in my `TMDCustomDataSet` class, as different datasets can either have a local field for this value (as in case of the stream-based dataset, which has an `FRecordCount` field) or compute it on-the-fly.

Another group of optional methods is used to get the current record number (used by the DBGrid component to show a proportional vertical scroll bar), set the current record number, or determine the number of records. These methods are quite easy to understand, if you recall that the range of the internal `FCurrentRecord` field is from 0 to the number of records minus 1. In contrast, the record number reported to the system ranges from 1 to the number of records:

```
function TMDCustomDataSet.GetRecordCount: Longint;
begin
  CheckActive;
  Result := InternalRecordCount;
end;

function TMDCustomDataSet.GetRecNo: Longint;
begin
  UpdateCursorPos;
  if FCurrentRecord < 0 then
    Result := 1
  else
    Result := FCurrentRecord + 1;
end;

procedure TMDCustomDataSet.SetRecNo(Value: Integer);
begin
  CheckBrowseMode;
  if (Value > 1) and (Value <= FRecordCount) then
  begin
    FCurrentRecord := Value - 1;
    Resync([]);
  end;
end;
```

Notice that it is the generic custom dataset class that implements all the methods of this section. The derived stream-based dataset doesn't need to modify any of them.

Section III: Record Buffers and Field Management

Now that we've covered all the support methods, we can examine the core of a custom dataset. Besides opening and creating records and moving around between them, the component really needs to move the data from the stream (the persistent file) to the record buffers, and from the record buffers to the `TField` objects that are connected to the data-aware controls. The management of record buffers is quite complex, because each dataset also needs to allocate, empty, and free the memory it requires:

```
function TMDCustomDataSet.AllocRecordBuffer: PChar;
begin
  GetMem (Result, FRecordBufferSize);
end;

procedure TMDCustomDataSet.FreeRecordBuffer (var Buffer: PChar);
begin
  FreeMem (Buffer);
end;
```

The reason for allocating memory this way is that a dataset generally adds more information to the record buffer, so the system has no way of knowing how much memory to allocate. You'll notice that in the `AllocRecordBuffer` method, the component allocates the memory for the record buffer, including both the database data and the record information. In fact, in the `InternalOpen` method I wrote

```
FRecordBufferSize := InternalRecordSize + sizeof (TMdRecInfo);
```

The component also needs to implement a function to reset the buffer, `InternalInitRecord`, usually filling it with numeric zeros or spaces.

Oddly enough, we must also implement a method that returns the size of each record, but only the data portion—not the entire record buffer. This method is necessary for implementing the read-only `RecordSize` property, used only in a couple of peculiar cases in the entire VCL source code. In the generic custom dataset, the `GetRecordSize` method returns the value of the `FRecordSize` field.

Now we've actually reached the core of our custom dataset component. The methods of this group are `GetRecord`, which reads data from the file, `InternalPost` and `InternalAddRecord`, which update or add new data to the file, and `InternalDelete`, which removes data and is not implemented in my sample dataset.

The most complex method of this group is probably `GetRecord`, which serves multiple purposes. In fact, this method is used by the system to retrieve the data for the current record, fill a buffer passed as a parameter, and retrieve the data of the next or previous records. The `GetMode` parameter determines its action:

```
type
  TGetMode = (gmCurrent, gmNext, gmPrior);
```

Of course, a previous or next record might not exist. Even the current record might not exist; for example, when the table is empty (or in case of an internal error). In these cases we don't retrieve the data but return an error code. Therefore, this method's result can be one of the following values:

```
type
  TGetResult = (grOK, grBOF, grEOF, grError);
```

Checking to see if the requested record exists is slightly different than you might expect. We don't have to determine if the current record is in the proper range, only if the requested one is. For example, in the gmCurrent branch of the case statement, we use the standard expression CurrentRecord>=InternalRecourdCount. To fully understand the various cases, you might want to read the code a couple of times.

It took me some trial and error (and system crashes caused by recursive calls) to get it straight when I wrote my first custom dataset a few years back. To test it, consider that if you use a DBGrid, the system will perform a series of GetRecord calls, until either the grid is full or GetRecord return grEOF. Here's the entire code of the GetRecord method:

```
// III: Retrieve data for current, previous, or next record
// (moving to it if necessary) and return the status
function TMdCustomDataSet.GetRecord(Buffer: PChar;
  GetMode: TGetMode; DoCheck: Boolean): TGetResult;
begin
  Result := grOK; // default
  case GetMode of
    gmNext: // move on
      if FCurrentRecord < InternalRecordCount - 1 then
        Inc (FCurrentRecord)
      else
        Result := grEOF; // end of file
    gmPrior: // move back
      if FCurrentRecord > 0 then
        Dec (FCurrentRecord)
      else
        Result := grBOF; // begin of file
    gmCurrent: // check if empty
      if FCurrentRecord >= InternalRecordCount then
        Result := grError;
  end;
  // load the data
  if Result = grOK then
    InternalLoadCurrentRecord (Buffer)
  else if (Result = grError) and DoCheck then
    raise EMdDataSetError.Create ('GetRecord: Invalid record');
end;
```

If there's an error and the DoCheck parameter was True, GetRecord raises an exception. If everything goes fine during record selection, the component loads the data from the stream, moving to the position of the current record (given by the record size multiplied by the record number). In addition, we need to initialize the buffer with the proper bookmark flag and bookmark (or record number) value. This is accomplished by another virtual method I introduced, so that derived classes will only need to implement this portion of the code, while the complex GetRecord method remains unchanged:

```
procedure TMdDataSetStream.InternalLoadCurrentRecord (Buffer: PChar);
begin
  FStream.Position := FDataFileHeaderSize + FRecordSize * FCurrentRecord;
  FStream.ReadBuffer (Buffer^, FRecordSize);
  with PMdRecInfo(Buffer + FRecordSize)^ do
  begin
    BookmarkFlag := bfCurrent;
    Bookmark := FCurrentRecord;
  end;
end;
```

We move data to the file in two different cases: when you modify the current record (that is, a post after an edit) or when you add a new record (a post after an insert or append). We use the InternalPost method in both cases, but we can check the dataset's State property to determine which type of post we're performing. In both cases we don't receive a record buffer as a parameter, so we must use the ActiveRecord property of TDataSet, which points to the buffer for the current record:

```
procedure TMdDataSetStream.InternalPost;
begin
  CheckActive;
  if State = dsEdit then
  begin
    // replace data with new data
    FStream.Position := FDataFileHeaderSize + FRecordSize * FCurrentRecord;
    FStream.WriteBuffer (ActiveBuffer^, FRecordSize);
  end
  else
  begin
    // always append
    InternalLast;
    FStream.Seek (0, soFromEnd);
    FStream.WriteBuffer (ActiveBuffer^, FRecordSize);
    Inc (FRecordCount);
  end;
end;
```

In addition, there's another related method, InternalAddRecord. This method is called by the AddRecord method, which in turn is called by InsertRecord and AppendRecord. These last two are public methods a user can call. This is an alternative to inserting or appending a new record to the dataset, editing the values of the various fields, and then posting the data, since the InsertRecord and AppendRecord calls receive the values of the fields as parameters. All we must do at that point is replicate the code used to add a new record in the InternalPost method:

```
procedure TMdDataSetOne.InternalAddRecord(Buffer: Pointer; Append: Boolean);
begin
  // always append at the end
  InternalLast;
  FStream.Seek (0, soFromEnd);
  FStream.WriteBuffer (ActiveBuffer^, FRecordSize);
  Inc (FRecordCount);
end;
```

The last file operation I should have implemented is one that removes the current record. This operation is common, but it is actually quite complex. If we take a simple approach, such as creating an empty spot in the file, then we'll need to keep track of that spot and make the code for reading or writing a specific record work around that spot. An alternate solution is to make a copy of the entire file, without the given record, and then replace the original file with the copy. Given these choices, I felt that for this example I could forgo supporting record deletion.

Section IV: From Buffers to Fields

In the last few methods, we've seen how datasets move data from the data file to the memory buffer. However, there's little Delphi can do with this record buffer, because it doesn't yet know how to interpret the data in the buffer. We need to provide two more methods: GetData, which copies the data from the record buffer to the field objects of the dataset, and SetData, which moves the data back from the fields to the record buffer. What Delphi will do automatically for us is move the data from the field objects to the data-aware controls, and back.

The code for these two methods isn't very complex, primarily because we saved the field offsets inside the record data in a TList object called FFieldOffset. By simply incrementing the pointer to the initial position in the record buffer of the current field's offset, we'll be able to get the specific data, which takes Field.DataSize bytes.

A confusing element of these two methods is that they both accept a Field parameter and a Buffer parameter. At first, one might think that the buffer passed as parameter is the record buffer. Actually, I found out that the Buffer is a pointer to the field object's raw data. If you use one of the field object's methods to move that data, it will call the dataset's GetData or

SetData methods, probably causing an infinite recursion. Instead, you should use the ActiveBuffer pointer to access the record buffer, use the proper offset to get to the data for the current field in the record buffer, and then use the provided Buffer to access the field data. The only difference between the two methods is the direction we're moving the data:

```
function TMdDataSetOne.GetFieldData (Field: TField; Buffer: Pointer): Boolean;
var
  FieldOffset: Integer;
  Ptr: PChar;
begin
  Result := False;
  if not IsEmpty and (Field.FieldNo > 0) then
  begin
    FieldOffset := Integer (FFieldOffset [Field.FieldNo - 1]);
    Ptr := ActiveBuffer;
    Inc (Ptr, FieldOffset);
    if Assigned (Buffer) then
      Move (Ptr^, Buffer^, Field.DataSize);
    Result := True;
    if (Field is TDateTimeField) and (PInteger(Ptr)^ = 0) then
      Result := False;
  end;
end;

procedure TMdDataSetOne.SetFieldData(Field: TField; Buffer: Pointer);
var
  FieldOffset: Integer;
  Ptr: PChar;
begin
  if Field.FieldNo >= 0 then
  begin
    FieldOffset := Integer (FFieldOffset [Field.FieldNo - 1]);
    Ptr := ActiveBuffer;
    Inc (Ptr, FieldOffset);
    if Assigned (Buffer) then
      Move (Buffer^, Ptr^, Field.DataSize)
    else
      raise Exception.Create (
        'Very bad error in TMdDataSetStream.SetField data');
    DataEvent (deFieldChange, Longint(Field));
  end;
end;
```

The GetField method should return True or False to indicate whether the field contains data or is empty. However, unless you use a special marker for blank fields, it's very difficult to determine this, since we're storing values of different data types. For example, a test such as `Ptr^<>#0` makes sense only if you are using a string representation for all of the fields. If you use this test, zero integer values and empty strings will show as null values (the data-aware controls will be empty), which may be what you want. The problem is that Boolean False values won't show up. Even worse, floating-point values with no decimals and few digits won't be displayed, because the exponent portion of their representation will be zero! However, to make this example work in Delphi 6, I had to consider as empty each date/time field with an initial zero. Without this code, Delphi tries to convert the illegal *internal* zero date (internally, date fields don't use a `TDateTime` data type but a different representation) raising an exception. The code used to work with past versions of Delphi.

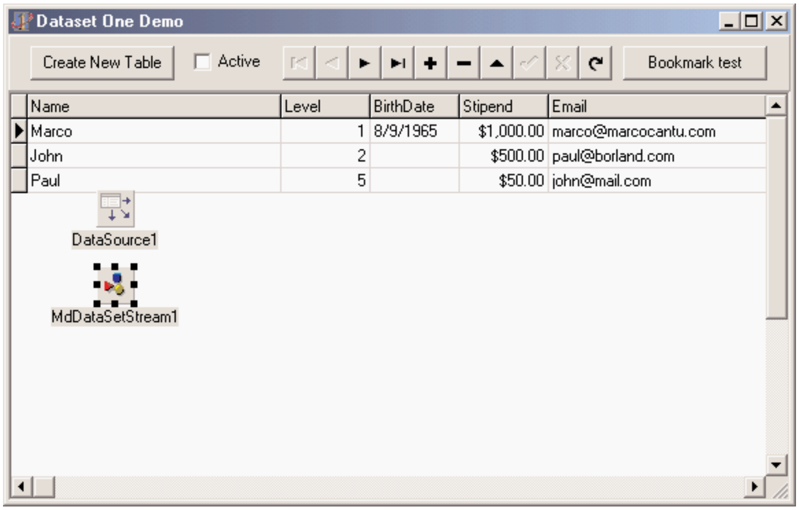
WARNING While trying to fix this problem, I also found out that if you call `IsNull` for a field, this request is resolved by calling `GetFieldData` without passing any buffer to fill but looking only for the result of the function call. This is the reason for the `if Assigned (Buffer)` test within the code.

There's one final method, which doesn't fall into any category: `InternalHandleException`. Generally, this method silences the exception, as it is activated only at design time.

Testing the Stream-Based DataSet

After all this work, we're finally ready to test an application example of the custom dataset component, installed in the component's package for this chapter. The form displayed by the StreamDSDemo program is quite simple, as you can see in Figure 18.6. It has a panel with two buttons, a check box, and a navigator component, plus a DBGrid filling its client area.

FIGURE 18.6: The form of the StreamDS-Demo example. The custom dataset has been activated, so we can already see the data at design time.



Name	Level	BirthDate	Stipend	Email
Marco	1	8/9/1965	$1,000.00	marco@marcocantu.com
John	2		$500.00	paul@borland.com
Paul	5		$50.00	john@mail.com

Figure 18.6 shows the form of the example at design time, but we've activated the custom dataset so that its data is already visible. Of course we'd already prepared the INI file with the table definition (it's the file we already listed when discussing the dataset initialization), and we executed the program to add some data to the file.

It's also possible to modify the form using Delphi's Fields editor and set the properties of the various field objects. Everything works as it does with one of the standard dataset controls! However, to make this work you'll need to enter the name of the custom dataset's file in the `TableName` property, using the complete path.

WARNING As the demo program defines the absolute path of the table file at design time, you'll need to fix it if you copy the examples to a different drive or directory. In the example, the `TableName` property is used only at design time. At run time, in fact, the program looks for the table in the current directory.

The code of the example is rather simple, especially compared to the code of the custom dataset. If the table doesn't exist yet, you can click the Create button:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  MdDataSetStream1.CreateTable;
  MdDataSetStream1.Open;
  CheckBox1.Checked := MdDataSetStream1.Active;
end;
```

You'll notice that we create the file first, open and close it, and then open the table. This is the same behavior as the `TTable` component (which accomplishes this using the `CreateTable` method). To simply open or close the table, you can click the check box:

```
procedure TForm1.CheckBox1Click(Sender: TObject);
begin
  MdDataSetStream1.Active := CheckBox1.Checked;
end;
```

Finally, I've created a method that tests custom dataset's bookmark management code and seems to work.

A Directory in a Dataset

An important idea related to datasets in Delphi is that they simply represent a set of data, regardless where this data comes from. An SQL server or a local file are examples of traditional datasets, but you can use the same technology to show a list of users of a system, a list of files of a folder, the properties of some objects, some XML-based data, and so on.

As an example, the second (and last) dataset presented in this chapter is a list of files. This is based once more on a generic approach. I've built a generic dataset based on a list of objects in memory (using a TObjectList), then derived a version in which the objects correspond to the files of a folder. The actual example is simplified by the fact it is a read-only dataset, so you might even find it simpler than the previous dataset I presented.

NOTE Some of the ideas presented here were discussed in an article I wrote for the Borland Community Web site, http://community.borland.com, published in June 2000.

A List as a Dataset

The generic list-based dataset is called TMdListDataSet and contains the list of objects, created when you open the dataset and freed when you close it. This dataset doesn't store the actual record data within the buffer; rather, it saves in the buffer only the position in the list of the entry corresponding to the record's data. This is the class definition:

```
type
  TMdListDataSet = class (TMdCustomDataSet)
  protected
    // the list holding the data
    FList: TObjectList;
    // dataset virtual methods
    procedure InternalPreOpen; override;
    procedure InternalClose; override;
    // custom dataset virtual methods
    function InternalRecordCount: Integer; override;
    procedure InternalLoadCurrentRecord (Buffer: PChar); override;
  end;
```

You can see that by writing a generic custom data class, we can override few virtual methods of the TDataSet class and of this custom dataset class, and have a working dataset (although this is still an abstract class, which requires extra code from subclasses to work). When the dataset is opened, we have to create the list and set the record size, to indicate we're simply saving the list index in the buffer:

```
procedure TMdListDataSet.InternalPreOpen;
begin
  FList := TObjectList.Create (True); // owns the objects
  FRecordSize := 4; // an integer, the list item id
end;
```

Further subclasses at this point should also fill the list with actual objects.

TIP

Similarly to the ClientDataSet, my list dataset keeps all of its data in memory. However, using some smart techniques, you can also create a list of “fake” objects, and then load the actual objects only when you are accessing them.

Closing is simply a matter of freeing the list, which has a record count corresponding to the list size:

```
function TMdListDataSet.InternalRecordCount: Integer;
begin
  Result := fList.Count;
end;
```

The only other method is used to save the data of the current record in the record buffer, including the bookmark information. The core data is simply the position of the current record, which matches the list index (and also the bookmark):

```
procedure TMdListDataSet.InternalLoadCurrentRecord (Buffer: PChar);
begin
  PInteger (Buffer)^ := fCurrentRecord;
  with PMdRecInfo(Buffer + FRecordSize)^ do
  begin
    BookmarkFlag := bfCurrent;
    Bookmark := fCurrentRecord;
  end;
end;
```

Directory Data

The derived directory dataset class has to provide a way to load the objects in memory when the dataset is opened, to define the proper fields, and to read and write the value of those fields. Of course, it has also a property indicating the directory to work on, or to be more precise, the directory plus the file mask used for filtering the files (as in `c:\docs\*.txt`):

```
type
  TMdDirDataset = class(TMdListDataSet)
  private
    FDirectory: string;
    procedure SetDirectory(const NewDirectory: string);
  protected
    // TDataSet virtual methdos
    procedure InternalInitFieldDefs; override;
    procedure SetFieldData(Field: TField; Buffer: Pointer); override;
    function GetCanModify: Boolean; override;
    // custom dataset virtual methods
    procedure InternalAfterOpen; override;
  public
```

```
    function GetFieldData(Field: TField; Buffer: Pointer): Boolean; override;
  published
    property Directory: string read FDirectory write SetDirectory;
  end;
```

The GetCanModify function is another virtual method of TDataSet, used to determine if the dataset is read-only. In this case, it simply returns False. Also, we won't have to write any code for the SetFieldData procedure, but we have to define it because it is an abstract virtual method.

As I am dealing with a list of objects, the unit includes also a class for those objects. In this case, I am working with file data extracted by a TSearchRec buffer by the TFileData class constructor:

```
type
  TFileData = class
  public
    ShortFileName: string;
    Time: TDateTime;
    Size: Integer;
    Attr: Integer;
    constructor Create (var FileInfo: TSearchRec);
  end;

constructor TFileData.Create (var FileInfo: TSearchRec);
begin
  ShortFileName := FileInfo.Name;
  Time := FileDateToDateTime (FileInfo.Time);
  Size := FileInfo.Size;
  Attr := FileInfo.Attr;
end;
```

This constructor is called for each folder while opening the dataset:

```
procedure TMdDirDataset.InternalAfterOpen;
var
  Attr: Integer;
  FileInfo: TSearchRec;
  FileData: TFileData;
begin
  // scan all files
  Attr := faAnyFile;
  FList.Clear;
  if SysUtils.FindFirst(fDirectory, Attr, FileInfo) = 0 then
  repeat
    FileData := TFileData.Create (FileInfo);
    FList.Add (FileData);
  until SysUtils.FindNext(FileInfo) <> 0;
  SysUtils.FindClose(FileInfo);
end;
```

The next step is to define the fields of the dataset, which in this case are fixed and depend on the available directory data:

```
procedure TMdDirDataset.InternalInitFieldDefs;
begin
  if fDirectory = '' then
    raise EMdDataSetError.Create ('Missing directory');

  // field definitions
  FieldDefs.Clear;
  FieldDefs.Add ('FileName', ftString, 40, True);
  FieldDefs.Add ('TimeStamp', ftDateTime);
  FieldDefs.Add ('Size', ftInteger);
  FieldDefs.Add ('Attributes', ftString, 3);
  FieldDefs.Add ('Folder', ftBoolean);
end;
```

Finally, the component has to move the data from the object of the list referenced by the current record buffer (the `ActiveBuffer` value) to each field of the dataset, as requested by the `GetFieldData` method. This function uses either `Move` or `StrCopy`, depending on the data type and does some conversions for the attributes codes (*H* for hidden, *R* for read-only, and *S* for system) extracted from the related flags and used also to determine whether a file is actually a folder. Here is the code:

```
function TMdDirDataset.GetFieldData (Field: TField; Buffer: Pointer): Boolean;
var
  FileData: TFileData;
  Bool1: WordBool;
  strAttr: string;
  t: TDateTimeRec;
begin
  FileData := fList [PInteger(ActiveBuffer)^] as TFileData;
  case Field.Index of
    0: // filename
      StrCopy (Buffer, pchar(FileData.ShortFileName));
    1: // timestamp
    begin
      t := DateTimeToNative (ftdatetime, FileData.Time);
      Move (t, Buffer^, sizeof (TDateTime));
    end;
    2: // size
      Move (FileData.Size, Buffer^, sizeof (Integer));
    3: // attributes
    begin
      strAttr := '   ';
      if (FileData.Attr and SysUtils.faReadOnly) > 0 then
        strAttr [1] := 'R';
        if (FileData.Attr and SysUtils.faSysFile) > 0 then
          strAttr [2] := 'S';
        if (FileData.Attr and SysUtils.faHidden) > 0 then
          strAttr [3] := 'H';
        StrCopy (Buffer, pchar(strAttr));
      end;
      4: // folder
      begin
        Bool1 := FileData.Attr and SysUtils.faDirectory > 0;
        Move (Bool1, Buffer^, sizeof (WordBool));
      end;
    end; // case
    Result := True;
  end;
```

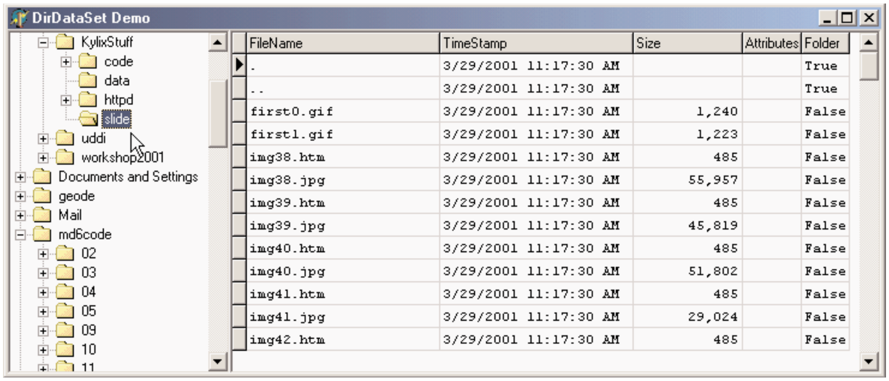
The tricky part in writing this code was figuring out the internal format of dates stored within date/time fields. This is not the common TDateTime format used by Delphi, and not even the internal TTimeStamp, but what is called the internally called the "native" date time format. I've written a conversion function cloning one I've found in the VCL code for the date/time fields:

```
function DateTimeToNative(DataType: TFieldType; Data: TDateTime): TDateTimeRec;
var
  TimeStamp: TTimeStamp;
begin
  TimeStamp := DateTimeToTimeStamp(Data);
  case DataType of
    ftDate: Result.Date := TimeStamp.Date;
    ftTime: Result.Time := TimeStamp.Time;
  else
    Result.DateTime := TimeStampToMSecs(TimeStamp);
  end;
end;
```

With this dataset available, building the demo program (shown in Figure 18.7) was simply a matter of connecting a DBGrid component to it and adding a folder-selection component, Delphi 6's ShellTreeView control. This control is set up to work only on files, by setting its Root property to C:\. When the user selects a new folder, the OnChange event handler of the ShellTreeView control refreshes the dataset.

FIGURE 18.7:

The output of the DirDemo example, which uses a rather unusual dataset, showing directory data.



FileName	TimeStamp	Size	Attributes	Folder
.	3/29/2001 11:17:30 AM			True
..	3/29/2001 11:17:30 AM			True
first0.gif	3/29/2001 11:17:30 AM	1,240		False
first1.gif	3/29/2001 11:17:30 AM	1,223		False
img38.htm	3/29/2001 11:17:30 AM	485		False
img38.jpg	3/29/2001 11:17:30 AM	55,957		False
img39.htm	3/29/2001 11:17:30 AM	485		False

img42.htm	3/29/2001 11:17:30 AM	485		False

```
procedure TForm1.ShellTreeView1Change(Sender: TObject; Node: TTreeNode);
begin
  MdDirDataset1.Close;
  MdDirDataset1.Directory := ShellTreeView1.Path + '\*.*';
  MdDirDataset1.Open;
end;
```

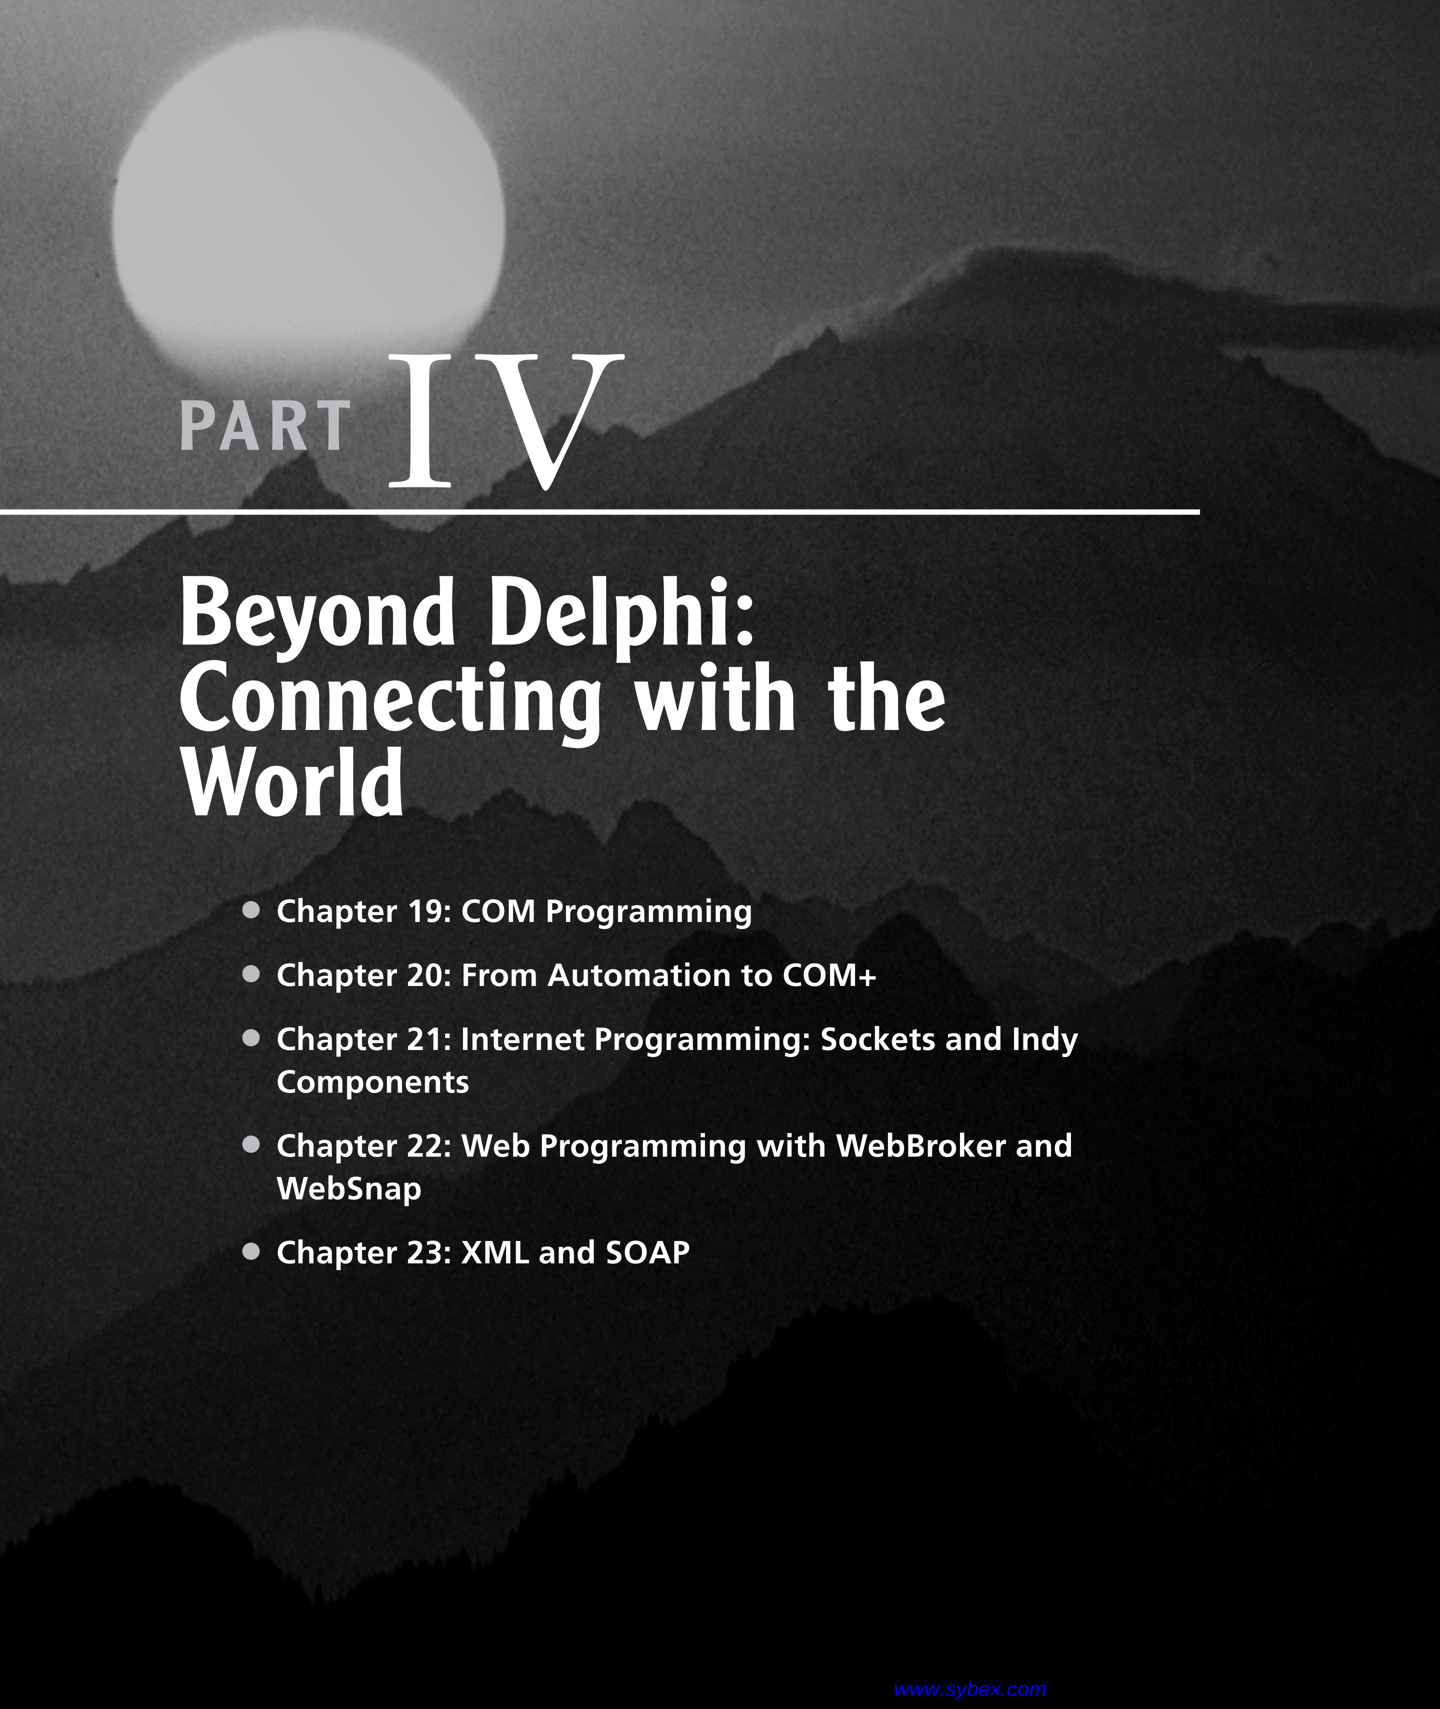
What’s Next?

In this chapter we’ve delved inside Delphi’s database architecture, by first examining the development of data-aware controls and then studying the internals of the `TDataSet` class to write a couple of custom dataset components. With this information, and all the other ideas presented in this part devoted to database programming, you should probably be able to choose the architecture of your database applications, depending on your needs.

NOTE I’ve actually extended the list-based dataset to build an object-based version, hosting the business logic of an application and mapped to a relational database. Refer to my Web site (`www.marcocantu.com`) or contact me for the availability of this code.

Database programming is certainly a core element of Delphi, the reason for devoting several chapters of the book to this topic. We’ll get back to this topic when focusing on presenting database data over the Web, in Chapters 21 and 22.

For the moment, though, we have to introduce another important element of Windows applications, COM and OLE Automation, covered in the next two chapters.



PART IV

Beyond Delphi: Connecting with the World

CHAPTER 19

COM Programming

- What are OLE and COM?
- COM, GUIDs, and class factories
- Delphi interfaces and COM
- The VCL COM-support classes
- Windows shell interfaces

For about 10 years, starting soon after the release of Windows 3.0, Microsoft has kept promising that its operating system and their API would be based on a real object model instead of functions. According to the speculations, Windows 95 (and later Windows 2000) should have been based on this revolutionary approach. Nothing like this happened, but Microsoft kept pushing COM (Component Object Model), built the Windows 95 shell on top of it, pushed applications integration with COM and derivative technologies (such as Automation), and reached the peak by introducing COM+ with Windows 2000.

Now, soon after the release of the complete foundation required for high-level COM programming, Microsoft has decided to switch to a new core technology, part of the dotNet (or .Net, if you prefer) initiative. My impression is that COM wasn't really suited for the integration of fine-grained objects, though it succeeded in providing an architecture for integrating applications or large objects.

NOTE dotNet is a mix of interesting new technologies and pure marketing hype, and this book doesn't discuss it in detail. Even if it were possible to predict how dotNet will affect programmers using Microsoft development tools, it is far from clear how it will affect Delphi programmers. dotNet, in fact, is based on a class library very similar to Delphi's VCL, and it is unclear what the advantage will be of switching to it. If Borland could bundle the VCL with an operating system, along with its core run-time packages, you'd have a situation very similar to dotNet, as far as the library is concerned. Instead, if you are looking for a virtual machine and portable code, you can certainly consider Java and the portability between Windows and Linux possible with the CLX library of Delphi 6 and Kylix. Having said this, I'm not underestimating dotNet, but this is a book on Delphi programming. In any case, we'll get back to many core elements of dotNet in the final chapters, discussing XML and SOAP. Finally, the system can expose dotNet objects as COM objects, so after you learn COM you'll also have a chance to interact with dotNet.

In this chapter, we'll build our first COM object and integrate COM objects with the Windows shell. Type libraries, Automation, and other topics will be covered in the next chapter. I will stick to the basic elements to let you understand the role of this technology without delving heavily into the details. I'll bear in mind the clouds on the future of COM, declared obsolete by Microsoft after the announcement of dotNet but still heavily used by the same company inside their applications and operating systems.

A Short History of OLE and COM

Part of the confusion related to COM technology comes from the fact that Microsoft has used different names for it for marketing reasons. Everything started with Object Linking and Embedding (OLE, for short), which was an extension of the DDE (Dynamic Data Exchange) model. Using the Clipboard allows you to copy some raw data, and using DDE allows you to connect parts of two documents. OLE allows you to copy data from a server application to a client application, along with information regarding the server or a reference to information stored in the Windows Registry. The raw data might be copied along with the link (object embedding) or kept in the original file (object linking). OLE Documents are now called *Active Documents*.

Microsoft updated OLE to OLE 2 and started adding new features, such as OLE Automation and OLE Controls. The next step was to build the Windows 95 shell using OLE technology and interfaces and then to rename the OLE Controls (previously known also as OCX) as ActiveX controls, changing the specification to allow for lightweight controls suitable for distribution over the Internet. For a while, Microsoft promoted ActiveX controls as suitable for the Internet, but the idea was never fully accepted by the development community, certainly not as "suitable" for Internet development.

As this technology was extended and became increasingly important to the Windows platform, Microsoft changed the name to OLE, and then to COM, and now to COM+ for Windows 2000. These changes in naming are only partially related to technological changes and are driven to a large extent by marketing purposes.

What, then, is COM? Basically, the Component Object Model, or COM, is a technology that defines a standard way for a client module and a server module to communicate through a specific interface. Here, "module" indicates an application or a library (a DLL); the two modules may execute on the same computer or on different machines connected via a network. Many interfaces are possible, depending on the role of the client and server, and you can add new interfaces for specific purposes. These interfaces are implemented by server objects. A server object usually implements more than one interface, and all the server objects have a few common capabilities, because they must all implement the `IUnknown` interface.

The good news is that Delphi is fully compliant with COM. When you look at the source code, Object Pascal seems to be easier to use than C++ or other languages for writing COM objects. This simplicity mainly derives from the incorporation of interface types into the Object Pascal language. By the way, interfaces are also similarly used to integrate Java with COM on the Windows platform.

The purpose of COM interfaces is to communicate between two software modules, two executable files, or one executable file and a DLL. Implementing COM objects in DLLs is generally simpler, because in Win32, a program and the DLL it uses reside in the same memory address space. This means that if the program passes a memory address to the DLL, the address remains valid. When you use two executable files, COM has a lot of work to do behind the scenes to let the two applications communicate. This mechanism is called *marshaling*. Note that a DLL implementing COM objects is described as an *in-process* server, whereas when the server is a separate executable, it is called an *out-of-process* server. However, when DLLs are executing on another machine (DCOM) or inside a host environment (MTS), they are also out-of-process.

Implementing *IUnknown*

Before we start looking to an example of COM development, I would like to introduce a few COM basics. The first is that every COM object must implement the IUnknown interface, also dubbed IInterface in Delphi 6 for non-COM usage of interfaces (as we saw in Chapter 3, "The Object Pascal Language: Inheritance and Polymorphism"). This is the base interface from which every Delphi interface inherits, and Delphi provides a couple of different classes with ready-to-use implementations of IUnknown/IInterface, including TInterfacedObject and TComObject. The first can be used to have an internal object unrelated with COM, while the second is used to create objects that can be exported by servers. As I'll discuss in Chapter 20, "From Automation to COM+," several other classes inherit from TComObject and provide support for more interfaces, which are required by Automation servers or ActiveX controls.

As mentioned in Chapter 3, the IUnknown interface has three methods: _AddRef, _Release, and QueryInterface. Here is the definition of the IUnknown interface (extracted from the System unit):

```
type
  IUnknown = interface
    ['{00000000-0000-0000-C000-000000000046}']
    function QueryInterface(const IID: TGUID;
      out Obj): Integer; stdcall;
    function _AddRef: Integer; stdcall;
    function _Release: Integer; stdcall;
  end;
```

The _AddRef and _Release methods are used to implement reference counting. The QueryInterface method handles the type information and type compatibility of the objects.

NOTE In the code above, you can see an example of an **out** parameter, a parameter passed back from the method to the calling program but without an initial value passed by the calling program to the method. The **out** parameters have been added to Delphi's Object Pascal language specifically to support COM. It's also important to note that although Delphi's language definition for the interface type is designed for compatibility with COM, Delphi interfaces do not require COM. This was already highlighted in Chapter 3, where I built a complex interface-based example with no COM support whatsoever.

You don't usually need to implement these methods, as you can inherit from one of the Delphi classes already supporting them. The most important class is `TComObject`, defined in the ComObj unit. When you build a COM server, you'll generally inherit from this class. Because `TComObject` is a complex class, this excerpt shows only its key elements:

```
type
  TComObject = class(TObject, IUnknown, ISupportErrorInfo)
  private
    FNonCountedObject: Boolean;
    FRefCount: Integer;
  protected
    { IUnknown }
    function IUnknown.QueryInterface = ObjQueryInterface;
    function IUnknown._AddRef = ObjAddRef;
    function IUnknown._Release = ObjRelease;
    { ISupportErrorInfo }
    function InterfaceSupportsErrorInfo(const iid: TIID): HResult; stdcall;
  public
    constructor Create;
    destructor Destroy; override;
    procedure Initialize; virtual;
    function ObjAddRef: Integer; virtual; stdcall;
    function ObjQueryInterface(const IID: TGUID; out Obj): HResult;
      virtual; stdcall;
    function ObjRelease: Integer; virtual; stdcall;
    property RefCount: Integer read FRefCount;
  end;
```

This class implements the `IUnknown` interface (using the `ObjAddRef`, `ObjQueryInterface`, and `ObjRelease` methods, as indicated by the method-mapping statements in the protected portion of the class) and the `ISupportErrorInfo` interface (through the `InterfaceSupportsErrorInfo` method). The implementation of reference counting for the `TComObject` class has been extended to support threading. Instead of using `Inc` and `Dec`, the code uses the thread-safe `InterlockedIncrement` and `InterlockedDecrement` API functions, as you can see in the source code of the class:

```
function TComObject.ObjAddRef: Integer;
begin
  Result := InterlockedIncrement(FRefCount);
end;

function TComObject.ObjRelease: Integer;
begin
  Result := InterlockedDecrement(FRefCount);
  if Result = 0 then Destroy;
end;
```

As you can see, the implementation of Release destroys the object when there are no more references to it. At first sight, the need to call this method each time you operate on an object seems like a lot of work. However, you might remember from Chapter 3 that when you're using interface variables to refer to objects, Delphi automatically adds the reference-counting calls to the compiled code, which automatically destroys unreferenced objects. This labor-saving feature makes Delphi a convenient tool for COM development.

The most complex method is QueryInterface, which in Delphi is actually implemented through the GetInterface method of the TObject class:

```
function TComObject.ObjQueryInterface(const IID: TGUID; out Obj): HResult;
begin
  if GetInterface(IID, Obj) then
    Result := S_OK
  else
    Result := E_NOINTERFACE;
end;
```

The role of the QueryInterface method is twofold:

- QueryInterface is used for type checking. The program can ask an object the following questions: Are you of the type I'm interested in? Do you implement the interface I want to call? And the specific methods? If the answer is no, the program can look for another object, maybe asking another server.
- If the answer is yes, QueryInterface usually returns a pointer to the object, using its reference output parameter (out).

To understand the role of the QueryInterface method, it is important to keep in mind that a COM object can implement multiple interfaces, as the event TComObject does. When you call QueryInterface, you might ask for one of the possible interfaces of the object, using the TGUID parameter.

Globally Unique Identifiers

The QueryInterface method has a special parameter of the TGUID type. This is an ID that identifies any COM server class and any interface in the system. When you want to know whether an object supports a specific interface, you ask the object whether it implements the interface that has a given ID (which for the default OLE interfaces is determined by Microsoft).

Another ID is used to indicate a specific class, a specific server. The Windows Registry stores this ID, with indications of the related DLL or executable file. The developers of an OLE server define the class identifier.

Both of these IDs are known as GUIDs, or *globally unique identifiers*. If each developer uses a number to indicate its own OLE servers, how can we be sure that these values are not duplicated? The short answer is that we cannot. The real answer is that a GUID is such a long number (with 16 bytes, or 128 bits, or a number with 38 digits!) that it is almost impossible to come up with two random numbers having the same value. Moreover, programmers should use the specific API call `CoCreateGuid` (directly or through their development environment) to come up with a valid GUID that reflects some system information.

In fact, GUIDs created on machines with network cards are guaranteed to be unique, because network cards contain unique serial numbers that form a base for the GUID creation. GUIDs created on machines with CPU IDs (such as the Pentium III) should also be guaranteed unique, even without a network card. With no unique hardware identifier, GUIDs are unlikely to ever duplicate.

WARNING Besides being careful not to copy the GUID from someone else's program (which can result in two completely different COM objects using the same GUID), you should never make up your own ID by entering a casual sequence of numbers. Windows checks the IDs, and using a casual sequence won't generate a valid ID. An OLE server with an invalid ID is not recognized, and you won't get an error message! Windows also won't include an API or technique to validate a GUID. The risk with creating class or interface IDs by hand is that you could coincidentally duplicate a GUID that is already in use somewhere else in the system. However, to avoid this problem, simply press Ctrl+Shift+G in the Delphi editor, and you will get a new, properly defined, unique GUID.

Delphi defines a `TGUID` data type (in the System unit) to hold these numbers:

```
type
  TGUID = record
    D1: Integer;
    D2: Word;
    D3: Word;
    D4: array [0..7] of Byte;
  end;
```

This structure is actually quite odd but is required by Windows. You can assign a value to a GUID using the standard hexadecimal notation stored inside a string, as in this code fragment:

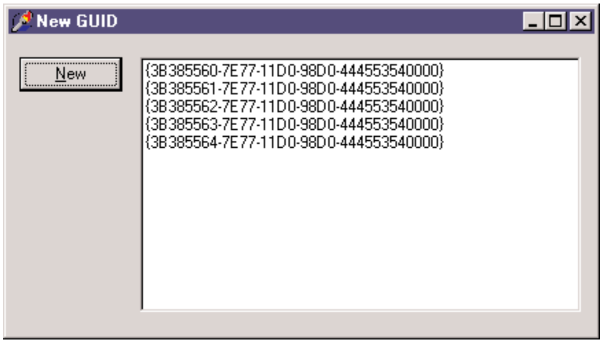
```
const
  Class_ActiveForm1: TGUID = '{1AFA6D61-7B89-11D0-98D0-444553540000}';
```

If you need to generate a GUID manually and not in the Delphi environment, you can simply call the `CoCreateGuid` Windows API function, as demonstrated by the NewGuid example (see Figure 19.1). This example is so simple that I've decided not to list its code.

(You can find the source code for this application, along with the chapter's other examples, in the folder for Chapter 19 on the companion CD.)

FIGURE 19.1:

An example of the GUIDs generated by the NewGuid example. Values depend on my computer and the time I run this program.



```
{3B385560-7E77-11D0-98D0-444553540000}
{3B385561-7E77-11D0-98D0-444553540000}
{3B385562-7E77-11D0-98D0-444553540000}
{3B385563-7E77-11D0-98D0-444553540000}
{3B385564-7E77-11D0-98D0-444553540000}
```

To handle GUIDs, Delphi provides the `GUIDToString` function and the opposite `StringToGUID` function. You can also use the corresponding Windows API functions, such as `StringFromGuid2`, but in this case, you must use the WideString type instead of the string type. Any time OLE is involved, you have to use the WideString type, unless you use Delphi functions that automatically do the required conversion for you. Actually, OLE API functions use the `PWChar` type (pointer to null-terminated arrays of wide characters), but simply casting a WideString to `PWChar` does the trick.

TIP Keep in mind that GUIDs come in different flavors. The two most important types are interface IDs (or IID), which refer to an interface, and class IDs (or CLSID), which refer to a specific object in a server. These two kinds of IDs both use the GUID style.

The Role of Class Factories

When we register the GUID of a COM object in the Registry, we can use a specific API function to create the object, such as the `CreateComObject` API:

```
function CreateComObject (const ClassID: TGUID): IUnknown;
```

This API function will look into the Registry, find the server registering the object with the given GUID, load it, and, if the server is a DLL, call the `DLLGetClassObject` method of the DLL. This is a function every in-process server must provide and export:

```
function DllGetClassObject (const CLSID, IID: TGUID;
  var Obj): HResult; stdcall;
```

This API function receives as parameters the requested class and interface, and it returns an object in its reference parameter. The object returned by this function is a *class factory*.

Now, what is a class factory? As the name suggests, a class factory is an object capable of creating other objects. Each server can have multiple objects. The server exposes the class factory, and the class factory can create one of these various objects. Each object, then, can have multiple interfaces. One of the many advantages of the Delphi simplified approach to COM development is that the system can provide a class factory for us. For this reason, I'm not going to add a class factory to our simple example.

The call to the CreateComObject API doesn't stop at the creation of the class factory, however. After retrieving the class factory, CreateComObject calls the CreateInstance method of the IClassFactory interface. This method creates the requested object and returns it. If no error occurs, this object becomes the return value of the CreateComObject API.

By setting up this mechanism (including the class factory and the DLLGetClassObject call), you make it very simple to create objects. CreateComObject is just a simple function call with a complex behavior behind the scenes. What's great in Delphi is that the complex mechanism is handled for you by the run-time system. So it's time to start looking in detail at how Delphi makes COM really easy to master.

Class Factories and Other Delphi COM Classes

Besides the TComObject class, Delphi includes several other predefined COM classes. We'll use them in the following sections, but here is a list of the most important COM classes of the Delphi VCL:

- TInterfacedObject, defined in the System unit, inherits from TObject and implements the IUnknown interface. It is used only for internal objects.
- TComObject, defined in the ComObj unit, inherits from TObject and implements both the IUnknown interface and the ISupportErrorInfo interface. Unlike TInterfacedObject, this class also has a related class factory.
- TTypedComObject, defined in the ComObj unit, inherits from TComObject and implements the IProvideClassInfo interface (in addition to the IUnknown and ISupportErrorInfo interfaces already implemented by the base class, TComObject).
- TAutoObject, defined in the ComObj unit, inherits from TTypedComObject and implements also the IDispatch interface.
- TActiveXControl, defined in the AxCtrls unit, inherits from TAutoObject and implements several interfaces (IPersistStreamInit, IPersistStorage, IOleObject, and IOleControl, to name just a few).

For each of these classes, Delphi also defines a class factory. The class factory classes form another hierarchy, with the same structure. Their names are TComObjectFactory, TTypedComObjectFactory, TAutoObjectFactory, and TActiveXControlFactory. Class factories are important, and every COM server requires them. Usually we simply use class factories by creating an object in the initialization section of the unit defining the corresponding server object class.

A First COM Server

There is no better way to understand COM than to build a simple COM server hosted by a DLL. A library hosting a COM object is indicated in Delphi as an ActiveX library. For this reason we can start the development of this project by selecting File ➢ New ➢ Other, moving to the ActiveX page, and selecting the ActiveX Library option. This generates a project file I've saved as FirstCom on the companion CD. This is the complete source code:

```
library FirstCom;

uses
  ComServ;

exports
  DllGetClassObject,
  DllCanUnloadNow,
  DllRegisterServer,
  DllUnregisterServer;

{$R *.RES}

begin
end.
```

The four functions exported by the DLL are required for COM compliance and are used by the system as follows:

- To access the class library (`DllGetClassObject`)
- To check whether the server has destroyed all its objects and can be unloaded from memory (`DllCanUnloadNow`)
- To add or remove information about the server in the Windows Registry (`DllRegisterServer` and `DllUnregisterServer`)

You generally don't have to implement these functions, because Delphi provides a default implementation in the ComServ unit. For this reason, in the code of our server, we only need to export them.

COM Interfaces and Objects

Now that we have the structure of our COM server in place, we can start developing it. The first step is to write the code of the interface we want to implement in the server. The interface can be very similar to the code of an abstract class, listing all the methods we want to make available from our server. (I have already discussed Object Pascal interfaces in Chapter 3.) Here is the code of a simple interface, which you should add to a separate unit (called NumIntf in the example):

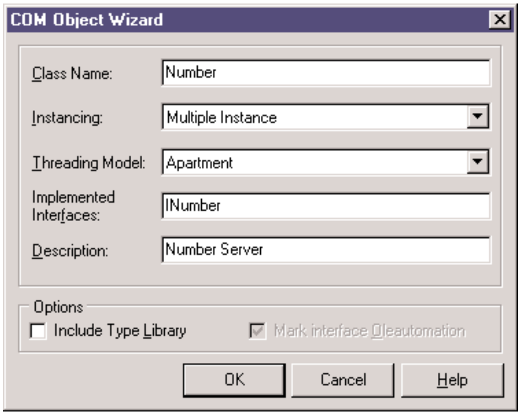
```
type
  INumber = interface
    ['{B4131140-7C2F-11D0-98D0-444553540000}']
    function GetValue: Integer; stdcall;
    procedure SetValue (New: Integer); stdcall;
    procedure Increase; stdcall;
  end;
```

The IID was added to the code by pressing the Ctrl+Shift+G key combination.

After declaring the custom interface, we can add the actual object to the server. To accomplish this, we can use the COM Object Wizard (available in the ActiveX page of the File ➢ New ➢ Other dialog box). You can see this wizard's dialog box in Figure 19.2. Here you should enter the name of the class of the server, the interface you want to implement, and a description. I've disabled the generation of the type library to avoid introducing too many topics at once. You should also choose an instancing and a threading model, as described in the related sidebar.

FIGURE 19.2:

The COM Object Wizard



COM Object Wizard

Class Name: Number

Instancing: Multiple Instance

Threading Model: Apartment

Implemented Interfaces: INumber

Description: Number Server

Options

☐ Include Type Library ☑ Mark interface Oleautomation

The code generated by the COM Object Wizard is actually quite simple. The interface contains the definition of the class to fill with methods and data:

```
type
  TNumber = class(TComObject, INumber)
    protected
      {Declare INumber methods here}
    end;
```

The server class inherits from the TComObject class, which I discussed in the last section. In the code generated by the wizard, after the server class comes the definition of the GUID for the server:

```
const
  Class_Number: TGUID = '{5B2EF181-3AAE-11D3-B9F1-00000100A27B}';
```

Finally, there is some code in the initialization section (which uses most of the options we've set up in the wizard's dialog box):

```
initialization
  TComObjectFactory.Create(ComServer, TNumber, Class_Number, 'Number',
    'Number Server', ciMultiInstance, tmApartment);
```

This code creates an object of the TComObjectFactory class, passing as parameters the global ComServer object, a class reference to the class we've just defined, the GUID for the class, the server name, the server description, and the instancing and threading models we want to use.

The global ComServer object, defined in the ComServ unit, is a manager of the class factories available in the server library. It uses its own ForEachFactory method to look for the class supporting a given COM object request, and it keeps track of the number of allocated objects. As we've already seen, in fact, the ComServ unit implements the functions required by the DLL to be a COM library.

Having examined the source code generated by the wizard, we can now complete it by adding to the TNumber class the methods required for implementing the INumber interface. First, write the declaration of the methods:

```
type
  TNumber = class(TComObject, INumber)
  private
    fValue: Integer;
  public
    function GetValue: Integer; virtual; stdcall;
    procedure SetValue (New: Integer); virtual; stdcall;
    procedure Increase; virtual; stdcall;
  end;
```

At this point, simply activate class completion by pressing Shift+Ctrl+C and fill the methods with the proper code. This is so straightforward that I'm not going to list it here; you can find the source code on the companion CD.

COM Instancing and Threading Models

When you create a COM server, you should choose a proper instancing and threading model, which can significantly affect the behavior of the COM server.

Instancing affects only out-of-process servers (any COM server in a separate executable file, rather than a DLL) and can assume three values:

Multiple indicates that when several client applications require the COM object, the system starts multiple instances of the server.

Single indicates that, even when several client applications require the COM object, there is only one instance of the server application; it creates multiple internal objects to service the requests.

Internal indicates that the object can only be created inside the server; client applications cannot ask for one.

The second decision relates to the thread support of the COM object, which is valid for in-process servers only (DLLs). The threading model is a joint decision of the client and the server application: if both sides agree on one model, it is used for the connection. If no agreement is found, COM can still set up a connection using marshaling, which can slow down the operations. And keep in mind that a server must not only publish its threading model in the Registry (as a result of setting the option in the wizard); it must also follow the rules for that threading model in the code. Here are the key highlights of the various threading models:

The Single model indicates no real support for threads. The requests reaching the COM server are serialized, so that the client can perform one operation at a time.

The Apartment model, or "single-threaded Apartment" indicates that only the thread that created the object can call its methods. This means that the requests for each server object are serialized, but other objects of the same server can receive requests at the same time. For this reason, the server object must take extra care only to access global data of the server (using critical sections, mutexes, or some other synchronization techniques). This is the threading model generally used for ActiveX controls inside Internet Explorer.

The Free model, or "multi-threaded Apartment" indicates that the client has no restrictions, which means that multiple threads can use the same object at the same time. For this reason, every method of every object must protect itself and the nonlocal data it uses against multiple simultaneous calls. This threading model is more complex for a

Continued on next page

server to support than the Single and Apartment models, because even access to the object's own instance data must be handled with thread-safe care.

The fourth option, Both indicates that the server object supports both the Apartment model and the Free model.

The final option, Neutral was introduced in Windows 2000 and is available only under COM+. It indicates that multiple clients can call the object on different threads at the same time, but COM guarantees you that the same method is not invoked twice at the same time. Guarding for concurrent access to the data of the objet is required. Under COM, it is mapped to the Apartment model.

Initializing the COM Object

If you look back at the definition of the TComObject class, you will notice it has a nonvirtual constructor. (Actually, it has multiple nonvirtual constructors, which I've omitted from the listing.) Each TComObject constructor calls the virtual Initialize method. For this reason, if you want to customize the creation of an object and then initialize it, you should not define a new constructor (which will never be called). What you should do is override its Initialize method, as I've done in the TNumber class. Here is the final version of this class:

```
type
  TNumber = class(TComObject, INumber)
  private
    fValue: Integer;
  public
    function GetValue: Integer; virtual; stdcall;
    procedure SetValue (New: Integer); virtual; stdcall;
    procedure Increase; virtual; stdcall;
    procedure Initialize; override;
    destructor Destroy; override;
  end;
```

As you can see, I've also overridden the destructor of the class, because I wanted to test the automatic destruction of the COM objects provided by Delphi. Here is the code for this pseudoconstructor and the destructor:

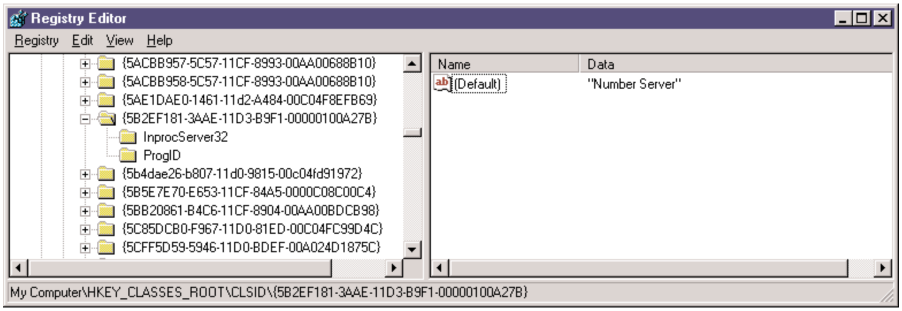
```
procedure TNumber.Initialize;
begin
  inherited;
  fValue := 10;
end;
```

```
destructor TNumber.Destroy;
begin
  inherited;
  MessageBox (0, 'Object Destroyed', 'TDLLNumber', mb_OK); // API call
end;
```

In the first method, calling the inherited version is good practice, even though the `TComObject.Initialize` method has no code in this version of Delphi. The destructor, instead, must call the base class version. This is the code required to make our COM object work properly and to let us know when an object is actually destroyed.

Testing the COM Server

Now that we've finished writing our COM server object, we can register and use it. Simply compile its code and then use the Run ➢ Register ActiveX Server menu command in Delphi. You do this to register the server on your own machine, with the results you can see in Figure 19.3.



```
{5ACBB957-5C57-11CF-8993-00AA00688B10}
{5ACBB958-5C57-11CF-8993-00AA00688B10}
{5AE1DAE0-1461-11d2-A484-00C04F8EFB69}
{5B2EF181-3AAE-11D3-B9F1-00000100A27B}
    InprocServer32
    ProgID
{5b4dae26-b807-11d0-9815-00c04fd91972}
{5B5E7E70-E653-11CF-84A5-0000C08C00C4}
{5BB20861-B4C6-11CF-8904-00AA00BDCB98}
{5C85DCB0-F967-11D0-81ED-00C04FC99D4C}
{5CFF5D59-5946-11D0-BDEF-00A024D1875C}
```

Name	Data
(Default)	"Number Server"

My Computer\HKEY_CLASSES_ROOT\CLSID\{5B2EF181-3AAE-11D3-B9F1-00000100A27B}

FIGURE 19.3:

The new registered server in Windows RegEdit

When you distribute this server, you should install it on the client computers. To accomplish this, you can write a REG file to install the server in the Registry. However, this is not really the best approach, because the server already includes a function you can activate to register the server. This function can be activated by the Delphi environment, as we've seen, or in a few other ways:

- You can pass the COM server DLL as a command-line parameter to Microsoft's `RegSvr32.exe` program, found in the `\Windows\System` directory.
- You can use the similar `TRegSvr.exe` demo program that ships with Delphi. (The compiled version is in the `\Bin` directory, and its source code is in the `\Demos\ActiveX` directory.)
- You can let an installation builder program call the registration function of the server.

Having registered the server, we can now turn to the client side of our example. This time, the example is called TestCom and is stored in a separate directory. In fact, the program loads the server DLL through the OLE/COM mechanism, thanks to the server information present in the Registry, so it's not necessary for the client to know which directory the server resides in.

The form displayed by this program is very similar to the one we've used to test the object inside the DLL. In the client program, you must include the source code file with the interface and redeclare the COM server GUID. Of course, the code of the program's `FormCreate` method should be updated to create the required COM objects. The program starts with all the buttons disabled (at design time), and it enables them only after an object has been created. This way, if an exception is raised while creating one of the objects, the buttons related to the object won't be enabled:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  // create first object
  Num1 := CreateComObject (Class_Number) as INumber;
  Num1.SetValue (SpinEdit1.Value);
  Label1.Caption := 'Num1: ' + IntToStr (Num1.GetValue);
  Button1.Enabled := True;
  Button2.Enabled := True;

  // create second object
  Num2 := CreateComObject (Class_Number) as INumber;
  Label2.Caption := 'Num2: ' + IntToStr (Num2.GetValue);
  Button3.Enabled := True;
  Button4.Enabled := True;
end;
```

Notice in particular the call to `CreateComObject` and the following `as` cast. The API call starts the COM object-construction mechanism I've already described in detail. This call also dynamically loads the server DLL. The return value is an `IUnknown` object. This object must be converted to the proper interface type before assigning it to the `Num1` and `Num2` fields, which now have the interface type `INumber` as their data type:

```
type
  TForm1 = class(TForm)
    ...
  private
    Num1, Num2 : INumber;
```

WARNING To downcast an interface to the actual type, *always* use the `as` cast, which for interfaces performs a `QueryInterface` call behind the scenes. This provides some protection, because it raises an exception if the interface you are casting to is not supported by the given object. In the case of interfaces, the `as` cast is the only way to *extract* an interface from another interface. If you write a plain cast of the form `INumber(CreateComObject(Class_Number))`, the program will crash, even if the cast seems to make sense, as in the case above. Casting an interface pointer to another interface pointer is an error. Period. Never do it.

In Figure 19.4, you can see the output of this test program, which is very similar to the previous version. Notice that this time, `Num2` shows the initial value of the object at start-up, as set up in its `Initialize` method. Notice also that I've added one more button, which creates a third temporary COM object:

```
procedure TForm1.Button5Click(Sender: TObject);
var
  Num3: INumber;
begin
  // create a new temporary COM object
  Num3 := CreateComObject (Class_Number) as INumber;
  Num3.SetValue (100);
  Num3.Increase;
  ShowMessage ('Num3: ' + IntToStr (Num3.GetValue));
end;
```

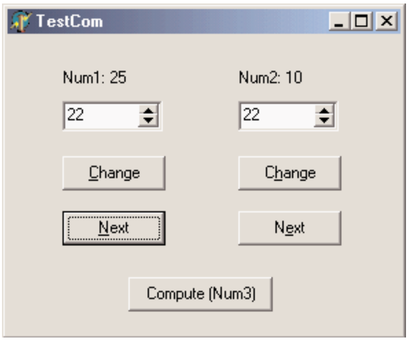


FIGURE 19.4: The output of the TestCom example, a COM client

Pressing this button, you simply get the value of the number following 100. To see why I added this method to the example, you need to press the button a second time, after the message showing the result. Now you get a second message, indicating that the object has been destroyed. This demonstrates that simply letting an interface object go out of scope automatically calls the object's `Release` method, decreases the object's reference count, and destroys the object if its reference count reaches zero. Chapter 3 described this reference-counting mechanism in more detail.

The same happens to the other two objects as soon as the program terminates. Even if the program doesn't explicitly destroy the two objects in the FormDestroy method, they are indeed destroyed, as the message shown by their Destroy destructor clearly demonstrates. This happens because they were declared to be of an interface type, and Delphi is going to use reference counting for them.

Using Interface Properties

As a further small step, we can extend the example by adding a property to the INumber interface. When you add a property to an interface, you indicate the data type and then the read and write directives. You can have read-only or write-only properties, but the read and write clauses must always refer to a method because interfaces don't hold anything else but methods.

Here is the updated interface, which is part of the PropCom example:

```
type
  INumberProp = interface
    ['{B36C5800-8E59-11D0-98D0-444553540000}']
    function GetValue: Integer; stdcall;
    procedure SetValue (New: Integer); stdcall;
    property Value: Integer read GetValue write SetValue;
    procedure Increase; stdcall;
  end;
```

I've given this interface a new name and, what's even more important, a new interface ID. I could have inherited the new interface type from the previous one, but this would have provided no real advantage. COM by itself doesn't really support inheritance, and from the perspective of COM, all interfaces are different simply because they have different interface IDs. Needless to say, in Delphi we can use inheritance to improve the structure of the code of the interfaces and of the server objects implementing them.

In the PropCom example, I've updated the server class declaration simply by writing:

```
type
  TDllNumber = class (TComObject, INumberProp)
  ...
```

This class also has a new server object ID. The client program, also on the CD, can now simply use the Value property instead of the SetValue and GetValue methods. Here is a small excerpt from the FormCreate method:

```
Num1 := CreateComObject (Class_NumPropServer) as INumberProp;
Num1.Value := SpinEdit1.Value;
Label1.Caption := 'Num1: ' + IntToStr (Num1.Value);
```

The difference between using methods and properties for an interface is only syntactical, because interface properties cannot access private data as class properties can. By using properties, we can make the code a little more readable.

Calling Virtual Methods

We've built a couple of examples based on COM, but you might still feel uncomfortable with the idea of a program calling methods of objects that are created within a DLL. How is this possible if those methods are not exported by the DLL? The COM server, the DLL, creates an object and returns it to the calling application. By doing this, the DLL creates an object with a *virtual method table* (VMT). (Remember that all the interface methods are virtual by default.)

Because every object embeds a pointer to its VMT, the main program receives an object, and also a way to work on it, by calling its virtual methods. The main program doesn't need to know the memory address of those methods, because the objects know it, exactly as they do with a polymorphic call. But COM is even more powerful than this: you don't even have to know which programming language was used to create the object, provided its VMT follows the standard dictated by COM.

TIP The COM-compatible VMT implies also a strange effect. The method names are not important, provided their address is in the proper position in the VMT. This is why you can map a method of an interface to an actual function implementing it.

To sum things up, we can say that COM provides a language-independent binary standard for objects. The objects you share among modules are compiled, and their VMT has a particular structure, determined by COM and not by the development environment you've used.

Windows Shell Programming

In the last section, we built a fully standard COM object, packaged it as an in-process server, and used it from a standard client. However, the COM interface we implemented was a custom interface we'd built. Now we can try to build clients and servers related to the Windows shell interfaces, which are all based on COM. The original Windows API was basically a collection of functions, but all the most recent APIs are generally based on COM.

The following sections use some existing servers that are part of the Windows shell; we'll write a client application and use the COM servers provided by the system. This case illustrates the difference from the traditional use of the Windows API calls. I'm also going to write some COM servers to be used by the Windows system, particularly the Explorer. This case illustrates the difference from the traditional development of a callback function invoked by the system.

Creating Shortcuts

One of the simplest shell interfaces we can use in a client application is the `IShellLink` interface. This interface relates to Windows shortcuts and allows programmers to access the information of an existing shortcut or to create a new one. In the ShCut example on the CD-ROM, I'm going to create various types of shortcuts, all referring to the program itself. Of course, once you understand how to do this, you can easily extend the example and create shortcuts for any program or file.

The example has an edit box for the name of the shortcut, a few check boxes, and two buttons. When the Create button is pressed, the text in the edit box is used as the name of a new shortcut, which is placed in the current directory, on the desktop, or in the Start menu. These options are not exclusive; a user can create multiple shortcuts at once.

The most important code is at the very beginning of this method. The `CreateComObject` call creates a system object, as indicated by the GUID passed as a parameter. The result of this call (which is an `IUnknown` interface) is converted both to an `IShellLink` interface and to an `IPersistFile` interface:

```
uses
  ComObj, ActiveX, ShlObj, Registry;

procedure TForm1.Button1Click(Sender: TObject);
var
  AnObj: IUnknown;
  ShLink: IShellLink;
  PFile: IPersistFile;
  FileName: string;
  WFileName: WideString;
  Reg: TRegIniFile;
begin
  // access the two interfaces of the object
  AnObj := CreateComObject (CLSID_ShellLink);
  ShLink := AnObj as IShellLink;
  PFile := AnObj as IPersistFile;
```

Actually, we could have written the last three lines of code above using this shorter notation:

```
ShLink := CreateComObject (CLSID_ShellLink) as IShellLink;
PFile := ShLink as IPersistFile;
```

If you look at similar examples built in other languages, you'll notice that to access the IPersistFile interface, the programs use custom calls to the QueryInterface method. The two as expressions basically call QueryInterface for us.

Once we have the IShellLink interface, we can call some of its methods, such as SetPath and SetWorkingDirectory:

```
// get the name of the application file
FileName := ParamStr (0);
// set the link properties
ShLink.SetPath (PChar (FileName));
ShLink.SetWorkingDirectory (PChar (ExtractFilePath (FileName)));
```

Once we've set up the shell link object, we have to save it, depending on the status of the three check boxes, calling the Save method of the IPersistFile interface of the object. The simplest version is the one used to save the link in the current directory:

```
// save the file in the current dir
if cbDir.Checked then
begin
  // using a WideString
  WFileName := ExtractFilePath (FileName) + EditName.Text + '.lnk';
  PFile.Save (PWChar (WFileName), False);
end;
```

The call to the Save method (which creates the physical LNK file) requires a "pointer to wide char" parameter. The simplest way to obtain this is to declare a long string and then cast it to a PWChar. Do not try casting a plain string to PWChar—the compiler will emit a warning and the program won't work!

To create the shortcut on the desktop or in the Start menu, we should first determine the corresponding system folder by looking up the proper value in the Registry. By writing the program this way, we ensure it will work on different versions of Windows and on localized versions as well. Here is the source code for the last two check boxes:

```
// save on the desktop
if cbDesktop.Checked then
begin
  Reg := TRegIniFile.Create(
    'Software\MicroSoft\Windows\CurrentVersion\Explorer');
  WFileName := Reg.ReadString ('Shell Folders', 'Desktop', '') +
    '\' + EditName.Text + '.lnk';
  Reg.Free;
  PFile.Save (PWChar (WFileName), False);
end;
// save in the Start Menu
if cbStartMenu.Checked then
begin
```

```
    Reg := TRegIniFile.Create(
      'Software\MicroSoft\Windows\CurrentVersion\Explorer');
    WFileName := Reg.ReadString ('Shell Folders', 'Start Menu', '') +
      '\' + EditName.Text + '.lnk';
    Reg.Free;
    PFile.Save (PWChar (WFileName), False);
  end;
```

To look up the information in the Registry, I've used the `TRegIniFile` class, although there are other related classes in the VCL, such as the `TRegistry` class. The effect of running this program and pressing the button is that Windows will add a new link in the directory of the project, on the desktop, or in the Start menu. You can see an example of the program in Figure 19.5.

FIGURE 19.5:

Shortcut Filename: Shortcut to ShCut.exe Delphi Demo

Create in
☑ Current Directory
☑ Desktop
□ Start Menu

9 object(s) | 396 KB | My Computer

Using Shell APIs and Objects

As an extra feature, the program can also add a new document to the list of recently used ones, calling the `SHAddToRecentDocs` method:

```
procedure TForm1.Button2Click(Sender: TObject);
var
  ProjectFile: string;
begin
  ProjectFile := ChangeFileExt (ParamStr (0), '.dpr');
  SHAddToRecentDocs (SHARD_PATH, PChar(ProjectFile));
end;
```

This has very little to do with COM, and I've added it to the example only to highlight that there is a very large number of shell-related APIs, available in the ShlObj unit, besides the original and more limited ShellApi unit.

Another example, available in the source code for this chapter and called FindFolders, highlights the use of another *plain* (non-COM) shell function, `SHBrowseForFolder`. In the example you can see the following code:

```
procedure TForm1.btnBrowseClick(Sender: TObject);
var
  bi: TBrowseInfo;
  pidl: pItemIdList;
  strpath, displayname: string;
begin
  SetLength (displayname, 100);

  bi.hwndOwner := Handle;
  bi.pidlRoot := nil;
  bi.pszDisplayName := pChar (displayname);
  bi.lpszTitle := 'Select a folder';
  bi.ulFlags := bif_StatusText;
  bi.lpfn := nil;
  bi.lParam := 0;

  pidl := SHBrowseForFolder (bi);

  SetLength (strPath, 100);
  SHGetPathFromIdList (pidl, PChar(strPath));
  Edit1.Text := strPath;
end;
```

The FindFolders example even shows some Delphi-specific APIs to interact with files and folders (available also on Linux) including `SelectDirectory`, which has the same effect of `SHBrowseForFolder` but a different user interface. The example also uses the `DirectoryExists` and `ForceDirectories` functions, available in the FileCtrl unit. You can see how they are used by looking in the source code of the example.

NOTE Notice that in Delphi 6, some of the Shell API is also encapsulated in the sample ShellListView, ShellTreeView, and ShellComboBox controls. I've used these controls in a few examples throughout the book, including the DirDemo example of Chapter 18, "Writing Database Components."

The "To-Do File" Application

As a second example of integrating a Delphi program with the system shell, I've tried to write a simple real-world application that uses file dragging and a context menu handler. I'll start with the file dragging first, because this will actually introduce some of the techniques used by the context menu handler.

As I mentioned, this application is actually useful; you can use it to create a sort of "to-do list." It is based on a Paradox table that stores filenames and notes about the files. The form of the application has a DBGrid component showing only a single column containing the filenames and a memo control hosting the notes related to the current file. You can see this form at design time in Figure 19.6.

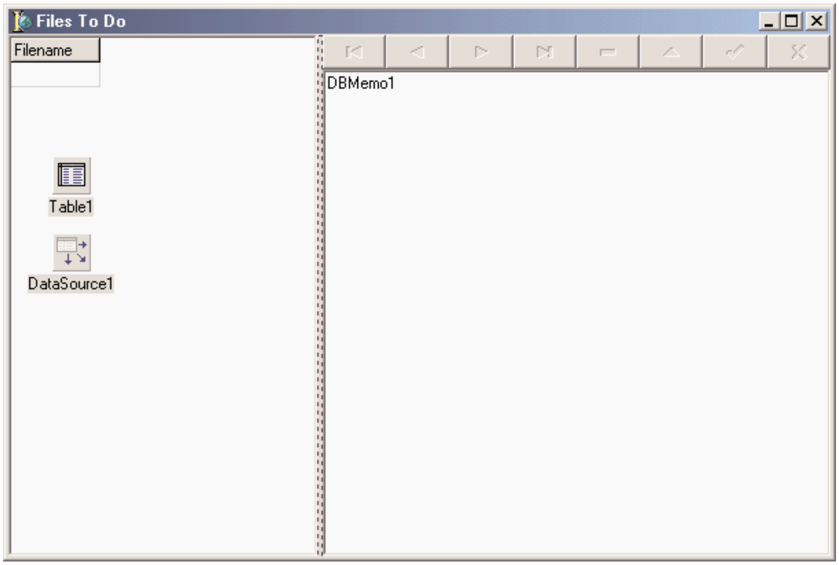

FIGURE 19.6: The form of the ToDoFile example at design time

TIP Using a single-column DBGrid is the only way in Delphi to show a list of the available records in a list-box format. The alternative, of course, is to fill a list box with custom code and then manually navigate in the database table when the selection in the list box changes. This manual approach is, of course, less efficient when we have many records, because the program needs to scan them all to fill the list box, while the DBGrid loads only the record it currently displays.

Notice that the navigator component has no "New Record" button, and the DBGrid is set up as a read-only component. In fact, users should not be able to create new records except by dragging a file onto the form, and they're not allowed to change the filename field in any way (except by deleting it). All the user can do is edit the notes field, entering a description of the operations to be done on the file.

Creating the Database

To create the database table for this example, I've used the `FieldDefs` property to define the structure and set the `StoreDefs` property to True to save the table definition along with the form DFM file. The table has two fields, a string field called Filename and a memo field called Notes. Of course, you can also create the table at design time, using the table component's local menu. The program, however, calls the `CreateTable` method in the `OnCreate` event handler, unless this has already been done:

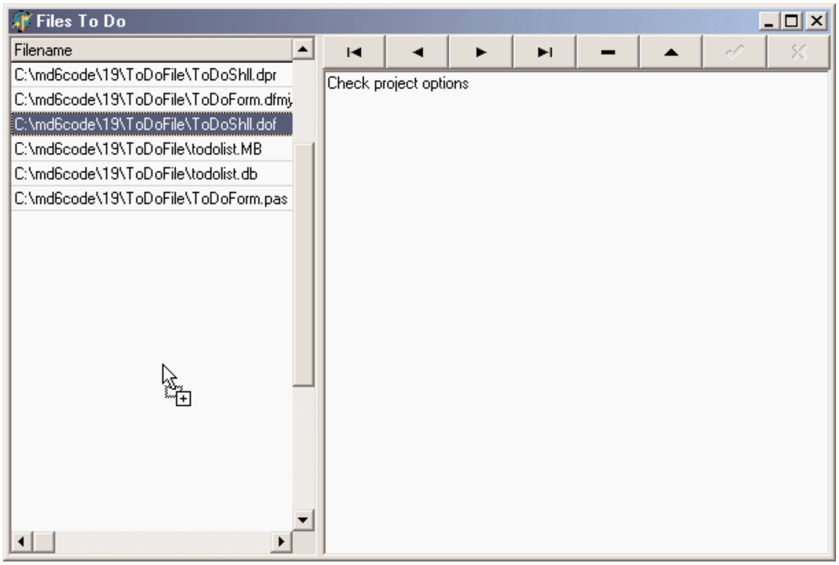
```
procedure TToDoFileForm.FormCreate(Sender: TObject);
begin
  // eventually create the table
  if not Table1.Exists then
    Table1.CreateTable;
  // activate the table
  Table1.Activate;
  // accept dragging to the form
  DragAcceptFiles (Handle, True);
end;
```

Dragging Files to the Form

As you can see in the listing above, the form initialization code also registers the window with the system as a file-dragging target, by calling the `DragAcceptFiles` Windows API function. As a result, the application's cursor changes to the typical "drag accept" icon when a file is dragged over it. You can see an example of this cursor in Figure 19.7.

FIGURE 19.7:

The drag-accept cursor displayed by the ToDoFile application as a user drags a file over it



Filename
C:\md6code\19\ToDoFile\ToDoShll.dpr
C:\md6code\19\ToDoFile\ToDoForm.dfm
C:\md6code\19\ToDoFile\ToDoShll.dof
C:\md6code\19\ToDoFile\todolist.MB
C:\md6code\19\ToDoFile\todolist.db
C:\md6code\19\ToDoFile\ToDoForm.pas

Check project options

When a file-dragging operation is performed, the system sends the window a wm_DropFiles message. This message passes (among its other parameters) a handle to a file-drop structure from which you can extract information by using the DragQueryFile API function. When this API function is called with the $FFFFFFFF parameter, it returns the number of files dragged to the window; when it is called with a numeric parameter, it fills a buffer with the name of that file. For this reason, the code of a wm_DropFiles message handler gets the number of files first and then loops for each of the files, as the following listing demonstrates:

```
procedure TToDoFileForm.DropFiles(var Msg: TWmDropFiles);
var
  nFiles, I: Integer;
  Filename: string;
begin
  // get the number of dropped files
  nFiles := DragQueryFile (Msg.Drop, $FFFFFFFF, nil, 0);
  // for each file
  try
    for I := 0 to nFiles - 1 do
    begin
      // allocate memory
      SetLength (Filename, 80);
      // read the file name
      DragQueryFile (Msg.Drop, I, PChar (Filename), 80);
      // normalize file
      Filename := PChar (Filename);
      // add a new record
      Table1.InsertRecord ([Filename, '']);
    end;
  finally
    DragFinish (Msg.Drop);
  end;
  // open the (last) record in edit mode
  Table1.Edit;
  // move the input focus to the memo
  DBMemo1.SetFocus;
end;
```

As you can see in the preceding code, for every new file, the program inserts a new record with the corresponding filename and an empty field for the notes. Then, for the last file being dragged, the program opens the record in edit mode and moves the focus to the memo control, so that a user can fill the notes for the file.

Creating a Context-Menu Handler

Now that we have the base program running, we can add a shell extension to the system to let the user simply select a file and "send" it to the application without having to do the dragging operation, which is not always handy when there are many programs running. A context-menu extension is one of the available Windows shell extensions and is activated every time a user right-clicks a file in the Windows Explorer.

Technically, a context menu is a COM server exposing an internal object that is going to be created and used by the system. A context-menu COM object must implement two different interfaces, `IContextMenu` and `IShellExtInit`. The first interface defines specific actions for the context menu, such as defining the number of menu items to add and their text, while the second interface defines a way to access the file or files the user is operating on. This is the resulting definition of the COM server object class:

```
type
  TToDoMenu = class(TComObject, IUnknown, IContextMenu, IShellExtInit)
  private
    fFileName: string;
  protected
    {Declare IContextMenu methods here}
    function QueryContextMenu(Menu: HMENU; indexMenu,
      idCmdFirst, idCmdLast, uFlags: UINT): HResult; stdcall;
    function InvokeCommand(
      var lpici: TCMInvokeCommandInfo): HResult; stdcall;
    function GetCommandString(idCmd, uType: UINT; pwReserved: PUINT;
      pszName: LPSTR; cchMax: UINT): HResult; stdcall;
    {Declare IShellExtInit methods here}
    function IShellExtInit.Initialize = InitShellExt;
    function InitShellExt (pidlFolder: PItemIDList;
      lpdobj: IDataObject; hKeyProgID: HKEY): HResult; stdcall;
  end;
```

Notice that the class implements the `Initialize` method of the `IShellExtInit` interface with a differently named method, `InitShellExt`. The reason is that I wanted to avoid confusion with the `Initialize` method of the `TComObject` base class, which is the hook we have to initialize the object, as described earlier in this chapter. Let's examine the `InitShellExt` method first; it is definitely the most complex one:

```
function TToDoMenu.InitShellExt(pidlFolder: PItemIDList;
  lpdobj: IDataObject; hKeyProgID: HKEY): HResult; stdcall;
var
  medium: TStgMedium;
  fe: TFormatEtc;
begin
  Result := E_FAIL;
```

```
    // check if the lpdobj pointer is nil
    if Assigned (lpdobj) then
    begin
      with fe do
      begin
        cfFormat := CF_HDROP;
        ptd := nil;
        dwAspect := DVASPECT_CONTENT;
        lindex := -1;
        tymed := TYMED_HGLOBAL;
      end;
      // transform the lpdobj data to a storage medium structure
      Result := lpdobj.GetData(fe, medium);
      if not Failed (Result) then
      begin
        // check if only one file is selected
        if DragQueryFile (medium.hGlobal, $FFFFFFFF, nil, 0) = 1 then
        begin
          SetLength (fFileName, 1000);
          DragQueryFile (medium.hGlobal, 0, PChar (fFileName), 1000);
          // realign string
          fFileName := PChar (fFileName);
          Result := NOERROR;
        end
        else
          Result := E_FAIL;
      end;
      ReleaseStgMedium(medium);
    end;
  end;
```

The initial portion of the method transforms the pointer to the IDataObject interface, which we receive as a parameter, into the same data structure used in a file drop operation, so that we can read the file information by using the DragQueryFile function again. This complex way of coding is actually the simplest one you can use! At the end of this operation, we have the value of the filename. Any selection of multiple files is not accepted.

We can now look at the methods of the IContextMenu interface. The first, QueryContextMenu, is used to add new items to the local menu of the file. In this case, we add a new menu item (calling the InsertMenu API function) only if the ToDoFile application is running. We can determine this by searching for a window corresponding to the TToDoFileForm class, which should be unique in the system. The result of the function is the number of items added to the menu:

```
function TToDoMenu.QueryContextMenu(Menu: HMENU;
  indexMenu, idCmdFirst, idCmdLast, uFlags: UINT): HResult;
begin
```

```
    // add entry only if the program is running
    if FindWindow ('TToDoFileForm', nil) <> 0 then
    begin
      // add a new item to context menu
      InsertMenu (Menu, indexMenu, MF_STRING or MF_BYPOSITION, idCmdFirst,
        'Send to ToDoFile');
      // return the number of menu items added
      Result := 1;
    end
    else
      Result := 0;
  end;
```

Now that items have been added to the menu, a user can select them. While he or she moves over the items, a descriptive message is displayed in the status bar of the Windows Explorer. The menu ID (idCmd) we receive in the GetCommandString method is simply the relative number, starting with zero, of the items we have added to the menu. When the cursor is over an item, we simply copy a string with its description to the buffer provided by the system:

```
function TToDoMenu.GetCommandString(idCmd, uType: UINT;
  pwReserved: PUINT; pszName: LPSTR; cchMax: UINT): HRESULT;
begin
  if idCmd = 0 then
  begin
    // return help string for menu item
    strCopy (pszName, 'Add file to the ToDoFile database');
    Result := NOERROR;
  end
  else
    Result := E_INVALIDARG;
end;
```

The final step is the operation to do once a menu item is actually selected. The InvokeCommand method receives a pointer to a structure holding the request. This method follows a standard pattern of first checking that the request is valid by looking at the two 16-bit words of the lpici.lpVerb value. After these preliminary (but required) steps, we check the value to see which menu item was activated; or, if the context menu has only one item, as in this case, we simply test for a value of zero. The following is the skeleton of the code, before we add the specific action:

```
function TToDoMenu.InvokeCommand (var lpici: TCMInvokeCommandInfo): HResult;
begin
  Result := NOERROR;
  // make sure we are not being called by an application
  if HiWord(Integer(lpici.lpVerb)) <> 0 then
  begin
    Result := E_FAIL;
    Exit;
    end;
    // make sure we aren't being passed an invalid argument number
    if LoWord(lpici.lpVerb) > 0 then
    begin
      Result := E_INVALIDARG;
      Exit;
    end;
    // execute the command specified by lpici.lpVerb
    if LoWord(lpici.lpVerb) = 0 then
    begin
      // actual code still missing here
    end
  end;
```

Sending Data to Another Application with *wm_CopyData*

Because we have the filename the user is operating on, all we have to do in the context-menu handler is send this name to the main form of the ToDoFile application. The problem is that the context-menu handler DLL runs in the Windows Explorer process, so it cannot send the value of a memory pointer to another process. This would simply be useless; as in Win32, different applications have separate memory address spaces.

We saw in the last chapter that one way to share data among applications is to use a memory-mapped file. Another technique, which is actually better in this case, is to use the wm_CopyData message. This is a special Windows message, which can be used to send a memory buffer to another application: Windows will resolve all the memory conversion problems for us. A program basically fills the CopyDataStruct data structure with the data and indicates its length, and then must use the SendMessage API to forward it to a destination window. For this reason we need to use FindWindow again to get the handle of the main window of the ToDoFile application. Here is the rest of the code of the InvokeCommand method:

```
  var
    hwnd: THandle;
    cds: CopyDataStruct;
  begin
    ...
    if LoWord(lpici.lpVerb) = 0 then
    begin
      // get the handle of the window
      hwnd := FindWindow ('TToDoFileForm', nil);
      if hwnd <> 0 then
      begin
        // prepare the data to copy
        cds.dwData := 0;
        cds.cbData := length (fFileName);
        cds.lpData := PChar (fFileName);
      // activate the destination window
      SetForegroundWindow (hwnd);
      // send the data
      SendMessage (hwnd, wm_CopyData, lpici.hWnd, Integer (@cds));
    end;
  end;
```

NOTE Before sending the data, we must activate the destination window by calling the `SetForegroundWindow` API. This is necessary because we are going to activate a window that was created by another thread, something Windows doesn't normally do. Notice also that if you write this call in the ToDoFile application as it receives the `wm_CopyData` message, it will produce no effect at all.

As the context-menu handler sends data to it, the application has to be extended to handle the `wm_CopyData` message. In this event handler, we receive the same structure we sent for the other side, although between the send operation done by the context-menu handler and the receive operation done by the application. Windows takes care of mapping the data properly to the other address space. As a result, extracting the filename is actually very simple, but keep in mind that this is so only because Windows does a lot of work behind the scenes. Using a plain Windows message other than `wm_CopyData` will never work!

Here is the code I've added to the form of the ToDoFile application. It does several things: It restores the application if it was minimized, retrieves the name of the file, inserts a new record in the database table, copies the filename, and moves the focus to the memo control once more.

```
procedure TToDoFileForm.CopyData(var Msg: TWmCopyData);
var
  Filename: string;
begin
  // restore the window if minimized
  if IsIconic (Application.Handle) then
    Application.Restore;

  // extract the filename from the data
  Filename := PChar (Msg.CopyDataStruct.lpData);
  // insert a new record
  Table1.Insert;
  // set up the file name
  Table1.FieldByName ('Filename').AsString := Filename;
  // move the input focus to the memo
  DBMemo1.SetFocus;
end;
```

Registering the Shell Extension

After writing this shell extension, we must register it. With the usual Run ➢ Register ActiveX Server command, we can register the server in the system, but we still have to provide some extra information to register it as a shell extension, in this case for any type of file. There are several approaches: you can edit the Registry manually, you can write a REG file, or you can add registration information right into the COM server library, which is my preferred approach. In a Delphi COM server, the default registration takes place in the `TComObjectFactory` class, when the `UpdateRegistry` method is executed. We can modify the default registration by inheriting a class from the standard class factory class and overriding this method:

```
type
  TToDoMenuFactory = class (TComObjectFactory)
  public
    procedure UpdateRegistry (Register: Boolean); override;
  end;
```

In this method, we should either add the entry in the Registry or delete it, depending on the value of the Boolean parameter:

```
procedure TToDoMenuFactory.UpdateRegistry(Register: Boolean);
var
  Reg: TRegistry;
begin
  inherited UpdateRegistry (Register);

  Reg := TRegistry.Create;
  Reg.RootKey := HKEY_CLASSES_ROOT;
  try
    if Register then
      if Reg.OpenKey('\*\ShellEx\ContextMenuHandlers\ToDo', True) then
        Reg.WriteString('', GUIDToString(Class_ToDoMenuMenu))
    else
      if Reg.OpenKey('\*\ShellEx\ContextMenuHandlers\ToDo', False) then
        Reg.DeleteKey ('\*\ShellEx\ContextMenuHandlers\ToDo');
  finally
    Reg.CloseKey;
    Reg.Free;
  end;
end;
```

WARNING I've checked this code under Windows 2000, but I'm not completely sure it works also on Windows 98/Me, as the shell portion of the registry has been subject to subtle changes among different versions of Windows.

In the initialization section of the COM object unit, we also need to create a new global object of this class instead of the base class factory class:

```
initialization
  TToDoMenuFactory.Create (ComServer, TToDoMenu, Class_ToDoMenuMenu,
    'ToDoMenu', 'ToDoMenu Shell Extension', ciMultiInstance, tmApartment);
```

Now you can simply register the server and set it up as a context-menu handler by using the Delphi Run ➢ Register ActiveX Server menu command, the RegSrv32 application, or most of the tools used to create installation programs.

What’s Next?

In this chapter I have discussed the foundations of Microsoft’s COM technology. We’ve seen how Delphi supports COM and built a few simple servers. In the second part of the chapter, we’ve spend some time discussing the COM-based Shell API and the development of a shell extension.

The next chapter opens up COM to its higher-level techniques, covering Automation, Documents, and ActiveX Controls. Now that we know the foundations, exploring these COM-technologies will definitely be simpler, although we won’t delve into the low-level details of these technologies.

CHAPTER 20

From Automation to COM+

- OLE Automation
- Creating and using Automation servers
- Using type libraries
- Automating office programs
- The OLE Container component
- Building an ActiveX and an ActiveForm
- Introducing COM+

After the last chapter, which was devoted to the foundations of Microsoft's COM architecture, it is time to look into some of the actual high-level Windows programming techniques based on COM. We'll start by discussing Automation and the role of type libraries. Also, we'll see how to work properly with Delphi data types in Automation servers and clients.

Later, we'll focus on the use of the Automation support provided by Microsoft Office applications, made simple thanks to the ready-to-use components that embed Office server programs and documents. In the final part of the chapter, we'll explore the use of embedded objects, with the OleContainer component, and the development of OLE controls or ActiveX controls.

I'll also introduce stateless COM (MTS and COM+) technologies and a few other advanced ideas. But let's begin with more foundational material.

OLE Automation

In the last chapter, we saw that you can use COM to let an executable file and a library share objects, and that this can be used to interact with the Windows shell. Most of the time, however, users want applications that can talk to each other. One of the approaches you can use for this goal is OLE Automation. After presenting a couple of examples that use custom interfaces based on type libraries, I'll cover the development of Word and Excel OLE controllers, showing how to transfer database information to those applications.

NOTE The current Microsoft documentation uses the term *Automation* instead of *OLE Automation,* and uses the terms *active document* and *compound document* instead of *OLE Document*. This book uses this new terminology along with the older "OLE" terminology incorporated into many Delphi component names and other identifiers.

In Windows, applications don't live in separate worlds; users often want them to interact. The Clipboard and DDE offer a simple way for applications to interact, as users can copy and paste data between applications. However, more and more programs offer an OLE Automation interface to let other programs drive them. Beyond the obvious advantage of programmed automation compared to manual user operations, these interfaces are completely language-neutral, so you can use Delphi, C++, Visual Basic, or a macro language to drive an OLE Automation server regardless of the programming language used to write it.

OLE Automation is quite straightforward to implement in Delphi, thanks to the extensive work by the compiler and VCL to shield developers from its intricacies. To support OLE Automation, Delphi provides a wizard and a powerful type-library editor, and it supports dual interfaces.

When you use an in-process DLL, the client application can use the server and call its methods directly, because they are in the same address space. When you use OLE Automation, the situation is more complex. The client (called the *controller*) and the server are two separate applications running in different address spaces. For this reason, the system must dispatch the method calls using a complex mechanism called *marshaling* (something I won't cover in detail). What is important to know is that there are two ways a controller can call the methods exposed by a server:

- It can ask for the execution of a method, passing its name in a string, in a way similar to the dynamic call to a DLL. This is what Delphi does when you use a variant to call the OLE Automation server. This technique is very easy to use, but it is rather slow and provides very little compiler type-checking.
- It can import the definition of a Delphi interface for the object on the server and call its methods in a more direct way (simply dispatching a number). This technique, based on interfaces, allows the compiler to check the types of the parameters and produces faster code, but it requires a little more effort from the programmer. Also, you end up binding your controller application to a specific version of the server. A variation of this technique involves the use of dispatch interfaces, based on the definition of the interfaces.

In the following examples, we'll use all these techniques and compare them a little further.

Introducing Type Libraries

The most important difference between the two approaches is that the second generally requires a *type library*, one of the foundations of OLE and COM. A type library is basically a collection of type information. This collection generally describes all of the elements (the objects, the interfaces, and other type information) made available by a server. The key difference between a type library and other descriptions of these elements (such as some C or Pascal code) is that a type library is language-independent. The type elements are defined by OLE as a subset of the standard elements of programming languages, and any development tool can use them. Why do we need this information?

As mentioned before, an OLE Automation controller can use variants and have no type information about the server it is using. This means that, behind the scenes, every function call has to be dispatched to the server using the `Invoke` method of `IDispatch`, passing the function name as a string parameter and hoping the name corresponds to an existing function of the server.

Although this sounds difficult, a small code fragment using the old Automation interface of Microsoft Word, registered as `Word.Basic`, illustrates how simple it is for a programmer:

```
var
  VarW: Variant;
begin
  VarW := CreateOleObject ('Word.Basic');
  VarW.FileNew;
  VarW.Insert ('Mastering Delphi by Marco Cantù');
```

NOTE As we'll see later, recent versions of Word still register the `Word.Basic` interface, which corresponds to the internal WordBasic macro language, but it also registers the new interface `Word.Application`, which corresponds to the VBA macro language. We'll also see that Delphi provides some components that simplify the connection with Microsoft Office applications.

These three lines of code start Word (unless it was already running), create a new document, and add a few words to it. You can see the effect of this code in Figure 20.1. The code uses a variant, which is a *type-variant* data type. A variant can assume as its value different data types, including a COM object supporting the `IDispatch` interface. Variants are type-checked at run time; this is why the compiler can compile the code even if it doesn't know about the methods of the OLE Automation server.

Send Text to Word.Application

Mastering Delphi by Marco Cantù

FIGURE 20.1: This Word document is being created and composed by a Delphi application, WordTest.

Unfortunately, the Delphi compiler has no way to check whether the methods exist. Doing all the type checks at run time is risky, because if you make even a minor spelling error in a function name, you get no warning whatsoever of your error until you run the program and reach that line of code. For example, if you type `VarW.Isnert`, the compiler will not complain about the misspelling at all, but at run time, you'll get an error. Because it doesn't recognize the name, Word assumes the method does not exist.

Although the OLE `IDispatch` interface supports the approach we've just seen, it is also possible—and safer—for a server to export the description of its interfaces and objects using a type library. This type library can then be converted by a specific tool (such as Delphi) into definitions written in the language you want to use to write your client or controller program (such as Object Pascal). This makes it possible for a compiler to check whether the code is correct.

Once the compiler has done its checks, it can use either of two different techniques to send the request to the server. It can use a plain VTable (that is, an entry in an interface type declaration), or it can use a `dispinterface` (dispatch interface). We used an interface type declaration in the last chapter, so it should be familiar. A `dispinterface` is basically a way to map each entry in an interface to a number. Calls to the server can then be dispatched by number. We can consider this an intermediate technique, in between dispatching by function name and using a direct call in the VTable.

NOTE The term *dispinterface* is actually a keyword. A `dispinterface` is automatically generated by the type-library editor for every interface. Along with `dispinterface`, Delphi uses other related keywords: `dispid` indicates the number to associate with each element; `readonly` and `writeonly` are optional specifiers for properties.

The term used to describe this ability to connect to a server in two different ways, using a more dynamic or a more static approach, is *dual interfaces*. This means that in writing an OLE controller, you can choose to access the methods of a server in two ways: you can use late binding and the mechanism provided by the `dispinterface`, or you can use early binding and the mechanism based on the VTables, the interface types.

It is important to keep in mind that (along with other considerations) different techniques result in faster or slower execution. Looking up a function by name (and doing the type checking at run time) is the slowest approach, using a `dispinterface` is much faster, and using the direct VTable call is the fastest approach. We'll do this kind of test in the TlibCli example, later in this chapter.

Writing an OLE Automation Server

We'll start by writing an OLE Automation server. To create an OLE Automation object, you can use Delphi's Automation Object Wizard. Start with a new application, open the Object Repository by selecting File ➢ New, move to the ActiveX page, and choose Automation Object. In the resulting Automation Object Wizard (shown in Figure 20.2), enter the name of the class (without the initial *T*, because this will be added automatically for you) and click OK. Delphi will now open the type-library editor.

FIGURE 20.2:

Threading Model: Apartment

Options

□ Generate Event support code

As you can see in Figure 20.2, Delphi can generate OLE Automation servers that also export events. Select the corresponding check box of the Wizard, and Delphi will add the proper entries in the type library and in the source code it generates.

The Type-Library Editor

The type-library editor is the tool you can use to define a type library in Delphi. Figure 20.3 shows its window after I've added some elements to it. The type-library editor allows you to add methods and properties to the OLE Automation server object we've just created. Once this is done, it can generate both the type library (TLB) file and the corresponding Object Pascal source code.

FIGURE 20.3:

The type-library editor, showing the details of an interface

Version: 1.0

Parent Interface: IDispatch

Help

Help String: Dispatch interface for FirstServer Object

Help Context:

Help String Context:

To build a first example, we can add to the server a property and a method. In the editor, we actually add these two elements to the interface, which should be called `IFirstServer`. Select it, and then click the Method button of the toolbar. (The names of these buttons can be displayed by using the shortcut menu of the toolbar.) Now you have to give it a name, such as `ChangeColor`. You can type the name either in the Tree View control on the left side of the window or in the Name edit box on the right side. Delphi automatically defines the new method as a function in the Invoke Kind box and (as you'll see on the Parameters page) assigns it an `HRESULT` return value and no parameters. This corresponds to the Pascal definition:

```
procedure ChangeColor; safecall;
```

There are two reasons for this difference in the type of method. The first is that in the IDL language used by COM, all methods are indicated as functions (following the C language style); the second is that Delphi handles the `HRESULT` error codes automatically in every method that uses the `safecall` calling convention.

NOTE The methods contained in OLE Automation interfaces in Delphi generally use the `safecall` calling convention. This wraps a **`try`**/**`except`** block around each method and provides a default return value indicating error or success.

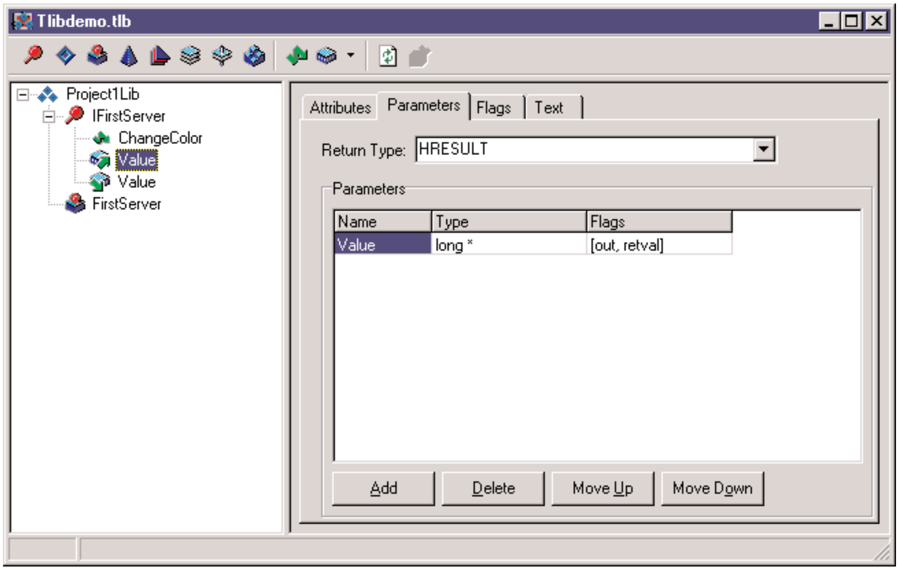
Now we can add a property to the interface by clicking the Property button of the type-library editor's toolbar. Again, we can type a name for it, such as `Value`, and select a data type in the Type combo box. Besides selecting one of the many types already listed, you can also enter other types directly, particularly interfaces of other objects. Keep in mind, however, that OLE Automation supports only a subset of Delphi types. In this example, we can select the `long` type, which corresponds to Delphi's `Integer` type.

If you look again in the Parameters page for this example (see Figure 20.4), you can see that both the `Set` and `Get` (actually called `Put` and `Get` in the COM jargon) methods have the `HRESULT` return value. You can also see that while the `Put` method uses the property's data type as its parameter (as with Delphi properties), the `Get` method uses a pointer to the type as its `out` parameter. This definition corresponds to the following elements of the Pascal interface:

```
function Get_Value: Integer; safecall;
procedure Set_Value(Value: Integer); safecall;
property Value: Integer read Get_Value write Set_Value;
```

FIGURE 20.4:

The Parameters page of the type-library editor



Return Type: HRESULT

Name	Type	Flags
Value	long *	[out, retval]

Clicking the Refresh button on the type-library editor toolbar generates the Pascal version of the interface. We'll examine it shortly, but first I want you to focus on the Text page of the editor, which includes the definition we've just created, written in the IDL language:

```
interface IFirstServer: IDispatch
{
  [id(0x00000001)]
  HRESULT _stdcall ChangeColor( void );
  [propget, id(0x00000002)]
  HRESULT _stdcall Value([out, retval] long * Value );
  [propput, id(0x00000002)]
  HRESULT _stdcall Value([in] long Value );
};
```

Fortunately, Delphi's type-library editor saves you from writing similar code by hand, and the Delphi environment options (in the Type Library page) include a radio button to select Pascal or IDL in the text displayed by the type-library editor.

The Code of the Server

Now we can close the type-library editor and save the changes. This operation adds three items to the project: the type library file, a corresponding Pascal definition, and the declaration of the server object. The type library is connected to the project using a resource-inclusion statement, added to the source code of the project file:

```
{$R *.TLB}
```

You can always reopen the type-library editor by using the View ➢ Type Library command or by selecting the proper TLB file in the normal File Open dialog box of Delphi.

As mentioned earlier, the type library is also converted into an interface definition and added to a new Pascal unit. This unit is quite long, so I've listed in the book only its key elements. The most important part is the new interface declaration:

```
type
  IFirstServer = interface(IDispatch)
    ['{89855B42-8EFE-11D0-98D0-444553540000}']
    procedure ChangeColor; safecall;
    function Get_Value: Integer; safecall;
    procedure Set_Value(Value: Integer); safecall;
    property Value: Integer read Get_Value write Set_Value;
  end;
```

Then comes the `dispinterface`, which associates a number with each element of the `IFirstServer` interface:

```
type
  IFirstServerDisp = dispinterface
    ['{89855B42-8EFE-11D0-98D0-444553540000}']
    procedure ChangeColor; dispid 1;
    property Value: Integer dispid 2;
  end;
```

The last portion of the file includes the so-called CoClass (also shown in the type-library editor), a class used to create an object on the server (and for this reason used on the client side of the application, not on the server side):

```
type
  CoFirstServer = class
    class function Create: IFirstServer;
    class function CreateRemote(const MachineName: string): IFirstServer;
  end;
```

All the declarations of this file (I've skipped some others) can be considered an internal, hidden implementation support. You don't need to understand them fully in order to write most OLE Automation applications.

Finally, Delphi generates a file with the declaration of the actual object. This unit is added to the application and is the one we'll work on to finish the program. This unit declares the class of the server object, which must implement the interface we've just defined:

```
type
  TFirstServer = class(TAutoObject, IFirstServer)
  protected
    function Get_Value: Integer; safecall;
    procedure ChangeColor; safecall;
    procedure Set_Value(Value: Integer); safecall;
  end;
```

Delphi already provides us with the skeleton code of the methods, so you only need to fill the lines in between. This is the final code of the server object methods of the TLibDemo example from the companion CD:

```
function TFirstServer.Get_Value: Integer;
begin
  Result := ServerForm.Value;
end;

procedure TFirstServer.ChangeColor;
begin
  ServerForm.ChangeColor;
end;

procedure TFirstServer.Set_Value(Value: Integer);
begin
  ServerForm.Value := Value;
end;
```

In this case, the three methods refer to a property and two methods I've added to the form. In general, you should not add code related to the user interface inside the class of the server object. It is better to refer to a user interface element, such as a form class, and let it perform the actions.

I've added a property to the form because I want to change the `Value` property and have a side effect (displaying the value in an edit box). The server object, in this example, exposes some properties and methods of the application. Here is the part of the declaration of the `TServerForm` class I've edited manually:

```
type
  TServerForm = class(TForm)
    ...
  private
    CurrentValue: Integer;
  protected
    procedure SetValue (NewValue: Integer);
  public
    property Value: Integer read CurrentValue write SetValue;
    procedure ChangeColor;
  end;
```

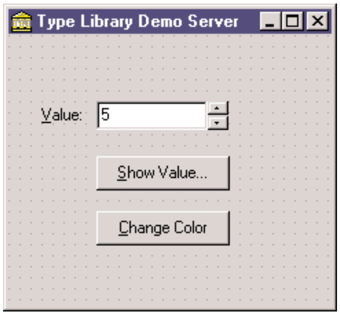
The implementation of these methods is quite straightforward, and you can easily guess what their code looks like. What's important is the `SetValue` method, which might produce a side effect:

```
procedure TServerForm.SetValue (NewValue: Integer);
begin
  if NewValue <> CurrentValue then
  begin
    CurrentValue := NewValue;
    UpDown1.Position := CurrentValue;
  end;
end;
```

The form of this example has an edit box with an associated UpDown component as well as a couple of buttons to show the current value and change the color. You can see this form at design time in Figure 20.5.

FIGURE 20.5:

The form of the TLibDemo example at design time



Registering the Automation Server

The unit containing the server object has one more statement, added by Delphi to the `initialization` section:

```
initialization
  TAutoObjectFactory.Create(ComServer, TFirstServer, Class_FirstServer,
    ciMultiInstance);
end.
```

NOTE In this case, I've selected multiple instancing. For the various instancing styles possible in COM, see the sidebar "COM Instancing and Threading Models" in Chapter 19, "COM Programming."

This is not very different from the creation of class factories we saw in the examples of the last chapter. Combined with the call to the `Initialize` method of the `Application` object, which Delphi adds by default to the project source code of any program, the `initialization` code above makes the registration of this server straightforward.

You can add the server information to the Windows Registry by running this application on the target machine (the computer where you want to install the OLE Automation server), passing to it the `/regserver` parameter on the command line. You can do this by selecting Start ➢ Run, by using the Explorer or File Manager, or by running the program within

Delphi after you've entered a command-line parameter (using the Run ➢ Parameters command). Another command-line parameter, `/unregserver`, is used to remove this server from the Registry.

Writing a Client for Our Server

Now that we have built a server, we can prepare a client program to test it. This client can connect to the server either by using variants or by using the new type library. This second approach can be implemented manually or by using the techniques introduced in Delphi 5 for wrapping components around Automation servers. We'll actually try out all of these approaches.

Create a new application—I've called it TLibCli—and then open the type library file of the server, after (optionally) copying it to the project's directory. Save the type library file, using Delphi's File ➢ Save menu command, and a new version of the interface declarations will be generated for you. Of course, in this case you could have grabbed the Pascal declarations from the server source code, but I'm trying to follow a more general approach, which also applies when you haven't written the server yet. In fact, you can usually extract the type library directly from the executable file of the server or from a DLL shipped with the program.

WARNING Do not add the type library to the client application, though, because we are writing the OLE Automation controller, not a server. The Delphi project of a controller should not include the type library of the server it connects to.

You can refer to the Pascal file generated by the type-library editor in the code of the main form:

```
uses
  TlibdemoLib_TLB;
```

I've already mentioned that one of the elements of this unit generated by the type library is the *creation* class, or CoClass, a special class with two class functions you can use to create a server object locally or remotely (using DCOM). I've already shown you the interface of this class, but here is the implementation:

```
class function CoFirstServer.Create: IFirstServer;
begin
  Result := CreateComObject(Class_FirstServer) as IFirstServer;
end;

class function CoFirstServer.CreateRemote(
  const MachineName: string): IFirstServer;
begin
  Result := CreateRemoteComObject(MachineName, Class_FirstServer)
    as IFirstServer;
end;
```

You can use the first of these two functions, `Create`, to create a server object (and possibly start the server application) on the same computer. You can use the second function, `CreateRemote`, to create the server on a different computer, as long as your version of the operating system supports DCOM.

The two functions are a shortcut of the `CreateComObject` call, which allows you to create an instance of a COM object if you know its GUID. As an alternative, you can also use the `CreateOleObject` function, which requires as a parameter the registered name of the server. There is another difference between these two creation functions: `CreateComObject` returns an object of the `IUnknown` type, whereas `CreateOleObject` returns an object of the `IDispatch` type.

In my example, I'm going to use the `CoFirstServer.Create` shorthand. When you create the server object, you get as return value an `IFirstServer` interface. You can use it directly or store it in a variant variable. Here is an example of the first approach:

```
var
  MyServer: Variant;
begin
  MyServer := CoFirstServer.Create;
  MyServer.ChangeColor;
```

This code, based on variants, is not very different from that of the first controller we built in this chapter (the one that used Microsoft Word). Here is the alternative code, which has exactly the same effect:

```
var
  IMyServer: IFirstServer;
begin
  IMyServer := CoFirstServer.Create;
  IMyServer.ChangeColor;
```

Interfaces, Variants, and Dispatch Interfaces: Testing the Speed Difference

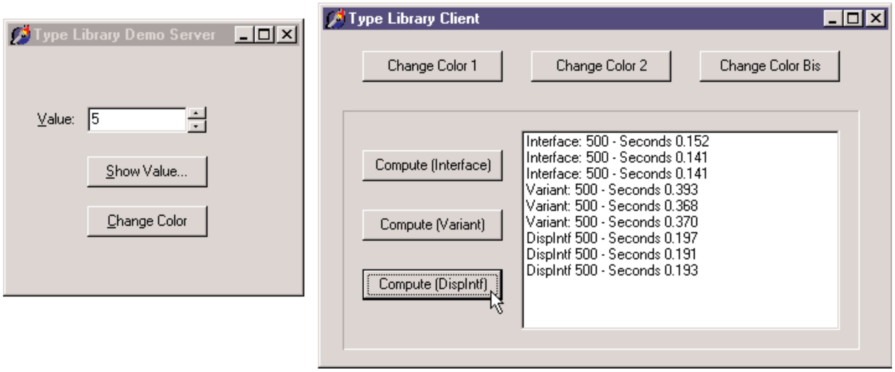
As I mentioned in the section introducing type libraries, one of the differences between these approaches is speed. It is actually quite complex to assess the exact performance of each technique because there are many factors involved. I've added a simple test to the TLibCli example on the companion CD, just to give you an idea. Here is the code of the test, a loop that accesses the `Value` of the server. The total value is displayed only to fool the optimizer, which might otherwise remove some of the code. The real output of the program relates to the timing, which is determined by calling the `GetTickCount` API function before and after executing the loop. (Two alternatives are to use Delphi's own time functions, which are slightly less precise, or to use the very precise timing functions of the multimedia support unit, MMSystem.) Here is the code of one of the methods; they are quite similar:

```
procedure TClientForm.BtnIntfClick(Sender: TObject);
var
  I, K: Integer;
  Ticks: Cardinal;
begin
  Screen.Cursor := crHourglass;
  try
    Ticks := GetTickCount;
    K := 0;
    for I := 1 to 100 do
      K := K + IMyServer.Value;
    Ticks := GetTickCount - Ticks;
    ListResult.items.Add (Format (
      'Interface: %d - Seconds %.3f', [K, Ticks / 1000]));
  finally
    Screen.Cursor := crDefault;
  end;
end;
```

With this program, you can compare the output obtained by calling this method based on an interface, the corresponding version based on a variant, and even a third version based on a dispatch interface. An example of the output (which is added to a list box so you can do several tests and compare the results) is shown in Figure 20.6. Obviously, the timing depends on the speed of your computer, and you can also alter the results by increasing or decreasing the maximum value of the loop counter.

FIGURE 20.6:

The TLibCli OLE Automation controller can access the server in different ways, with different performance results. Notice the server window in the background.



Value: 5

```
Interface: 500 - Seconds 0.152
Interface: 500 - Seconds 0.141
Interface: 500 - Seconds 0.141
Variant: 500 - Seconds 0.393
Variant: 500 - Seconds 0.368
Variant: 500 - Seconds 0.370
DispIntf 500 - Seconds 0.197
DispIntf 500 - Seconds 0.191
DispIntf 500 - Seconds 0.193
```

We've already seen how you can use the interface and the variant. What about the dispatch interface? You can declare a variable of the dispatch interface type, in this case:

```
var
  DMyServer: IFirstServerDisp;
```

Then you can use it to call the methods as usual, after you've assigned an object to it by casting the object returned by the CoClass:

```
DMyServer := CoFirstServer.Create as IFirstServerDisp;
```

Looking at the timing and at the internal code of the example, there is apparently very little difference between the use of the interface and of the dispatch interface, because the two are actually connected. In other words, we can say that dispatch interfaces are a technique in between variants and interfaces, but they deliver almost all of the speed of interfaces.

The Scope of Automation Objects

Another important element to keep in mind is the *scope* of the automation objects. Variants and interface objects use reference-counting techniques, so if a variable that is related to an interface object is declared locally in a method, at the end of the method the object will be destroyed and the server may terminate (if all the objects created by the server have been destroyed). For example, writing a method with this code produces very little effect:

```
procedure TClientForm.ChangeColor;
var
  IMyServer: IFirstServer;
begin
  IMyServer := CoFirstServer.Create;
  IMyServer.ChangeColor;
end;
```

Unless the server is already active, a copy of the program is created, and the color is changed, but then the server is immediately closed as the interface-typed object goes out of scope. The alternative approach I've used in the TLibCli example is to declare the object as a field of the form and create the COM objects at start-up, as in this procedure:

```
procedure TClientForm.FormCreate(Sender: TObject);
begin
  IMyServer := CoFirstServer.Create;
end;
```

With this code, as the client program starts, the server program is immediately activated. At the program termination, the form field is destroyed and the server closes. A further alternative is to declare the object in the form, but then create it only when it is used, as in these two code fragments:

```
// MyServerBis: Variant;
if varType (MyServerBis) = varEmpty then
  MyServerBis := CoFirstServer.Create;
MyServerBis.ChangeColor;

// IMyServerBis: IFirstServer;
if not Assigned (IMyServerBis) then
  IMyServerBis := CoFirstServer.Create;
IMyServerBis.ChangeColor;
```

NOTE A variant is initialized to the `varEmpty` type when it is created. If you instead assign the value null to the variant, its type becomes `varNull`. Both `varEmpty` and `varNull` represent variants with no value assigned, but they behave differently in expression evaluation. The `varNull` value always propagates through an expression (making it a null expression), while the `varEmpty` value quietly disappears.

The Server in a Component

When creating a client program for our server or any other Automation server, we can use a better approach, namely, wrapping a Delphi component around the COM server. Actually, if you look at the final portion of the `TlibdemoLib_TLB` file, you can find the following declaration:

```
// OLE Server Proxy class declaration
TFirstServer = class(TOleServer)
private
  FIntf: IFirstServer;
  FProps: TFirstServerProperties;
  function GetServerProperties: TFirstServerProperties;
  function GetDefaultInterface: IFirstServer;
protected
  procedure InitServerData; override;
  function Get_Value: Integer;
  procedure Set_Value(Value: Integer);
public
  constructor Create(AOwner: TComponent); override;
  destructor  Destroy; override;
  procedure Connect; override;
  procedure ConnectTo(svrIntf: IFirstServer);
  procedure Disconnect; override;
  procedure ChangeColor;
  property  DefaultInterface: IFirstServer read GetDefaultInterface;
  property Value: Integer read Get_Value write Set_Value;
published
  property Server: TFirstServerProperties read GetServerProperties;
end;
```

This is a new component, derived from `TOleServer`, that the system registers in the `Register` procedure, which is part of the unit. If you add this unit to a package, the new server component will become available on the Delphi Component Palette. You can also import the type library of the new server (with the Project ➢ Import Type Library menu command), add the server to the list (by clicking the Add button and selecting the server's executable file), and install it in a new or existing package. The component will be placed in the Servers page of the Palette. The Import Type Library dialog box indicating these operations is visible in Figure 20.7.

FIGURE 20.7: The Import Type Library dialog box can be used to import an Automation server object as a new Delphi component.

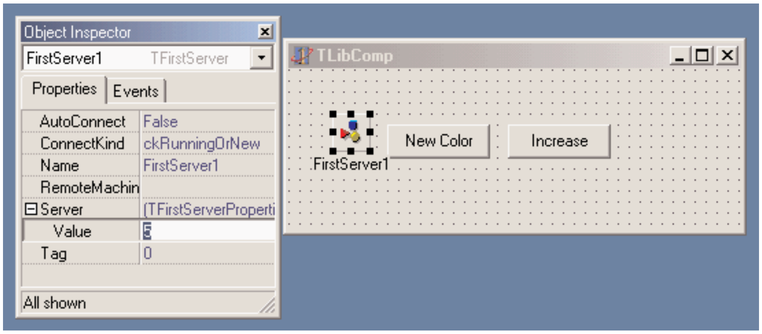
☑ Generate Component Wrapper

I've created a new package, PackAuto, available in the directory of the TlibDemo project. In this package, I've added the directive `LIVE_SERVER_AT_DESIGN_TIME` in the Directories/Conditionals page of the Project Options dialog box of the package. This enables an extra feature that you don't get by default: at design time, the server component will have an extra property that lists as subitems all the properties of the Automation server. You can see an example in Figure 20.8, taken from the TLibComp example at design time.

WARNING The `LIVE_SERVER_AT_DESIGN_TIME` directive should be used with care with the most complex Automation servers (including programs such as Word, Excel, PowerPoint, and Visio). In fact, this setting requires the application to be in a particular mode before you can use some properties of their automation interfaces. For example, you'll get exceptions if you touch the Word server before a document has been opened in Word. That's why this feature is not active by default in Delphi—it's problematic at design time for many servers.

FIGURE 20.8:

A server component, with the live properties at design time



Object Inspector

FirstServer1 TFirstServer

Properties | Events

Property	Value
AutoConnect	False
ConnectKind	ckRunningOrNew
Name	FirstServer1
RemoteMachin	
⊟Server	(TFirstServerProperti
Value	5
Tag	0

All shown

As you can see in the Object Inspector, the component has few properties. AutoConnection indicates when to start up the server component at design time and as soon as the client program starts. As an alternative, the Automation server is started the first time one of its methods is called. Another property, ConnectKind, indicates how to establish the connection with the server. It can always start a new instance (ckNewInstance), use the running instance (ckRunningInstance, which causes an access violation if the server is not already running), or select the current instance or start a new one if none is available (ckRunningOrNew). Finally, you can ask for a remote server with ckRemote and directly attach a server in the code after a manual connection with ckAttachToInterface.

OLE Data Types

OLE and COM do not support all of the data types available in Delphi. This is particularly important for OLE Automation, because the client and the server are often executed in different address spaces, and the system must move the data from one side to the other. Also keep in mind that OLE interfaces should be accessible by programs written in any language.

COM data types include basic data types such as Integer, SmallInt, Byte, Single, Double, WideString, Variant, and WordBool (but not Boolean). Table 20.1 presents the mapping of some basic data types, available in the type-library editor, to the corresponding Delphi types.

TABLE 20.1: OLE and Delphi Data Types

OLE Type	Delphi Type
BSTR	WideString
byte	ShortInt
CURRENCY	Currency
DATE	TDateTime
DECIMAL	TDecimal

Continued on next page

TABLE 20.1 continued: OLE and Delphi Data Types

OLE Type	Delphi Type
double	Double
float	Single
GUID	GUID
int	SYSINT
long	Integer
LPSTR	PChar
LPWSTR	PWideChar
short	SmallInt
unsigned char	Byte
unsigned int	SYSUINT
unsigned long	UINT
unsigned short	Word
VARIANT	OleVariant

Notice that SYSINT is currently defined as an Integer, so don't worry about the apparently strange type definition. Besides the basic data types, you can also use OLE types for complex elements such as fonts, string lists, and bitmaps, using the IFontDisp, IStrings, and IPictureDisp interfaces. The following sections describe the details of a server that provides a list of strings and a font to a client.

Exposing Strings Lists and Fonts

The ListServ example is a practical demonstration of how you can expose two complex types, such as a list of strings and a font, from an OLE Automation server written in Delphi. I've chosen these two specific types simply because they are both supported by Delphi.

The IFontDisp interface is actually provided by Windows and is available in the ActiveX unit. The AxCtrls Delphi unit extends this support by providing conversion methods like GetOleFont and SetOleFont. The IStrings interface is provided by Delphi in the StdVCL unit, and the AxCtrls unit provides conversion functions for this type (along with a third type I'm not going to use, TPicture).

WARNING To run this and similar applications, the StdVCL library must be installed and registered on the client computer. On your computer, it is registered during Delphi's installation.

The server we are building has a plain form containing a list-box component. It includes an Automation object built around the following interface:

```
type
  IListServer = interface (IDispatch)
    ['{323C4A84-E400-11D1-B9F1-004845400FAA}']
    function Get_Items: IStrings; safecall;
    procedure Set_Items(const Value: IStrings); safecall;
    function Get_Font: IFontDisp; safecall;
    procedure Set_Font(const Value: IFontDisp); safecall;
    property Items: IStrings read Get_Items write Set_Items;
    property Font: IFontDisp read Get_Font write Set_Font;
  end;
```

The server object has the same four methods listed in its interface as well as some private data storing the status, the initialization function, and the destructor:

```
type
  TListServer = class (TAutoObject, IListServer)
  private
    fItems: TStrings;
    fFont: TFont;
  protected
    function Get_Font: IFontDisp; safecall;
    function Get_Items: IStrings; safecall;
    procedure Set_Font(const Value: IFontDisp); safecall;
    procedure Set_Items(const Value: IStrings); safecall;
  public
    destructor Destroy; override;
    procedure Initialize; override;
  end;
```

The code of the methods is limited to few statements. The pseudoconstructor creates the internal objects, and the destructor destroys them. Here is the first of the two:

```
procedure TListServer.Initialize;
begin
  inherited Initialize;
  fItems := TStringList.Create;
  fFont := TFont.Create;
end;
```

The `Set` and `Get` methods copy information from the OLE interfaces to the local data and then from this to the form and vice versa. The two methods of the strings, for example, do this by calling the `GetOleStrings` and `SetOleStrings` Delphi functions.

After we've compiled and registered the server, we can turn our attention to the client application. This embeds the Pascal translation of the type library of the server, as in the previous example, and then implements an object that uses the interface. Instead of creating the server when the object starts, the client program creates it when it is required. I've described this technique earlier, but the problem is that because there are several buttons a user can click, and we don't want to impose an order, every event should have a handler like this:

```
if not Assigned (ListServ) then
  ListServ := CoListServer.Create;
```

This kind of code duplication is quite dangerous, so I've decided to use an alternative approach. I've defined a property corresponding to the interface of the server and defined a read method for it. The property is mapped to some internal data I've defined with a different name to avoid the error of using it directly. Here are the definitions added to the form class:

```
private
  fInternalListServ: IListServer;
  function GetListSrv: IListServer;
public
  property ListSrv: IListServer read GetListSrv;
```

The implementation of the `Get` method can check whether the object already exists. This code is going to be repeated often, but that should not slow down the application noticeably:

```
function TListCliForm.GetListSrv: IListServer;
begin
  // eventually create the server
  if not Assigned (fInternalListServ) then
    fInternalListServ := CoListServer.Create;
  Result := fInternalListServ;
end;
```

You can see an example of the client application running (along with the server) in Figure 20.9.

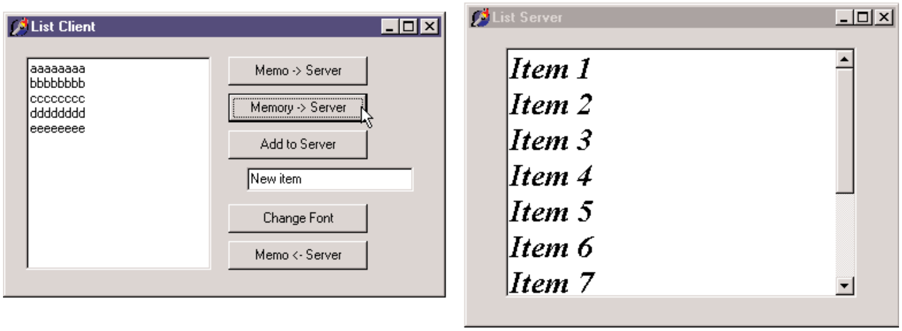


FIGURE 20.9: The ListCli and ListServ applications share complex data, namely fonts and lists of strings.

This is an example of the selection of a font, which is then sent to the server:

```
procedure TListCliForm.btnFontClick(Sender: TObject);
var
  NewFont: IFontDisp;
```

```
begin
  // select a font and apply it
  if FontDialog1.Execute then
  begin
    GetOleFont (FontDialog1.Font, NewFont);
    ListSrv.Font := NewFont;
  end;
end;
```

There are also several methods related to the strings, which you can see by looking at the source code of the program.

Using Office Programs

So far, we've built both the client and the server side of the OLE Automation connection. If your aim is just to let two applications you've built cooperate, this is certainly a useful technique, although it is not the only one. We've seen some alternative data-sharing approaches in the last two chapters (using memory-mapped files and the `wm_CopyData` message). The real value of OLE Automation is that it is a standard, so you can use it to integrate your Delphi programs with other applications your users own. A typical example is the integration of a program with office applications, such as Microsoft Word and Microsoft Excel, or even with stand-alone applications, such as AutoCAD.

Integration with these applications provides a two-fold advantage:

- You can let your users work in an environment they know—for example, generating reports and memos from database data in a format they can easily manipulate.
- You can avoid implementing complex functionality from scratch, such as writing your own word-processing code inside a program. Instead of just reusing components, you can reuse complex applications.

There are also some drawbacks with this approach, which are certainly worth mentioning:

- The user must own the application you plan to integrate with, and they may also need a recent version of it to support all the features you are using in your program.
- You have to learn a new programming language and programming structure, often with limited documentation at hand. It is true, of course, that you are still using Pascal, but the code you write depends on the OLE data types, the types introduced by the server, and in particular, a collection of interrelated classes that are often difficult to understand.
- You might end up with a program that works only with a specific version of the server application, particularly if you try to optimize the calls by using interfaces instead of variants. In particular, Microsoft does not attempt to maintain script compatibility between major releases of Word or other Office applications.

We've already seen a small source code excerpt from the WordTest example, but now I want to complete the coverage of this limited but interesting test program by providing a few extra features.

Sending Data to Microsoft Word

Delphi simplifies the use of Microsoft Office applications by preinstalling some ready-to-use components that wrap the Automation interface of these servers. These components, available in the Servers page of the Palette, have been installed using the same technique I demonstrated in the last section.

NOTE What I want to underline here is that the real plus of Delphi lies in this technique of creating components to wrap existing Automation servers, rather than in the availability of some predefined server components.

Technically, it is possible to use variants to interact with Automation servers, as we've seen in the section "Introducing Type Libraries." Using interfaces and the type libraries is certainly better, because the compiler helps you catch errors in the source code and produces faster code. Thanks to the new server component, this process is also quite straightforward.

I've written a program, called DBOffice, which uses predefined server components to send a table to Word and to Excel. In both cases, you can use the application object, the document/worksheet object, or a combination of the two. There are other specialized components, for tasks such as handling Excel charts, but this example will suffice to introduce use of the built-in Office components.

NOTE The DBOffice program was tested with Office 97. I'm currently using StarOffice more often than the Microsoft suite, so I never feel compelled to give Microsoft more money by upgrading to their newer offerings.

In case of Microsoft Word, I use only a document object with default settings. The code used to send the table to Word starts by adding some text to a document:

```
procedure TFormOff.BtnWordClick(Sender: TObject);
begin
  WordDocument1.Activate;
  // insert title
  WordDocument1.Range.Text := 'American Capitals from ' + Table1.TableName;
  WordDocument1.Range.Font.Size := 14;
```

This code follows the typical `while` loop, which scans the database table and has the following code inside:

```
while not Table1.EOF do
begin
  // send the two fields
```

```
    WordDocument1.Range.InsertParagraphAfter;
    WordDocument1.Paragraphs.Last.Range.Text :=
      Table1.FieldByName ('Name').AsString + #9 +
      Table1.FieldByName ('Capital').AsString;
    Table1.Next;
  end;
```

The final part of the code gets a little more complex. It works on a selection and on a row of the table, respectively stored in two variables of the `Range` and `Row` types defined by Word and available in the Word97 unit (the program will have to be updated if you choose the Office 2000 version of the server component while installing Delphi).

```
procedure TFormOff.BtnWordClick(Sender: TObject);
var
  RangeW: Word97.Range;
  v1: Variant;
  ov1: OleVariant;
  Row1: Word97.Row;
begin
  // code above...
  RangeW := WordDocument1.Content;
  v1 := RangeW;
  v1.ConvertToTable (#9, 19, 2);
  Row1 := WordDocument1.Tables.Item(1).Rows.Get_First;
  Row1.Range.Bold := 1;
  Row1.Range.Font.Size := 30;
  Row1.Range.InsertParagraphAfter;
  ov1 := ' ';
  Row1.ConvertToText (ov1);
end;
```

As you can see in the last statement above, in order to pass a parameter, you must first save it in an `OleVariant` variable, because many parameters are passed by reference, so you cannot pass a constant value. This implies that if there are many parameters, you must still define some, even if you are fine with the default values. An often-useful alternative is to use a temporarily variant variable and apply the method to it, because variants don't require strict type-checking on the parameters. This technique is used in the code above to call the `ConvertToTable` method, which has more than 10 parameters.

Building an Excel Table

In the case of Excel, I've used a slightly different approach and worked with the application object. The code creates a new Excel spreadsheet, fills it with a database table, and formats the result. It uses an Excel internal object, Range, which is not to be confused with a similar type available in Word (the reason this type is prefixed with the name of the unit defining the Excel type library). Here is the complete code:

```
procedure TFormOff.BtnExcelClick(Sender: TObject);
var
  RangeE: Excel97.Range;
  I, Row: Integer;
  Bookmark: TBookmarkStr;
begin
  // create and show
  ExcelApplication1.Visible [0] := True;
  ExcelApplication1.Workbooks.Add (NULL, 0);
  // fill is the first row with field titles
  RangeE := ExcelApplication1.ActiveCell;
  for I := 0 to Table1.Fields.Count - 1 do
  begin
    RangeE.Value := Table1.Fields [I].DisplayLabel;
    RangeE := RangeE.Next;
  end;
  // add field data in following rows
  Table1.DisableControls;
  try
    Bookmark := Table1.Bookmark;
    try
      Table1.First;
      Row := 2;
      while not Table1.EOF do
      begin
        RangeE := ExcelApplication1.Range ['A' + IntToStr (Row),
          'A' + IntToStr (Row)];
        for I := 0 to Table1.Fields.Count - 1 do
        begin
          RangeE.Value := Table1.Fields [I].AsString;
          RangeE := RangeE.Next;
        end;
        Table1.Next;
        Inc (Row);
      end;
    finally
      Table1.Bookmark := Bookmark;
    end;
  finally
    Table1.EnableControls;
  end;
  // format the section
  RangeE := ExcelApplication1.Range ['A1', 'E' + IntToStr (Row - 1)];
  RangeE.AutoFormat (3, NULL, NULL, NULL, NULL, NULL, NULL);
end;
```

You can see the effect of this code in Figure 20.10. Notice that in the code I don't handle any events of the Office applications, but many are available. Handling these events was quite complex in the past, but they now become as simple to handle as events of native Delphi components. The presence of these events is a reason to have specific objects for documents and other specific elements: you might want to know when the user closes a document, and that therefore this is an event of the document object, not of the application object.

The Excel spreadsheet \generated by the DBOffice application

NOTE When using the Office server components, one of the key problems is the lack of adequate documentation. Although Microsoft distributes some of it with the high-end version of the Office suite, this is certainly not Delphi friendly. A totally alternative approach to solve the problem is to use OfficePartner, a set of components from TurboPower Software (**`www.turbopower.com`**). These components map the Office servers, like those available in Delphi, but they also provide extensive property editors that allow you to work visually with the internal structure of these servers. With these property editors, you can create documents, paragraphs, tables, and all the other internal objects even at design time! From my experience, this can really save a lot of time.

Using Compound Documents

Compound documents, or active documents, are Microsoft's names for the technology that allows in-place editing of a document within another one (for example, a picture in a Word document). This is the technology that originated the term OLE, but although it is still in use, its role is definitely more limited than Microsoft envisioned when it was introduced in the early 1990s. Compound documents actually have two different capabilities, o*bject linking* and *embedding* (hence the term OLE):

- Embedding an object in a compound document corresponds to a smart version of the copy and paste operations you make with the Clipboard. The key difference is that when you copy an OLE object from a server application and paste it into a container application, you copy both the data and some information about the server (its GUID). This allows you to activate the server application from within the container to edit the data.
- Linking an object to a compound document instead copies only a reference to the data and the information about the server. You generally activate object linking by using the Clipboard and making a Paste Link operation. When editing the data in the container application, you'll actually modify the original data, which is stored in a separate file.

Because the server program refers to an entire file (only part of which might be linked in the client document), the server will be activated in a stand-alone window, and it will act upon the entire original file, not just the data you've copied. When you have an embedded object, instead, the container might support visual (or *in-place*) editing, which means that you can modify the object in context, inside the container's main window. The server and container application windows, their menus, and their toolbars are merged automatically, allowing the user to work within a single window on several different object types—and therefore with several different OLE servers—without leaving the window of the container application.

Another key difference between embedding and linking is that the data of an embedded object is stored and managed by the container application. The container saves the embedded object in its own files. By contrast, a linked object physically resides in a separate file, which is handled by the server exclusively, even if the link refers only to a small portion of the file.

In both cases, the container application doesn't have to know how to handle the object and its data—not even how to display it—without the help of the server. Accordingly, the server application has a lot of work to do, even when you are not editing the data. Container applications often make a copy of the image of an OLE object and use the bitmap to represent the data, which speeds up some operations with the object itself. The drawback of this approach is that many commercial OLE applications end up with bloated files (because two copies of the same data are saved). If you consider this problem along with the relative slowness of OLE and the amount of work necessary to develop OLE servers, you can understand why the use of this powerful approach is still somewhat limited, compared with what Microsoft envisioned a few years ago.

Compound document containers can support OLE in varying degrees. You can place an object in a container by inserting a new object, by pasting or *paste-linking* one from the Clipboard, by dragging one from another application, and so on.

Once the object is placed inside the container, you can then perform operations on it, using the server's available *verbs*, or actions. Usually the *edit verb* is the default action—the action performed when you double-click on the object. For other objects, such as video or sound clips, *play* is defined as the default action. You can typically see the list of actions supported by the current contained object by right-clicking it. The same information is available in many programs via the Edit ➢ Object menu item, which has a submenu that lists the available verbs for the current object.

NOTE Delphi provides no *visual* support for building compound document servers. You can always write a server implementing the proper interfaces. Compound document container support, instead, is easily available through the OleContainer component.

The OLE Container Component

To create an OLE container application in Delphi, place an OleContainer component in a form. Then select the component and right-click to activate its shortcut menu, which will have an Insert Object command. When you select this command, Delphi displays the standard OLE Insert Object dialog box. This dialog box allows you to choose from one of the server applications registered on the computer.

Once the OLE object is inserted in the container, the shortcut menu of the control container component will have several more custom menu items. The new menu items include commands to change the properties of the OLE object, insert another one, copy the existing object, or remove it. The list also includes the verbs, or actions, of the object (such as Edit, Open, or Play). Once you have inserted an OLE object in the container, the corresponding server will launch to let you edit the new object. As soon as you close the server application, Delphi updates the object in the container and displays it at design time in the form of the Delphi application you are developing.

If you look at the textual description of a form containing a component with an object inside, you'll notice a `Data` property, which contains the actual data of the OLE object. Although the client program stores the data of the object, it doesn't know how to handle and show that without the help of the proper server (which must be available on the computer where you run the program). This means that the OLE object is *embedded*.

To fully support compound documents, a program should provide a menu and a toolbar or panel. These extra components are important because in-place editing implies a merging of the user interface of the client and that of the server program. When the OLE object is activated in place, some of the pull-down menus of the server application's menu bar are added to the menu bar of the container application.

OLE menu merging is handled almost automatically by Delphi. You only need to set the proper indexes for the menu items of the container, using the GroupIndex property. Any menu item with an odd index number is replaced by the corresponding element of the active OLE object. More specifically, the File (0) and Window (4) pull-down menus belong to the container application. The Edit (1), View (3), and Help (5) pull-down menus (or the groups of pull-down menus with those indexes) are taken by the OLE server. A sixth group, named Object and indicated with the index 2, can be used by the container to display another pull-down menu between the Edit and View groups, even when the OLE object is active. The OleCont demo program I've written to demonstrate these features allows a user to create a new object by calling the InsertObjectDialog method of the TOleContainer class.

The InsertObjectDialog method shows a system dialog box, but it doesn't automatically activate the OLE object:

```
procedure TForm1.New1Click(Sender: TObject);
begin
  if OleContainer1.InsertObjectDialog then
    OleContainer1.DoVerb (OleContainer1.PrimaryVerb);
end;
```

Once a new object has been created, you can execute its primary verb using the DoVerb method. The program also displays a small toolbar with some bitmap buttons. I placed some TWinControl components in the form to let the user select them and thus disable the OleContainer. To keep this toolbar/panel visible while in-place editing is occurring, you should set its Locked property to True. This forces the panel to remain present in the application and not be replaced by a toolbar of the server.

To show what happens when you don't use this approach, I've added to the program a second panel, with some more buttons. Because I haven't set its Locked property, this new toolbar will be replaced with that of the active OLE server. When in-place editing launches a server application that displays a toolbar, that server's toolbar replaces the container's toolbar, as you can see in the lower part of Figure 20.11.

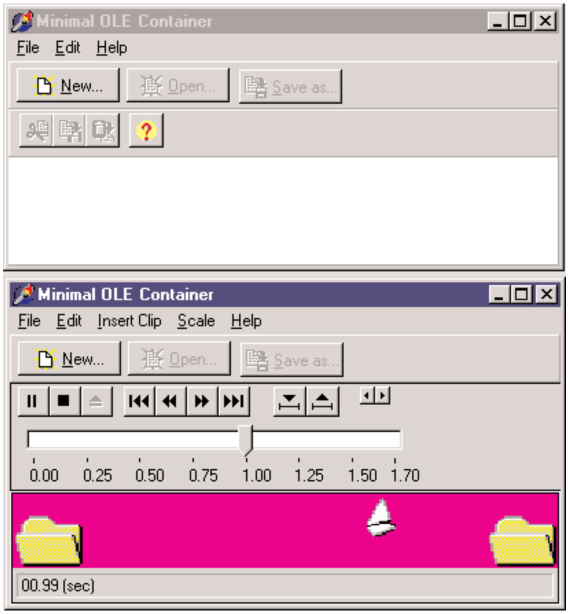
TIP

To make all the automatic resizing operations work smoothly, you should place the OLE container component in a panel component and align both of them to the client area of the form.

Another way to create an OLE object is to use the PasteSpecialDialog method, called in the PasteSpecial1Click event handler of the example. Another standard OLE dialog box, wrapped in a Delphi function, is the one showing the properties of the object, which is activated with the Object Properties item in the Edit pull-down menu by calling the ObjectPropertiesDialog method of the OleContainer component.

FIGURE 20.11:

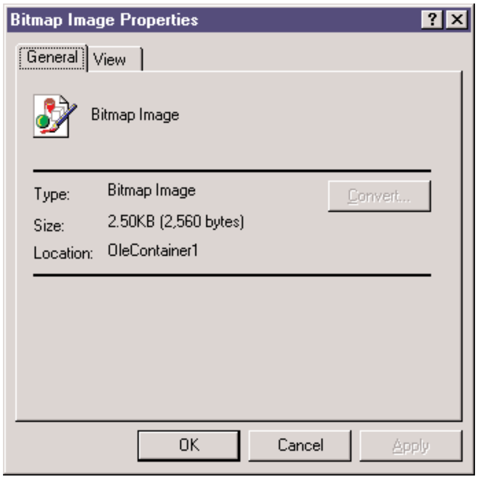
The second toolbar of the OleCont example (top) is replaced by the toolbar of the server (bottom).



You can see an example of the resulting standard OLE dialog box in Figure 20.12. Obviously, this dialog box changes depending on the nature of the active OLE object in the container. The last feature of the OleCont program is support for files; this is actually one of the simplest additions we can make, because the OLE container component already provides file support.

FIGURE 20.12:

The standard OLE Object Properties dialog box, available in the OleCont example



Type: Bitmap Image

Size: 2.50KB (2,560 bytes)

Location: OleContainer1

Using the Internal Object

In the preceding program, the user determined the type of the internal object created by the program. In this case, there is little you can do to interact with the internal objects. Suppose, instead, that you want to embed a Word document in a Delphi application and then modify it by code. You can do this by using OLE Automation with the embedded object, as demonstrated by the WordCont example (the name stands for *Word container*).

WARNING Since the WordCont example includes an object of a specific type, a Microsoft Word document, it won't run if you don't have that server application installed. Having a different version of the server might also create problems if the Automation methods used by the client program are not available in that version of the server.

In the form of this example, I've added an OleContainer component, set its `AutoActivate` property to aaManual (so that the only possible interaction is with our code), and added a toolbar with a couple of buttons. The code for the two buttons is quite straightforward, once you know that the embedded object corresponds to a Word document:

```
procedure TForm1.Button1Click(Sender: TObject);
var
  Document: Variant;
begin
  // activates if not running
  if not (OleContainer1.State = osRunning) then
    OleContainer1.Run;
  // get the document
  Document := OleContainer1.OleObject;
  // first paragraph to bold
  Document.Paragraphs.Item(1).Range.Bold := 1;
end;

procedure TForm1.Button3Click(Sender: TObject);
var
  Document, Paragraph: Variant;
begin
  // activate if not running
  if not (OleContainer1.State = osRunning) then
    OleContainer1.Run;
  // get the document
  Document := OleContainer1.OleObject;
  // add paragraphs, getting the last one
  Document.Paragraphs.Add;
  Paragraph := Document.Paragraphs.Add;
  // add text to the paragraph, using random font size
```

```
    Paragraph.Range.Font.Size := 10 + Random (20);
    Paragraph.Range.Text := 'New text (' +
      IntToStr (Paragraph.Range.Font.Size) + ')'#13;
  end;
```

You can see the effect of this code in Figure 20.13. The code is not terribly powerful, but it does show how you can merge the usage of OLE Containers and OLE Automation techniques.

FIGURE 20.13:

The WordCont example shows how to use OLE Automation with an embedded object.

Introducing ActiveX Controls

Microsoft's Visual Basic was the first program development environment to introduce the idea of supplying software components to the mass market. Actually, the concept of reusable software components is older than Visual Basic—it's well rooted in the theories of object-oriented programming (OOP). But OOP languages never delivered the reusability they promised, probably more because of marketing and standardization problems than for any other reason. Although Visual Basic does not fully exploit OOP, it applies the component concept through its standard way of building and distributing new controls that developers can integrate into the environment.

The first technical standard promoted by Visual Basic was *VBX*, a 16-bit specification that was fully available in the 16-bit version of Delphi. In moving to the 32-bit platforms, Microsoft replaced the VBX standard with the more powerful and more open *ActiveX* controls.

NOTE ActiveX controls used to be called OLE controls (or OCX). The name change reflects a new marketing strategy from Microsoft rather than a technical innovation. Technically, ActiveX can be considered a minor extension to the OCX technology. Not surprisingly, then, ActiveX controls are usually saved in files with the `.ocx` extension.

From a general perspective, an ActiveX control is not very different from a Windows, Delphi, or Visual Basic control. A control in any of these languages is always a window, with its associated code defining its behavior. The key difference between various families of controls is in the *interface* of the control—the interaction between the control and the rest of the application. Typical Windows controls use a message-based interface; VBX controls use properties and events; OLE Automation objects use properties and methods; and ActiveX controls use properties, methods, and events. These three elements of properties, methods, and events are also found in Delphi's own components.

Using OLE jargon, an ActiveX control is a "compound document object which is implemented as an in-process server DLL and supports OLE Automation, visual editing, and inside-out activation." Perfectly clear, right? Let's see what this definition actually means. An ActiveX control uses the same approach as OLE server objects, which are the objects you can insert into an OLE Document, as we saw in the last chapter. The difference between a generic OLE server and an ActiveX control is that, whereas ActiveX controls can only be implemented in one way, OLE servers can be implemented in three different ways:

- As stand-alone applications (for example, Microsoft Excel)
- As out-of-process servers—that is, executables files that cannot be run by themselves and can only be invoked by a server (for example, Microsoft Graph and similar applications)
- As in-process servers, such as DLLs loaded into the same memory space as the program using them

ActiveX controls can only be implemented using the last technique, which is also the fastest: as in-process servers. Furthermore, ActiveX controls are OLE Automation servers. This means you can access properties of these objects and call their methods. You can see an ActiveX control in the application that is using it and interact with it directly in the container application window. This is the meaning of the term *visual editing*, or *in-place activation*. A single click activates the control rather than the double-click used by OLE Documents, and the control is active whenever it is visible (which is what the term *inside-out activation* means), without having to double-click it.

As I've mentioned before, an ActiveX control has properties, methods, and events. Properties can identify states, but they can also activate methods. (This is particularly true for ActiveX controls that are *updated* VBX controls, because in a VBX there *was* no other way to activate a method than by setting a property.) Properties can refer to aggregate values, arrays, subobjects, and so on. Properties can also be dynamic (or read-only, to use the Delphi term).

In an ActiveX control, properties are divided into different groups: stock properties that most controls need to implement; ambient properties that offer information about the container (similar to the `ParentColor` or `ParentFont` properties in Delphi); extended properties managed by the container, such as the position of the object; and custom properties, which can be anything.

Events and methods are, well, events and methods. *Events* relate to a mouse click, a key press, the activation of a component, and other specific user actions. *Methods* are functions and procedures related to the control. There is no major difference between the ActiveX and Delphi concepts of events and methods.

ActiveX Controls Versus Delphi Components

Before I show you how to use and write ActiveX controls in Delphi, let's go over some of the technical differences between the two kinds of controls. ActiveX controls are DLL-based. This means that when you use them, you need to distribute their code (the OCX file) along with the application using them. In Delphi, the code of the components can be statically linked to the executable file or dynamically linked to it using a run-time package, so you can always choose.

Having a separate file allows you to share code among different applications, as DLLs usually do. If two applications use the same control (or run-time package), you need only one copy of it on the hard disk and a single copy in memory. The drawback, however, is that if the two programs have to use two different versions (or builds) of the ActiveX control, some compatibility problems might arise. An advantage of having a self-contained executable file is that you will also have fewer installation problems.

Now, what is the drawback of using Delphi components? The real problem is not that there are fewer Delphi components than ActiveX controls, but that if you buy a Delphi component, you'll only be able to use it in Delphi and Borland C++Builder. If you buy an ActiveX control, on the other hand, you'll be able to use it in multiple development environments from multiple vendors. Even so, if you develop mainly in Delphi and find two similar components based on the two technologies, I suggest you buy the Delphi one—it will be more integrated with your environment, and therefore easier for you to use. Also, the native Delphi component will probably be better documented (from the Pascal perspective), and it will take advantage of Delphi and Object Pascal features not available in the general ActiveX interface, which is traditionally based on C and C++.

Using ActiveX Controls in Delphi

Delphi comes with some preinstalled ActiveX controls, and you can buy and install more third-party ActiveX controls easily. After this description of how ActiveX controls work in general, I'll demonstrate one in an example.

The Delphi installation process is very simple. Select Component ➢ Import ActiveX Control in the Delphi menu. This opens the Import ActiveX dialog box, where you can see the list of ActiveX control libraries registered in Windows. If you choose one, Delphi will read its type library, list its controls, and suggest a filename for its unit. If the information is correct, click the Create Unit button to view the Pascal source code file created by Delphi as a *wrapper* for the ActiveX control. Click the Install button to add this new unit to a Delphi package and to the Component Palette.

Using the WebBrowser Control

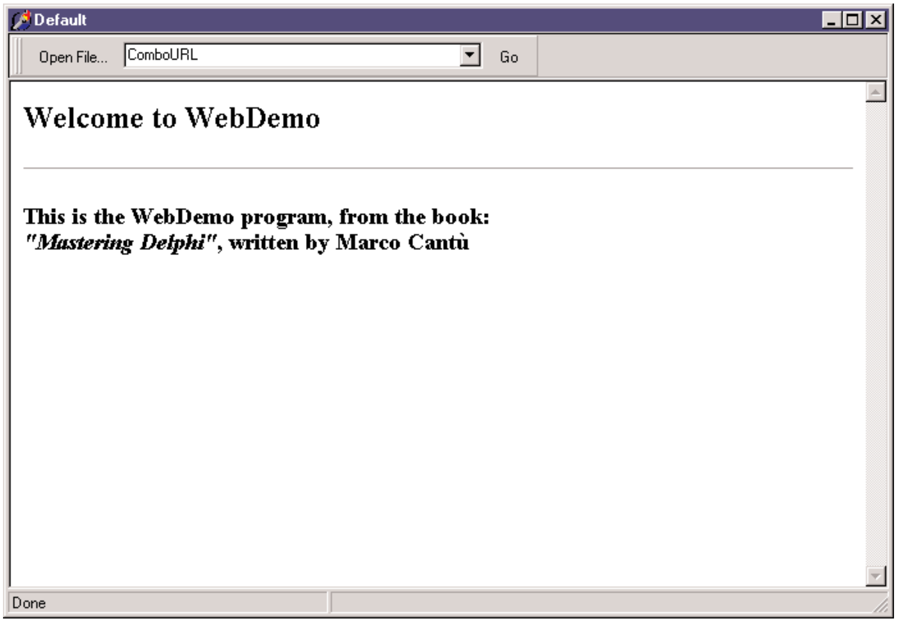
To build my example, I've used a preinstalled ActiveX control available in Delphi. Unlike the third-party controls, this is not available in the ActiveX page of the palette, but in the Internet page. The control, called WebBrowser, is a wrapper around Microsoft's Internet Explorer engine. The example is a very limited Web browser.

The WebBrows program on the CD-ROM has a `TWebBrowser` ActiveX control covering its client area and a control bar at the top and a status bar at the bottom. To move to a given Web page, a user can type in the combo box of the toolbar, select one of the visited URLs (saved in the combo box), or click on the Open File button to select a local file.

The actual implementation of the code used to select a Web or local HTML file is in the `GotoPage` method:

```
procedure TForm1.GotoPage(ReqUrl: string);
begin
  WebBrowser1.Navigate (ReqUrl, EmptyParam, EmptyParam, EmptyParam,
    EmptyParam);
end;
```

`EmptyParam` is a predefined OleVariant you can use whenever you want to pass a default value as a reference parameter. This is a handy shortcut you can use to avoid creating an empty OleVariant each time you need a similar parameter. This method is called for by a file, when the user clicks on the Enter key in the combo box, or by selecting the Go button, as you can see in the source code on the companion CD.



Welcome to WebDemo

This is the WebDemo program, from the book:
"Mastering Delphi", written by Marco Cantù

FIGURE 20.14: The WebDemo program at startup: it fully supports graphics and all other Web extensions, as it is based on the Internet Explorer engine.

The program also handles four events of the WebBrowser control. When the download operations start and end, the program updates the text of the status bar and also the drop-down list of the combo box:

```
procedure TForm1.WebBrowser1DownloadBegin(Sender: TObject);
begin
  StatusBar1.Panels[0].Text := 'Downloading ' +
    WebBrowser1.LocationURL + '...';
end;

procedure TForm1.WebBrowser1DownloadComplete(Sender: TObject);
var
  NewUrl: string;
begin
  StatusBar1.Panels[0].Text := 'Done';
  // add URL to combobox
  NewUrl := WebBrowser1.LocationURL;
  if (NewUrl <> '') and (ComboURL.Items.IndexOf (NewUrl) < 0) then
    ComboURL.Items.Add (NewUrl);
end;
```

Two other useful events are the `OnTitleChange`, used to update the caption with the title of the HTML document, and the `OnStatusTextChange` event, used to update the second part of the status bar. This code basically duplicates the information displayed in the first part of the status bar by the previous two event handlers.

Writing ActiveX Controls

Besides using existing ActiveX controls in Delphi, you can easily develop new ones. Although you can write the code of a new ActiveX control yourself, implementing all the required OLE interfaces (and there are many), it's much easier to use one of the techniques directly supported by Delphi:

- You can use the ActiveX Control Wizard to turn a VCL control into an ActiveX control. You start from an existing VCL component, which must be a `TWinControl` descendant, and Delphi wraps an ActiveX around it. During this step, Delphi adds a type library to the control. (Wrapping an ActiveX control around a Delphi component is exactly the opposite of what we did to use an ActiveX inside Delphi.)
- You can create an ActiveForm, place several controls inside it, and ship the entire form (without borders) as an ActiveX control. This second technique is the same one used by Visual Basic and is generally aimed at building Internet applications. However, it is also a very good alternative for the construction of an ActiveX control based on multiple Delphi controls or on Delphi components that do not descend from `TWinControl`.

An optional step you can take in both cases is to prepare a property page for the control, to use as a sort of property editor for setting the initial value of the properties of the control in any development environment—a kind of alternative to the Object Inspector in Delphi. Because most development environments allow only limited editing, it is more important to write a property page than it is to write a component or a property editor for a Delphi control.

Building an ActiveX Arrow

As an example of the development of an ActiveX control, I've decided to take the Arrow component we developed in Chapter 11, "Creating Components," and turn it into an ActiveX. We cannot use that component directly, because it was a graphical control, a subclass of `TGraphicControl`. However, turning a graphical control into a window-based control is usually a straightforward operation.

In this case, I've just changed the base class name to `TCustomControl` (and changed the name of the class of the control, as well, to avoid a name clash):

```
type
  TMdWArrow = class(TCustomControl)
  ...
```

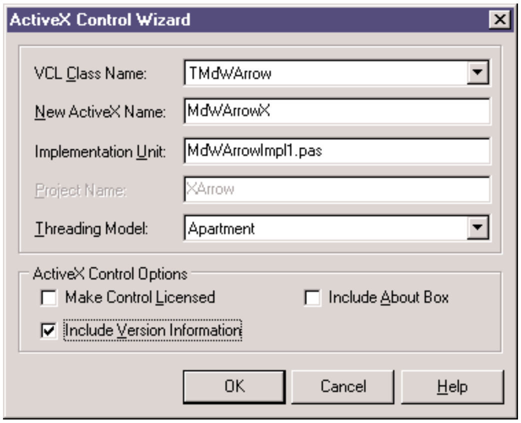
The `TWinControl` class has very minimal support for graphical output. Its `TCustomControl` subclass, however, has basically the same capabilities as the `TGraphicControl` class. The key difference is that a `TCustomControl` object has a window handle.

After installing this new component in Delphi, we are ready to start developing the new example. To create a new ActiveX library, select File ➢ New, move to the ActiveX page, and choose ActiveX library. Delphi creates the bare skeleton of a DLL, as we saw at the beginning of this chapter. I've saved this library as `XArrow`, in a directory with the same name, as usual.

Now it is time to use the ActiveX Control Wizard, available in the ActiveX page of the Object Repository—Delphi's New dialog box. In this wizard (shown in Figure 20.15), you select the VCL class you are interested in, customize the names shown in the edit boxes, and click OK; Delphi then builds the complete source code of an ActiveX control for you.

FIGURE 20.15:

Delphi's ActiveX Control Wizard



ActiveX Control Wizard

VCL Class Name: TMdWArrow

New ActiveX Name: MdWArrowX

Implementation Unit: MdWArrowImpl1.pas

Project Name: XArrow

Threading Model: Apartment

ActiveX Control Options

☐ Make Control Licensed

☐ Include About Box

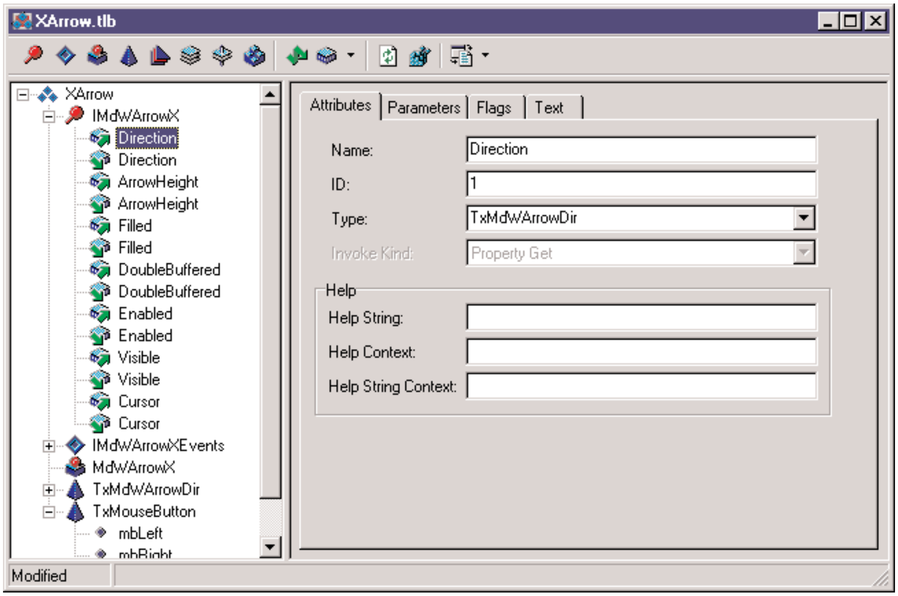
☑ Include Version Information

The use of the three check boxes at the bottom of the ActiveX Control Wizard window may not be obvious. If you include design-time license support, the user of the control won't be able to use it in a design environment without the proper *license key* for the control. The second check box allows you to include version information for the ActiveX, in the OCX file. If the third check box is selected, the ActiveX Control Wizard automatically adds an About box to the control.

Take a look at the code the ActiveX Control Wizard generates. The key element of this wizard is the generation of a type library. You can see the library generated for our arrow control in Delphi's type-library editor in Figure 20.16. From the type library information, the Wizard also generates an import file with the definition of an interface, the `dispinterface`, and other types and constants.

FIGURE 20.16:

The type-library editor with the type library of the demo ActiveX control I've created



Name: Direction
ID: 1
Type: TxMdWArrowDir
Invoke Kind: Property Get
Help String:
Help Context:
Help String Context:

In this example, the import file is named `XArrow_TLB.PAS`. The first part of this file includes a couple of GUIDs, one for the library as a whole and one for the control, and other constants for the definition of values corresponding to the OLE enumerated types used by properties of the Delphi control, for example:

```
type
  TxMdWArrowDir = TOleEnum;
const
  adUp = $00000000;
  adLeft = $00000001;
  adDown = $00000002;
  adRight = $00000003;
```

The real meat is the declaration of the `IMdWArrowX` interface, which I suggest you look at in the source code. Notice that the final part of the import unit includes the declaration of the `TMdWArrowX` class. This is a `TOleControl`-derived class you can use to install the control in Delphi, as we've seen in the first part of this chapter. You don't need this class to build the ActiveX control; you need it to install the ActiveX control in Delphi. The class used by the ActiveX server has the same class name but a different implementation.

The rest of the code, and the code you'll customize, is in the main unit, which in my example is called MdWArrowImpl1. This unit has the declaration of the ActiveX server object, `TMdWArrowX`, which inherits from `TActiveXControl` and implements the specific `IMdWArrowX` interface.

NOTE The TActiveXControl class does most of the work for providing ActiveX support in Delphi. This class implements interfaces required by every ActiveX control: IConnectionPointContainer, IDataObject, IObjectSafety, IOleControl, IOleInPlaceActiveObject, IOleInPlaceObject, IOleObject, IPerPropertyBrowsing, IPersistPropertyBag, IPersistStorage, IPersistStreamInit, IQuickActivate, ISimpleFrameSite, ISpecifyPropertyPages, IViewObject, and IViewObject2. Just the declaration of the TActiveXControl class takes more than 250 lines of code, and its implementation code is responsible for a good part of the 4,000 lines of code of the AxCtrls unit.

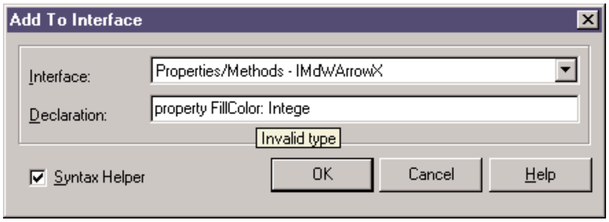
Before we customize this control in any way, let's see how it works. You should first compile the ActiveX library and then register it using Delphi's Run ➢ Register ActiveX Server menu command. Now you can install the ActiveX control as we've done in the past, except you have to specify a different name for the new class to avoid a name clash. If you use this control, it doesn't look much different from the original VCL control, but the advantage is that the same component can now be installed also in other development environments.

Adding New Properties

Once you've created an ActiveX control, adding new properties, events, or methods to it is—surprisingly—simpler than doing the same operation for a VCL component. Delphi, in fact, provides specific visual support for the former, not for the latter.

You can open the Pascal unit with the implementation of the ActiveX control, and choose Edit ➢ Add To Interface. As an alternative, you can use the same command from the shortcut menu of the editor. Delphi opens the Add To Interface dialog box (see Figure 20.17). In the combo box of this dialog box, you can choose between a new property, method, or event. In this example, the first selection will affect the IMdWArrowX interface and the second the IMdWArrowXEvents interface.

FIGURE 20.17: The Add To Interface dialog box, with the syntax helper in action



Add To Interface

Interface: Properties/Methods - IMdWArrowX

Declaration: property FillColor: Intege

Invalid type

☑ Syntax Helper

In the edit box, you can then type the declaration of this new interface element. If the Syntax Helper check box is activated, you'll get hints describing what you should type next and highlighting any errors. You can see the syntax helper in action in Figure 20.17. When you define a new ActiveX interface element, keep in mind that you are restricted to OLE data types. In the XArrow example, I've added two properties to the ActiveX control. Because the Pen and the Brush properties of the original Delphi components are not accessible, I've made their color available. These are examples of what you can write in the edit box of the Add To Interface dialog (executing it twice):

```
property FillColor: Integer;
property PenColor: Integer;
```

NOTE Since a TColor is a specific Delphi definition, it is not legal to use it. TColor is an Integer subrange that defaults to Integer size, so I've used the standard Integer type directly.

The declarations you enter in the Add To Interface dialog box are automatically added to the control's type library (TLB) file, to its import library unit, and to its implementation unit:

```
type
  IMdWArrowX = interface(IDispatch)
    function Get_FillColor: Integer; safecall;
    procedure Set_FillColor(Value: Integer); safecall;
    function Get_PenColor: Integer; safecall;
    procedure Set_PenColor(Value: Integer); safecall;
    ...
    property FillColor: Integer read Get_FillColor write Set_FillColor;
    property PenColor: Integer read Get_PenColor write Set_PenColor;
```

All you have to do to finish the ActiveX control is fill in the Get and Set methods of the implementation. Here is the code of the first property:

```
function TMdWArrowX.Get_FillColor: Integer;
begin
  Result := ColorToRGB (FDelphiControl.Brush.Color);
end;

procedure TMdWArrowX.Set_FillColor(Value: Integer);
begin
  FDelphiControl.Brush.Color := Value;
end;
```

If you now install this ActiveX control in Delphi once more, the two new properties will appear. The only problem with this property is that Delphi uses a plain integer editor, making it quite difficult to enter the value of a new color by hand. A program, by contrast, can easily use the RGB function to create the proper color value.

Adding a Property Page

As it stands, other development environments can do very little with our component, because we've prepared no property page—no property editor. A property page is fundamental so that programmers using the control can edit its attributes. However, adding a property page is not as simple as adding a form with a few controls. The property page, in fact, will integrate with the host development environment. The property page for our control will show up inside a property page dialog of the host environment, which will provide the OK, Cancel, and Apply buttons, and the tabs for showing multiple property pages (some of which might be provided by the host environment).

The nice thing is that support for property pages is built into Delphi, so adding one takes little time. You open an ActiveX project, then open the usual New Items dialog box, move to the ActiveX page, and choose Property Page. What you get is not very different from a form. In fact, the `TPropertyPage1` class (created by default) inherits from the `TPropertyPage` class of VCL, which in turn inherits from `TCustomForm`.

TIP Delphi provides four built-in property pages for colors, fonts, pictures, and strings. The GUIDs of these classes are indicated by the constants `Class_DColorPropPage`, `Class_DFontPropPage`, `Class_DPicturePropPage`, and `Class_DStringPropPage` in the AxCtrls unit.

In the property page, you can add controls as in a normal Delphi form, and you can write code to let the controls interact. I've added to the property page a combo box with the possible values of the `Direction` property, a check box for the `Filled` property, an edit box with an UpDown control to set the `ArrowHeight` property, and two shapes with corresponding buttons for the colors. The only code added to the form relates to the two buttons used to change the color of the two shape components, which offer a preview of the colors of the actual ActiveX control. The `OnClick` event of the button uses a ColorDialog component, as usual:

```
procedure TPropertyPage1.ButtonPenClick(Sender: TObject);
begin
  with ColorDialog1 do
  begin
    Color := ShapePen.Brush.Color;
    if Execute then
    begin
      ShapePen.Brush.Color := Color;
      Modified; // enable Apply button!
    end;
  end;
end;
```

What is important to notice in this code is the call to the `Modified` method of the `TPropertyPage` class. This call is required to let the property page dialog box know we've modified one of the values and to enable the Apply button. When a user interacts with one of the other controls of this form, this call is made automatically. For the two buttons, however, we need to add this line ourselves.

TIP Another tip relates to the Caption of the property page form. This will be used in the property dialog box of the host environment as the caption of the tab corresponding to the property page.

The next step is to associate the controls of the property page with the actual properties of the ActiveX control. The property page class automatically has two methods for this: UpdateOleObject and UpdatePropertyPage. As their names suggest, these two methods copy data from the property page to the ActiveX control and vice versa. Here is the code for my example:

```
procedure TPropertyPage1.UpdatePropertyPage;
begin
  { Update your controls from the OleObject }
  ComboDir.ItemIndex := OleObject.Direction;
  CheckFilled.Checked := OleObject.Filled;
  EditHeight.Text := IntToStr (OleObject.ArrowHeight);
  ShapePen.Brush.Color := OleObject.PenColor;
  ShapePoint.Brush.Color := OleObject.FillColor;
end;

procedure TPropertyPage1.UpdateObject;
begin
  { Update the OleObject from your controls }
  OleObject.Direction := ComboDir.ItemIndex;
  OleObject.Filled := CheckFilled.Checked;
  OleObject.ArrowHeight := UpDownHeight.Position;
  OleObject.PenColor := ColorToRGB (ShapePen.Brush.Color);
  OleObject.FillColor := ColorToRGB (ShapePoint.Brush.Color);
end;
```

The final step is to connect the property page itself to the ActiveX control. When the control was created, the Delphi ActiveX Control Wizard automatically added a declaration for the DefinePropertyPages method to the implementation unit. In this method, we call the DefinePropertyPage method (this time the method name is singular) for each property page we want to add to the ActiveX. This method has as its parameter the GUID of the property page, something you can find in the corresponding unit. (Of course, you'll need to add a uses statement referring to that unit.) Here is the code of my example:

```
procedure TMdWArrowX.DefinePropertyPages(
  DefinePropertyPage: TDefinePropertyPage);
begin
  DefinePropertyPage(Class_PropertyPage1);
end;
```

NOTE The connection between the ActiveX control and its property page takes place using a GUID. This is possible because the property page object can be created through a class factory, and its GUID is stored in the Windows Registry when you register the ActiveX control library. To see what's going on, look at the `initialization` section of the property page unit, which calls `TActiveXPropertyPageFactory.Create`.

Now that we've finished developing the property page, and after recompiling and reregistering the ActiveX library, we can install the ActiveX control inside a host development environment (including Delphi itself) and see how it looks. Figure 20.18 shows an example. (If you've already installed the ActiveX control in Delphi, you should uninstall it prior to rebuilding it. This process might also require closing and reopening Delphi itself.)

ActiveForms

As I've mentioned, Delphi provides an alternative to the use of the ActiveX Control Wizard to generate an ActiveX control. You can use an ActiveForm, which is an ActiveX control that is based on a form and can host one or more Delphi components. This is exactly the technique used in Visual Basic to build new controls, and it makes sense when you want to create a compound component.

For example, to create an ActiveX clock, we can place on an ActiveForm a label (a graphic control that cannot be used as a starting point for an ActiveX control) and a timer, and connect the two with a little code. The form/control becomes basically a container of other controls, which makes it very easy to build compound components (easier than for a VCL compound component).

To build such a control, close the current project, and select the ActiveForm icon in the ActiveX page of the File ➢ New dialog box. Delphi asks you for some information in the following ActiveForm Wizard dialog box, similar to the ActiveX Control Wizard dialog box.

ActiveForm Internals

Before we continue with the example, let's look at the code generated by the ActiveForm Wizard. The key difference from a plain Delphi form is in the declaration of the new form class, which inherits from the TActiveForm class and implements a specific ActiveForm interface:

```
type
  TAXForm1 = class(TActiveForm, IAXForm1)
```

As usual, the IAXForm interface is declared in the type library and in a corresponding Pascal file generated by Delphi. Here is a small excerpt of the IAXForm1 interface from the XF1Lib.pas file, with some comments I've added:

```
type
  IAXForm1 = interface(IDispatch)
    ['{51661AA1-9468-11D0-98D0-444553540000}']
    // Get and Set methods for TForm properties
    function Get_Caption: WideString; safecall;
    procedure Set_Caption(const Value: WideString); safecall;
    ...
    // TForm methods redeclared
    procedure Close; safecall;
    ...
    // TForm properties
    property Caption: WideString read Get_Caption write Set_Caption;
```

The code generated for the TAXForm1 class implements all the Set and Get methods, which change or return the corresponding properties of the form, and it implements the events, which again are the events of the form. Here is a small excerpt:

```
  private
    procedure ActivateEvent(Sender: TObject);
  protected
    procedure Initialize; override;
    function Get_Caption: WideString; safecall;
    procedure Close; safecall;
    procedure Set_Caption(const Value: WideString); safecall;
```

Let's look at the implementation of properties first:

```
function TAXForm1.Get_Caption: WideString;
```

```
begin
  Result := WideString(Caption);
end;

procedure TAXForm1.Set_Caption(const Value: WideString);
begin
  Caption := TCaption(Value);
end;
```

The TForm events are set to the internal methods when the form is created:

```
procedure TAXForm1.Initialize;
begin
  OnActivate := ActivateEvent;
  ...
end;
```

Each event then maps itself to the external ActiveX event, as in the following two methods:

```
procedure TAXForm1.ActivateEvent(Sender: TObject);
begin
  if FEvents <> nil then FEvents.OnActivate;
end;
```

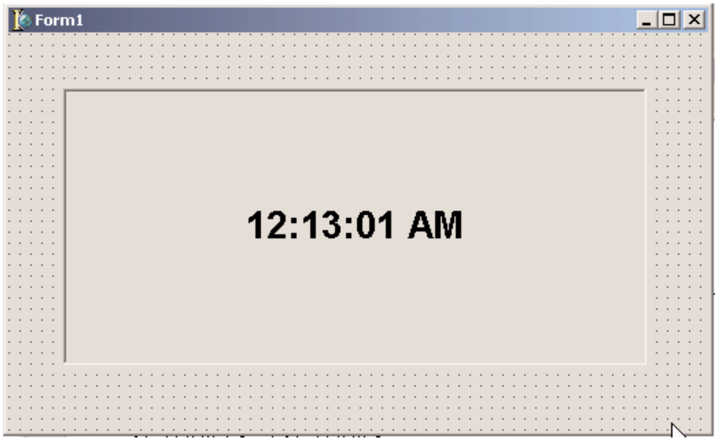
Because of this mapping, you should not handle the events of the form directly. Instead, you can either add some code to these default handlers or override the TForm methods that end up calling the events. (This is exactly the approach you use when building a Delphi component.) Keep in mind that the interface properties of an ActiveForm are meant for developers using it as a control, not for final users of the ActiveForm on the Web. This mapping problem refers only to the events of the form itself, not to the events of the components of the form. You can continue to handle the events of the components as usual.

The XClock ActiveX Control

Now that we've looked at the code generated by Delphi, we can return to the development of the XClock example. Place on the form a label with a large font and centered text, aligned to the client area and a timer. Then write an event handler for its OnTimer event, so that the control updates the output of the label with the current time every second:

```
procedure TXClock.Timer1Timer(Sender: TObject);
begin
  Label1.Caption := TimeToStr (Time);
end;
```

Now compile this library, register it, and install it in a package to test it in the Delphi environment. You can see an example of its use in Figure 20.19. Notice in this figure the effect of the sunken border. This is controlled by the AxBorderStyle property of the active form, one of the few properties of active forms that is not available for a plain form.



12:13:01 AM

FIGURE 20.19:
The ActiveX timer installed in a Delphi package

ActiveForms are usually considered as a technique to deploy a Delphi application via the Internet. However, the ActiveX and ActiveForm support provided by Delphi represent to different ways to build ActiveX controls, which can be used both on a Web page and in another development environment.

ActiveX in Web Pages

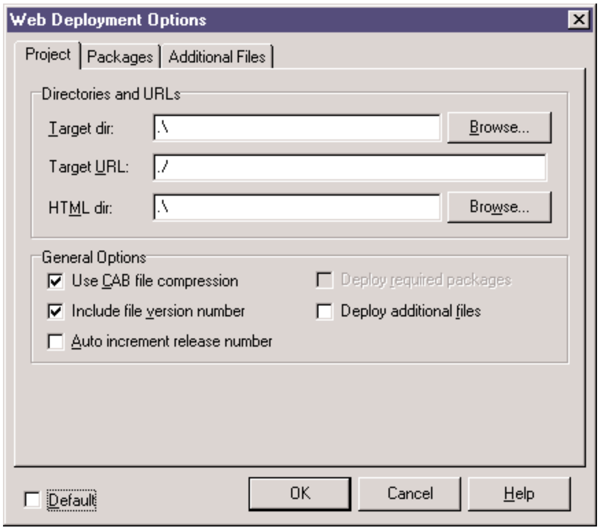
In the last example, we used Delphi's ActiveForm technology to create a new ActiveX control. In fact, an ActiveForm is an ActiveX control based on a form. Borland documentation often implies that ActiveForms should be used in HTML pages, but you can use any ActiveX control on a Web page.

NOTE Microsoft once promoted ActiveX as an Internet technology for delivering interactive content. Due to complexities and security problems inherent in downloading executable code, the market never really bought into this. Microsoft has since dropped ActiveX from its Internet technologies list. Still, this technology might have a value in an intranet to let you deliver small applications to users of your local area network, as you can relax the security settings when accessing local Web sites.

Basically, each time you create an ActiveX library, Delphi enables the Project ➢ Web Deployment Options and Project ➢ Web Deploy menu items. The first allows you to specify how and where to deliver the proper files. As shown in Figure 20.20, in this dialog box you can set the server directory for deploying the ActiveX component, the URL of this directory, and the server directory for deploying the HTML file (which will have a reference to the ActiveX library using the URL you provide).

FIGURE 20.20:

The Web Deployment Options dialog box



Directories and URLs

Target dir: .\

Target URL: ./

HTML dir: .\

General Options

☑ Use CAB file compression

☑ Include file version number

□ Auto increment release number

□ Deploy required packages

□ Deploy additional files

□ Default

You can also specify the use of a compressed CAB file, which can store the OCX file and other auxiliary files, such as packages, making it easier and faster to deliver the application to the user. A compressed file, in fact, means a faster download. Using the options shown in Figure 20.20, Delphi generates the HTML file and CAB file for the XClock project in the same directory. Opening this HTML file in Internet Explorer produces the output shown in Figure 20.21.

WARNING At times, when you load an HTML page referring to an ActiveX, all you get is a red *X* marker indicating a failure to download the control. There are various possible explanations for this problem. First, Internet Explorer must be set up properly, allowing the download of controls and (if the control is not signed) lowering the security level. Second, other problems might arise when the control requires a DLL or a package that is not part of the downloaded CAB file. Third, you might get the red slash marker when there is a mismatch in the version number—*or* you might see an older version of the control in action.

Delphi 6 ActiveX Test Page

You should see your Delphi 6 forms or controls embedded in the form below.

1:25:41 PM

Besides showing you how to deploy the XClock control on a Web page, I've created the XForm1 example to demonstrate the problems with event handlers of ActiveForms mentioned in the previous section "ActiveForm Internals." Because the form events are exported as events of the control, you should not handle the events of the form directly but add some code to the default handlers provided by the Active Form. For example, if you add a handler for the `OnPaint` event of the form and write the following code, it will never be executed:

```
procedure TFormX1.FormPaint(Sender: TObject);
begin
  Canvas.Brush.Color := clYellow;
  Canvas.Ellipse(0, 0, Width, Height);
end;
```

If you want to paint something on the form's background, instead, you have to modify the corresponding handler installed by the ActiveForm Wizard:

```
procedure TFormX1.PaintEvent(Sender: TObject);
begin
  Canvas.Brush.Color := clBlue;
  Canvas.Rectangle (20, 20, ClientWidth - 20, ClientHeight - 20);
  if FEvents <> nil then FEvents.OnPaint;
end;
```

As an alternative, you can place a frame, a panel, or another component on the surface of the form, and handle *its* events. In the XForm1 example, I've added a PaintBox component, with a bevel component behind it to make the area of the PaintBox visible.

The Role of an ActiveX Form on a Web Page

Before we look at another example, it is important to stop for a second to consider the role of an ActiveX form placed inside a Web page. Basically, placing a form in a Web page corresponds to letting a user download and execute a custom Windows application. There is little else happening. You download an executable file and start it. This is one of the reasons the ActiveX technology raises so many concerns about security.

The XFUser example highlights the situation. It calls the `GetUserName` Windows API function and shows the user name on the screen. Its effect is certainly not astonishing, as the name of the user will be displayed in a label. However, this example highlights a couple of important points (which apply both to ActiveForms and ActiveX controls in general):

- In an ActiveX control or form, you can call any Windows API function (which means the user viewing the Web page must have Windows on his or her computer) or certain Windows API–compatible libraries.
- An ActiveX can access the system information of the computer, such as the user name, the directory structure, and so on. This is why, before downloading an ActiveX, Web browsers check whether the ActiveX has a proper authentication, or signature. (You should note that this signature identifies the author of the control and that the module has not been corrupted or tampered with since the author published it; it doesn't prove in any way that the control is safe.)

Well, I could continue, but I think my point is clear. ActiveX controls and ActiveForms inside Web pages have problems, and even Microsoft has slowly abandoned this technology. For this reason, I'm going to show you only one more example, which is instructive on how external environments can interact with an ActiveX control.

Setting Properties for the XArrow

An ActiveForm has a few properties you can set when you use it inside a development environment, and a plain ActiveX control has even more. For example, if you want to set properties in the HTML file hosting the control, you can use a special `param` tag, but the control must support a special interface known as `IPersistPropertyBag`.

Starting with Delphi 4, the `IPersistPropertyBag` support is built in, providing support for all of the properties of the ActiveX control or ActiveForm. As an example, I've used the Web Deploy options on the XArrow control. Then, I've modified the automatically generated HTML file with three `param` tags:

```
<object classid="clsid:482B2145-4133-11D3-B9F1-00000100A27B"
  codebase="./XArrow.cab" width="350" height="250" align="center"
  hspace="0" vspace="0">
  <param name="ArrowHeight" value="100">
  <param name="Filled" value="-1">
  <param name="FillColor" value="111829">
</object>
```

You can compare the default and customized output of the control in Figure 20.22.

FIGURE 20.22:

By using the `param` tag, we can set values for the properties of an ActiveX control in the HTML file hosting it. The two copies of the program show the default and the customized output.

Introducing COM+

In addition to plain COM servers, Delphi also allows you to create enhanced COM objects, including stateless objects and transaction support. This type of COM object was first introduced by Microsoft with the MTS (Microsoft Transaction Server) acronym, and later renamed as COM+ in Windows 2000.

Delphi 6 supports building both standard stateless objects and DataSnap remote data modules based on stateless objects. In both cases you'll start the development by using one of the available Delphi wizards, using the New Items dialog box and selecting the Transactional Object icon of the ActiveX page or the Transactional Data Module icon of the Multitier page. You must add these objects to an ActiveX library project, not to a plain application. Another icon, COM+ Event Object, is used to support COM+ events.

MTS is an operating-system service you can install on Windows NT and 98; it was renamed as COM+ in Windows 2000, so I'll call it COM+ but this actually refers to both. This system service provides a run-time environment supporting database transaction services, security, resource pooling, and an overall improvement in robustness for DCOM applications. The run-time environment manages objects called *COM+ components*. These are COM objects stored in an in-process server (that is, a DLL). While other COM objects run directly in the client application, COM+ objects are handled by this run-time environment, in which you install the COM+ libraries. COM+ objects must support specific COM interfaces, starting with `IObjectControl`, which is the base interface (like `IUnknown` for a COM object).

Before getting into too many technical and low-level details, let's consider COM+ from a different perspective. What are the benefits of this approach? COM+ provides a few interesting features, including:

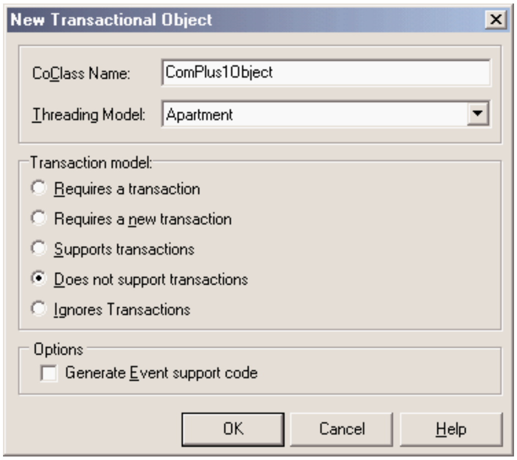
Role-based security The role assigned to a client determines whether it has the right to access the interface of a data module.

Reduced database resources You can reduce the number of database connections, as the middle tier logs on to the server and uses the same connections for multiple clients (although you cannot have more clients connected at once than you have licenses for the server).

Database transactions COM+ transaction support includes operations on multiple databases, although few SQL servers other than Microsoft's support COM+ transactions.

Creating a COM+ Component

The starting point for creating a COM+ component is the creation of an ActiveX library project. After this step you can select a new Transactional Object in the ActiveX page of the New Items dialog box. In the resulting dialog box (see Figure 20.23), enter the name of the new component (*ComPlus1Object* in my ComPlus1 example).



CoClass Name: ComPlus1Object

Threading Model: Apartment

Transaction model:

- ○ Requires a transaction
- ○ Requires a new transaction
- ○ Supports transactions
- ● Does not support transactions
- ○ Ignores Transactions

Options

- □ Generate Event support code

FIGURE 20.23: Delphi's New Transactional Object dialog box, used to create a COM+ object

The New Transactional Object dialog box allows you to enter a name for the class of the COM+ object, the threading model (because COM+ serializes all the requests, Single or Apartment will generally do), and a transactional model:

> **Requires A Transaction** indicates that each call from the client to the server is considered to be a transaction (unless the caller supplies an existing transaction context).
>
> **Requires A New Transaction** indicates that each call is considered a new transaction.
>
> **Supports Transactions** indicates that the client must explicitly provide a transaction context.
>
> **Does Not Support Transaction** (the default choice, and the one I've used) indicates that the remote data module won't be involved in any transaction.

As you close this dialog, Delphi adds a type library and an implementation unit to the project and opens the type-library editor, where you can define the interface of your new COM object. For this example I've added a `Value` integer property, an `Increase` method having as parameter an amount, and an `AsText` method returning a WideString with the formatted value. As you accept the edits in the type-library editor (clicking the Refresh button or closing the window), Delphi shows the Implementation File Update Wizard, if the corresponding IDE option is set. This wizard will ask for your confirmation before adding four methods to the class, including the get and set methods of the property. You can now write some code for the COM object, which for my example was quite trivial.

"Ignores Transactions" indicates that objects do not participate in transactions, regardless of whether the □ client has a transaction. The difference from the setting "Does not support transactions" prevents the object □ from being activated if the client has a transaction.

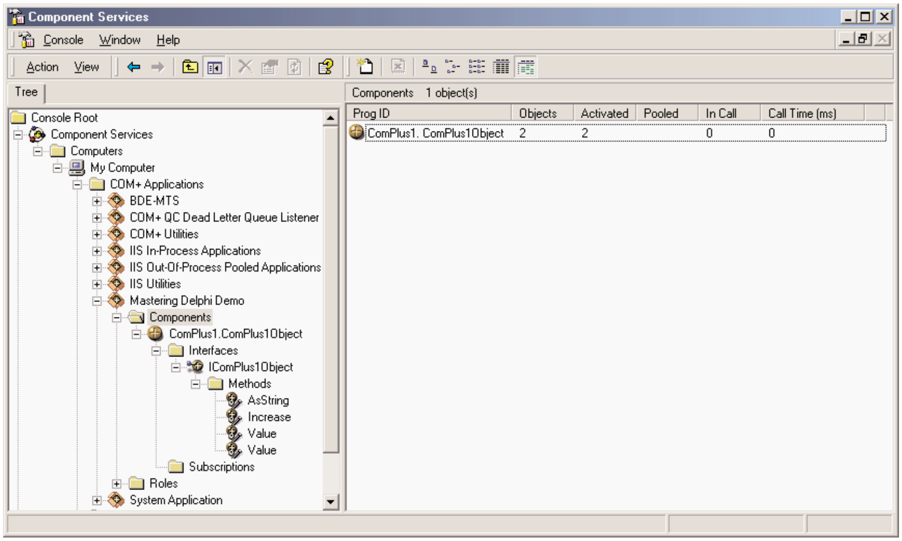
As you've compiled an ActiveX library, or COM library, which hosts a COM+ component, you can use the Component Services administrative tool (shown in the Microsoft Management Console, or MMC) to install and configure the COM+ component. Even better, you can use the Delphi IDE to install the COM+ component using the Run ➢ Install COM+ Object menu command. In the subsequent dialog box, you'll be able to select the component to install (as a library can host multiple components), and choose the COM+ application where to install the component.

A COM+ application is nothing more than a way to group COM+ components; it is not an actual program or anything like one (why they call it application is not fully clear to me). So in the Install COM+ Object dialog, you can select an existing application/group, choose the Install Into New Application page, and enter a name and description for it.

I've called the COM+ application *Mastering Delphi Demo*, as you can see in Figure 20.24 in the Component Services administration. This is the front end you can use to fine-tune the behavior of your COM+ components, setting their activation model (just-in-time activation, object pooling, and so on), their transaction support, and the security and concurrency models you want to use. You can also use this console to monitor the objects and the actual method calls (in case these take a long time to execute). In Figure 20.24, you can see that there are currently two active objects.

FIGURE 20.24:

The newly installed COM+ component inside a custom COM+ application (as shown by Microsoft's Component Services tool)



Prog ID	Objects	Activated	Pooled	In Call	Call Time (ms)
ComPlus1. ComPlus1Object	2	2		0	0

TIP Because you've created one or more objects, the COM library remains loaded in the COM+ environment and some of the objects might be kept in cache, even if there are no clients connected to them. For this reason, you cannot generally recompile the COM library after using it, unless you use the MMC to shut it down.

I've actually created a client program for the COM+ object, but this is exactly like any other Delphi COM client. After importing the type library, which is automatically registered while installing the component, I created an interface-type variable referring to it and called its methods as usual. You can find the example on the CD accompanying this book.

Transactional Data Modules

The same types of features are available when creating a *transactional data module*—that is, a remote data module within a COM+ component. Once you've created a transactional data module, you can build a Delphi DataSnap application as we've done in Chapter 17, "Multitier Database Applications with DataSnap." You can add one or more dataset components, add one or more providers, and export the provider(s). You can also add custom methods to the data module type library by editing the type library or using the Add To Interface command.

Within a COM+ component or transactional data module, you can also use the `GetObjectContext` method, which returns the `IObjectContext` interface of the COM+ object. The `IObjectContext` interface provides support for transactions:

- You can use `SetComplete` to tell the COM+ environment that the object has finished working and can be deactivated, so that the transaction can be committed.
- You can call `EnableCommit` to indicate that the object hasn't finished but the transaction should be committed.
- You can call `DisableCommit` to stop the commit operation, even if the method is done, disabling the object deactivation between method calls.
- You can call `SetAbort` to say that the object has finished and can be activated but the transaction cannot be committed.
- You can call `IsInTransaction` to check whether the object is part of a transaction.

Other methods of the `IContextObject` interface include `CreateInstance`, which creates another COM+ object in the same context and within the current transaction, `IsCallerInRole`, which checks if the object's caller is in a particular "security" role, and `IsSecurityEnabled` (whose name is self-explanatory).

Once you've built a transactional data module within a server library, you can install it as I've shown above for a plain COM+ object. After the transactional data module has been installed, it will be directly available to other applications and visible in the management console.

An important feature of COM+ is that it becomes much easier to configure DCOM support using this environment. In fact, the COM+ environment of a client computer can grab information from the COM+ environment of a server computer, including registration information for the COM+ object you want to be able to call over a network. The same network configuration is way more complex if done with plain DCOM, without MTS or COM+.

TIP Even though COM+ configuration is much better than DCOM configuration, still you are limited to computers with a recent version of the Windows operating system. Considering that even Microsoft is moving away from DCOM technology, before you build a large system based on this technology you should at least evaluate the alternative provided by SOAP (discussed in Chapter 23, "XML and SOAP").

COM+ Events

Client applications that use traditional COM objects and Automation servers can call methods of those servers, but this is not an efficient way to check whether the server has updated data for the client. For this reason, it is possible for a client to define a COM object that implements a *callback* interface, pass this object to the server, and let the server call it. Traditional COM events (which use the `IConnectionPoint` interface) are simplified by Delphi for Automation objects, but are still quite complex to handle.

COM+ introduces a simplified event model, in which the events are COM+ components and the COM+ environment manages the connections. In traditional COM callbacks, the server object doesn't have to keep track of the multiple clients it has to notify to, which is one of the reasons for the complexity of its code. In COM+, the server calls into a single event interface, and the COM+ environment will forward the event to all clients that have expressed interest for it. This way, the client and the server are less coupled, making it possible for a client to receive notification from different servers, without any change in its code.

NOTE Some critics say that Microsoft introduced this model only because it was very complex to handle COM events in the traditional way for Visual Basic developers. Windows 2000 actually provides a few operating-system features specifically intended for VB developers.

To create a COM+ event, you should create a COM library (or ActiveX library) and use the COM+ Event Object wizard. The resulting project will contain a type library with the definition of the interface used to fire the events, plus some *fake* implementation code. The actual server that will receive the notification of the events, in fact, will provide the actual implementation of the interface. The fake code is there only to support Delphi's COM registration system.

While building the MdComEvents library, I added to the type library a single method with two parameters, resulting in the following code (in the interface definition file):

```
type
  IMdInform = interface(IDispatch)
    ['{202D2CC8-8E6C-4E96-9C14-1FAAE3920ECC}']
    procedure Informs(Code: Integer; const Message: WideString); safecall;
  end;
```

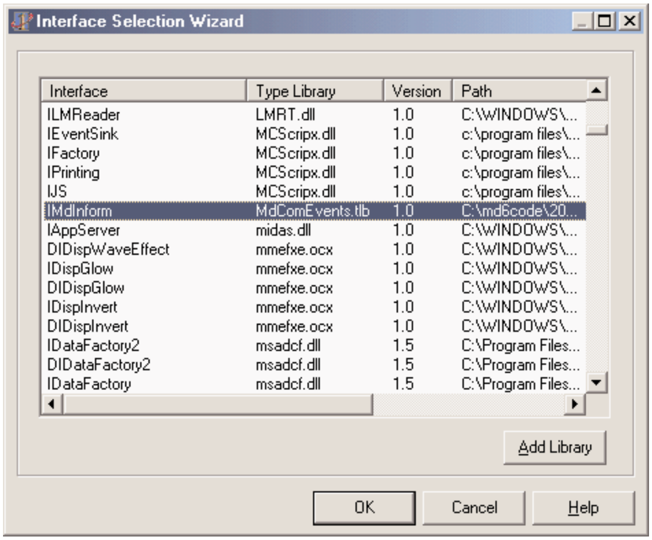
The main unit includes the fake COM object and its class factory, to let the server register itself. The code looks like this (notice that the method is `abstract`, and it has no implementation):

```
type
  // fake abstract class
  TMdInform = class (TAutoObject, IMdInform)
  protected
    procedure Informs(Code: Integer; const Message: WideString);
      virtual; safecall; abstract;
  end;

begin
  TAutoObjectFactory.Create(ComServer, TMdInform, Class_MdInform,
    ciMultiInstance, tmApartment);
end.
```

At this point, you can compile the library and install it in the COM+ environment. Again, after selecting a COM+ application (that is, a group of COM+ components), use the shortcut menu of its Components folder to add a new component to it. In the COM Component Install Wizard, click the Install New Event Class button and select the library you've just compiled. Your COM+ event definition will be automatically installed.

To test whether it works, you'll have to build an actual implementation of this event interface and a client invoking it. The implementation can be added to another ActiveX library, hosting a plain COM object. Within Delphi's COM Object Wizard you can select the interface to implement, choosing it in the list that appears when you select the List button. An example of this rather long list, dubbed Interface Selection Wizard, is shown in Figure 20.25.



Interface	Type Library	Version	Path
ILMReader	LMRT.dll	1.0	C:\WINDOWS\...
IEventSink	MCScripx.dll	1.0	c:\program files\...
IFactory	MCScripx.dll	1.0	c:\program files\...
IPrinting	MCScripx.dll	1.0	c:\program files\...
IJS	MCScripx.dll	1.0	c:\program files\...
IMdInform	MdComEvents.tlb	1.0	C:\md6code\20...
IAppServer	midas.dll	1.0	C:\WINDOWS\...
DIDispWaveEffect	mmefxe.ocx	1.0	C:\WINDOWS\...
IDispGlow	mmefxe.ocx	1.0	C:\WINDOWS\...
DIDispGlow	mmefxe.ocx	1.0	C:\WINDOWS\...
IDispInvert	mmefxe.ocx	1.0	C:\WINDOWS\...
DIDispInvert	mmefxe.ocx	1.0	C:\WINDOWS\...
IDataFactory2	msadcf.dll	1.5	C:\Program Files...
DIDataFactory2	msadcf.dll	1.5	C:\Program Files...
IDataFactory	msadcf.dll	1.5	C:\Program Files...

FIGURE 20.25:

Delphi 6's new Interface Selection Wizard, used in this case to select an event interface

The resulting library, which in my example is called EvtSubscriber, exposes an Automation object, a COM object implementing the `IDispatch` interface (which is mandatory for COM+ Events). In my example, the object has the following definition and code:

```
type
  TInformSubscriber = class(TAutoObject, IMdInform)
  protected
    procedure Informs(Code: Integer; const Message: WideString); safecall;
  end;

procedure TInformSubscriber.Informs(Code: Integer; const Message: WideString);
begin
  ShowMessage ('Message <' + IntToStr (Code) + '>: ' + Message);
end;
```

After compiling this library, you can first install it into the COM+ environment, then you have to bind it to the event. This second step is accomplished in the Component Services management console by selecting the `Subscriptions` folder under the event object registration, and using the New ➢ Subscription shortcut menu. In the resulting wizard, you can choose the interface to implement (but there is probably only one interface in your COM+ event library), then you'll see a list of COM+ components that implement this interface. Selecting one or more of them you'll set up the subscription binding, which is listed under the `Subscriptions` folder. You can see an example of my configuration while building this example in Figure 20.26.

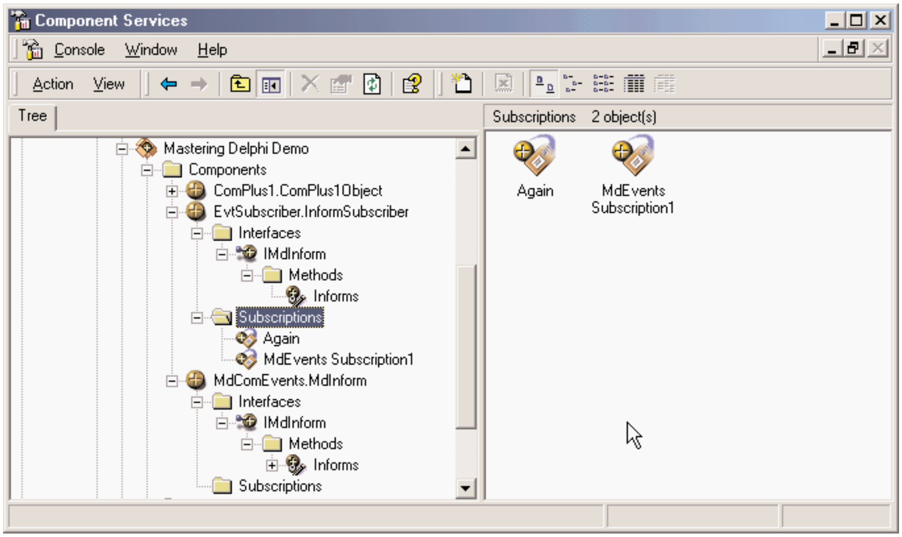


FIGURE 20.26: A COM+ Event with two subscriptions in the Component Services management console.

Finally, we can focus on the application that fires the event, which I've called Publisher, as it publishes the information other COM objects are interested in. This is actually the simplest step of this process, as it is a plain COM client that uses the event server. After importing the COM+ event type library, you can add to the publisher code like this:

```
var
  Inform: IMdInform;
begin
  Inform := CoMdInform.Create;
  Inform.Informs (20, Edit1.Text);
```

My example actually creates the COM object in the `FormCreate` method to keep the reference around, but the effect is the same. Now the client program thinks it is calling the COM+ event object, but this object, provided by the COM+ environment, actually calls the method for each of the active subscribers. In this case you'll end up seeing a message box. To make things a little more interesting, you can actually subscribe twice the same server to the event interface. The net effect is, without touching your client code, you'll get two message boxes, one for each of the subscribed servers.

Obviously this effect becomes interesting when you have multiple different COM components that can handle the event, as you can easily enable and disable each of them in the management console, changing the COM+ environment without modifying the code of any program.

What’s Next?

In this chapter, I have discussed applications of Microsoft’s COM technology, covering automation, documents, controls, and more. We’ve seen how Delphi makes the development of Automation servers and clients, and ActiveX controls, reasonably simple. Delphi even enables us to wrap components around Automation servers, such as Word and Excel.

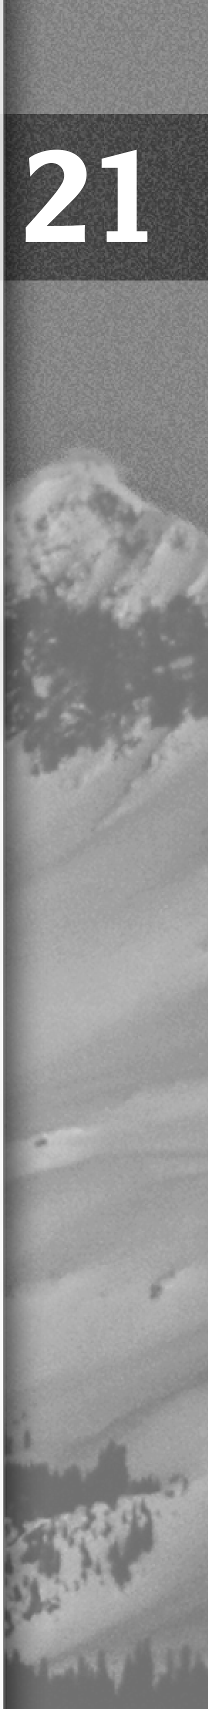
I’ve also introduced elements of COM+ provided by Delphi 6 and discussed briefly the use of ActiveForms inside a browser. I’ve stated this is not really a very good approach to Internet Web programming—the topic discussed in the next two chapters.

As I mentioned earlier, if COM has a key role in Windows 2000, future versions of Microsoft’s operating systems will downplay its role to push the dotNet infrastructure including SOAP and XML. But you’ll have to *wait* until Chapter 23 to see a complete discussion of Delphi 6 XML support.

CHAPTER 21

Internet Programming: Sockets and Indy Components

- Using sockets
- The WinInet API
- Standard Internet actions
- The Internet Direct (Indy) components
- Mail and HTTP



In this chapter I'll provide an introduction to Internet programming in Delphi, using some of the components available in the IDE. With the advent of the Internet era, writing programs based on Internet protocols has become commonplace, so I've devoted three chapters to this topic. This chapter focuses on low-level socket programming and Internet protocols; the next chapter is devoted to server-side Web programming; and the final chapter of the book covers Web services, XML, and SOAP.

We'll start by looking at the use of Delphi socket components, then we'll move to the use of the Internet Direct (Indy) components supporting the most common Internet protocols. I will introduce some elements of HTTP programming, leading up to building HTML files out of database data.

Although you probably just want to use a high-level protocol, our discussion of Internet programming starts from the core concepts and low-level applications. The reason is that understanding TCP/IP and sockets will help you grasp most of the other concepts more easily.

Specifically, I'm going to focus on the use of the connectivity provided by Delphi socket components, which are based on TCP/IP and the low-level Windows sockets. Before we look into the foundations of sockets, let me list a couple of alternative approaches you can use for Internet programming, which I'll cover in more detail in later sections:

- The Delphi socket components provide a good interface for direct use of the Windows sockets API, implementing some custom protocols of your own.
- For standard protocols, you can also use the Indy components, included in Delphi 6.

Foundations of Socket Programming

To understand the description of the socket components in the Delphi Help file, and also to read along with the description of the examples in the book, you need to be confident with several terms related to the Internet in general and with sockets in particular.

The heart of the Internet is the Transmission Control Protocol/Internet Protocol (TCP/IP for short), a combination of two separate protocols that work together to provide connection over the Internet (and can also provide connection over a private intranet). In brief, IP is responsible for defining and routing the *datagrams* (Internet transmission units) and specifying the addressing scheme. TCP is responsible for higher-level transport services.

Configuring a Local Network: IP Addresses

If you have a local network available, you'll be able to test the following programs on it; otherwise, you can simply use the same computer as client and server. In this case, as I've done in the examples, use the address 127.0.0.1 (or *localhost*), which is invariably the address of the current computer. If your network is complex, ask your network administrator to set up proper IP addresses for you. If you want to set up a simple network with a couple of spare computers, you can simply set up the IP address yourself, a 32-bit number usually represented with each of its four components (called *octets*) separated by dots. These numbers have a complex logic underneath them, with the first octet indicating the class of the address.

Specific IP addresses are actually reserved for unregistered internal networks. Internet routers will ignore these address ranges, so you can freely do your tests without interfering with an actual network. For example, the "free" IP address range 192.168.0.0 through 192.168.0.255 can be used for experiments on a network of fewer than 255 machines.

Local Domain Names

How does the IP address map to a name? On the Internet, the client program looks up the values on a domain name server. But it is also possible to have a local *hosts* file, a text file that you can easily edit to provide nice local mappings. You can take a look at the `HOSTS.SAM` file (installed in a subdirectory of the `Windows` directory) to see a sample and then eventually rename the file as `HOSTS`, without the extension, to activate local host mapping.

Should you use an IP or a hostname in your programs? Hostnames are easier to remember and won't require a change if the IP address changes (for whatever reason). On the other hand, IP addresses don't require any resolution, while hostnames must be resolved (a time-consuming operation if the lookup takes place on the Web).

TCP Ports

Each TCP connection takes place though a *port*, which is represented by a 16-bit number. The IP address and the TCP port together specify an Internet connection, or a *socket* (to use a more precise term). Different processes running on the same machine cannot use the same socket—the same port.

Some TCP ports have a standard usage for specific high-level protocols and services. In other words, you should use those port numbers when implementing those services and stay away from them in any other case. Here is a short list:

Protocol	**Port**
HTTP (Hypertext Transfer Protocol)	80
FTP (File Transfer Protocol)	21
SMTP (Simple Mail Transfer Protocol)	25
POP3 (Post Office Protocol, version 3)	110
Telnet	23

The `Services` file (another text file similar to the `Hosts` file) lists the standard ports used by services. You can add your own entry to the list, giving your service a name of your own choosing. Client sockets always specify the port number or the service name of the server socket to which they want to connect.

High-Level Protocols

I've used the term *protocol* many times now, but what does it mean exactly? A protocol is a set of rules the client and server agree upon to determine the communication flow. The low-level Internet protocols, such as TCP/IP, are usually implemented by an operating system. But the term *protocol* is also used for high-level Internet standard protocols (such as HTTP, FTP, or SMTP). These protocols are defined in standard documents available on the Web on the site of the Internet Engineering Task Force (`www.ietf.org`).

If you want to implement a custom communication, you can define your own (possibly simple) protocol, a set of rules determining which request the client can send to the server and how the server can respond to the various possible requests. We'll see an example of a custom protocol later on. Transfer protocols are at a higher level than transmission protocols, because they abstract from the transport mechanism provided by TCP/IP. This makes the protocols independent not only from the operating system and the hardware but also from the physical network.

Socket Connections

How do you start communication through a socket? The server program starts running first, but it simply waits for a request from a client. The client program requests a connection indicating the server it wishes to connect to. When the client sends the request, the server can accept the connection, starting a specific server-side socket, which connects to the client-side socket.

To support this model, there are three different types of socket connections:

- *Client connections* are initiated by the client and connect a local client socket with a remote server socket. Client sockets must describe the server they want to connect to, by providing either its hostname or IP address and its port.
- *Listening connections* are passive server sockets waiting for a client. Once a client makes a new request, the server spawns a new socket devoted to that specific connection and then gets back to listening. Listening server sockets must indicate the port that represents the service they provide. (In fact, the client is going to connect through that port.)
- *Server connections* are the connections activated by servers, as they accept a request from a client.

These different types of connections are important only for establishing the link from the client to the server. Once the link is established, both sides are free to make requests and to send data to the other side.

Delphi Socket Components

Delphi 6 ships with three sets of socket components you can use to read and write information over a TCP/IP connection. The Internet page of the palette hosts the ClientSocket and ServerSocket components (already available in Delphi 5) plus the new TcpClient and TcpServer components (also available in Kylix). To these *native* Borland sockets, the Indy components add the IdTCPClient and the IdTCPServer components. These three sets of components have very similar features, which depend on the underlying protocol. There are technical differences, of course, and platform issues, which can determine your choice.

Host and Port

To use a socket component, you must provide a host and a service. On the server side the host is the address of the current computer; on the client side you can indicate either a domain name or an IP address. The ClientSocket component uses two different properties for these settings (`Host` and `Address`), while the TcpClient component and the IdTCPClient component use a single string property and can determine whether it is a hostname or an address by looking at its content (the property is called `RemoteHost` and `Host`, respectively).

Similarly the service is indicated with the `Port` property or the `Service` property, in a ClientSocket, and with the single `RemotePort` string in a TcpClient and with the single numeric `Port` in an IdTCPClient. The respective servers determine their listening port using analogous properties (called `Port`, `LocalPort`, and `DefaultPort` in the three components).

NOTE The Indy server sockets allow binding to multiple IP addresses and/or ports, using the `Bindings` collection.

Blocking, Nonblocking, and Multithreaded Connections

When working with sockets in Windows, multiple approaches are possible. Reading data from a socket or writing to it can happen asynchronously, so that it does not block the execution of other code in your network application. This is called a *nonblocking connection*. Nonblocking connections read and write asynchronously: the Windows socket support basically sends a message when data is available. Using the ClientSocket and ServerSocket components, for example, the system fires the `OnRead` or `OnWrite` events of the client, and the

OnClientRead or OnClientWrite events of servers inform your socket when the other end of the connection tries to read or write some data.

As an alternative to the asynchronous approach, you can also use *blocking connections*, where your application waits for the reading or writing to be completed before executing the next line of code. In this case, you have to write the code in sequence on both sides, because otherwise the events won't be triggered. When using a blocking connection, you must use a thread on the server, and you'll generally use a thread also on the client.

The Indy components use an in-between approach. They use blocking connections exclusively, and you can either place their code in a thread or use a special helper component (IdAntiFreeze). Using blocking connections for implementing a protocol has the advantage of simplifying the program logic, because you don't have to use the state-machine approach of nonblocking connections, as exemplified later.

Finally, when writing threaded code with the ServerSocket components working on a blocking connection, you can use the TWinSocketStream class to do the actual reading and writing operations. You can use the WaitForData method of the TWinSocketStream class to wait until the socket on the other end is ready to write. You can also create the socket stream class and specify a timeout value, so that if the connection is lost, it won't hang forever.

Using Sockets

After all that theory, let's take a look at a couple of examples. The first is the Sock1 program on the companion CD and is made of the Server1 and Client1 applications, built with the ClientSocket and ServerSocket components in nonblocking mode. The server has a form with the following component:

```
object ServerSocket1: TServerSocket
  Active = True
  Port = 50
  ServerType = stNonBlocking
  OnClientConnect = ServerSocket1ClientConnect
  OnClientDisconnect = ServerSocket1ClientDisconnect
  OnClientRead = ServerSocket1ClientRead
end
```

All the code of the application relates to the events of this component, as the program provides no specific interaction with the user. However, the server has three list boxes for outputting the status, the messages sent from the client, and a log of the events. For example, as a client connects, the server adds the client address to the log:

```
procedure TForm1.ServerSocket1ClientConnect(Sender: TObject;
  Socket: TCustomWinSocket);
begin
```

```
    lbLog.Items.Add ('Connected: ' + Socket.RemoteHost + ' (' +
      Socket.RemoteAddress + ')' );
    PostMessage (Handle, wm_RefreshClients, 0, 0);
  end;
```

Notice that the OnClientConnect event indicates the first occasion for the server to know about the connected client. Using the Socket property, which refers to the low-level TCustomWinSocket, the server can track who is trying to connect. At the end of this and other events, I want to update the list of the connections, using the ActiveConnections property of the server. However, in the OnClientConnect event handler, this list is still not updated, so I post a message to the form to delay the operation:

```
const
  wm_RefreshClients = wm_User;

procedure TForm1.RefreshClients; // message wm_RefreshClients
var
  I: Integer;
begin
  lbClients.Clear;
  for I := 0 to ServerSocket1.Socket.ActiveConnections - 1 do
    with ServerSocket1.Socket.Connections [I] do
      lbClients.Items.Add (RemoteAddress + ' (' + RemoteHost + ')');
end;
```

Similar code is executed as the client disconnects from the server:

```
procedure TForm1.ServerSocket1ClientDisconnect(Sender: TObject;
  Socket: TCustomWinSocket);
begin
  lbLog.Items.Add ('Disconnected: ' + Socket.RemoteHost + ' (' +
    Socket.RemoteAddress + ')' );
  PostMessage (Handle, wm_RefreshClients, 0, 0);
end;
```

Finally, as the client sends some information to the server (writes to the socket), the server can read the message by calling the ReceiveText function. You should do this read operation only when there is some data available—that is, when the OnClientRead event is fired. Notice also that this is a *destructive* read: the information extracted from the stream is removed from it. Here is the code:

```
procedure TForm1.ServerSocket1ClientRead(Sender: TObject;
  Socket: TCustomWinSocket);
begin
  // read from the client
```

```
    lbMsg.Items.Add (Socket.RemoteHost + ': ' + Socket.ReceiveText);
  end;
```

Now we can move to the client side of the application, which has a form hosting a client-socket component with the following properties:

```
object ClientSocket1: TClientSocket
  Active = False
  Address = '127.0.0.1'
  ClientType = ctNonBlocking
  Port = 50
  OnConnect = ClientSocket1Connect
  OnDisconnect = ClientSocket1Disconnect
end
```

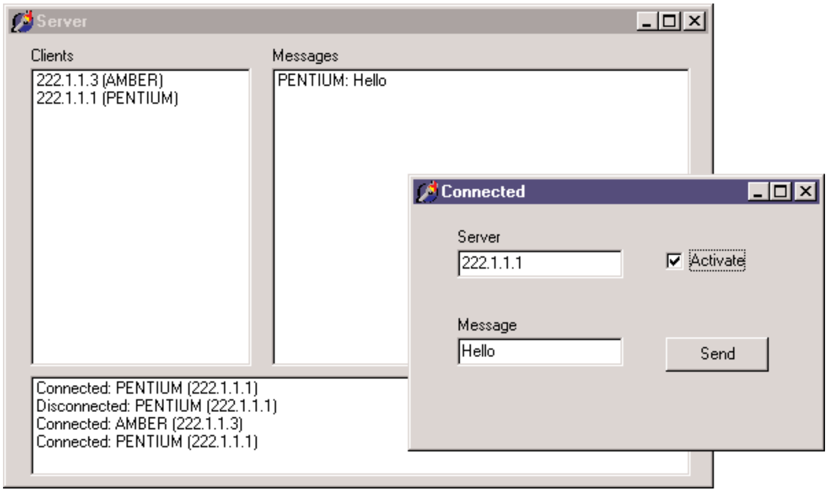
The client form is more interactive. It has two edit boxes and a check box. In the first edit box, you can type the address of the server you want to connect to (to replace the default value listed above), using the check box to activate or deactivate the socket connection:

```
procedure TForm1.cbActivateClick(Sender: TObject);
begin
  if not ClientSocket1.Active then
    ClientSocket1.Address := EditServer.Text;
  ClientSocket1.Active := cbActivate.Checked;
end;
```

As you connect or disconnect, the program simply updates the caption of the form. In the second edit box, you can type a message to send to the server and a button you can press to send the message:

```
procedure TForm1.btnSendClick(Sender: TObject);
begin
  ClientSocket1.Socket.SendText (EditMsg.Text);
end;
```

Notice that this example program doesn't check whether the connection is active before using it, which can result in errors. In Figure 21.1, you can see an example of the client and the server. As the server indicates, a second copy of the client application is running on another computer and is connected to it.



Clients:
222.1.1.3 (AMBER)
222.1.1.1 (PENTIUM)

Connected: PENTIUM (222.1.1.1)

Server: 222.1.1.1

Message: Hello

FIGURE 21.1: The client and server applications of the Sock1 example, demonstrating the use of the socket components

Using Sockets with a Custom Protocol

Unless you want to send and receive only simple text messages, you might want to define some communication rules between the client and the server. A set of communication rules is generally indicated as a protocol. Basically, the server can receive different requests and, depending on the type of request and whether it can be accomplished, reply to the client.

The server program of the Sock2 example accepts four types of requests: the listing of a directory, a bitmap file, a text file, and the execution of a program on the server. When the server sends back a file, its reply should indicate both what it is going to send back and the actual information. The only method modified from the Sock1 example is the `ServerSocket1ClientRead` procedure, which starts by extracting the five initial characters of the text received by the client that host the command:

```
strCommand := Socket.ReceiveText;
lbLog.Items.Add ('Client: ' + Socket.RemoteAddress + ': ' + strCommand);
// extract the file name (all commands have 5 characters)
strFile := Copy (strCommand, 6, Length (strCommand) - 5);
```

The actual code depends on the initial command defined by the protocol (in this case either *EXEC!* to execute a file on the server, *TEXT!* to return a text file, *BITM!* to retrieve a bitmap file, or *LIST!* to return a directory listing). Here is the code for two of these four alternatives:

```
// send back a text file
if Pos ('TEXT!', strCommand) = 1 then
begin
```

```
    if FileExists (strFile) then
    begin
      strFeedback := 'TEXT!';
      Socket.SendText (strFeedback);
      Socket.SendStream (TFileStream.Create (strFile,
        fmOpenRead or fmShareDenyWrite));
    end
    else
    begin
      strFeedback := 'ERROR' + strFile + ' not found';
      Socket.SendText (strFeedback);
    end;
  end
  // send back a directory listing
  else if Pos ('LIST!', strCommand) = 1 then
  begin
    if DirectoryExists (strFile) then
    begin
      strFeedback := 'LIST!';
      Socket.SendText (strFeedback);
      FileListBox1.Directory := strFile;
      Socket.SendText (FileListBox1.Items.Text);
    end
    else
    begin
      strFeedback := 'ERROR' + strFile + ' not found';
      Socket.SendText (strFeedback);
    end;
  end
  else
  begin
    strFeedback := 'ERROR' + 'Undefined command: ' + strCommand;
    Socket.SendText (strFeedback);
  end;
```

For the directory listings, I've used an invisible FileListBox component. For sending back the text file, I've used the SendStream method, creating a new stream on the fly. The advantage is that there is no need to destroy the temporary stream, as the SendStream method becomes the owner of the stream and destroys it when it is done.

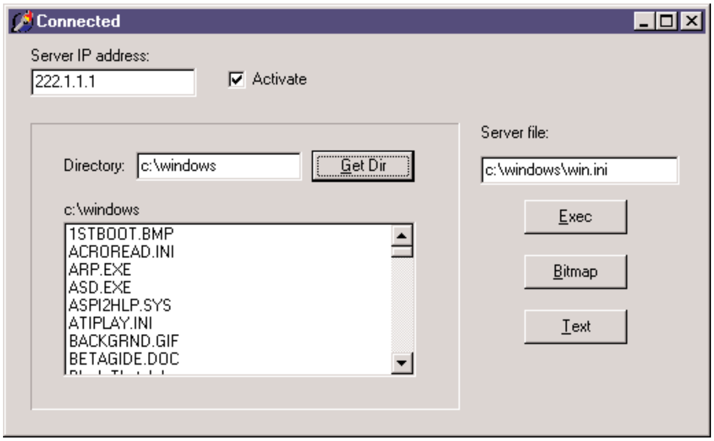
The program sends back multiple pieces of information one after the other. This will create a few problems on the client side, as all the information is received in a single stream. However, the server responds with a five-character header that we can use to determine the content of the rest of the stream. After receiving these headers, the client application sets a status field so that it knows which type of information is coming next. In other words, in the client program, we implement a very simple finite-state machine, a typical technique for socket programming. The client application has five possible states, listed in an enumerated type:

```
type
  TCliStatus = (csIdle, csList, csBitmap, csText, csError);
```

This type is used for the `CliStatus` field of the form. The form has two edit boxes referring to a directory or a file a user can request from the server. When the user presses the Get Dir button, the client program passes to the server the name of the directory indicated by the first edit box. The server will return a list of files, which the client program saves in a list box. At this point, the user can select one of the files from the list box, and the client program will copy it, along with the complete path, into the second edit box. The text of this second edit box is used by the other three buttons—Exec, Bitmap, and Text—which send further requests to the server. In Figure 21.2, you can see an example of the main form of the client program after a directory has been retrieved.

FIGURE 21.2:

The form of the Client2 program after the server has returned the list of the files of a directory



Connected

Server IP address: 222.1.1.1

☑ Activate

Directory: c:\windows

Server file: c:\windows\win.ini

c:\windows

1STBOOT.BMP
ACROREAD.INI
ARP.EXE
ASD.EXE
ASPI2HLP.SYS
ATIPLAY.INI
BACKGRND.GIF
BETAGIDE.DOC

The core of the program is in the `ClientSocket1Read` method, triggered by the socket when there is data to read. The method is first used to get the header indicating which type of data is reaching the program and to set the client program to the proper status:

```
case CliStatus of
  // look for data to receive
  csIdle:
  begin
    Socket.ReceiveBuf (Buffer, 5);
    strIn := Copy (Buffer, 1, 5);
    if strIn = 'TEXT!' then
      CliStatus := csText
    else if strIn = 'BITM!' then
      CliStatus := csBitmap
    // .. and so on
```

Since we don't retrieve all the data, the event is triggered again soon afterward, and this time we are ready to get the actual data. Here are two more branches of the `case` statement:

```
// get a directory listing
csList:
  begin
    ListFiles.Items.Text := Socket.ReceiveText;
    cliStatus := csIdle;
  end;
// read a bitmap file
csBitmap:
  with TFormBmp.Create (Application) do
  begin
    Stream := TMemoryStream.Create;
    Screen.Cursor := crHourglass;
    try
      while True do
      begin
        nReceived := Socket.ReceiveBuf (Buffer, sizeof (Buffer));
        if nReceived <= 0 then
          Break
        else
          Stream.Write (Buffer, nReceived);
        // delay (200 milliseconds)
        Sleep (200);
      end;
      // reset and load the temporary file
      Stream.Position := 0;
      Image1.Picture.Bitmap.LoadFromStream (Stream);
    finally
      Stream.Free;
      Screen.Cursor := crDefault;
    end;
    Show;
    cliStatus := csIdle;
  end;
```

For loading the bitmap, I simply move the data to a `Buffer` (declared as `array [0..9999] of Char`) and then from the buffer to a memory stream, which is later loaded in the Image component of the secondary form. Because the data flow can slow down, the program has a hard-coded delay of 200 milliseconds every time some data is read. Unlike file-reading operations, the loop doesn't stop when the data read is less than the data requested, but only when *no* data is read. (In case of error, the value returned by the `ReceiveBuff` method is –1.)

Sending Database Data over a Socket Connection

Using the techniques we've seen so far, we can write an application that moves database records over a socket. The idea will be to write a front end for data input and a back end for data storage. The client application will have a simple data-entry form and use a database table with string fields for Company, Address, State, Country, Email, and Contact, and a floating-point field for the company ID (called CompID).

NOTE Moving database records over a socket is exactly what you can do with DataSnap and a socket connection component, or with the SOAP support built into Delphi 6 and discussed in Chapter 23, "XML and SOAP."

The client program I've come up with works on a table with this structure saved in the current directory. (You can see the related code in the `OnCreate` event handler.) The core method on the client side is the handler of the `OnClick` event of the Send All button, which sends all the new records to the server. The new records are determined by looking to see whether the record has a valid value for the CompID field. This field, in fact, is not set up by the user but is determined by the server application when the data is sent.

For all new records, the client program packages the field information in a string list, using the structure *FieldName=FieldValue*, obtained using the `Values` property of the string list. The string corresponding to the entire list is then sent to the server. At this point, the program stops in an apparently infinite loop:

```
// save database data in a string list
Data := TStringList.Create;
table1.First;
while not Table1.Eof do
begin
  // if the record is still not logged
  if Table1CompID.IsNull or (Table1CompId.AsInteger = 0) then
  begin
    lbLog.Items.Add ('Sending ' + Table1Company.AsString);
    Data.Clear;
    // create strings with structure "FieldName=Value"
    for I := 0 to Table1.FieldCount - 1 do
      Data.Values [Table1.Fields[I].FieldName] := Table1.Fields [I].AsString;
    // send the record
    ClientSocket1.Socket.SendText (Data.Text);
    // wait for response
    fWaiting := True;
    while fWaiting do
      Application.ProcessMessages;
  end;
  Table1.Next;
end;
```

The program waits forever … or until the handler of another message sets the fWaiting field of the form to False. This happens when the server sends some feedback indicating that the record was received or when the user presses the Stop button. The btnSendAllClick method automatically connects to the server at the beginning and disconnects at the end.

Now let us look at the server. This program has a database table, again stored in the local directory, with two new fields added to the client application's table: LoggedBy, a string field; and LoggedOn, a data field. The values of the two extra fields are determined automatically by the server as it receives data, along with the value of the CompID field. All these operations are done in the ServerSocket1ClientRead method after unpacking the data received by the client:

```
// read from the client
strCommand := Socket.ReceiveText;
// reassemble the data
Data := TStringList.Create;
try
  Data.Text := strCommand;
  // new record
  Table1.Insert;
  // set the fields using the strings
  for I := 0 to Table1.FieldCount - 1 do
    Table1.Fields [I].AsString := Data.Values [Table1.Fields[I].FieldName];
  // complete with random ID, sender, and date
  Table1CompID.AsInteger := GetTickCount;
  Table1LoggedBy.AsString := Socket.RemoteAddress;
  Table1LoggetOn.AsDateTime := Date;
  Table1.Post;
  // get the value to return
  strFeedback := Table1CompID.AsString;
  // send results back
  lbLog.Items.Add (strFeedback);
  Socket.SendText (strFeedback);
finally
  Data.Free;
end;
```

Except for the fact that some data might be lost, there is no problem when fields have a different order and if they do not match, because the data is stored in the *FieldName=FieldValue* structure. After receiving all the data and posting it to the local table, the server sends back the company ID to the client. The client program, after sending the record, goes into *waiting mode*, a situation modified by receiving feedback from the server:

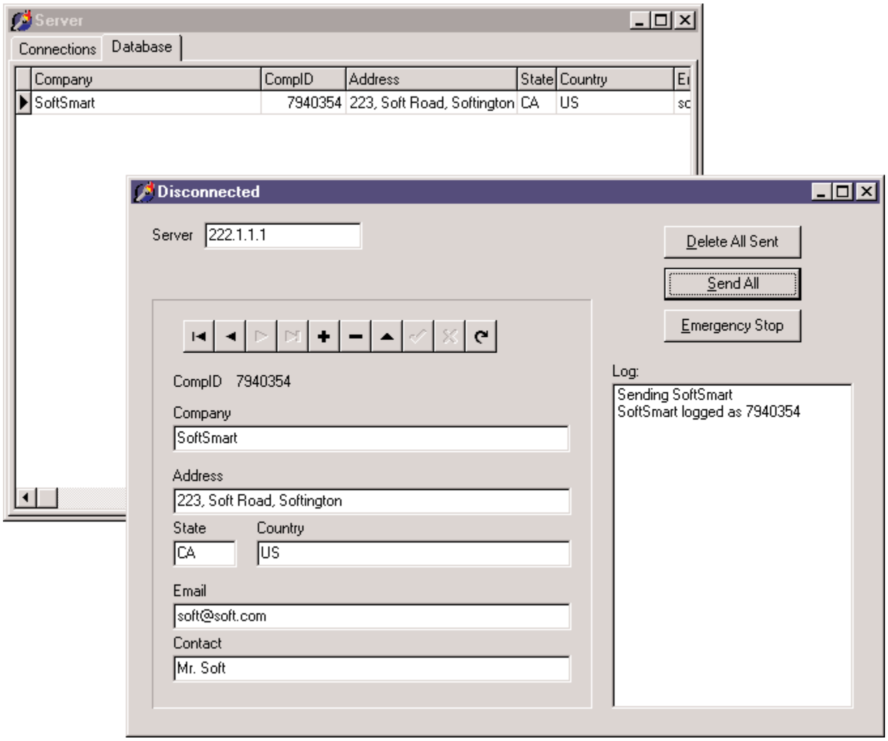
```
procedure TForm1.ClientSocket1Read(Sender: TObject;
  Socket: TCustomWinSocket);
begin
  if fWaiting then
  begin
    Table1.Edit;
  Table1CompId.AsString := Socket.ReceiveText;
  Table1.Post;
  lbLog.Items.Add (Table1Company.AsString + ' logged as ' +
   Table1CompId.AsString);
  fWaiting := False;
 end;
end;
```

When receiving feedback, the client program saves the company ID, which marks the record as sent. If the user modifies the record, there is no way to send an update to the server. To accomplish this, you might add a modified field to the client database table and make the server check to see if it is receiving a new field or a modified field. With a modified field, the server should not add a new record but update the existing one.

This is one of the many additions you can make to the program, to make it usable in a real-world environment. The existing code of the program and the previous examples on sockets should provide all you need to complete a similar task. I've limited myself to this version of the application, as shown in Figure 21.3. Notice that the server program has two pages, one with the usual log and the other with a DBGrid showing the current data of the server database table.

FIGURE 21.3:

The client and server programs of the database socket example (DbSock)



Company	CompID	Address	State	Country	E
SoftSmart	7940354	223, Soft Road, Softington	CA	US	sc

Server 222.1.1.1

CompID 7940354

Company SoftSmart

Address 223, Soft Road, Softington

State CA

Country US

Email soft@soft.com

Contact Mr. Soft

Log:

```
Sending SoftSmart
SoftSmart logged as 7940354
```

Working with Blocking Sockets and Threads

A program like the one I've just built is nice, but it won't really scale up on a large system, because the server uses a blocking connection and the requests are processed in sequence. Now, even if making the database-related code multithreading wouldn't be easy, I'll take the excuse of this example to show you how to build a program based on blocking sockets and threads. (If you don't know much about threads, read the sidebar "Working with Threads" before proceeding.)

Working with Threads

Win32 has an API to allow two procedures or methods execute at the same time. Delphi provides a `TThread` class that will let us create and control threads. The first thing to know about the `TThread` class is that you never use it directly, because it is an abstract class—a class with a virtual abstract method. To use threads, you always subclass `TThread` (optionally starting with the Thread Object of the New Items dialog box (File ➢ New ➢ Other) and use the features of this base class.

The `TThread` class has a constructor with a single parameter (`CreateSuspended`) that lets you choose whether to start the thread immediately or suspend it until later. There are also some public synchronization methods:

```
procedure Resume;
procedure Suspend;
function Terminate: Integer;
function WaitFor: Integer;
```

The published properties include `Priority`, `Suspended`, and two read-only, low-level values: `Handle` and `ThreadID`. The class also provides a protected interface, which includes two key methods for your thread subclasses:

```
procedure Execute; virtual; abstract;
procedure Synchronize(Method: TThreadMethod);
```

The `Execute` method, declared as a virtual abstract procedure, must be redefined by each thread class. It contains the main code of the thread, the code you would typically place in a *thread function* when using the Windows API.

The `Synchronize` method is used to avoid concurrent access to VCL components. The VCL code runs inside the main thread of the program, and you need to synchronize access to VCL to avoid reentry problems (errors from reentering a function before a previous call is completed) and concurrent access to shared resources. The only parameter of `Synchronize` is a method that accepts no parameters, typically a method of the same thread class. As you cannot pass parameters to this method, it is common to save some values within the data of the thread object in the `Execute` method and use those values in the *synchronized* methods.

Continued on next page

Another way to avoid conflicts is to use the synchronization techniques offered by the operating system. The SyncObjs unit defines VCL classes for some of these low-level synchronization objects: events (with the `TEvent` class and the `TSingleEvent` class) and critical sections (with the `TCriticalSection` class).

In the server program (see the SockDbThread example on the companion CD), the socket component now has a thread-blocking type and has handlers for many events, including in particular `OnGetThread`. No methods are hooked to the read and write events, as they won't be triggered anymore (they are used exclusively by message-based nonblocking sockets):

```
object ServerSocket1: TServerSocket
  Active = True
  Port = 51
  ServerType = stThreadBlocking
  OnAccept = ServerSocket1Accept
  OnGetThread = ServerSocket1GetThread
  OnClientConnect = ServerSocket1ClientConnect
  OnClientDisconnect = ServerSocket1ClientDisconnect
end
```

The `OnAccept`, `OnClientConnect`, and `OnClientDisconnect` event handlers are used only for logging information to the screen, while the `OnGetThread` event handler has a key role of creating the server-side thread object:

```
procedure TForm1.ServerSocket1GetThread(Sender: TObject; ClientSocket:
  TServerClientWinSocket; var SocketThread: TServerClientThread);
begin
  lbLog.Items.Add('GetThread: ' + ClientSocket.RemoteHost + ' (' +
    ClientSocket.RemoteAddress + ')' );
  SocketThread := TDbServerThread.Create(False, ClientSocket);
end;
```

This must be an object of a class inherited by the specific `TServerClientThread` class (not the generic Delphi `TThread` class) and with its core code placed in an overridden `ClientExecute` method (not the generic `Execute` method):

```
type
  TDbServerThread = class(TServerClientThread)
  private
    strCommand: string;
    strFeedback: string;
  public
    procedure ClientExecute; override;
    procedure Log;
    procedure LogFeedback;
    procedure AddRecord;
  end;

procedure TDbServerThread.ClientExecute;
var
  Stream: TWinSocketStream;
  Buffer, strIn: string;
  nRead: Integer;
begin
  // keep going
  Stream := TWinSocketStream.Create(ClientSocket, 5000);
  try
    while not Terminated and ClientSocket.Connected do
    begin
      // initialize (thread might be reused)
      Buffer := '';
      strIn := '';
      SetLength(Buffer, 64);
      repeat
        nRead := Stream.Read(Buffer[1], 64);
        if nRead = 0 then
        begin
          ClientSocket.Close;
          Break;
        end;
        SetLength (Buffer, nRead);
        StrIn := StrIn + Buffer;
      until (Pos(#10#13'.'#10#13, Buffer) > 0);

      if strIn = '' then
        Continue // keep going
      else
      begin
        // handle the request, if anything arrived
        StrCommand := Copy (strIn, 1, Pos (#10#13'.'#10#13, strIn) -1);
        Synchronize(Log);
        Synchronize(AddRecord);
        // send results back
        Synchronize(LogFeedback);
        Stream.Write(strFeedback[1], Length (strFeedback));
      end;
    end;
  finally
    Stream.Free;
  end;
end;
```

The server reads data from the client and sends the feedback using a TWinSocketStream, a compulsory approach for blocking servers. The thread is kept active, as it can be reused for subsequent calls, and reads from a buffer until it find a specific separator (in this case, a dot between two line separators, exactly as occurs in the SMTP protocol). When the data is received, the server does a *synchronized* call to the AddRecord method, which is similar to the code of the previous version of the example.

WARNING This approach is far from perfect, as all database accesses are serialized, but you could solve the problem by moving the database access component within the thread and adding a Session object in case of a BDE application. Not all databases like multithreaded access, though, so serializing the calls is not always a bad idea.

This is the multithreaded server application. The client program, instead, uses a standard thread class, derived from TThread. The class creates a client server object internally, so that multiple threads could spawn multiple socket connections in parallel (something the program doesn't really use) and receives a table to work on as parameter in the constructor:

```
type
  TLogEvent = procedure(Sender: TObject; LogMsg: String) of object;

  TSendThread = class(TThread)
  private
    ClientSocket: TClientSocket;
    FTable: TTable;
    FOnLog: TLogEvent;
    FLogMsg: String;
    procedure SetOnLog(const Value: TLogEvent);
  protected
    procedure Execute; override;
    procedure DoLog;
  public
    constructor Create(ATable: TTable);
    property OnLog: TLogEvent read FOnLog write SetOnLog;
  end;
```

On the client side, the finite-state machine logic (send, set the wait flag, receive another event, disable the flag, get the next record) is now replaced by a continual and more logical flow of operations, all part of the Execute method of the thread. You need to add some code to let the program wait until the server sends a reply. Again, the blocking socket of the client is not used directly but via a TWinSocketStream object:

```
procedure TSendThread.Execute;
var
  I: Integer;
  Data: TStringList;
  Stream: TWinSocketStream;
  Buf: String;
begin
  try
    Data := TStringList.Create;
    ClientSocket := TClientSocket.Create (nil);
    Stream := nil;
    try
      ClientSocket.Address := EditServer.Text;
      ClientSocket.ClientType := ctBlocking;
      ClientSocket.Port := 51;
      ClientSocket.Active := True;
      Stream := TWinSocketStream.Create(ClientSocket.Socket, 30000);

      FTable.First;
      while not FTable.Eof do
      begin
        // if the record is still not logged
        if FTable.FieldByName('CompID').IsNull or
          (FTable.FieldByName('CompID').AsInteger = 0) then
        begin
          FLogMsg := 'Sending ' + Table.FieldByName('Company').AsString;
          Synchronize(DoLog);
          Data.Clear;
          // create strings with structure "FieldName=Value"
          for I := 0 to FTable.FieldCount - 1 do
            Data.Values [FTable.Fields[I].FieldName] :=
              FTable.Fields [I].AsString;
          // send the record followed by separator
          Buf := Data.Text + #10#13'.'#10#13;
          ClientSocket.Socket.SendText(Buf);
          // wait for reponse
          if Stream.WaitForData(30000) then
          begin
            FTable.Edit;
            SetLength(Buf, 256);
            SetLength(Buf, Stream.Read(Buf[1], Length(Buf)));
            FTable.FieldByName('CompID').AsString := Buf;
            FTable.Post;
            FLogMsg := FTable.FieldByName('Company').AsString +
              ' logged as ' + FTable.FieldByName('CompID').AsString;
          end
          else
            FlogMsg := 'No response for ' +
              FTable.FieldByName('Company').AsString;
          Synchronize(DoLog);
        end;
        FTable.Next;
      end;
    finally
      ClientSocket.Active := False;
      ClientSocket.Free;
      Stream.Free;
      Data.Free;
    end;
  except
    // trap exceptions
  end;
end;
```

The thread also has an event handler to let the forms using it define the effect of the `OnLog` operation, in the synchronized `DoLog` method. Finally, this is how the thread starts, when the user clicks a button in the form:

```
procedure TForm1.Button2Click(Sender: TObject);
var
  SendThread: TSendThread;
begin
  SendThread := TSendThread.Create(Table1);
  SendThread.OnLog := OnLog;
  SendThread.Resume;
end;
```

Internet Protocols

After discussing the low-level socket components, we are ready to delve into the core topic of this chapter, the use of higher-level Internet protocols.

As already mentioned, Delphi 6 now ships with a collection of open-source Internet components called Internet Direct, or Indy for short. The Indy components, previously called WinShoes (a pun on the term WinSockets), are built by a group of developers led by Chad Hower and are available also in Kylix. You can find more information and possibly updated versions of the actual components at `www.nevrona.com/indy`.

The Indy components are available within the Delphi IDE, but they are not the only set of Internet components. Delphi 6 Component Palette also has another page of Internet protocol components, the FastNet page. These are available for compatibility with Delphi 5 and earlier versions. Third-party solutions, both freely available or for sale, also provide implementations of Internet protocols.

Here and in the next chapter, I'm going to focus exclusively on the Indy components. This chapter focuses on the use of Internet protocols within Windows applications, while the next shows examples of the use of these protocols within Web server applications.

Sending and Receiving Mail

Probably the most common operation you do on the Internet is to send and receive e-mail. There is generally very little need to write a complete application to handle e-mail, as some of the existing programs are actually rather complete. For this reason, I have no intention of writing a general-purpose mail program here. You can find some examples of those among Delphi Internet demos.

Other than creating a general-purpose mail application, what else can one do with the mail components and protocols? There are many possibilities, which I've tried to group in two areas:

Automatic generation of mail messages An application you've written can have an About box for sending a registration message back to your marketing department or a specific menu item for sending a request to your tech support. You might even decide to enable a tech-support connection whenever an exception occurs. Another related task would be automating the dispatching of a message to a list of people or generating an automatic message from your Web site, an example I'll show you toward the end of this chapter.

Use of mail protocols for communication with users who are only occasionally online When you must move data between users who are not always online, you can write an application on a server to synchronize among them, and you can give each user a specialized client application for interacting with the server. An alternative is to use an existing server application, such as a mail server, and write the two specialized programs based on the mail protocols. The data sent over this connection will generally be formatted in special ways, so you'll want to use a specific e-mail addresses for these messages (not your primary e-mail address). As an example, you could rewrite the earlier DbSock example to dispatch mail messages instead of using a custom socket connection. This will give you the advantage of being firewall-friendly and allowing the server to be temporarily offline, as the requests would be kept on the mail server.

Sending Messages with Your Mail Program

The simplest technique for automating the generation of an e-mail message is to use your existing mail application, adding a message to its outbox. Using the `ShellExecute` API function, you can easily send a message to the default mail program registered on the computer.

To test this technique, I've prepared a simple form with two edit boxes and a memo for the input. Pressing a button creates a string with all the information about the message and then sends it, simply executing the string with the *mailto:* prefix. Here is the code of the Send button of the MailGen example from the companion CD:

```
uses
  ShellApi;

procedure TForm1.BtnSendClick(Sender: TObject);
var
  strMsg: string;
  I: Integer;
begin
  // set the basic information
  strMsg := 'mailto:' + EditAddress.Text + '?Subject=' + EditSubject.Text +
    '&Body=';
  // add first line
  if Memo1.Lines.Count > 0 then
    strMsg := strMsg + Memo1.Lines [0];
  // add subsequent lines separated by the newline symbol
  for I := 1 to Memo1.Lines.Count - 1 do
    strMsg := strMsg + '%0D%0A' + Memo1.Lines [I];
  // send the message
  ShellExecute (Handle, 'open', pChar (strMsg), '', '', SW_SHOW);
end;
```

To show the body of the message on multiple lines, you can separate each line with the carriage return and line feed characters (usually indicated in Delphi as #13 and #10). These values should be explicitly added to the string in hexadecimal format and prefixed by the % sign, as required by a URL. You can actually obtain this encoding automatically by using the NMURL component.

NOTE You can also send mail with the `TSendMail` predefined action, which is based on the MAPI standard.

Mail In and Out

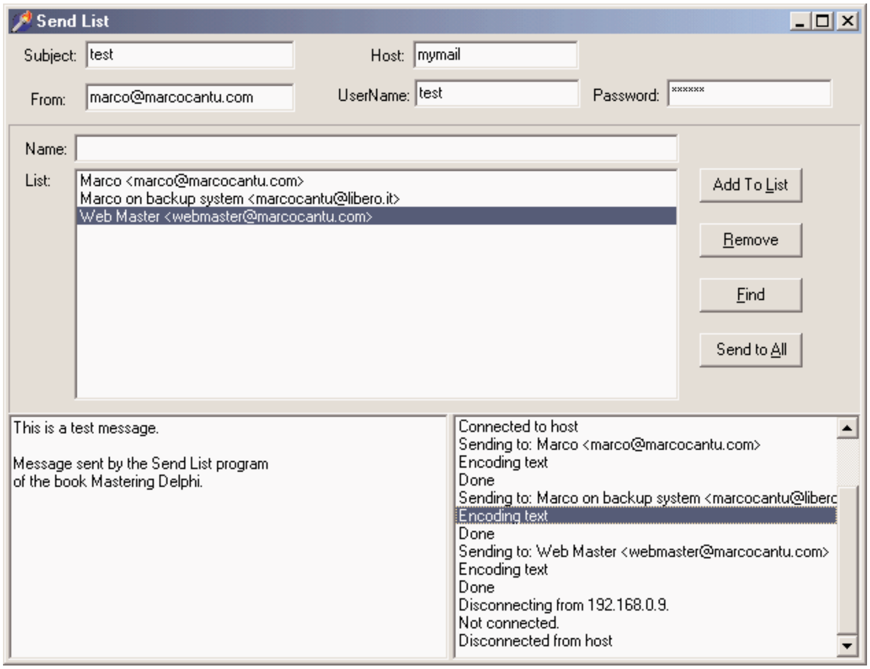
To showcase the development of simple e-mail management programs, I could build an example of how you can send and receive mail. The Indy components, though, include a rather complete set of examples, and I don't see any reason to duplicate those, as using the mail protocols means placing a message component (IdMessage) in your application, filling it with data, and then using the IdSMTP component to send the mail message. To *retrieve* a mail message from your mailbox, use the IdPop3 component, which will return you an IdMessage object.

Just to give you an idea of how this works, I've written a program for sending mail to multiple people at once, using a list stored in an ASCII file. I originally used this program myself for sending mail to people who sign up on my Web site, but later I extended the program by adding database support and reading subscriber logs automatically. The original version of the program is still a good introduction to the use of the SMTP component of Indy.

The SendList program keeps a list of names and e-mail addresses in a local file, which is displayed in a list box. A few buttons allow you to add and remove items, or modify them by removing the item, editing it, and then adding the item again. When the program closes, the updated list is automatically saved. Now let's get to the interesting portion of the program. The top-most panel, shown in Figure 21.4, allows you to enter the subject, the sender address, and the information used to connect to the mail server (hostname, username, and eventually a password).

FIGURE 21.4:

The SendList program in action



Subject: test
From: marco@marcocantu.com
Host: mymail
UserName: test
Password: ******
Name:
List:
Marco <marco@marcocantu.com>
Marco on backup system <marcocantu@libero.it>
Web Master <webmaster@marcocantu.com>

This is a test message.

Message sent by the Send List program
of the book Mastering Delphi.

```
Connected to host
Sending to: Marco <marco@marcocantu.com>
Encoding text

Sending to: Web Master <webmaster@marcocantu.com>
Encoding text
Done
Disconnecting from 192.168.0.9.
Not connected.
Disconnected from host
```

You'll probably want to make the value of these edit boxes persistent, possibly in an INI file. I haven't done this, only because I don't really want you to see my mail connection details! The value of these edit boxes, along with the list of addressee, allows you to send the series of mail messages, after customizing each of them, with the following code:

```
procedure TMainForm.BtnSendAllClick(Sender: TObject);
var
  nItem: Integer;
  Res: Word;
begin
  Res := MessageDlg ('Start sending from item ' +
    IntToStr (ListAddr.ItemIndex) + ' (' +
    ListAddr.Items [ListAddr.ItemIndex] + ')?'#13 +
    '(No starts from 0)', mtConfirmation, [mbYes, mbNo, mbCancel], 0);
  if Res = mrCancel then
    Exit;
  if Res = mrYes then
    nItem := ListAddr.ItemIndex
  else
    nItem := 0;
  // connect
  Mail.Host := eServer.Text;
  Mail.UserID := eUserName.Text;
  if ePassword.Text <> '' then
  begin
    Mail.Password := ePassword.Text;
    Mail.AuthenticationType := atLogin;
  end;
  Mail.Connect;
  // send the messages, one by one, prepending a custom message
  try
    // set the fixed part of the header
    MailMessage.From.Name := eFrom.Text;
    MailMessage.Subject := eSubject.Text;
    MailMessage.Body.SetText (reMessageText.Lines.GetText);
    MailMessage.Body.Insert (0, 'Hello');
    while nItem < ListAddr.Items.Count do
    begin
      // show the current selection
      Application.ProcessMessages;
      ListAddr.ItemIndex := nItem;
      MailMessage.Body [0] := 'Hello ' + ListAddr.Items [nItem];
      MailMessage.Recipients.EMailAddresses := ListAddr.Items [nItem];
      Mail.Send(MailMessage);
      Inc (nItem);
    end;
  finally // we're done
    Mail.Disconnect;
  end;
end;
```

Another interesting example of the use of the mail is to notify developers of problems within applications, something you might want to use more in an internal application than in one you'll distribute widely. You can obtain this effect by modifying the ErrorLog example of Chapter 4, "The Run-Time Library," and sending mail when an exception (or one of a given type only) occurs.

Working with HTTP

Handling mail messages is certainly interesting, and mail protocols are probably still the most widespread Internet protocols. The other popular protocol is HTTP, the one used by Web servers and Web browsers. This is the protocol to which we'll devote the rest of this chapter and all of the following.

On the client side of the Web, the main activity is browsing—reading HTML files. Besides building a custom browser, you can embed the Internet Express ActiveX control within your program (as I've done in WebDemo example in Chapter 20, "From Automation to COM+"). You can also directly activate the browser installed on the computer of the user, for example, opening an HTML page by calling the `ShellExecute` method (defined in the ShellApi unit):

```
ShellExecute (Handle, 'open', FileName, '', '', sw_ShowNormal);
```

Using `ShellExecute`, we can simply execute a document, such as a file. Windows will start the program associated with the HTM extension, using the action passed as the parameter (in this case, *open*). You can use a similar call to view a Web site, by using a string like '*http://www.example.com*' instead of a filename. In this case, the system recognizes the *http* section of the request as requiring a Web browser and launches it.

On the server side, you generate and make available the HTML pages. At times, it may be enough to have a way to produce static pages, occasionally extracting new data from a database table to update the HTML files as needed. In other cases, you'll need to generate pages dynamically based on a request from a user.

As a starting point, I'll discuss HTTP by building a simple but complete client and server, then we'll move on to discussing HTML producer components and introducing the Web server extension technologies (CGI and ISAPI). In the next chapter, we'll move from this "core technology" level to the RAD development style for the Web supported by Delphi 6, discussing the WebBroker and WebSnap architectures.

Grabbing HTTP Content

As an example of the use of the HTTP protocols, I've decided to write a very specific search application. The program simply hooks onto the Google Web site, searches for a keyword, and retrieves the first hundred sites found. Instead of showing the resulting HTML file, the program parses it to extract only the URLs of the related sites to a list box. The description of these sites is kept in a separate string list and is displayed as you click a list-box item. So the program demonstrates two techniques at once: retrieving a Web page and parsing its HTML code.

To demonstrate how you should work with blocking connections, such as those used by Indy, I've implemented the program using a background thread for the actual processing. (See the sidebar "Working with Threads," earlier in this chapter, for a very short introduction to this topic.) This approach also gives the advantage of being able to start multiple searches at once. The thread class used by the WebFind application receives as input a URL to look for, `strUrl`.

The class has two output procedures, `AddToList` and `ShowStatus`, to be called inside the `Synchronize` method. The code of these two methods sends some results or some feedback to the main form, respectively adding a line to the listbox and changing the status bar `SimpleText` property. The key method of the thread is the `Execute` method. Before we look at it, however, let me show you how the thread is activated by the main form:

```
const
  strSearch = 'http://www.google.com/search?as_q=';

procedure TForm1.BtnFindClick(Sender: TObject);
var
  FindThread: TFindWebThread;
begin
  // create suspended, set initial values, and start
  FindThread := TFindWebThread.Create (True);
  FindThread.FreeOnTerminate := True;
  // grab the first 100 entries
  FindThread.strUrl := strSearch + EditSearch.Text +'&num=100';
  FindThread.Resume;
end;
```

The URL string is made of the main address of the search engine, followed by some parameters. The first, `as_q`, indicates the words you are looking for. The second, `num=100`, indicates the number of sites to retrieve; you cannot use numbers at will but are limited to few alternatives, with 100 being the largest possible value.

WARNING The WebFind program works with the server on the Google Web site at the time this book was written and tested. The custom software on the site can change any day, however, which might prevent WebFind from operating correctly.

The Execute method of the thread, activated by the Resume call, simply calls the two methods actually doing the work and shown in Listing 21.1. In the first, GrabHtml, the program connects to the HTTP server using a dynamically created IdHttp component, and reads the HTML with the result of the search. The second method, HtmlToList, extracts the URLs referring to other Web sites from the result, the strRead string.

Listing 21.1: The *TFindWebThread* class (of the WebFind program)

```
unit FindTh;

interface

uses
  Classes, IdComponent, SysUtils, IdHTTP;

type
  TFindWebThread = class(TThread)
  protected
    Addr, Text, Status: string;
    procedure Execute; override;
    procedure AddToList;
    procedure ShowStatus;
    procedure GrabHtml;
    procedure HtmlToList;
    procedure HttpWork (Sender: TObject; AWorkMode: TWorkMode;
      const AWorkCount: Integer);
  public
    strUrl: string;
    strRead: string;
  end;

implementation

{ TFindWebThread }

uses
  WebFindF;

procedure TFindWebThread.AddToList;
begin
  if Form1.ListBox1.Items.IndexOf (Addr) < 0 then
  begin
    Form1.ListBox1.Items.Add (Addr);
    Form1.DetailsList.Add (Text);
  end;
end;

procedure TFindWebThread.Execute;
begin
```

```
  GrabHtml;
  HtmlToList;
  Status := 'Done with ' + StrUrl;

  Status := 'Received ' + IntToStr (AWorkCount) + ' for ' + strUrl;
  Synchronize (ShowStatus);
end;

procedure TFindWebThread.ShowStatus;
begin
  Form1.StatusBar1.SimpleText := Status;
end;

end.
```

The program looks for subsequent occurrences of the `href="http` substring, copying the text up to the closing > character. If the found string contains the word *google*, or its target text includes the word *cached*, it is omitted from the result. You can see the effect of this code in the output of Figure 21.5. Notice that I've already gotten the result of a request, but the program is currently retrieving another page, as indicated in the status bar. You can start multiple searches at the same time, but be aware that the results will all be added to the same memo component.

The WinInet API

When you need to use the FTP and HTTP protocols, as alternatives to using particular VCL components, you can use a specific API provided by Microsoft in the WinInet DLL. This library is part of the core operating system and implements the FTP and HTTP protocols on top of the Windows sockets API.

With just three calls—`InternetOpen`, `InternetOpenURL`, and `InternetReadFile`—you can retrieve a file corresponding to any URL and store a local copy or analyze it. Other simple methods can be used for FTP; I suggest you look for the source code of the Delphi unit, listing all the functions, and for the specific Help file for the DLL, which is not part of the SDK Help shipping with Delphi.

The `InternetOpen` function establishes a generic connection and returns a handle you can use in the `InternetOpenURL` call. This second call returns a handle to the URL that you can pass to the `InternetReadFile` function in order to read blocks of data. In the following sample code, the data is stored in a local string. When all the data has been read, the program closes the connection to the URL and the Internet session by calling the `InternetCloseHandle` function twice.

```
var
  hHttpSession, hReqUrl: HInternet;
  Buffer: array [0..1023] of Char;
  nRead: Cardinal;
  strRead: string;
  nBegin, nEnd: Integer;
begin
  strRead := '';
  hHttpSession := InternetOpen ('FindWeb', INTERNET_OPEN_TYPE_PRECONFIG,
    nil, nil, 0);
  try
    hReqUrl := InternetOpenURL (hHttpSession, PChar(StrUrl), nil, 0,0,0);
    try // read all the data
      repeat
        InternetReadFile (hReqUrl, @Buffer, sizeof (Buffer), nRead);
        strRead := strRead + string (Buffer);
      until nRead = 0;
    finally
      InternetCloseHandle (hReqUrl);
    end;
  finally
    InternetCloseHandle (hHttpSession);
  end;
end;
```

Browsing on Your Own

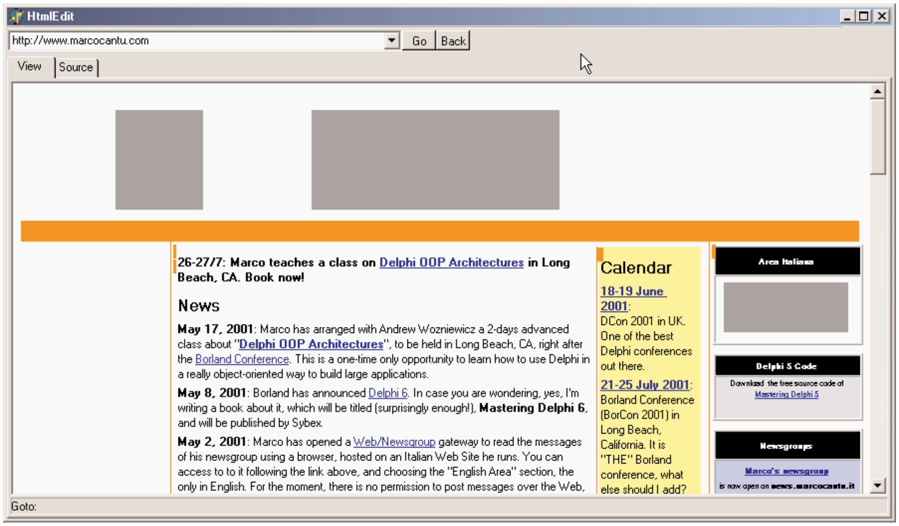
Although I doubt you are interested in writing a new Web browser, it might be interesting anyway to see how you can grab an HTML file from the Internet and display it locally, using the HTML viewer available in CLX (the TextBrowser control). Connecting this control to an Indy HTTP client, you can come up with a simplistic text-only browser with limited navigation in minutes. The core is to write

```
TextBrowser1.Text := IdHttp1.Get (NewUrl);
```

where NewUrl is complete location of the Web resource you want to access to. In the BrowseFast example on the CD-ROM, this URL is entered in a combo box, which keeps track of recent requests. The effect of a similar call is to return the textual portion of a Web page (see Figure 21.6), as grabbing the graphic content requires much more complex coding. The TextBrowser control, in fact, is better defined as a local file viewer than as a browser.

FIGURE 21.6:

The output of the BrowseFast text-only browser



26-27/7: Marco teaches a class on Delphi OOP Architectures in Long Beach, CA. Book now!

News

May 17, 2001: Marco has arranged with Andrew Wozniewicz a 2-days advanced class about "**Delphi OOP Architectures**", to be held in Long Beach, CA, right after the Borland Conference. This is a one-time only opportunity to learn how to use Delphi in a really object-oriented way to build large applications.

May 8, 2001: Borland has announced Delphi 6. In case you are wondering, yes, I'm writing a book about it, which will be titled (surprisingly enough!), **Mastering Delphi 6**, and will be published by Sybex.

May 2, 2001: Marco has opened a Web/Newsgroup gateway to read the messages of his newsgroup using a browser, hosted on an Italian Web Site he runs. You can access to to it following the link above, and choosing the "English Area" section, the only in English. For the moment, there is no permission to post messages over the Web,

Calendar

18-19 June 2001: DCon 2001 in UK. One of the best Delphi conferences out there.

21-25 July 2001: Borland Conference (BorCon 2001) in Long Beach, California. It is "THE" Borland conference, what else should I add?

Area Italiana

Delphi 5 Code

Download the free source code of Mastering Delphi 5

Newsgroups

Marco's newsgroup

is now open on **news.marcocantu.it**

In any case, I've added to the program only very limited support for hyperlinks. When a user moves the mouse over a link, its link text is copied to a local variable (NewRequest), which is then used in case of a click on the control to compute the new HTTP request to forward. Merging the current address (LastUrl) with the request, though, is far from trivial, even with the help of the IdUrl class provided by Indy. Here is the code I've come up with, which handles only the simplest cases:

```
procedure TForm1.TextBrowser1Click(Sender: TObject);
var
  Uri: TIdUri;
```

```
begin
  if NewRequest <> '' then
  begin
    Uri := TIdUri.Create (LastUrl);
    if Pos ('http:', NewRequest) > 0 then
      GoToUrl (NewRequest)
    else if NewRequest [1] = '/' then
      GoToUrl ('http://' + Uri.Host + NewRequest)
    else
      GoToUrl ('http://' + Uri.Host + Uri.Path + NewRequest);
  end;
end;
```

Again, this example is really trivial and is far from usable, but building a browser involves a *little* more than the ability to connect via HTTP and display HTML files.

A Simple HTTP Server

The situation with the development of an HTTP server is quite different. Building a server to deliver static pages based on HTML files is far from simple, although one of the Indy demos provides a rather good starting point for this. A custom HTTP server, instead, might be interesting when building a totally dynamic site, something I'll focus on in more detail in the next chapter.

To show you how you can start the development of a custom HTTP server, I've built the HttpServ example. This program has a form with a list box used for logging requests and an IdHTTPServer component, with these settings:

```
object IdHTTPServer1: TIdHTTPServer
  Active = True
  DefaultPort = 8080
  OnCommandGet = IdHTTPServer1CommandGet
end
```

The server uses the port 8080 instead of the standard port 80, so that you can run it alongside another Web server. All of the custom code is in the `OnCommandGet` event handler, which simply returns a fixed page plus some information about the request itself:

```
procedure TForm1.IdHTTPServer1CommandGet(AThread: TIdPeerThread;
  RequestInfo: TIdHTTPRequestInfo; ResponseInfo: TIdHTTPResponseInfo);
var
  HtmlResult: String;
begin
  // log
  Listbox1.Items.Add (RequestInfo.Document);
  // respond
  HtmlResult := '<h1>HttpServ Demo</h1>' +
      '<p>This is the only page you''ll get from this example.</p><hr>' +
      '<p>Request: ' + RequestInfo.Document + '</p>' +
      '<p>Host: ' + RequestInfo.Host + '</p>' +
      '<p>Params: ' + RequestInfo.UnparsedParams + '</p>' +
      '<p>The headers of the request follow: <br>' +
      RequestInfo.Headers.Text + '</p>';
    ResponseInfo.ContentText := HtmlResult;
  end;
```

By passing a path and some parameters in the command line of the browser, you'll see them reinterpreted and displayed. For example, Figure 21.7 shows the effect of the command line:

```
http://localhost:8080/test?user=marco
```

FIGURE 21.7:

The page displayed by connecting a browser to the custom HttpServ program

HttpServ Demo

This is the only page you'll get from this example

Request: /test

Host: localhost:8080

Params: user=marco

The headers of the request follow:
Accept: image/gif, image/x-xbitmap, image/jpeg, image/pjpeg, application/vnd.ms-excel, application/msword, application/vnd.ms-powerpoint, */* Accept-Language: en-us Accept-Encoding: gzip, deflate User-Agent: Mozilla/4.0 (compatible; MSIE 5.01; Windows NT 5.0; DigExt) Host: localhost:8080 Connection: Keep-Alive

If this example seems too trivial, you'll see a slightly more interesting version in the next section, as I discuss the generation of HTML with Delphi's producer components.

NOTE If you plan building an advanced Web server or other Internet servers with Delphi, then as an alternative to the Indy components, have a look at the DXSock components from Brain Patchwork DX (`www.dxsock.com`).

Generating HTML

The Hypertext Markup Language, better known by its acronym HTML, is the most widespread format for content on the Web. HTML is the format Web browsers typically read; it is a standard defined by the W3C, the World Wide Web Consortium, which is one of the bodies controlling the Internet. The current standard is represented by HTML 4, although not all browsers fully support that. When building a Web site, you always need to choose a lowest-common-denominator approach to support most of the browsers in use—that is, unless you are targeting a specific group of users whom you ask to adopt a specific browser (as happens in intranet situations). If you don't know much about the tags included in HTML files, you may want to read the sidebar "The Format of HTML Files" for a fast introduction.

The Format of HTML Files

If you have a little familiarity with HTML but don't work with it often enough to have all the basic elements "down cold," here's a quick summary.

HTML files are basically ASCII text files. Besides plain text, an HTML file contains many tags, which might determine the style of the font, the type of paragraph, or a link to another HTML file or an image, among other things.

Most tags are paired as opening tags and closing tags (the closing tag is usually the same as the opening tag but is preceded by a slash, /) to indicate where the style or content begins and ends. For example, you write `<b>important</b>` to set the word *important* in bold, and you write `<title>Document Title</title>` to define the title of a document as *Document Title*. (A few elements, such as `<br>` for a line break and `<img>` for a graphic or "image," stand alone and do not use a matching closing tag.)

An HTML document begins with the `<html>` tag and is divided into two parts, marked as `<head>` and `<body>`. Each of these three tags requires the corresponding terminator. In the head portion of the HTML file, you'll generally write the title (often displayed in the title bar of the browser) and a few other generic elements.

In the body, you write the contents of the file, generally starting with its visible title. You can use headings with different levels, marked with the `<hX>` tag, where you'd replace *X* with a number from 1 to 6. These are followed by plain paragraphs (`<p>`), preformatted paragraphs (`<pre>`, a style generally used for program listings), various types of lists, and many other elements. The text will often have links to other pages or other parts of the current page, using the `<a>` ("anchor") tag.

Another relevant element of HTML is tables. The `<table>` and `</table>` tags indicate the beginning and the end of the table, and its optional `border` attribute displays borders with a given width. The `<tr>` and `</tr>` tags introduce and close each row, and the tags

Continued on next page

`<th>…</th>` and `<td>…</td>` indicate a table header cell and a table data cell, respectively. The number of columns depends on the items in each row. Different rows, in fact, can have different numbers of items.

HTML was recently refined by the W3C to be more consistent, flexible, and interoperable with advanced systems such as XML; the new version is named XHTML (Extensible HTML). HTML and XHTML are the subject of many books, and you can find dozens of tutorials on them just by browsing the Web. A good, complete source on the topic is *Mastering XHTML* by Tittel et al. (Sybex, 2001).

Delphi's HTML Producer Components

If your version of Delphi includes the HTML producer components (available on the Internet page of the Component Palette), you can use them to generate the HTML files and particularly to turn a database table into an HTML table. Many developers believe that the use of these components makes sense only when writing a Web server extension. Although they were introduced for this purpose and are part of the WebBroker technology, you can still use three out of the four producer components in any application in which you must generate a static HTML file.

Before looking at the HtmlProd example, which demonstrates the use of these HTML producer components, let me summarize their role:

- The simplest of the HTML producer components is the PageProducer, which manipulates an HTML file in which you've embedded special tags. The advantage of this approach is that you can generate such a file using the HTML editor you prefer. At run time, the PageProducer converts the special tags to actual HTML code, giving you a straightforward method for modifying sections of an HTML document. The special tags have the basic format `<#tagname>`, but you can also supply named parameters within the tag. You'll process the tags in the `OnTag` event handler of the PageProducer.
- The DataSetPageProducer extends the PageProducer by automatically replacing tags corresponding to field names of a connected data source.
- The DataSetTableProducer component is generally useful for displaying the contents of a table, query, or other dataset. The idea is to produce an HTML table from a dataset, in a simple yet flexible way. The component has a very nice preview, so you can see how the HTML output will look in a browser directly at design time.
- The QueryTableProducer is similar to the previous one (it is actually a subclass), but it's specifically tailored for building parametric queries based on input from an HTML

search form. For this reason, I'll delay the coverage of this component to the next chapter.

Producing HTML Pages

A very simple example of using tags is creating an HTML file that displays fields with the current date or a date computed relative to the current date, such as an expiration date. If you examine the HtmlProd example, you'll find the following component in the main form:

```
object PageProducer1: TPageProducer
  HTMLDoc.Strings = (...)
  OnHTMLTag = PageProducer1HTMLTag
end
```

The source HTML can be specified using an external file (with the advantage that you can edit it without having to recompile the application using it) or a string list, stored in the `HTMLDoc` property. This is a plain HTML file that might contain a few special tags introduced by the # symbol:

```
<html>
<head>
<title>Producer Demo</title>
</head>
<body>
<h1>Producer Demo</h1>
<p>This is a demo of the page produced by the <b><#appname></b> application on
<b><#date></b>.</p>
<hr>
<p>The prices in this catalog are valid until <b><#expiration
days=21></b>.</p>
</body>
</html>
```

WARNING If you prepare this file with an HTML editor (something I suggest you do), it might automatically place quotes around tag parameters, as in `days="21"`, because this is required by HTML 4 and XHTML 1. The PageProducer component has a `StripParamQuotes` property, which can be activated to remove those extra quotes when the component parses the code (before calling the `OnHTMLTag` event handler).

The Demo Page button simply copies the PageProducer component's output to the `Text` of a Memo with the statement

```
Memo1.Text := PageProducer1.Content;
```

As you call the `Content` function of the PageProducer component, it reads the input HTML code, parses it, and triggers the `OnTag` event handler for every special tag. In this method, we check the value of the tag (passed in the `TagString` parameter) and return a different HTML text (in the `ReplaceText` reference parameter), producing the output of Figure 21.8.

My Computer

Producer Demo

This is a demo of the page produced by the **HTMLPROD.EXE** application on **8/3/99**.

The prices in this catalog are valid until **8/24/99**.

FIGURE 21.8: The output of the HtmlProd example, a simple demonstration of the PageProducer component, when the user clicks the Demo Page button

```
procedure TFormProd.PageProducer1HTMLTag(Sender: TObject;
  Tag: TTag; const TagString: String; TagParams: TStrings;
  var ReplaceText: String);
var
  nDays: Integer;
begin
  if TagString = 'date' then
    ReplaceText := DateToStr (Now)
  else if TagString = 'appname' then
    ReplaceText := ExtractFilename (Forms.Application.Exename)
  else if TagString = 'expiration' then
  begin
    nDays := StrToIntDef (TagParams.Values['days'], 0);
    if nDays <> 0 then
      ReplaceText := DateToStr (Now + nDays)
    else
      ReplaceText := '<i>{expiration tag error}</i>';
  end;
end;
```

Notice, in particular, the code we've written to convert the last tag, `#expiration`, which requires a parameter. The PageProducer places the entire text of the tag parameter (in this case, *days=21*) in a string that's part of the `TagParams` list. To extract the value portion of this string (the portion after the equal sign), you can use the `Values` property of the `TagParams` string list and search for the proper entry at the same time. If it can't locate the parameter or if its value isn't an integer, the DLL displays an error message.

TIP The PageProducer component supports user-defined tags, which can be any string you like, but you should first review the special tags defined by the `TTags` enumeration. The possible values include tgLink (for the `link` tag), tgImage (for the `img` tag), tgTable (for the `table` tag), and a few others. If you create a custom tag, as in the PageProd example, the value of the `Tag` parameter to the HTMLTag handler will be tgCustom.

Producing Pages of Data

The HtmlProd example also has a DataSetPageProducer component, with the following settings and HTML source code:

```
object DataSetPageProducer1: TDataSetPageProducer
  HTMLDoc.Strings = (
    '<html><head>'
    '<title>Data for <#name></title>'
    '</head><body>'
    '<h1><center>Data for <#name></center></h1>'
    '<p>Capital: <#capital></p>'
    '<p>Continent: <#continent></p>'
    '<p>Area: <#area></p>'
    '<p>Population: <#population></p>'
    '<hr>'
    '<p>Last updated on <#date><br>'
    'HTML file produced by the program <#program>.</p>'
    '</body></html>')
  OnHTMLTag = DataSetPageProducer1HTMLTag
  DataSet = Table1
end
```

Simply by using tags with the names of the fields of the connected dataset (the usual COUNTRY.DB database table), the program automatically gets the value of the fields of the current record and replaces it automatically. This produces the output of Figure 21.9, which shows a browser connected to the HtmlProd example working as an HTTP server, as I'll discuss later. In the source code of the program related to this component, in fact, there is no reference to the database data:

```
procedure TFormProd.BtnLineClick(Sender: TObject);
begin
  Memo1.Clear;
  Memo1.Text := DataSetPageProducer1.Content;
  BtnSave.Enabled := True;
end;

procedure TFormProd.DataSetPageProducer1HTMLTag(Sender: TObject; Tag: TTag;
  const TagString: String; TagParams: TStrings; var ReplaceText: String);
```

```
begin
  if TagString = 'program' then
    ReplaceText := ExtractFilename (Forms.Application.Exename)
  else if TagString = 'date' then
    ReplaceText := DateToStr (Date);
end;
```

Producing HTML Tables

The last button of the HtmlProd example is Print Table. This button is connected to a DataSetTableProducer component, again calling its `Content` function and copying its result to the `Text` of the Memo. By simply connecting the `DataSet` property of the DataSetTableProducer to `Table1`, you can produce a standard HTML table. Actually, the component by default generates only 20 rows, as indicated by the `MaxRows` property. If you want to get all the records of the table, you can set this property to `-1`, a simple but undocumented setting.

TIP The DataSetTableProducer component starts from the current record rather than from the first one. This means that the second time you press the Print Table button, you'll see no records in the output. Adding a call to the `First` method of the table before calling the `Content` method of the producer component fixes the problem.

To make the output of this producer component more complete, you can do two different operations. The first is to provide some `Header` and `Footer` information, to generate the HTML heading and closing elements, and add a `Caption` to the HTML table. The second is to customize the table itself, by using the setting specified by the `RowAttributes`, `TableAttributes`, and `Columns` properties. The property editor of the columns, which is also the default component editor, allows you to set most of these properties, providing at the same time a very nice preview of the output, as you can see in Figure 21.10. Before using this editor, you can set up properties for fields of the table, using the Fields editor. This is how, for example, you can format the output of the population and area fields to use thousands separators.

FIGURE 21.10:

The editor of the `Columns` property of the DataSetTableProducer component provides you with a preview of the final HTML table (if the database table is active).

DataSetTableProducer Demo

American Countries

Country	Capital	Continent	Area	Population
Argentina	Buenos Aires	South America	2,777,815	32,300,003
Bolivia	La Paz	South America	1,098,575	7,300,000
Brazil	Brasilia	South America	8,511,196	150,400,000

There are three techniques you can use to customize the HTML table, and it's worth reviewing each of them:

- You can use the table producer component's `Column` property to set properties, such as the text and color of the title, or the color and the alignment for the cells in the rest of the column.
- You can use the `TField` properties, particularly those related to output. In the example, I've set the `DisplayFormat` property of the `Table1Continent` field object to `###,###,###`. This is the approach to use if you want to determine the actual output of each field. You might go even further and embed HTML tags in the output of a field.
- You can handle the DataSetTableProducer component's `OnFormatCell` event to customize the output further. In this event, you can set the various column attributes

uniquely for a given cell, but you can also customize the output string (stored in the CellData parameter) and embed HTML tags. This is something you can't do using the Columns property.

In the HtmlProd example, I've used a handler for this event to turn the text of the Population and Area columns to bold font and to a red background for large values (unless it is the header row). Here is the code:

```
procedure TFormProd.DataSetTableProducer1FormatCell(
  Sender: TObject; CellRow, CellColumn: Integer;
  var BgColor: THTMLBgColor; var Align: THTMLAlign;
  var VAlign: THTMLVAlign; var CustomAttrs, CellData: String);
begin
  if (CellRow > 0) and
    (((CellColumn = 3) and (Length (CellData) > 8)) or
    ((CellColumn = 4) and (Length (CellData) > 9))) then
  begin
    BgColor := 'red';
    CellData := '<b>' + CellData + '</b>';
  end;
end;
```

The rest of the code is summarized by the settings of the table producer component (formatted slightly to make it more readable and take less space):

```
object DataSetTableProducer1: TDataSetTableProducer
  Caption = '<h2>American Countries</h2>'
  Columns = <
    item FieldName = 'Name'
      BgColor = 'silver'
      Title.Align = haLeft
      Title.BgColor = 'silver'
      Title.Caption = 'Country'
    end
    item FieldName = 'Capital'...
    item FieldName = 'Continent'...
    item FieldName = 'Area'
      Align = haRight
    end
    item FieldName = 'Population'
      Align = haRight
    end>
  Footer.Strings = ('<hr><i>Produced by HtmlProd</i></body></html>')
  Header.Strings = (<html><head><title>DataSetTableProducer Demo</title>'
    '</head><body><h1><center>DataSetTableProducer Demo</center></h1>')
  MaxRows = -1
  DataSet = Table1
```

```
    TableAttributes.Border = 1
    TableAttributes.CellPadding = 5
    OnFormatCell = DataSetTableProducer1FormatCell
  end
```

You can see the output of this program in Figure 21.11. I suggest you study the source code of the HTML file this program generates so that you can see the richness of its output and therefore the advantage of using this component.

Canada	Ottawa	North America	9,976,147	26,500,000
Chile	Santiago	South America	756,943	13,200,000

FIGURE 21.11: The output of the Print All button of the HtmlProd example, which is based on the DataSetTableProducer component

Using Style Sheets

The latest incarnations of HTML include a very powerful mechanism for separating content from presentation: Cascading Style Sheets (CSS). Using a style sheet, you can separate the formatting of the HTML (colors, fonts, font sizes, and so on) from the actual text displayed (the content of the page). This approach makes your code more flexible and your Web site easier to update. In addition, you can separate the task of making the site graphically appealing (the work of a Web designer) from automatic content generation (the work of a programmer). Style sheets are a rather complex technique, in which you give formatting values to the main types of HTML sections and to special “classes” (which have nothing to do with OOP). Again, see an HTML reference for the details.

How can we update table generation in the HtmlProd example to include style sheets? Simply enough, we can provide a link to the style sheet to use in the Header property of a second DataSetTableProducer component, with the line

```
<link rel="stylesheet" type="text/css" href="test.css">
```

We can then update the code of the OnFormatCell event handler with the following action (instead of the two lines changing the color and adding the bold font tag):

```
CustomAttrs := 'class="highlight"';
```

The style sheet I've provided (test.css, available in the source code of the example) defines a *highlight* style, which has exactly the bold font and red background that were hard-coded in the first DataSetTableProducer component.

The advantage of this approach is that now a graphic artist can modify the CSS file and give our table a nicer look without touching its code. When you want to provide many formatting elements, using a style sheet can also reduce the total size of the HTML file. This is an important element that can reduce download time.

Dynamic Pages from a Custom Server

The HtmlProd component can be used to generate static HTML files, but doubles as a Web server, using an approach similar to what I've demonstrated in the HttpServ example, but in a more realistic context. The program, in fact, accesses the request of one of the possible page producers, simply passing the name of the component in a request. This is a portion of the OnCommandGet event handler of its IdHTTPServer component, which uses the FindComponent method to locate the proper producer component:

```
var
  Req, Html: String;
  Comp: TComponent;
begin
  Req := RequestInfo.Document;
  if Req [1] = '/' then
    Req := Copy (Req, 2, 1000); // skip '/'
  Comp := FindComponent (Req);
  if (Req <> '') and Assigned (Comp) and
    (Comp is TCustomContentProducer) then
  begin
    Table1.First;
    Html := TCustomContentProducer (Comp).Content;
  end;
  ResponseInfo.ContentText := Html;
end;
```

In case the parameter is not there (or is not valid), the server responds with an HTML-based menu of the available components:

```
Html := '<h1>Html Proc Menu<h1><p><ul>';
for I := 0 to ComponentCount - 1 do
  if Components [i] is TCustomContentProducer then
    Html := Html + '<li><a href="/' + Components [i].Name + '">' +
      Components [i].Name + '</a></li>';
Html := Html + '</ul></p>';
```

Finally, if the program returns a table that uses CSS, the browser will request the CSS file from the server, so I've added some specific code to return it. With the proper generalizations, this code shows how a server can respond, returning files, and also how to indicate the MIME type of the response (ContentType):

```
if Pos ('test.css', Req) > 0 then
begin
  CssTest := TStringList.Create;
  try
    CssTest.LoadFromFile(ExtractFilePath(Application.ExeName) + 'test.css');
    ResponseInfo.ContentText := CssTest.Text;
    ResponseInfo.ContentType := 'text/css';
  finally
    CssTest.Free;
  end;
  Exit;
end;
```

Publishing Static Databases on the Web

Once you know how to produce files, you can simply add links from one to another and produce a series of cross-linked HTML files, representing a portion of a Web site. There are circumstances in which writing a program that examines a database and produces files is the best approach for publishing database data on a Web site. You can use a similar technique if the following conditions apply:

If the data doesn't change very often A catalogue updated monthly or weekly is a good example. Even if you can update the site automatically every night, this is still a possible technique. (For real-time information, of course, this is certainly not a good approach!)

If the amount of data is limited and available space not is an issue This seems obvious, but the formatted HTML output might take much more space than the original database files. If you use a server-side program (such as those I'll be discussing in the next chapter) to generate the HTML from the database data on the fly, you might need less disk space on the Web site. Keep in mind that preparing all the HTML files beforehand usually results in much better performance (faster server response time to Web requests, and lower memory overhead to process the requests) than generating the data on the fly.

If the number of ways to navigate is limited If there are three or four obvious paths of navigation (a main one and two or three cross-references), you can generate all of them statically. Otherwise, the cross-referencing HTML files will be much larger than the files with the actual data, and the time required to generate them may become excessive.

Even if only parts of these conditions apply to your specific needs, you can consider using a mixed approach. You can have a portion of the data and of the navigational files generated periodically and have a CGI and ISAPI application on the site, as well as let users do free searches and follow other less frequent paths.

NOTE On the companion CD you can find an example, called DbCross, that generates hundreds of HTML files out of a master/detail database structure. The program also collects other data about the records, while generating the files, and produces a complete cross-reference. At the end, you can navigate by customers–orders by each customer–details of the order or by sale parts–orders where each part appears–details of each order. The code is quite complex, but I've tried to comment it in some detail, so you should be able to follow it.

What's Next?

In this chapter, we've focused on some core Internet technologies, including the use of sockets and core Internet protocols. I've discussed the main idea and shown a few examples of the use of the mail and HTTP protocols. You can find many more examples of the use of the Indy components in the demos done by their developers.

After this introduction to the world of the Internet, we are now ready to delve into two key areas, the present and the future. The present is represented by the development of Web applications, and we'll explore the development of dynamic Web sites in the next chapter, focusing first on the *old* WebBroker technology and then moving to the new WebSnap architecture. The future is represented by the development of Web services and the use of XML and related technology, which will be discussed in Chapter 23.

CHAPTER 22

Web Programming with WebBroker and WebSnap

- Dynamic Web pages
- CGI, ISAPI, and Apache modules
- The WebBroker architecture
- The Web App debugger
- The new WebSnap architecture
- Adapters and server-side scripting

If the Internet has a growing role in the world, a good part of it depends on the success of the World Wide Web, based on the HTTP protocol. We've already discussed, in the preceding chapter, HTTP and the development of client- and server-side applications based on it. With the availability of several high-performance, scalable, and flexible Web servers, you'll rarely want to create your own. Dynamic Web server applications, in fact, are generally built by integrating scripting or compiled programs within Web servers, rather then replacing them with custom software.

This chapter is entirely focused on the development of server-side applications, which extend existing Web servers. We have already introduced the dynamic generation of HTML pages toward the end of the last chapter. Now we have to see how to integrate this dynamic generation within a server. This chapter is a logical continuation of the last one but won't complete the coverage of Internet programming, as the next chapter is further devoted to this topic, covering specifically XML and Web services.

WARNING To test some of the examples in this chapter, you'll need access to a Web server. The simplest solution is probably to use the version of Microsoft's IIS or Personal Web Server already installed on your computer. My personal preference, however, is to use the free and open-source Apache Web Server, available (along with extensive documentation) at `www.apache.org`. In any case, I won't spend much time giving you details on the configuration of your Web server to enable the use of applications; refer to its documentation for this.

Dynamic Web Pages

When you browse a Web site, you generally download static pages—HTML-format text files—from the Web server to your client computer. As a Web developer, you can create these pages manually, but for most businesses, it makes more sense to build the static pages from information in a database of some type (a SQL server, a series of files, and so on). Using this approach, you're basically generating a snapshot of the data in HTML format, which is quite reasonable if the data isn't subject to frequent changes. This approach was discussed in Chapter 21, "Internet Programming: Sockets and Indy Components."

As an alternative to static HTML pages, you can build dynamic ones. To do this, you extract information directly from a database in response to the browser's request, so that the HTML sent by your application displays current data, not an old snapshot of the data. This approach makes sense if the data changes frequently.

As mentioned earlier, there are a couple of ways you can program custom behavior at the Web server, and these are ideal ways for you to generate HTML pages dynamically. The two most common protocols for programming Web servers are CGI (the Common Gateway Interface) and the Web server APIs. Another technique, Active Server Pages (ASP), is quite popular in the Microsoft world, and I'll discuss it briefly because Delphi includes specific support for it.

NOTE Keep in mind that Delphi's WebBroker technology (available in both the Enterprise and Professional editions) flattens the differences between CGI, WinCGI, and ISAPI by providing a common class framework. This way, you can easily turn a CGI application into a WinCGI one, upgrade it to use the ISAPI model, or integrate it into Apache.

An Overview of CGI

CGI is a standard protocol for communication between the client browser and the Web server. It's not a particularly efficient protocol, but it is widely used and is not platform specific. This protocol allows the browser both to ask for and to send data, and it is based on the standard command-line input and output of an application (usually a console application). When the server detects a page request for the CGI application, it launches the application, passes command-line data from the page request to the application, and then sends the standard output of the application back to the client computer.

There are many tools and languages you can use to write CGI applications, and Delphi is only one of them. Given the obvious limitation that your Web server must be an Intel-based Windows or Linux system, you can build some fairly sophisticated CGI programs in Delphi and Kylix. Despite the fact that it's called a standard, there are actually different flavors of CGI. Traditional CGI uses the standard command-line input and output, along with environment variables. WinCGI uses an INI file passed as a command-line parameter to the application (instead of environment variables) and specific input and output files (instead of using command-line input/output). Server vendors developed WinCGI primarily for Visual Basic programmers, who cannot access environment variables. Another new variation, called FastCGI, is supposed to make the entire process of calling a CGI application much faster, but it's not widely supported yet.

To build a CGI program without using any support class, you can simply create a Delphi console application, remove the typical project source code, and replace it with the following statements:

```
program CgiDate;
{$APPTYPE CONSOLE}

uses SysUtils;

begin
```

```
  writeln ('content-type: text/html');
  writeln;
  writeln ('<html><head>');
  writeln ('<title>Time at this site</title>');
  writeln ('</head><body>');
  writeln ('<h1>Time at this site</h1>');
  writeln ('<hr>');
  writeln ('<h3>');
  writeln (FormatDateTime('"Today is " dddd, mmmm d, yyyy,' +
    '"<br> and the time is" hh:mm:ss AM/PM', Now));
  writeln ('</h3>');
  writeln ('<hr>');
  writeln ('<i>Page generated by CgiDate.exe</i>');
  writeln ('</body></html>');
end.
```

CGI programs produce a header followed by the HTML text using the standard output. If you execute this program directly, you'll see the text in a terminal window. If you run it instead from a Web server and send the output to a browser, the formatted HTML text will appear, as shown in Figure 22.1.

Page generated by CgiDate.exe

Building advanced and complex applications with plain CGI requires a lot of work. For example, to extract status information on the HTTP request, you need to access to the relevant environment variables, as in:

```
// get the pathname
GetEnvironmentVariable ('PATH_INFO', PathName, sizeof (PathName));
```

An Overview of ISAPI/NSAPI

A completely different approach is the use of the Web server APIs, the popular ISAPI (Internet Server API, introduced by Microsoft) and the less common NSAPI (Netscape Server API). These APIs allow you to write a DLL that the server loads into its own address space and usually keeps in memory for some time. Once it loads the DLL, the server can execute individual requests via threads within the main process, instead of launching a new EXE for every request (as it must in CGI applications).

When the server receives a page request, it loads the DLL (if it hasn't done so already) and executes the appropriate code, which may launch a new thread or use an existing one to process the page request (the IIS Web server offers thread pooling support to avoid creating a new thread for each request). The DLL code then sends the appropriate data back to the client that requested the page. Because this communication generally occurs in memory, this type of application is much faster than CGI, and a given system will be able to support more simultaneous page requests this way.

The main drawback to server API DLLs is that their tight integration with the server is an Achilles' heel; if the DLL crashes or produces memory leaks, the entire Web server can crash. However, the most recent releases of Microsoft's IIS Web server fix the problem by running the DLL in a *protected* space. Another problem is that when the DLL is in memory, you cannot compile an updated version; you need to unload the DLL first or momentarily stop the Web server (an operation you can do only on a test-bed computer).

Technically, ISAPI DLLs are not very different from plain Windows DLLs. They must export a couple of specific functions that the Web server will call: `GetExtensionVersion` and `HttpExtensionProc`. The server calls the first function when it loads the DLL for the first time and the second function for every following request. The parameters of these functions are complex data structures holding input data and server methods you can call to produce the result. Here is a sample of this function (taken from the IsapiDem example), which uses the `lpszPathInfo` field and the `WriteClient` function:

```
function HttpExtensionProc(var ECB: TEXTENSION_CONTROL_BLOCK): DWORD; stdcall;
var
  OutStr: string;
  StrLength: Cardinal;
begin
  with ECB do
  begin
    OutStr :=
      '<html><head><title>First Isapi Demo</title></head><body>' +
      '<h2><center>First Isapi Demo</center></h2>' +
      '<p>Hello Mastering Delphi Readers...</p><hr>' +
      '<p><b>Activated by ' + PChar(@lpszPathInfo[1]) + '</b></p>' +
      '<p><i>From IsapiDLL on ' + DateToStr(Now) + ' at ' + TimeToStr(Now) +
      '</i></p></body></html>';
    StrLength := Length(OutStr);
    WriteClient(ConnID, PChar (OutStr), StrLength, 0);
  end;
  Result := HSE_STATUS_SUCCESS;
end;
```

The program doesn't simply use the `lpszPathInfo` parameter but uses the substring starting with the second character, to get rid of the initial slash. To be more precise, the expression `PChar(@lpszPathInfo[1])` takes the string starting at the memory address of the second character of the path (a zero-based characters array).

Apache Modules

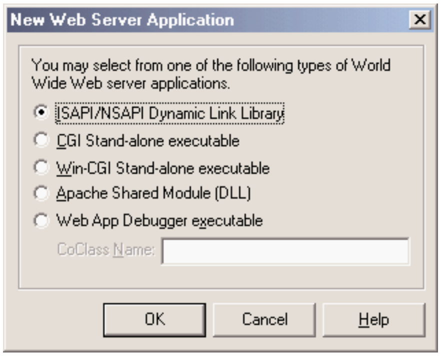
Similarly to Microsoft's IIS, the Apache server of the Apache Foundation (`www.apache.org`) allows server-side extensions by means of CGI or with specific extension libraries. In case of Apache, these libraries are called *modules*, or dynamic modules. In the Apache configuration, you can list the modules you are interested in and eventually connect them to a virtual directory.

Needless to say, you can program Apache modules in a similar low-level way to what I've just done for ISAPI, but I won't show you an example. I'll do it later using the Apache support added to the WebBroker architecture in Delphi 6.

Delphi's WebBroker Technology

The CGI and ISAPI code snippets I've shown you so far demonstrate the plain, direct approach to the protocol and API. Extending these examples at that level is certainly possible, but what is interesting in Delphi is to use the WebBroker technology. This comprises a class hierarchy within VCL and CLX, built to simplify server-side development on the Web, and a specific type of data modules, called WebModules. Both the Enterprise and Professional editions of Delphi 5 include this framework (differently from the more advanced and newer WebSnap framework, which is available only in the Enterprise version of Delphi 6).

Using the WebBroker technology, you can begin developing an ISAPI or CGI application or an Apache module very easily. On the first page (*New*) of the New Items dialog box, select the Web Server Application icon. The subsequent dialog box will offer you options (two more than in Delphi 5). As you can see in Figure 22.2, you can choose ISAPI, CGI, WinCGI, Apache module, and the Web App Debugger.



New Web Server Application

You may select from one of the following types of World Wide Web server applications.

● ISAPI/NSAPI Dynamic Link Library
○ CGI Stand-alone executable
○ Win-CGI Stand-alone executable
○ Apache Shared Module (DLL)
○ Web App Debugger executable

CoClass Name:

FIGURE 22.2:

The alternative options for building a Web server application in Delphi

TIP As a starting point for your server-side application, you can also use the DB Web Application Wizard, available in the Business page of the New Items dialog box. This wizard generates a program with a BDE table or query connected to a DataSetTableProducer. It can be helpful, but the generated code is really very limited and there is no support for Apache and the Web App Debugger.

For example, if you select the first option, Delphi will generate the basic structure of an ISAPI application for you. The application that Delphi generates (no matter which type you choose) is based on the `TWebModule` class, a container very similar to a data module. The WebModule code is similar to that of a data module, as we'll see in a moment, but the code of the library is worth looking at:

```
library Project1;

uses
  WebBroker,
  ISAPIThreadPool,
  ISAPIApp,
  Unit1 in 'Unit1.pas' {WebModule1: TWebModule};

{$R *.RES}

exports
  GetExtensionVersion,
  HttpExtensionProc,
  TerminateExtension;

begin
  Application.Initialize;
  Application.CreateForm(TWebModule1, WebModule1);
  Application.Run;
end.
```

WARNING This code changes slightly between Delphi versions. If you have older code around, you'll need to refer to the WebBroker unit instead of the previous HTTPApp unit. Delphi 6 adds the reference to the ISAPIThreadPool unit, which provides support for pooling threads under ISAPI (with a couple of classes not documented in the Help file).

Although this is a library that exports the ISAPI functions, the code looks similar to that of an application. However, it uses a trick—the `Application` object used by this program is not the typical global object of class `TApplication` but an object of a new class. This new `Application` object is of class `TISAPIApplication` (or `TCGIApplication` if you've built that type of application), which derives from `TWebApplication`.

Although these application classes provide the foundations, you won't use them very often (just as you don't use the `Application` object very often in a form-based Delphi application). The most important operations take place in the WebModule. This component derives from `TCustomWebDispatcher`, which provides support for all the input and output of our programs.

In fact, the `TCustomWebDispatcher` class defines `Request` and `Response` properties, which store the client request and the response we're going to send back to the client. Each of these properties is defined using a base abstract class (`TWebRequest` and `TWebResponse`), but an application initializes them using a specific object (such as the `TISAPIRequest` and `TISAPIResponse` subclasses). These classes make available all the information passed to the server, so you have a single, simple approach to accessing all the information. The same is true of a response, which is very easy to manipulate. One advantage to this approach is that an ISAPI DLL written with this framework is very similar to a CGI application; in fact, they are frequently identical in the source code you write.

If this is the structure of Delphi's framework, how do you write the application code? Well, in the WebModule, you can use the Actions editor (shown in Figure 22.3) to define a series of actions (stored in the `Actions` array property) depending on the *pathname* of the request. This pathname is a portion of the CGI or ISAPI application's URL, which comes after the program name and before the parameters, such as `path1` in the following URL:

```
http://www.example.com/scripts/cgitest.exe/path1?param1=date
```

By providing different actions, your application can easily respond to requests with different pathnames, and you can assign a different producer component or call a different `OnAction` event handler for every possible pathname. Of course, you can omit the pathname to handle a generic request. Consider also that, instead of basing your application on a WebModule, you can use a plain data module and add a WebDispatcher component to it. This is a good approach if you want to turn an existing Delphi application into a Web server extension.

FIGURE 22.3: The Actions property editor of the WebModule, along with the properties of one of the actions in the Object Inspector

WARNING The WebModule incorporates the WebDispatcher and doesn't require it as a separate component. Unlike WebSnap applications, in fact, WebBroker programs cannot have multiple dispatchers or multiple Web modules. Notice also that the actions of the WebDispatcher have absolutely nothing to do with the actions stored in a `TActionList` component.

When you define the accompanying HTML pages that launch the application, the links will make page requests to the URLs for each of those paths. Having one single ISAPI DLL that can perform different operations depending on a parameter (in this case, the pathname) allows the server to keep a copy of this DLL in memory and respond much faster to user requests. The same is partially true for a CGI application: The server has to run several instances but can cache the file and make it available faster.

The `OnAction` event is where you put the code to specify the *response* to a given *request*, the two main parameters passed to the event handler. Here is a simple example:

```
procedure TWebModule1.WebModule1WebActionItem1Action(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
begin
  Response.Content :=
    '<html><head><title>Hello Page</title></head><body>' +
    '<h1>Hello</h1>' +
    '<hr><p><i>Page generated by Marco</i></p></body></html>';
end;
```

The `Content` property of the `Response` parameter is where you enter the HTML code that you want users to see. The only drawback of this code is that the output in a browser will be correctly displayed on multiple lines, but looking at the HTML source code, you'll see a single line corresponding with the entire string. To make the HTML source code more readable, by splitting it up onto multiple lines, you can insert the `#13` newline character.

To let other actions handle this request, you'll set the last parameter, `Handled`, to False. Otherwise, the default value is True, and once you've handled the request with your action, the WebModule assumes you're finished. Most of an ISAPI application's code will be in the `OnAction` event handlers for the actions defined in the WebModule container. These actions receive a request from the client and return a response using the `Request` and `Response` parameters.

When using the producer components, your `OnAction` event often returns, as `Response.Content`, the `Content` of the producer component, with a simple assignment. You can shortcut this code by assigning a producer component to the `Producer` property of the action itself, with no need to write these simple event handlers anymore (but don't do both things, as that might get you into trouble).

TIP As an alternative to the `Producer` property, you can use the `ProducerContent` property introduced in Delphi 6. This new property allows you to connect custom producer classes that don't inherit from the `TCustomContentProducer` class but implement the `IProduceContent` interface. The `ProducerContent` property is *almost* an interface property: It behaves in the same way, but thanks to its property editor and not based on the new support for interfaced properties of Delphi 6.

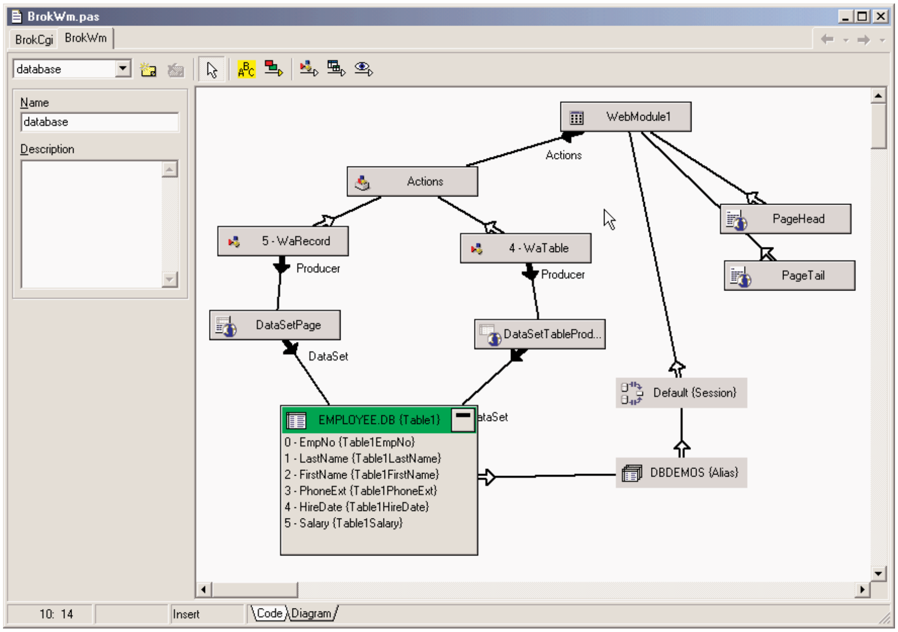
Building a Multipurpose WebModule

To demonstrate how easily you can build a feature-rich server-side application using Delphi's support, I've created the BrokDemo example. This example can be compiled as a CGI or an ISAPI application, simply by choosing the proper project file. The WebModule is shared by the two projects, without any difference in the source code, a practical proof that, using the WebBroker framework, you can move from ISAPI to CGI, from Apache to the Web App Debugger (although this last step requires a little extra tweaking in the source code). In the past, I tended to test programs with CGI (to avoid having to stop the server to free the library and recompile it) and then deploy them with ISAPI. Now I tend to test with the Web App Debugger and then deploy under Apache.

A key element is the list of actions we're going to support with this application. The actions can be managed in the Actions editor or directly in the Object TreeView, as we've already seen in Figure 22.3. Actions are also visible in the Designer page of the editor, so you can graphically see their relationship with database objects, as shown for the BrokDemo in Figure 22.4. If you examine the figure or the source code, you'll notice that I've given a specific name to every action. I've also given meaningful names to the `OnAction` event handlers. For instance, `TimeAction` as a method name should be much more understandable than the `WebModule1WebActionItem1Action` name automatically generated by Delphi.

FIGURE 22.4:

The structure of the BrokDemo example, as shown by the Designer



Every action has a different pathname, with one of them marked as default and executed even if no pathname is specified. The first interesting idea in this program is the use of two PageProducer components, used for the initial and final portion of every page, `PageHead` and `PageTail`. Centralizing this code makes it easier to modify it, particularly if it is based on external HTML files. The HTML produced by these components is added at the beginning and the end of the resulting HTML in the `OnAfterDispatch` event handler of the Web module:

```
procedure TWebModule1.WebModule1AfterDispatch(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
begin
  Response.Content := PageHead.Content + Response.Content + PageTail.Content;
end;
```

I'm adding the initial and final HTML at the end of the page generation simply because this allows the components to produce the HTML as if they were making all of it. Starting with some HTML in the `OnBeforeDispatch` event means that you cannot directly assign the producer components to the actions, or the producer component will override the `Content` you've already provided in the response. The `PageTail` component includes a custom tag for the script name, replaced by the following code, which uses the current request object available within the Web module:

```
procedure TWebModule1.PageTailHTMLTag(Sender: TObject; Tag: TTag;
  const TagString: String; TagParams: TStrings; var ReplaceText: String);
begin
  if TagString = 'script' then
    ReplaceText := Request.ScriptName;
end;
```

This code is activated to expand the <#script> tag of the PageTail component's HTMLDoc property. The code of the time and date actions is straightforward. The really interesting part begins with the Menu path, which is the default action. In its OnAction event handler, the application uses a for loop to build a list of the available actions (using their names without the first two letters, which are always Wa in my example), providing a link to each of them with an anchor (an <a> tag):

```
procedure TWebModule1.MenuAction(Sender: TObject; Request: TWebRequest;
  Response: TWebResponse; var Handled: Boolean);
var
  I: Integer;
begin
  Response.Content := '<h3>Menu</h3><ul>'#13;
  for I := 0 to Actions.Count - 1 do
    Response.Content := Response.Content + '<li> <a href="' +
      Request.ScriptName + Action[I].PathInfo + '"> ' +
      Copy (Action[I].Name, 3, 1000) + '</a>'#13;
  Response.Content := Response.Content + '</ul>';
end;
```

Another action of the BrokDemo example provides users with a list of the system settings related to the request, something that is quite useful for debugging. It is also instructive to learn how much information, and exactly what information, the HTTP protocol transfers from a browser to a Web server and vice versa. To produce this list, the program looks for the value of each property of the TWebRequest class, as this initial snippet demonstrates:

```
procedure TWebModule1.StatusAction(Sender: TObject; Request: TWebRequest;
  Response: TWebResponse; var Handled: Boolean);
var
  I: Integer;
begin
  Response.Content := '<h3>Status</h3>'#13 +
    'Method: ' + Request.Method + '<br>'#13 +
    'ProtocolVersion: ' + Request.ProtocolVersion + '<br>'#13 +
    'URL: ' + Request.URL + '<br>'#13 +
    'Query: ' + Request.Query + '<br>'#13 + ...
```

Dynamic Database Reporting

The BrokDemo example defines two more actions, indicated by the /table and /record pathnames. For these two last actions, our program produces a main list of names and then displays the details of one record, using a DataSetTableProducer component to format the entire table and a DataSetPageProducer component to build the record view. Here are the properties of these two components:

```
object DataSetTableProducer1: TDataSetTableProducer
  DataSet = Table1
  OnFormatCell = DataSetTableProducer1FormatCell
end
object DataSetPage: TDataSetPageProducer
  HTMLDoc.Strings = (
    '<h3>Employee: <#LastName></h3>'
    '<ul><li> Employee ID: <#EmpNo>'
    '<li> Name: <#FirstName> <#LastName>'
    '<li> Phone: <#PhoneExt>'
    '<li> Hired On: <#HireDate>'
    '<li> Salary: <#Salary></ul>')
  OnHTMLTag = PageTailHTMLTag
  DataSet = Table1
end
```

To produce the entire table, we simply connect the DataSetTableProducer to the Producer property of the corresponding actions, without providing any specific event handler. The table is made more powerful by adding internal links to the specific records. The following code is executed for each cell of the table but activated only for the first column or the first row (the one with the title):

```
procedure TWebModule1.DataSetTableProducer1FormatCell(Sender: TObject;
  CellRow, CellColumn: Integer; var BgColor: THTMLBgColor;
  var Align: THTMLAlign; var VAlign: THTMLVAlign;
  var CustomAttrs, CellData: String);
begin
  if (CellColumn = 0) and (CellRow <> 0) then
    CellData := '<a href="' + ScriptName + '/record?LastName=' +
      Table1['LastName'] + '&FirstName=' + Table1 ['FirstName'] + '"> ' +
      CellData + ' </a>';
end;
```

You can see the result of this action in Figure 22.5. When the user selects one of the links, the program is called again, and it can check the QueryFields string list and extract the parameters from the URL. It then uses the values corresponding to the table fields used for the record search (which is based on the FindNearest call).

FIGURE 22.5: The output corresponding to the *table* path of the BrokDemo example, which produces an HTML table with internal hyperlinks.

```
procedure TWebModule1.RecordAction(Sender: TObject; Request: TWebRequest;
  Response: TWebResponse; var Handled: Boolean);
begin
  Table1.Open;
  // go to the requested record
  Table1.FindNearest ([Request.QueryFields.Values['LastName'],
    Request.QueryFields.Values['FirstName']]);
  // get the output
  Response.Content := Response.Content + DataSetPage.Content;
end;
```

NOTE The example we've just built accesses a Paradox table via the BDE. The CGI version executes once for every request and will actually load and unload the BDE each time it runs. As alternatives, you can consider three different approaches: using ISAPI instead of CGI (to keep the application and the BDE loaded in memory), accessing the data from a plain file (or avoid the BDE with some other data access technology), or running another BDE application on the server (so that the BDE will remain loaded in memory). When using the BDE in an ISAPI application, though, you need to add a Session component to avoid concurrent access by multiple threads to the same BDE session.

Of Queries and Forms

The previous example used some of the HTML producer components introduced earlier in this chapter. There is another component of this group we haven't used yet, the QueryTableProducer. As we'll see in a moment, this component makes building even complex database programs a breeze. Suppose you want to search for some customers in a database. You might construct the following HTML form (embedded in an HTML table for better formatting):

```
<h4>Customer QueryProducer Search Form</h4>
<form action="/scripts/CustQueP.dll/search" method="POST">
<table>
<tr><td>State:</td>
  <td><input type="text" name="State"></td></tr>
<tr><td>Country:</td>
  <td><input type="text" name="Country"></td></tr>
<tr><td></td>
  <td><center><input type="Submit"></center></td></tr>
</table></form>
```

NOTE

As in Delphi, an HTML form hosts a series of controls (typically, things like input fields). There are visual tools to help you design these forms, or you can manually enter the proper HTML code. The available controls include buttons, input text (or edit boxes), selections (or combo boxes), and radio buttons (or input buttons). You can define buttons as specific types, such as Submit or Reset, which imply standard behaviors. An important element of forms is the *request method,* which can be either POST (data is passed behind the scenes, and you receive it in the `ContentFields` property) or GET (data is passed as part of the URL, and you extract it from the `QueryFields` property).

There is a very important element to notice in the form: the names of the input components (*State* and *Country*), which should match the parameters of a Query component:

```
select
  Company, State, Country
from
  CUSTOMER.DB
where
  State = :State or Country = :Country
```

This code is used in the CustQueP (customer query producer) example. To build it, I've placed a Query component inside the WebModule and generated the field objects for it. In the same WebModule, I've added a QueryTableProducer component connected to the `Producer` property of the `/search` action. The program will generate the proper response. How does this work? When we activate the QueryTableProducer component by calling its `Content` function, it initializes the Query component by obtaining the parameters from the HTTP request. The component can automatically examine the request method and then use either the `QueryFields` property (if the request is a GET) or the `ContentFields` property (if the request is a POST).

One problem with using a static HTML form as we did before is that it doesn't tell us which states and countries we can search for. To address this, we can use a selection control instead of an edit control in the HTML form. However, if the user adds new records to the database table, we'll need to update the element list automatically. As a final solution, we can design the ISAPI DLL to produce a form on-the-fly, and we can fill the selection controls with the available elements.

We'll generate the HTML for this page in the /form action, which we've connected to a PageProducer component. The PageProducer contains the following HTML text, which embeds two special tags:

```
<h4>Customer QueryProducer Search Form</h4>
<form action="CustQueP.dll/search" method="POST">
<table>
<tr><td>State:</td>
  <td><select name="State"><#State></select></td></tr>
<tr><td>Country:</td>
  <td><select name="Country"><option> </option><#Country></select></td></tr>
<tr><td></td>
  <td><center><input type="Submit"></center></td></tr>
</table></form>
```

You'll notice that the tags have the same name as some of the table's fields. When the PageProducer encounters one of these tags, it adds an <option> HTML tag for every distinct value of the corresponding field. Here's the OnTag event handler's code, which is quite generic and reusable:

```
procedure TWebModule1.PageProducer1HTMLTag(Sender: TObject; Tag: TTag;
  const TagString: String; TagParams: TStrings; var ReplaceText: String);
begin
  ReplaceText := '';
  Query2.SQL.Clear;
  Query2.SQL.Add ('select distinct ' + TagString + ' from customer');
  try
    Query2.Open;
    try
      Query2.First;
      while not Query2.EOF do
      begin
        ReplaceText := ReplaceText +
          '<option>' + Query2.Fields[0].AsString + '</option>'#13;
        Query2.Next;
      end;
    finally
      Query2.Close;
    end;
  except
    ReplaceText := '{wrong field: ' + TagString + '}';
  end;
end;
```

This method used a second Query component, which I manually placed on the form and connected to the DBDEMOS database, and it produces the output shown in Figure 22.6.

FIGURE 22.6:

The form action of the CustQueP example produces an HTML form with a selection component dynamically updated to reflect the current status of the database.

Country:

Bahamas
Belize
Bermuda
British West Indies
Canada
Columbia
Cyprus
Fiji
Greece
Republic So. Africa

Finally, this Web server extension, like many others we've built, allows the user to view the details of a specific record. As in the last example, we can accomplish this by customizing the output of the first column (column zero), which is generated by the QueryTableProducer component:

```
procedure TWebModule1.QueryTableProducer1FormatCell(
  Sender: TObject; CellRow, CellColumn: Integer;
  var BgColor: THTMLBgColor; var Align: THTMLAlign;
  var VAlign: THTMLVAlign; var CustomAttrs, CellData: String);
begin
  if (CellColumn = 0) and (CellRow <> 0) then
    CellData := '<a href="' + Request.ScriptName + '/record?' + CellData +
      '">' + CellData + '</a>'#13;
  if CellData = '' then
    CellData := '&nbsp;';
end;
```

TIP

When you have an empty cell in an HTML table, most browsers render it without the border. For this reason, I've added a "nonbreaking space" symbol (`&nbsp;`) into each empty cell. This is something you'll have to do in each HTML table generated with Delphi's table producers.

The action for this link is /record, and we'll pass a specific element after the ? parameter (without the parameter name, which is slightly nonstandard). The code we use to produce the HTML tables for the records doesn't use the producer components as we've been doing; instead, it is very similar to the code of an early ISAPI example:

```
procedure TWebModule1.RecordAction(Sender: TObject; Request: TWebRequest;
  Response: TWebResponse; var Handled: Boolean);
var
  I: Integer;
begin
  if Request.QueryFields.Count = 0 then
    Response.Content := 'Record not found'
  else
  begin
    Query2.SQL.Clear;
    Query2.SQL.Add ('select * from customer ' +
      'where Company="' + Request.QueryFields[0] + '"');
    Query2.Open;
    Response.Content :=
      '<html><head><title>Customer Record</title></head><body>'#13 +
      '<h1>Customer Record: ' + Request.QueryFields[0] + '</h1>'#13 +
      '<table border>'#13;
    for I := 1 to Query2.FieldCount - 1 do
      Response.Content := Response.Content +
        '<tr><td>' + Query2.Fields [I].FieldName + '</td>'#13'<td>' +
        Query2.Fields [I].AsString + '</td></tr>'#13;
    Response.Content := Response.Content + '</table><hr>'#13 +
      // pointer to the query form
      '<a href="' + Request.ScriptName + '/form">' +
      ' Next Query </a>'#13 + '</body></html>'#13;
  end;
end;
```

Debugging with the Web App Debugger

Debugging Web applications written in Delphi is often quite difficult. In fact, you cannot simply run the program and set breakpoints in it, but should convince the Web server to run your CGI program or library within the Delphi debugger. This can be accomplished by indicating a Host application in Delphi's Run Parameters dialog box, but it implies letting Delphi run the Web server (which is often a Windows service, not a stand-alone program).

To solve all of these issues, Borland has added to Delphi 6 a specific Web App Debugger program. This tool, activated by the corresponding item of the Tools menu, is a Web server, which waits for requests on a port you can set up (1024 by default). When a request arrives, the program can forward it to a stand-alone executable, using COM-based techniques. This means you can run the Web server application from within the Delphi IDE, set all the breakpoints you need, and then (when the program is activated through the Web App Debugger) debug the program as you'll do for a plain executable file.

The Web App Debugger does also a good job in logging all the received requests and the actual responses returned to the browser, as you can see in Figure 22.7. The program also has a Statistics page, which interestingly tracks the time required for each response, allowing you to test the efficiency of an application in different conditions.

```

☐ Translate Post ☐ Wrap Text

By using the corresponding option of the New Web Server Application dialog, you can easily create a new application compatible with the debugger. This defines a standard project, which creates both a main form and a data module. The (useless) form includes code for registering the application as an OLE automation server, as:

```
const
  CLASS_ComWebApp: TGUID = '{33A4D4F0-E082-4723-9165-5D8F95AF1577}';

initialization
  TWebAppAutoObjectFactory.Create(Class_ComWebApp, 'FirstDemo',
    'FirstDemo Object');
```

The information is used by the Web App Debugger to get a list of the available programs. This is done when you use the default URL for the debugger, indicated in the form as a link, as you can see (for example) in Figure 22.8. The list includes all of the registered servers, not only those running. In fact, the use of COM Automation accounts for the automatic activation of a server. Not that this is a good idea, though, as running and terminating the program each time will make the process much slower. Again, the idea is to run the program within the Delphi IDE, to be able to debug it easily. Notice, though that the list can be expanded with the detailed view, which includes a list of the actual executable files and many other details.

FIGURE 22.8:

A list of applications registered with the Web App Debugger is displayed when you hook to its *home* page.

The data module for this type of project has some initialization code as well:

```
uses WebReq;

initialization
  WebRequestHandler.WebModuleClass := TWebModule2;
```

This approach should be used only for debugging. To deploy the actual application you should then use one of the other options. What you can do is create the project files for another type of Web server program and add to the project the same Web module of the debug application. The presence of the extra initialization line won't create a problem.

The reverse is slightly more complex. To debug an existing application, you have to create a program of this type, remove the Web module, add the existing one, and patch it by adding a line to set the `WebModuleClass` of the `WebRequestHandler`, like the one in the preceding code snippet. To account for possible missing initialization of the `WebRequestHandler` object, you might want to change this type of code into:

```
if WebRequestHandler <> nil then
  WebRequestHandler.WebModuleClass := ... // Web module class
```

WARNING By doing this for the CustQueP example (it is the CustQueDebug project), I realized that some of the Web request settings are different. So instead of using the `ScriptName` property of the request (set to empty for a Web debug application), you have to use the `InternalScriptName` property.

There are other two interesting elements in the use of the Web App Debugger. The first is that you can test your programs without having a Web server installed and without having to tweak its settings. In other words, you don't have to deploy your programs to test them—you simply try them out right away. Another advantage is that, contrary to doing early development of the applications as CGI, you can start experimenting with a multithreaded architecture right away, without having to deal with the loading and unloading of libraries, which often implies shutting down the Web server and possibly even the computer.

NOTE If your aim is to build an ISAPI application, you can also use a specific ISAPI DLL debugging tool. One such tool, called IntraBob, has been built by Bob Swart and is available on his Web site (`www.drbob42.com`) as freeware.

Working with Apache

If you plan on using Apache instead of IIS or another Web server, you can certainly take advantage of the common CGI technology to deploy your applications on almost any Web server. However, using CGI means some reduced speed and some trouble handling state information (as you cannot keep any data in memory). This is a good reason for writing an ISAPI application or a dynamic Apache module. Using Delphi's WebBroker technology, you can also easily compile the same code for both technologies, so that moving your program to a different Web platform becomes much simpler. Finally, you can also recompile a CGI program or a dynamic Apache module with Kylix and deploy it on a Linux server.

As I've mentioned, Apache can run traditional CGI applications but has also a specific technology for keeping the server extension program loaded in memory at all times for faster response. To build such a program in Delphi 6, you can simply use the Apache Shared Module option of the New Web Server Application dialog box. You end up with a library having this type of source code for its project:

```
library Apache1;

uses
  WebBroker,
  ApacheApp,
  ApacheWm in 'ApacheWm.pas' {WebModule1: TWebModule};
```

```
{$R *.res}

exports
  apache_module name 'apache1_module';

begin
  Application.Initialize;
  Application.CreateForm(TWebModule1, WebModule1);
  Application.Run;
end.
```

Notice in particular the `exports` clause, which indicates the name used by Apache configuration files to reference the dynamic module. In the project source code, you can add two more definitions, the module name and the content type, in the following way:

```
ModuleName := 'Apache1_module';
ContentType:= 'Apache1-handler';
```

If you don't set them, Delphi will assign them some default values, which are built adding the *_module* and *-handler* strings to the project name, ending up with the two names I've used above.

An Apache module is generally not deployed within a script folder, but within the modules subfolder of the server itself (by default, `c:\Program Files\Apache\modules`). Then you have to edit the `http.conf` file, adding a line to load the module, as:

```
LoadModule apache1_module modules/apache1.dll
```

Finally, you have to indicate when the module is invoked. The handler defined by the module can be associated with a given file extension (so that your module will process all of the files having a given extension) or with a physical or virtual folder. In the latter case, the folder doesn't exist, but Apache pretends it is there. This is how you can set up a virtual folder for the simple Apache1 module:

```
<Location /Apache1>SetHandler Apache1-handler</Location>
```

As Apache is inherently case sensitive (because of its Linux heritage), you might also want to add a second, lowercase virtual folder:

```
<Location /apache1>SetHandler Apache1-handler</Location>
```

Now you can invoke the sample application with the URL `http://localhost/Apache1`. A great advantage of using virtual folder in Apache is that a user doesn't really distinguish between the physical and dynamic portions of your site, as we'll better see in the next example.

Because the development of Apache modules with WebBroker is almost identical to the development of other types of programs, instead of building an actual application (besides the over-simplistic Apache1 example) I've created a new version of the BrokDemo example, already available as a CGI or ISAPI program. To do this, I've taken the project file of an

Apache module from that example, added the local Web modules to it, and modified the project source code to reflect the proper module name and handler. I've actually defined them differently than the default, as the following code excerpt demonstrates:

```
library BrokApache;

exports apache_module name 'brokdemo_module';

begin
  ContentType:= 'brokdemo-handler';
```

After compiling the module and editing the `http.conf` file as explained above, the program was ready to be used in two different ways, CGI and dynamic module. An obvious difference between the two types of invocation is their URLs:

```
http://localhost/scripts/brokcgi.exe/table
http://localhost/brokdemo/table
```

Not only is the latter URL simpler, but it hides the fact that we are running an application with a `/table` parameter. In fact, it seems we are accessing a specific folder of the server. Actually, the Apache configuration file can be modified to also invoke CGI applications through virtual folders, which explains why CGI applications have a path-like command prefixing the request. Another related explanation is that Linux CGI applications, like any other executable file, have no extension whatsoever, so their names still seem to be part of a path.

Practical Examples

After this general introduction to the core idea of the development of server-side applications with WebBroker, let me end this part of the chapter with two simple practical examples. The first is a classic Web counter. The second is an extension of the WebFind program presented in the preceding chapter to produce a dynamic page instead of filling a list box.

A Web Hit Counter

The server-side applications we've built up to now were based only on text. Of course, you can easily add references to existing graphics files. What's more interesting, however, is to build server-side programs capable of generating graphics that change over time.

A typical example is a *page hit counter*. To write a Web counter, we save the current number of hits to a file and then read and increase the value every time the counter program is called. How do we return this information? If all we need is some HTML text with the number of hits, the code is straightforward:

```
procedure TWebModule1.WebModule1WebActionItem1Action(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
```

```
var
  nHit: Integer;
  LogFile: Text;
  LogFileName: string;
begin
  LogFileName := 'WebCont.log';
  System.Assign (LogFile, LogFileName);
  try
    // read if the file exists
    if FileExists (LogFileName) then
    begin
      Reset (LogFile);
      Readln (LogFile, nHit);
      Inc (nHit);
    end
    else
      nHit := 0;
    // saves the new data
    Rewrite (LogFile);
    Writeln (LogFile, nHit);
  finally
    Close (LogFile);
  end;
  Response.Content := IntToStr (nHit);
end;
```

WARNING This simple file handling does not scale. When multiple visitors hit the page at the same time, this code may return false results or fail with a file I/O error because a request in another thread has the file open for reading while this thread tries to open the file for writing. To support a similar scenario, you'll need to use a mutex (or a critical section in a multithreaded program) to let each subsequent thread wait until the thread currently using the file has completed its task.

What's a little more interesting is to create a graphical counter that can be easily embedded into any HTML page. There are basically two approaches for building a graphical counter: you can prepare a bitmap for each digit up front and then combine them in the program, or you can simply let the program draw over a memory bitmap to produce the graphic you want to return. In the WebCount program, I've chosen this second approach.

Basically, we can create an Image component that holds a memory bitmap, which we can paint on with the usual methods of the `TCanvas` class. Then we can attach this bitmap to a `TJpegImage` object. Accessing the bitmap through the JpegImage component converts the image to the JPEG format. At this point, we can save the JPEG data to a stream and return it. As you can see, there are many steps, but the code is not really complex:

```
// create a bitmap in memory
Bitmap := TBitmap.Create;
try
  Bitmap.Width := 120;
  Bitmap.Height := 25;
  // draw the digits
  Bitmap.Canvas.Font.Name := 'Arial';
  Bitmap.Canvas.Font.Size := 14;
  Bitmap.Canvas.Font.Color := RGB (255, 127, 0);
  Bitmap.Canvas.Font.Style := [fsBold];
  Bitmap.Canvas.TextOut (1, 1, 'Hits: ' +
    FormatFloat ('###,###,###', Int (nHit)));
  // convert to JPEG and output
  Jpeg1 := TJpegImage.Create;
  try
    Jpeg1.CompressionQuality := 50;
    Jpeg1.Assign(Bitmap);
    Stream := TMemoryStream.Create;
    Jpeg1.SaveToStream (Stream);
    Stream.Position := 0;
    Response.ContentStream := Stream;
    Response.ContentType := 'image/jpeg';
    Response.SendResponse;
    // the response object will free the stream
  finally
    Jpeg1.Free;
  end;
finally
  Bitmap.Free;
end;
```

The three statements responsible for returning the JPEG image are the two that set the `ContentStream` and `ContentType` properties of the `Response` and the final call to `SendResponse`. The content type must match one of the possible MIME types accepted by the browser, and the order of these three statements is relevant. There is also a `SendStream` method in the `Response` object, but it should be called only after sending the type of the data with a separate call.

You can see the effect of this program in Figure 22.9. To obtain it, I've added the following code to an HTML page:

```
<img src="http://localhost/scripts/webcount.exe" border=0 alt="hit counter">
```

Searching with a Web Search Engine

In Chapter 21, I discussed the use of the Indy HTTP client component to retrieve the result of a search on the Google Web site. Now I'm going to extend the example a little, turning it into a server-side application. The WebSearch program on the companion CD, available as a CGI application or a Web App Debugger executable, has an action that simply returns the HTML retrieved by the search engine and a second action that fills a client data set component, then hooked to a table page producer. This is the code of this second action:

```
const
  strSearch = 'http://www.google.com/search?as_q=borland+delphi&num=100';

procedure TWebModule1.WebModule1WebActionItem1Action(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
var
  I: integer;
begin
  if not cds.Active then
    cds.CreateDataSet
  else
    cds.EmptyDataSet;
  for i := 0 to 5 do // how many pages?
  begin
    // get the data form the search site
    GrabHtml (strSearch + '&start=' + IntToStr (i*100));
    // scan it to fill the cds
    HtmlStringToCds;
  end;
  cds.First;
  // return producer content
  Response.Content := DataSetTableProducer1.Content;
end;
```

The `GrabHtml` method is identical to the WebFind example, while the `HtmlStringToCds` method is similar to corresponding method (which adds the items to a list box) and adds the addresses and their textual descriptions by calling:

```
cds.InsertRecord ([0, strAddr, strText]);
```

The ClientDataSet component, in fact, is set up with three fields: the two strings plus a line counter. This extra empty field is used to have the extra column in the table producer. The code fills the column in the cell-formatting event, which also adds the hyperlink:

```
procedure TWebModule1.DataSetTableProducer1FormatCell(Sender: TObject; CellRow,
  CellColumn: Integer; var BgColor: THTMLBgColor; var Align: THTMLAlign;
  var VAlign: THTMLVAlign; var CustomAttrs, CellData: String);
begin
  if CellRow <> 0 then
  case CellColumn of
    0: CellData := IntToStr (CellRow);
    1: CellData := '<a href="' + CellData + '">' + SplitLong(CellData) + '</a>';
    2: CellData := SplitLong (CellData);
  end;
end;
```

The call to `SplitLong` is used to add some extra spaces within the output text, to avoid having grid columns that are too large, as the browser won't split the text on multiple lines unless it contains spaces or other special characters. The result of this program is a rather slow application (because of the multiple HTTP requests it must forward) producing output like Figure 22.10.

Active Server Pages

Another approach to the development of server-side applications is the use of scripting. Before looking at the scripting technology embedded in the WebSnap framework, let me shortly discuss Microsoft's Active Server Pages (ASP) technology and how you can use Delphi to support it. The idea behind ASP is to add scripts to the HTML code, so that part of the text on a Web page is directly available while other information can be added at run time on the server. The client receives a plain HTML file. The difference between this approach and ISAPI is that you don't need to recompile a program on the server to see a change; you simply update the script. ASP offers a complex model, where you can attach persistent data to a session (for example, a user moving from page to page of a section of your Web site) and to the entire application (the section of the Web site, regardless of the user).

ASP is quite a complex technology, and here I can only discuss it in relation to Delphi programming. One of the features of ASP is that it allows you to create COM objects within a script, and you can write those COM objects in Delphi. The Delphi IDE even provides specific support classes and a wizard to help you build ASP objects. Compared to ISAPI or CGI, one of the advantages is that your ASP object built in Delphi can get access to session and application information, exactly as an ASP script does. This means we automatically get extra features such as persistent user data built into our server-side object. By building a compiled ASP object, we can also increase the speed of complex server-side code. (ASP scripts are not always the best solution in term of performance.) But, again, I don't want to discuss ASP in detail, only focus on Delphi support.

To try this out, simply create a new ActiveX library, and then start the Active Server Object Wizard (from the ActiveX page of the File ➢ New dialog box). As you can see in Figure 22.11, the wizard has a couple of options. You can build an object integrated with the ASP script by selecting the Page-Level Event Methods radio button, or an internal object (which can be installed as an MTS object) by using the Object Context option. Only in the first case does the object automatically handle the `OnStartPage` method, which receives as parameter the *scripting context*. In both cases, however, the VCL classes you inherit from (`TASPObject` and `TASPMTSObject`, respectively) have properties to access the `Request`, `Response`, `Session`, `Server`, and `Application` ASP objects.

FIGURE 22.11:

● Page-level event methods (OnStartPage/OnEndPage)

○ Object Context

Options

☑ Generate a template test script for this object

☐ Generate Event support code

Once you've created the ASP object with the wizard (I've used the Page-Level Event Methods option for the AspTest example), Delphi will bring up the Type Library editor, where you can prepare a list of properties and methods for your ASP object. Simply add the features you need, and then write their code. For example, you can write the following simple test method:

```
procedure Tasptest.ShowData;
begin
  Response.Write ('<h3>Delphi wrote this text</h3>');
end;
```

and activate it from the following ASP script (only slightly modified from the demo script the Delphi wizard will generate for you):

```
<h4>Message</h4>
<% Set DelphiASPObj = Server.CreateObject("asptest1.asptest")
   DelphiASPObj.showData
%>
```

The interesting element is that the same script (or another ASP script of the same application) can also set global values our Delphi object can access. Similarly, multiple objects can communicate, setting global variables for the application and session variables for the specific user. For example, we can add the following text to the ASP page:

```
<h4>hello</h4>
<%
   Session.Value("UserName") = "Marco"
   DelphiASPObj.Hello
 %>
```

I've written the code used to set the property and the method invocation one after the other, but they can even be in different pages. This new *dynamic* property (Microsoft's term for these values added to an object) is saved in the session, so it depends on the current user. The `Hello` method can use the username to welcome them:

```
procedure Tasptest.Hello;
var
  strName: string;
begin
  strName := Session ['UserName'];
  Response.Write ('<h3>Hello, ' + strName + '</h3>');
  Response.Write ('<p>Page started at ' + TimeToStr (StartTime) + '</p>');
end;
```

You can see the result of this and the previous method combined in Figure 22.12. The last line of the method uses a variable that's set when the page is first loaded, in the `OnStartPage` method (despite the name, this is not an event handler, but a method the ASP engine will call as the page containing the object is activated):

Testing Delphi ASP
This is AspTest from Mastering Delphi

Message

Delphi wrote this text

hello

Hello, Marco

Page started at 4:08:04 PM

FIGURE 22.12: The Web page generated by the AspTest object I've built with Delphi

```
procedure Tasptest.OnStartPage(const AScriptingContext: IUnknown);
begin
  inherited OnStartPage(AScriptingContext);
  StartTime := Now;
end;
```

Technically, this method retrieves the scripting context. The TASPObject base class uses the method to initialize all the ASP objects (including the two, Response and Session, I use in the code), surfacing them as properties.

To generate more complex HTML from the Delphi ASP object, you can use Producer components, optionally connecting them to a dataset. In the AspTest example, I've added a Table component and a DataSetTableProducer, connected them as usual, and written the following code to activate it:

```
procedure Tasptest.ShowTable;
begin
  DataModule1 := TDataModule1.Create (nil);
  try
    Response.Write (DataModule1.DataSetTableProducer1.Content)
  finally
    DataModule1.Free;
  end;
end;
```

It will actually make more sense to create the data module when the COM object is created and destroyed (overriding Initialize and Destroy) or when the page is loaded and unloaded (with OnStartPage and OnEndPage).

WebSnap

After this lengthy introduction of the core elements of the development of Web server applications with Delphi, we can finally focus on some of the new related technologies introduced in Delphi 6. There were two good reasons for not jumping right into this topic from the beginning of this chapter. The first is that WebSnap builds on the foundation offered by WebBroker, so that you cannot learn how to use the new features if you don't know the core ones. For example, a WebSnap application is technically a CGI or WinCGI program, or an ISAPI or Apache module. The second reason is that since WebSnap is included only in the Enterprise version of Delphi, not all Delphi programmers have the chance to use it (needing to limit their expense to the Professional version of Delphi 6, which includes WebBroker).

WebSnap has a few definitive advantages over the plain WebBroker, such as allowing for multiple pages, integrating server-side scripting, and XSL and Delphi 5 Internet Express technology (these last two elements will be covered in the next chapter). Moreover, there are many ready-to-use components for handling common tasks, such as users' login, session management, and so on. Instead of listing all the features of WebSnap right away, though, I've decided to cover them in a sequence of simple and focused applications. All of these applications have been built using the Web App Debugger, for testing purposes, but you'll be able to easily deploy them using one of the other available technologies.

The starting point of the development of a WebSnap application is a dialog box that you can invoke either in the WebSnap page of the New items dialog box (File ➢ New ➢ Other) or using the new Internet toolbar of the IDE. The resulting dialog box, shown in Figure 22.13, allows you to choose the type of application (like in a WebBroker application) and to customize the initial application components (but you'll be able to add more later on). The bottom portion of the dialog determines the behavior of the first page, usually the default or home page of the program. A similar dialog box is displayed also for subsequent pages.

FIGURE 22.13:

The options offered by the New WebSnap Application dialog box include the type of server and a button for the selection of the core application components.

If you go ahead, choosing the defaults and typing in a name for the home page, the dialog box will create a project and open up a `TWebAppPageModule` for you. This module contains the components you've chosen, by default:

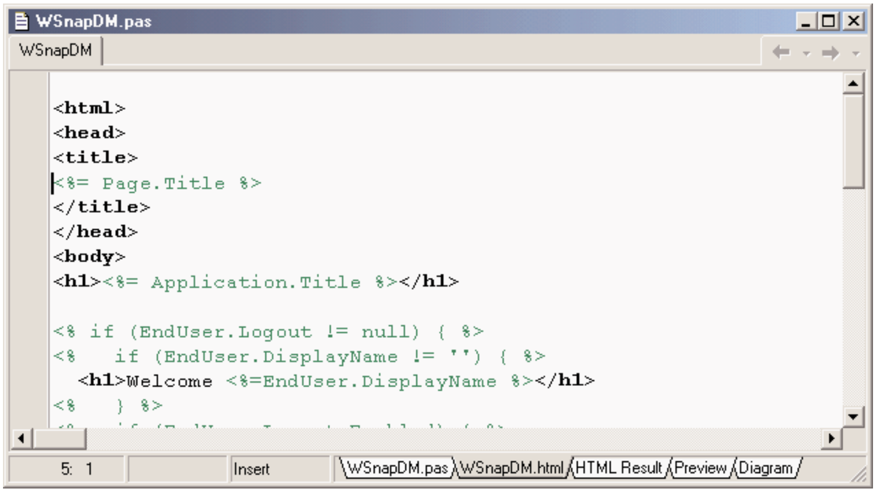
- A WebAppComponents component is a container of all of the centralized services of the WebSnap application, such as the user list, core dispatcher, session services, and so on. Not all of its properties must be available, as an application might not need all of the available services.
- One of these core services is offered by the PageDispatcher component, which (automatically) holds a list of the available pages of the application and defines the default one.
- Another core service is given by the AdapterDispatcher component, which handles HTML form submissions and image requests.
- The ApplicationAdapter is the first component we encounter of the *adapters* family. These components offer fields and actions to the server-side scripts evaluated by the

program. Specifically, the ApplicationAdapter is a fields adapter that exposes the value of its own `ApplicationTitle` property. By entering a value for this property, it will be made available to the scripts.

- Finally, the module hosts a PageProducer that includes the HTML code of the page—in this case, the default page of the program. Unlike WebBroker applications, the HTML for this component is not stored inside its `HTMLDoc` string list property or referenced by its `HTMLFile` property. The HTML file is an external file, stored by default in the folder hosting the source code of the project and referenced from the application using a statement similar to a resource include statement: `{*.html}`.

Because the HTML file included by the PageProducer is kept as a separate file (the LocateFileService component will eventually help you for its deployment), you can edit it to change the output of a page of your program without having to recompile the application. These possible changes relate not only to the fixed portion of the HTML file but also to some of its dynamic content, thanks to the support for server-side scripting. The default HTML file, based on a standard template, actually already has some scripting in it.

The HTML file is visible within the Delphi editor with reasonably good syntax highlighting, simply by selecting the corresponding lower tab, such as WSnapDM.html in my simple example, shown in Figure 22.14. The editor also has other pages for a WebSnap module, including by default an HTML Result page, where you can see the HTML generated after evaluating the scripts, and a Preview page hosting what a user will see inside a browser.



```
<html>
<head>
<title>
<%= Page.Title %>
</title>
</head>
<body>
<h1><%= Application.Title %></h1>

<% if (EndUser.Logout != null) { %>
<%   if (EndUser.DisplayName != '') { %>
  <h1>Welcome <%=EndUser.DisplayName %></h1>
<%   } %>
```

FIGURE 22.14: The Delphi 6 editor for a WebSnap module includes a simple HTML editor and a preview of its output.

TIP If you prefer editing the HTML of your Web application with another more sophisticated editor, you can set up your choice in the Internet page of the Environment Options dialog box. Within this page, you can see a list of file extensions. Selecting the Edit button for one of these groups of extensions, you can choose an external editor to use for these files. At this point, the External Editor button of the Internet toolbar will become active.

The standard HTML template used by WebSnap adds to any page of the program its title and the application title, using simple script lines such as:

```
<h1><%= Application.Title %></h1>
<h2><%= Page.Title %></h2>
```

We'll get back to the scripting in a while. But let me start the development of the WSnap1 example by simply creating a program with multiple pages. Before I do this, let me finish this overview by showing you the extra source code of a sample Web page module:

```
type
  Thome = class(TWebAppPageModule)
    ...
  end;

function home: Thome;

implementation

{$R *.dfm}  {*.html}

uses WebReq, WebCntxt, WebFact, Variants;

function home: Thome;
begin
  Result := Thome(WebContext.FindModuleClass(Thome));
end;

initialization
  if WebRequestHandler <> nil then
    WebRequestHandler.AddWebModuleFactory(TWebAppPageModuleFactory.Create(
      Thome, TWebPageInfo.Create([wpPublished {, wpLoginRequired}], '.html'),
        caCache));
end.
```

The module uses a global function instead of a typical global object of forms to support caching of the pages. This Web App Debugger application also has some extra code in the initialization section, particularly some registration code, to let the application know the role of the page and its behavior.

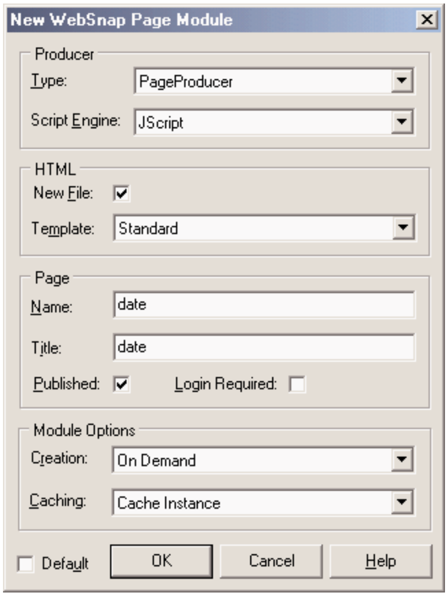
Managing Multiple Pages

The first notable difference between WebSnap and WebBroker is that, instead of having a single data module with multiple actions eventually connected to producer components, WebSnap has multiple data modules, each corresponding to an action and having a producer component with an HTML file attached to it. Actually, you can still add multiple actions to a page/module, but the idea is that you structure applications around pages and not around actions. Like actions, the name of the page is indicated in the request path.

As an example, I've added to the WebSnap application, built with default settings, two more pages. For the first, in the New WebSnap Page Module dialog (see Figure 22.15), I've chosen a standard page producer and given to it the name *date*. For the second, I've gone with a DataSetPageProducer and given it the name *country*. After saving the files, you can start testing the application. Thanks to some of the scripting I'll discuss later, each page lists all of the available pages (unless you've unchecked the Published check box in the New WebSnap Page Module dialog).

FIGURE 22.15:

The New WebSnap Page Module dialog box



New WebSnap Page Module

Producer

Type: PageProducer

Script Engine: JScript

HTML

New File: ☑

Template: Standard

Page

Name: date

Title: date

Published: ☑ Login Required: □

Module Options

Creation: On Demand

Caching: Cache Instance

□ Default

All of the pages will be rather empty, but at least we have the structure in place. To complete the home page, I've simply edited its linked HTML file directly. For the date page, I've employed the same approach as a WebBroker application. I've added to the HTML text some custom tags, as in:

```
<p>The time at this site is <#time>.</p>
```

and I've added some code to the `OnTag` event handler of the producer component to replace this tag with the current time.

For the third page, the country page, I've modified the HTML to include tags for the various fields of the country table, as in:

```
<h3>Country: <#name></h3>
```

Then I've attached the table to the page producer (and I've also added a session component to account for concurrent requests in multiple threads):

```
object DataSetPageProducer: TDataSetPageProducer
  DataSet = Table1
end
object Table1: TTable
  DatabaseName = 'DBDEMOS'
  SessionName = 'Session1_2'
  TableName = 'country.db'
end
object Session1: TSession
  Active = True
  AutoSessionName = True
end
```

To open this table when the page is first created and reset it to the first record in further invocations, I've handled the `OnBeforeDispatchPage` event of the Web page module, adding this code to it:

```
  Table1.Open;
  Table1.First;
```

The fact that a WebSnap page can be very similar to a portion of a WebBroker application (basically an action tied to a producer) is quite important, in case you want to port existing WebBroker code to this new architecture. You can even port your existing DataSetTableProducer components to the new architecture. Technically, you can generate a new page, remove its producer component, replace it with a DataSetTableProducer, and hook this component to the `PageProducer` property of the Web page module. In practice, this approach would cut out the HTML file of the page and its scripts.

In the WSnap1 program, I've used a better technique. I've added a custom tag (`<#htmltable>`) to the HTML file and used the `OnTag` event of the page producer to add to the HTML the result of the data set table:

```
if TagString = 'htmltable' then
  ReplaceText := DataSetTableProducer1.Content;
```

Server-Side Scripts

If having multiple pages in a server-side program, each associated with a different page module, changes the way you write a program, having the server-side scripts at hand offers an even more powerful approach. For example, the standard scripts of the WSnap1 example account for the application and page titles, and for the index of the pages. This is generated by an enumerator, the technique used to scan a list from within a WebSnap script code. Let's have a look at it:

```
<table cellspacing="0" cellpadding="0"><td>
<%  e = new Enumerator(Pages)
    s = ''
    c = 0
    for (; !e.atEnd(); e.moveNext())
    {
      if (e.item().Published)
      {
        if (c > 0) s += '&nbsp;|&nbsp;'
        if (Page.Name != e.item().Name)
          s += '<a href="' + e.item().HREF + '">' + e.item().Title + '</a>'
        else
          s += e.item().Title
        c++
      }
    }
    if (c>1) Response.Write(s)
%>
</td></table>
```

NOTE Typically, WebSnap scripts are written in JavaScript, an object-based language very common for Internet programming because it is the only scripting language generally available in browsers (on the client side). JavaScript, technically indicated as ECMAScript, borrows the core syntax of the C language and has almost nothing to do with Java. Actually, WebSnap uses Microsoft's ActiveScripting engine, which supports both JScript (a variation of JavaScript) and VBScript.

Inside the single cell of this table (which, oddly enough, has no rows), the script outputs a string with the `Reponse.Write` command. This string is built with a `for` loop over an enumerator of the pages of the application, stored in the `Pages` global entity. The title of each page is added to the string, only if the page is published and using an hyperlink only for pages different than the current one. Having this code in a script, instead of hard-coded into a Delphi component, allows you to pass it over to a good Web designer to turn it into something a little more visually appealing.

TIP To publish or unpublish a page, don't look for a property in the Web page module. This status is controlled by a flag of the `AddWebModuleFactory` method called in the Web page module initialization code. Simply comment or uncomment this flag to obtain the desired effect.

As a sample of what you can do with scripting, I've added to the WSnap2 example (an extension of the WSnap1 example) a *demoscript* page. The script of this page can generate a full table of multiplied values with the following scripting code (see Figure 22.16 for its output):

```
<table border=1 cellspacing=0>
<tr>
  <th>&nbsp;</th>
  <% for (j=1;j<=5;j++) { %>
  <th>Column <%=j %></th>
  <% } %>
</tr>
<% for (i=1;i<=5;i++) { %>
<tr>
  <td>Line <%=i %></td>
  <% for (j=1;j<=5;j++) { %>
  <td>Value= <%=i*j %></td>
  <% } %>
</tr>
<% } %>
</table>
```

FIGURE 22.16:

The WSnap2 example has a custom menu stored in an included file reference by each page.

WSnap2

home | date | country | countries | demoscript

demoscript

	Column 1	Column 2	Column 3	Column 4	Column 5
Line 1	Value= 1	Value= 2	Value= 3	Value= 4	Value= 5
Line 2	Value= 2	Value= 4	Value= 6	Value= 8	Value= 10
Line 3	Value= 3	Value= 6	Value= 9	Value= 12	Value= 15
Line 4	Value= 4	Value= 8	Value= 12	Value= 16	Value= 20
Line 5	Value= 5	Value= 10	Value= 15	Value= 20	Value= 25

In this script, the <%= symbol replaces the longer `Response.Write` command. Another important feature of server-side scripting is the inclusion of pages within other pages. For example, if you plan on modifying the menu, you can include the related HTML and script in a single file, instead of changing it and maintaining it in multiple pages. File inclusion is generally done with a statement like:

```
<!-- #include file="menu.html" -->
```

In Listing 22.1, you can find the complete source code of the include file for the menu, referenced by all the other HTML files of the project. In Figure 22.16, you can see an example of this menu, across the top of the page with the table generation script mentioned earlier.

Listing 22.1: The *menu.html* file included in each page of the WSnap2 example

```
<html>
<head>
<title><%= Page.Title %></title>
</head>
<body>
<h2><%= Application.Title %></h2>
<table cellspacing="0" cellpadding="2" border="1" bgcolor="#c0c0c0">
<tr>
<%  e = new Enumerator(Pages)
    for (; !e.atEnd(); e.moveNext())
    {
      if (e.item().Published)
      {
        if (Page.Name != e.item().Name)
          Response.Write ('<td><a href="' + e.item().HREF + '">' +
            e.item().Title + '</a></td>')
        else
          Response.Write ('<td>' + e.item().Title + '</td>')
      }
    }
%>
</tr>
</table>
<hr>
<h1><%= Page.Title %></h1>
<p>
```

This script for the menu uses the `Pages` list and the `Page` and `Application` global scripting objects. WebSnap makes available a few other global objects, including `EndUser` and `Session` objects (in case you add the corresponding adapters to the application), the `Modules` object, and the `Producer` object, which allows access to the Producer component of the Web page module. The script also has available the `Response` and `Request` objects of the Web module.

Adapters

Besides these global objects, within a script you can access all the adapters available in the corresponding Web page module. (Adapters in other modules, including shared Web data modules, must be referenced by prefixing their name with the `Modules` object and the corresponding module.) The idea is that adapters allow you to pass information from your compiled Delphi code to the interpreted script, providing a scriptable interface to your Delphi application. Adapters contain fields that represent data and host actions that represent commands. The server-side scripts can access these values and issue these commands, passing specific parameters to them.

NOTE Technically, adapters implement an `IDispatch` interface that can be accessed by the script through an Active Scripting engine language, such as JavaScript. The page producer component is responsible for invoking the Active Scripting engine and has a property indicating the language of the script. Because of this, you'll have to register two type libraries (and deploy the corresponding DLLs) to make this work on a machine where Delphi is not installed: `WebBrokerScript.tlb` and `stdvcl40.dll`. As the first is a type library, it must be installed with Delphi's TRegSvr utility (available in the `bin` subfolder) rather than Microsoft's RegSvr32 program. Of course, the server computer must also have Microsoft Active Scripting Engine installed in order to work.

Adapter Fields

For simple customizations, you can simply add new fields to the specific adapters. For instance, in the WSnap2 example, I've added a custom field to the application adapter. After selecting this component, you can either open up its Fields editor (accessible via its local menu) or simply work within the Object TreeView. After adding a new field (called `Count` in the example), you can assign a value to it in its `OnGetValue` event. As I want to count the hits (or requests) on any page of the Web application, I've also handled the `OnBeforePageDispatch` event of the *global* PageDispatcher component. Here is the code of the two methods:

```
procedure Thome.PageDispatcherBeforeDispatchPage(Sender: TObject;
  const PageName: String; var Handled: Boolean);
begin
  Inc (HitCount);
end;

procedure Thome.CountGetValue(Sender: TObject; var Value: Variant);
begin
  Value := HitCount;
end;
```

Of course, I could have used the page name to also count hits on each specific page (and I could have added some support for persistency, as the count is reset every time you run a new instance of the application). Now that I've added a custom field to an existing adapter (corresponding to the `Application` script object), I can access it from within any script, like this:

```
<p>Application hits since last activation:
<%= Application.Count.Value %></p>
```

Adapter Components

In the same way, you can also add custom adapters to specific pages. If you need to pass along a few fields, use the generic Adapter component. Other custom adapters (besides the global ApplicationAdapter we've already used) include these:

- The PagedAdapter component has built-in support for showing its content over multiple pages.
- The DataSetAdapter component is used to access a Delphi dataset from a script and is covered in the next section.
- The StringValuesList holds a list of name/value pairs, like a string list, and can be used directly or to provide a list of values to an adapter field. The inherited DataSetValuesList adapter has the same role but grabs the list of name/value pairs from a dataset, providing support for lookups and other selections.
- User-related adapters, such as the EndUser, EndUserSession, and LoginForm adapters, are used to access user and session information and to build a login form for the application, automatically tied to the users list. I'll cover these adapters in the section "Sessions, Users, and Permissions" later in this chapter.

Using the AdapterPageProducer

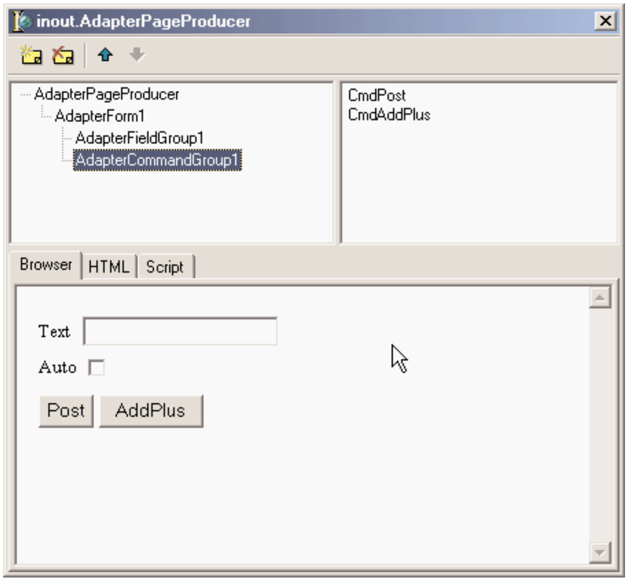
Most of these components are used in conjunction with an AdapterPageProducer component. The AdapterPageProducer, in fact, can generate portions of script after you visually design the desired result. As an example, I've added to the WSnap2 application the *inout* page, which has an adapter with two fields, one standard and one Boolean:

```
object Adapter1: TAdapter
  OnBeforeExecuteAction = Adapter1BeforeExecuteAction
  object TAdapterActions
    object AddPlus: TAdapterAction
      OnExecute = AddPlusExecute
    end
    object Post: TAdapterAction
      OnExecute = PostExecute
    end
  end
  object TAdapterFields
    object Text: TAdapterField
      OnGetValue = TextGetValue
    end
    object Auto: TAdapterBooleanField
      OnGetValue = AutoGetValue
    end
  end
end
```

The adapter has also a couple of actions, used to post the current user input and to add a plus sign to the text. The same plus sign is added anyway when the Auto field is enabled. Developing the user interface for this form, and the related scripting, would take some time using plain HTML. But the AdapterPageProducer component (used in this page) has an integrated HTML designer, which Borland calls Web Surface Designer. Using this tool, you can visually add a form to the HTML page and add an AdapterFieldGroup to it. Connect this field group to the adapter to have editors for the two fields automatically displayed. Then you can add an AdapterCommandGroup and connect it to the AdapterFieldGroup, to have buttons for all of the actions of the adapter. You can see an example of this designer in Figure 22.17.

FIGURE 22.17:

The Web Surface Designer of Delphi 6 for the *inout* page of the WSnap2 example, at design time



To be more precise, the fields and buttons are automatically displayed if the `AddDefaultFields` and `AddDefaultCommands` properties of the field group and command group are set. The effect of the visual operations I've done to build this form are summarized in the following DFM snippet:

```
object AdapterPageProducer: TAdapterPageProducer
  object AdapterForm1: TAdapterForm
    object AdapterFieldGroup1: TAdapterFieldGroup
      Adapter = Adapter1
      object FldText: TAdapterDisplayField
        FieldName = 'Text'
      end
      object FldAuto: TAdapterDisplayField
        FieldName = 'Auto'
      end
    end
    object AdapterCommandGroup1: TAdapterCommandGroup
      DisplayComponent = AdapterFieldGroup1
      object CmdPost: TAdapterActionButton
        ActionName = 'Post'
      end
      object CmdAddPlus: TAdapterActionButton
        ActionName = 'AddPlus'
      end
    end
  end
end
```

Now that we have an HTML page with some scripts to move data back and forth and issue commands, we can have a look at the source code required to make this work. First, you'll have to add to the class two local fields to store the adapter fields and manipulate them, and you need to implement the `OnGetValue` event for both, returning the field values. When each of the buttons is pressed, we have to retrieve the text passed by the user, which is not automatically copied into the corresponding adapter field. You can obtain this effect by looking at the `ActionValue` property of these fields, which is set only if something was entered (for this reason, when nothing is entered we set the Boolean field to False). To avoid repeating this code for both actions, I've placed it in the `OnBeforeExecuteAction` event of the Web page module:

```
procedure Tinout.Adapter1BeforeExecuteAction(Sender, Action: TObject;
  Params: TStrings; var Handled: Boolean);
begin
  if Assigned (Text.ActionValue) then
    fText := Text.ActionValue.Values [0];
  fAuto := Assigned (Auto.ActionValue);
end;
```

Notice that each action can have multiple values (in case of components allowing multiple selections); but this is not the case, so we can simply grab the first element. Finally, I've written the code for the OnExecute events of the two actions:

```
procedure Tinout.AddPlusExecute(Sender: TObject; Params: TStrings);
begin
  fText := fText + '+';
end;

procedure Tinout.PostExecute(Sender: TObject; Params: TStrings);
begin
  if fAuto then
    AddPlusExecute (Self, nil);
end;
```

As an alternative, adapter fields have a public EchoActionFieldValue property that you can set to get the value entered by the user and place it again in the resulting form. This technique is typically used in case of errors, to let the user change the input starting with the values already entered.

NOTE The AdapterPageProducer component has specific support for cascading style sheets (CSS). You can define the CSS for a page using either the StylesFile property or Styles string list. Any element of the editor of the items of the producer, at this point, can define a specific style or choose one of the styles of the attached CSS. This last operation (which is the suggested approach) is accomplished using the StyleRule property.

Scripts Rather Than Code?

Even this simple example of the combined use of an adapter and an adapter page producer, with its visual designer, shows the power of this architecture. However, this approach also has a big drawback. By letting the components generate the script (in the HTML, you have only the <#SERVERSCRIPT> tag), you save a lot of development time, but at the same time you end up mixing the script with the code, so that changes to the user interface will require updating the program. The division of responsibilities between the Delphi application developer and the HTML/script designer is lost. And, ironically, we end up having to run a script to accomplish something the Delphi program could have done right away, possibly even much faster!

So my opinion is that this is a very powerful architecture and a huge step forward from WebBroker, but it has to be used with some care, to avoid misusing some of these technologies just because they are simple and powerful (and they are indeed). For example, it might be worth using the designer of the AdapterPageProducer to generate the first version of a page, then grabbing the generated script and copying to the HTML of a plain PageProducer, so that a Web designer can modify the script with a specific tool.

For nontrivial applications, I tend to prefer the possibilities offered by XML and XSL, which are available within this architecture even if they don't have a central role. More on this specific topic in the next chapter.

WebSnap and Databases

One of the areas where Delphi has always shined is database programming. For this reason, it is not surprising to see a lot of support for handling datasets within the WebSnap framework. Specifically, you can use the DataSetAdapter component to connect to a dataset and display its values in a form or a table using the visual editor of the AdapterPageProducer component.

A WebSnap Data Module

As an example, I've built a new WebSnap application (called WSnapTable) with an AdapterPageProducer as its main page to display a table in a grid and another AdapterPageProducer in a secondary page to show a form with a single record. I've also added to the application a WebSnap Data Module, as a container of the dataset components. The data module has a ClientDataSet wired to a dbExpress dataset through a provider and based on an InterBase connection, as shown here:

```
object ClientDataSet1: TClientDataSet
  Active = True
  ProviderName = 'DataSetProvider1'
end
object SQLConnection1: TSQLConnection
  Connected = True
  ConnectionName = 'IBLocal'
  LoginPrompt = False
end
object SQLDataSet1: TSQLDataSet
  SQLConnection = SQLConnection1
  CommandText =
    'select CUST_NO, CUSTOMER, ADDRESS_LINE1, CITY, STATE_PROVINCE, ' +
    '  COUNTRY from CUSTOMER'
end
object DataSetProvider1: TDataSetProvider
  DataSet = SQLDataSet1
end
```

The DataSetAdapter

Now that we have a dataset available, we can add a DataSetAdapter to the first page, and connect it to the ClientDataSet of the Web module. The adapter automatically makes available all of the fields of the dataset and several predefined actions for operating on it (such as

Delete, Edit, and Apply). You can add them explicitly to the `Actions` and `Fields` collections to exclude some of them and customize their behavior, but this is not always required.

Like the PagedAdapter, the DataSetAdapter has a `PageSize` property where you can indicate the number of elements to display in each page. The component also has commands that you can use to navigate among pages. This approach is particularly suitable when you want to display a large dataset in a grid. These are the adapter settings for the main page of the WSnapTable example:

```
object DataSetAdapter1: TDataSetAdapter
  DataSet = WebDataModule1.ClientDataSet1
  PageSize = 6
end
```

The corresponding page producer has a form containing two command groups and a grid. The first command group (displayed above the gird) has the predefined commands for handling pages: `CmdPrevPage`, `CmdNextPage`, and `CmdGotoPage`. This last command generates a list of numbers for the pages, so that a user can jump to each of them directly. The AdapterGrid component has the default columns plus an extra one hosting a couple of commands, Edit and Delete. The bottom command group has a button used to create a new record. You can see an example of the output of the table in Figure 22.18 and the complete settings of the AdapterPageProducer in Listing 22.2.

FIGURE 22.18:

Listing 22.2: AdapterPageProducer settings for the WSnapTable main page

```
object AdapterPageProducer: TAdapterPageProducer
  object AdapterForm1: TAdapterForm
object AdapterCommandGroup1: TAdapterCommandGroup
  DisplayComponent = AdapterGrid1
  object CmdPrevPage: TAdapterActionButton
    ActionName = 'PrevPage'
    Caption = 'Previous Page'
  end
  object CmdGotoPage: TAdapterActionButton
    ActionName = 'GotoPage'
  end
  object CmdNextPage: TAdapterActionButton
    ActionName = 'NextPage'
    Caption = 'Next Page'
  end
end
object AdapterGrid1: TAdapterGrid
  TableAttributes.CellSpacing = 0
  TableAttributes.CellPadding = 3
  Adapter = DataSetAdapter1
  AdapterMode = 'Browse'
  object ColCUST_NO: TAdapterDisplayColumn
    FieldName = 'CUST_NO'
  end
  object ColCUSTOMER: TAdapterDisplayColumn
    FieldName = 'CUSTOMER'
  end
  object ColADDRESS_LINE1: TAdapterDisplayColumn
    FieldName = 'ADDRESS_LINE1'
  end
  object ColCITY: TAdapterDisplayColumn
    FieldName = 'CITY'
  end
  object ColSTATE_PROVINCE: TAdapterDisplayColumn
    FieldName = 'STATE_PROVINCE'
  end
  object ColCOUNTRY: TAdapterDisplayColumn
    FieldName = 'COUNTRY'
  end
  object AdapterCommandColumn1: TAdapterCommandColumn
    Caption = 'COMMANDS'
    object CmdEditRow: TAdapterActionButton
      ActionName = 'EditRow'
      Caption = 'Edit'
      PageName = 'formview'
      DisplayType = ctAnchor
    end
    object CmdDeleteRow: TAdapterActionButton
      ActionName = 'DeleteRow'
      Caption = 'Delete'
      DisplayType = ctAnchor
    end
  end
```

```
        end
        object AdapterCommandGroup2: TAdapterCommandGroup
          DisplayComponent = AdapterGrid1
          object CmdNewRow: TAdapterActionButton
            ActionName = 'NewRow'
            Caption = 'New'
            PageName = 'formview'
          end
        end
      end
    end
```

In this rather long listing, there are a few things to notice. First, the grid has the AdapterMode property set to Browse, other possibilities being Edit, Insert, and Query. This dataset display mode for adapters determines the type of user interface (text or edit boxes and other input controls) and the visibility of other buttons (for example, Apply and Cancel buttons are only present in the edit view, the opposite for the Edit command).

NOTE The adapter mode can also be modified using server-side script and accessing Adapter.Mode.

Second, I've modified the display of the commands inside the grid, using the ctAnchor value for the DisplayType property instead of the default button style. Similar properties are available in most components of this architecture to tweak the HTML code they produce.

Editing the Data in a Form

Finally, some of the commands are connected to a different page, the page that is going to be displayed after the commands are invoked. For example, the edit command has its PageName property set to formview. This second page of the application has an AdapterPageProducer with components hooked to the same DataSetAdapter of the other table, so that all of the request will be automatically synchronized. Selecting the edit command, in fact, the program will open the secondary page displaying the data of the record corresponding to the command.

Listing 22.3 shows the details of the page producer of the second page of the program. Again, building the HTML form visually using the Delphi specific designer (see Figure 22.19) was a very fast operation.

FIGURE 22.19:

The formview page shown by the WSnapTable example at design time, in the Web Surface Designer (or AdapterPageProducer editor)

COUNTRY	USA

Listing 22.3: AdapterPageProducer settings for the formview page

```
object AdapterPageProducer: TAdapterPageProducer
  object AdapterForm1: TAdapterForm
    object AdapterErrorList1: TAdapterErrorList
      Adapter = table.DataSetAdapter1
    end
    object AdapterCommandGroup1: TAdapterCommandGroup
      DisplayComponent = AdapterFieldGroup1
      object CmdApply: TAdapterActionButton
        ActionName = 'Apply'
        PageName = 'table'
      end
      object CmdCancel: TAdapterActionButton
        ActionName = 'Cancel'
        PageName = 'table'
      end
      object CmdDeleteRow: TAdapterActionButton
        ActionName = 'DeleteRow'
        Caption = 'Delete'
        PageName = 'table'
      end
    end
    object AdapterFieldGroup1: TAdapterFieldGroup
      Adapter = table.DataSetAdapter1
      AdapterMode = 'Edit'
      object FldCUST_NO: TAdapterDisplayField
        DisplayWidth = 10
        FieldName = 'CUST_NO'
      end
      object FldCUSTOMER: TAdapterDisplayField
        DisplayWidth = 27
        FieldName = 'CUSTOMER'
      end
      object FldADDRESS_LINE1...
      object FldCITY...
      object FldSTATE_PROVINCE...
      object FldCOUNTRY...
    end
  end
end
```

In the listing, you can see that all the operations send the user back the main page and that the AdapterMode is set to Edit, unless there are update errors or conflicts. In this case, the same page is displayed again, with a description of the errors obtained by adding an AdapterErrorList component at the top of the form.

The second page is not published, because selecting it without referring to a specific record would make very little sense. To unpublish the page, I've simply commented the corresponding flag in the initialization code. Finally, to make the changes to the database persistent, you can call the ApplyUdpates method in the OnAfterPost and OnAfterDelete events of the ClientDataSet component hosted by the data module. Another problem (which I haven't fixed) relates to the fact that the SQL server assigns the ID of each customer, so that when you enter a new record, the data in the ClientDataSet and in the actual database are not aligned any more. This can cause Record Not Found errors, a problem I've not fixed in the example.

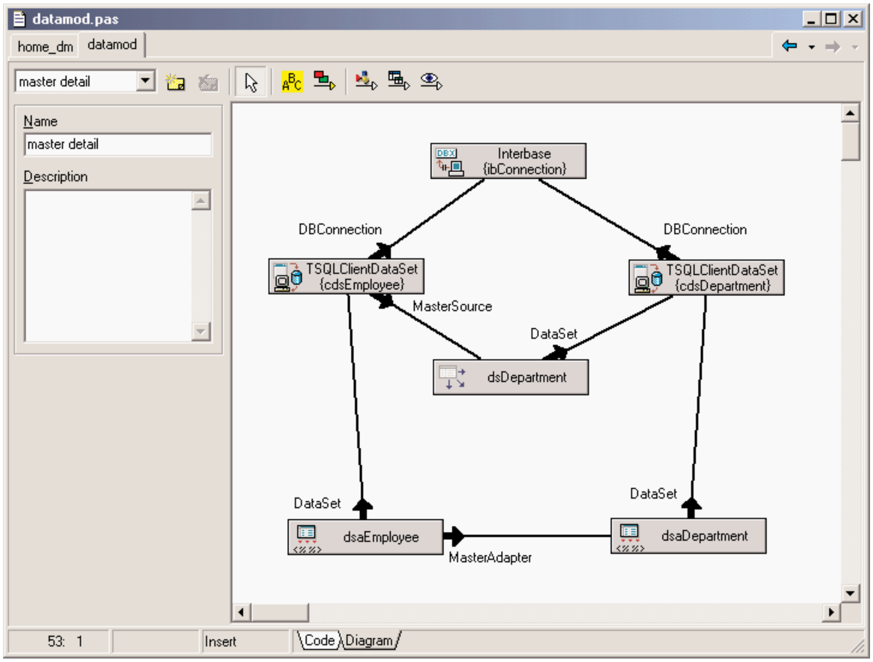
Master/Detail in WebSnap

The DataSetAdapter component has specific support for master/detail relationships between datasets. After you've created the relationship among the datasets, as usual, define an adapter for each dataset and then connect the MasterAdapter property of the adapter of the detail dataset. Setting up the master/detail relationship between the adapters makes them work in a more seamless way. For example, when you change the work mode of the master, or enter new records, the detail automatically enters into Edit mode or is refreshed.

In the WSnapMD example, I've defined such a relationship using two SQLClientDataSet components connected with an InterBase database via dbExpress. All these components and the related adapters are in a Web data module, which has the structure displayed in the design view in Figure 22.20. I haven't provided a complete listing of the details of these components, as it shouldn't be too difficult for you to rebuild it after looking at the example itself.

FIGURE 22.20:

The design view of the Web data module of the WSnapMD example. Both the datasets and the adapters have a master/detail relationship.



Name
master detail

Description

The only page of this WebSnap application has an AdapterPageProducer component hooked to both dataset adapters. The form of this page, in fact, has both a field group hooked to the master and a grid connected with the detail. Unlike other examples, I've tried to improve the user interface by adding custom attributes for the various elements, as you can see in the following detailed excerpt:

```
object AdapterPageProducer: TAdapterPageProducer
 object AdapterForm1: TAdapterForm
  Custom = 'Border="1" CellSpacing="0" CellPadding="10" ' +
   'BgColor="Silver" align="center"'
  object AdapterCommandGroup1: TAdapterCommandGroup
   DisplayComponent = AdapterFieldGroup1
```

```
      Custom = 'Align="Center"'
      object CmdFirstRow: TAdapterActionButton
        ActionName = 'FirstRow'
        Caption = '   First   '
      end
      object CmdPrevRow: TAdapterActionButton
        ActionName = 'PrevRow'
        Caption = ' Previous '
      end
      object CmdNextRow: TAdapterActionButton
        ActionName = 'NextRow'
        Caption = '   Next   '
      end
      object CmdLastRow: TAdapterActionButton
        ActionName = 'LastRow'
        Caption = '   Last   '
      end
    end
    object AdapterFieldGroup1: TAdapterFieldGroup
      Custom = 'BgColor="Silver"'
      Adapter = WDataMod.dsaDepartment
      AdapterMode = 'Browse'
    end
    object AdapterGrid1: TAdapterGrid
      TableAttributes.BgColor = 'Silver'
      TableAttributes.CellSpacing = 0
      TableAttributes.CellPadding = 3
      HeadingAttributes.BgColor = 'Gray'
      Adapter = WDataMod.dsaEmployee
      AdapterMode = 'Browse'
      object ColEMP_NO: TAdapterDisplayColumn...
      object ColFIRST_NAME: TAdapterDisplayColumn...
      object ColLAST_NAME: TAdapterDisplayColumn...
      object ColDEPT_NO: TAdapterDisplayColumn...
      object ColJOB_CODE: TAdapterDisplayColumn...
      object ColJOB_COUNTRY: TAdapterDisplayColumn...
      object ColSALARY: TAdapterDisplayColumn...
    end
  end
end
```

I've used a gray background, displayed some of the grid borders (HTML grids are used very often by the Web surface designer), centered most of the elements, and added some spacing. Notice that I've added some extra spaces to the button captions, to avoid them being too small. The effect of these settings (and the master/detail structure) is visible at run time in Figure 22.21.

FIGURE 22.21:

The WSnapMD example shows a master/detail structure and has some customized output.

Sessions, Users, and Permissions

Another very interesting area of the WebSnap architecture is its support for sessions and users. Sessions are supported using a classic approach: temporary cookies. These cookies are sent to the browser, so that following requests from the same user can be acknowledged by the system. By adding data to a session instead of an application adapter, you can have data that depends on the specific session or user (although a user can possibly run multiple sessions by opening multiple browser windows on the same computer). For supporting sessions, the application keeps data in memory, so this feature is not available in case of CGI programs.

Using Sessions

To underline the importance of this type of support, I've built a WebSnap application with a single page showing both the total number of hits and the total number of hits for each session. The program has a SessionService component with default values for its `MaxSessions` and `DefaultTimeout` properties. For every new request, the program increases both an `nHits` private field of the page module and the `SessionHits` value of the current session:

```
procedure TSessionDemo.WebAppPageModuleBeforeDispatchPage(Sender: TObject;
  const PageName: String; var Handled: Boolean);
begin
  // increase application and session hits
  Inc (nHits);
  WebContext.Session.Values ['SessionHits'] :=
    Integer (WebContext.Session.Values ['SessionHits']) + 1;
end;
```

NOTE The `WebContext` object (of type `TWebContext`) is a thread variable, created by WebSnap for each request, which provides thread-safe access to other global variables used by program.

The associated HTML displays status information both by using some custom tags evaluated by the `OnTag` event of the page producer and some script, evaluated by the engine. Here is the core portion of the HTML file:

```
<h3>Plain Tags</h3>
<p>Session id: <#SessionID>
<br>Session hits: <#SessionHits></p>
<h3>Script</h3>
<p>Session hits (via application): <%=Application.SessionHits.Value%>
<br>Application hits: <%=Application.Hits.Value%></p>
```

The parameters of the output are provided by the `OnTag` event handler and the `OnGetValue` events of the fields:

```
procedure TSessionDemo.PageProducerHTMLTag(Sender: TObject; Tag: TTag;
  const TagString: String; TagParams: TStrings; var ReplaceText: String);
begin
  if TagString = 'SessionID' then
    ReplaceText := WebContext.Session.SessionID
  else if TagString = 'SessionHits' then
    ReplaceText := WebContext.Session.Values ['SessionHits']
end;

procedure TSessionDemo.HitsGetValue(Sender: TObject; var Value: Variant);
begin
  Value := nHits;
end;

procedure TSessionDemo.SessionHitsGetValue(Sender: TObject; var Value: Variant);
begin
  Value := Integer (WebContext.Session.Values ['SessionHits']);
end;
```

The effect of this program is visible in Figure 22.22, where I've activated two sessions in two different copies of Internet Explorer.

TIP In this example, I've voluntarily used both the traditional WebBroker tag replacement and the newer WebSnap adapter fields and scripting, so that you can compare the two approaches and keep in mind that they are both available in a WebSnap application.

Requesting Login

Besides generic sessions, WebSnap also has specific support for users and login-based authorized sessions. You can add to an application a list of users (with the WebUserList component), each with a name and a password. My impression is that this component is rather rudimentary in the data it can store. Instead of filling it with your list of users, however, you can keep the list in a database table (or in some other proprietary format) and use the events of the WebUserList component to retrieve your custom users data and check the user passwords.

You'll generally also add to the application the SessionService and EndUserSessionAdapter components. At this point, you can ask the users to log in, indicating for each page whether it can be viewed by everyone or only by logged-in users. This is accomplished by setting the wpLoginRequired flag in the constructor of the `TWebPageModuleFactory` and `TWebAppPageModuleFactory` classes in the initialization code of the Web page unit.

NOTE The reason for having rights and publication information in the factory rather than in the WebPageModule, is that the program can check the access rights and list the pages even without loading the module.

When a user tries to see a page that requires the user identification, the login page indicated in the EndUserSessionAdapter component is displayed. You can create such a page rather easily by creating a new Web page module based on an AdapterPageProducer and adding to it the LoginFormAdapter. In the editor of the page, add a field group within a form, connect the field group to the LoginFormAdapter, and add a command group with the default Login button. The resulting login form will have fields for the username and its password, but also for the requested page. This last value is automatically filled with the requested page, in case this page required authorization and the user wasn't already logged in. This is done so that a user can immediately reach the requested page without being bounced back to a generic menu.

The login form is typically not published, because the corresponding Login command is already available when the user isn't logged into the system; when the user logs in, it is replaced by a Logout command. This is obtained by the standard script of the Web Page Module, and particularly:

```
<% if (EndUser.Logout != null) { %>
<%   if (EndUser.DisplayName != '') { %>
  <h1>Welcome <%=EndUser.DisplayName %></h1>
<%   } %>
<%   if (EndUser.Logout.Enabled) { %>
  <a href="<%=EndUser.Logout.AsHREF%>">Logout</a>
<%   } %>
<%   if (EndUser.LoginForm.Enabled) { %>
  <a href=<%=EndUser.LoginForm.AsHREF%>>Login</a>
<%   } %>
<% } %>
```

There isn't much else to say about the WSnapUsers application, as it has almost no custom code and settings. The access to the users data is demonstrated by the script of the standard template shown above.

Single Page Access Rights

Besides having pages that require a login for access, you can give specific users the right to see more pages than others. Any user, in fact, has a set of rights separated by semicolons or commas. The user must have all of the rights defined for the requested page generally listed in the `ViewAccess` and `ModifyAccess` properties of the adapters, which indicate respectively whether the user can see the given elements while browsing or can even edit them. These settings are very granular, and can be applied to entire adapters or some specific adapter fields (notice I'm referring to the adapter fields, not the user interface components within the designer). For example, you can hide some of the columns of a table to given users by hiding the corresponding fields (and also in other cases, as specified by the `HideOptions` property).

The global PageDispatcher component also has the `OnCanViewPage` and `OnPageAccessDenied` events that can also be used to control the access to the various pages of the program within the program code, allowing for even greater control.

What's Next?

In this chapter, I've covered Web server applications, using multiple techniques (CGI, ISAPI, Apache dynamic modules) and two different frameworks of the Delphi class library: WebBroker and WebSnap. This wasn't certainly an in-depth presentation, as one could write an entire book on this topic alone. It was intended as a starting point, and (as usual) I've tried to make the core concepts clear rather than building very complex examples.

If you want to learn more details of the WebSnap framework and see different examples in actions, refer to the extensive Delphi demos for this area, in the `\Demos\WebSnap` folder. Some of the other available options, relating to XML, XSL, and client-side scripts, will be examined in the next chapter, where I'll also discuss Web services as a powerful alternative to HTTP/HTML-based distributed applications.

CHAPTER 23

XML and SOAP

- Introducing XML, Extensible Markup Language
- Working with XML: DOM and SAX
- Delphi 6 and XML: interfaces and mapping
- Internet Express
- Using XSTL
- Web services
- SOAP and WSDL

Building applications for the Internet means using protocols and creating browser-based user interfaces, as we've done in the preceding two chapters, but also opens up the opportunity of exchanging business documents electronically. The emerging standards for this type of activity all center around the XML document format and include the SOAP transmission protocol, XML schemas for the validation of documents, and XSL for rendering them as HTML.

In this chapter, I'll discuss all of these technologies and the extensive support Delphi 6 offers for them, a series of features collectively known as BizSnap. Since you might not know XML and related technologies, I'll provide a little introduction about each of them, but you should refer to books specifically devoted to each subject to know more. What I won't try to do is to cover *why* this is a revolution for running the IT side of a business and what it opens up. In the conclusion of the chapter, I'll point you to some initiatives you might be interested in tracking.

Introducing XML

XML, or Extensible Markup Language, is a simplified version of SGML and is getting a lot of attention in the IT world. XML is a *markup language*, meaning it uses symbols to describe its own content—in this case, *tags* consisting of specially defined text enclosed in angle brackets. It is named *extensible* because it allows for free markers (in contrast, for example, to HTML, which has predefined markers). The XML language is a standard promoted by the World Wide Web Consortium (better known as W3C, `www.w3.org`).

TIP The XML Recommendation is at `www.w3.org/TR/REC-xml`.

XML has been touted as the ASCII of year 2000, to indicate a simple and widespread technology, and also to indicate that XML document is actually a plain text file (optionally with Unicode characters instead of plain ACSII text). The important element of XML is that it is descriptive, as every tag has an almost human-readable name. Here is a small example, in case you've never seen an XML document:

```
<book>
  <title>Mastering Delphi 6</title>
  <author>Cantu</author>
  <publisher>Sybex</publisher>
</book>
```

WARNING XML has also a few disadvantages I want to underline from the beginning. The biggest is that without a formal description, a document is worth very little. If you want to exchange documents with another company, you have to agree on what each tag means and also on the semantic meaning of the content. (For example, when you have a quantity, you have to agree on the measurement system or include it in the document.) Another disadvantage is that XML documents are much larger than other formats; using strings for numbers, for example, is far from efficient, and the repeated opening and closing tags eat up a lot of space. The good news is that XML compresses quite well, exactly for the same reasons.

Core XML Syntax

There are a few technical elements of XML that are worth knowing before discussing its usage within Delphi. Here is a short summary of the key elements of the XML syntax:

- White space (including the space character, carriage return, line feed, and tabs) is generally ignored (as in an HTML document). It is important to format an XML document to make it readable by a human being, but your programs won't care much.
- You can add comments within `<!--` and `-->` markers, which are basically ignored by any XML processor. There are also directives and processing instructions, enclosed within the `<?` and `?>` markers.
- There a few special or reserved characters you cannot use in the text. The only two symbols you can *never* use are the less-than character (or "left angle bracket," used to delimit a marker) replaced by `&lt;` and the ampersand character replaced by `&amp;`. Other optional special characters are `&gt;` for the greater-than symbol (right angle bracket), `&apos;` for the single quote, and `&quot;` for the double quote.
- To add non-XML content (for example, binary information or a script), you can use a CDATA section, enclosed within `<![CDATA[` and `]]>`.
- All markers are enclosed by angle brackets, < and >. Markers are case sensitive (in contrast to HTML).
- For each opening marker, you must have a matching closing marker, denoted by an initial slash character, as in:

  ```
  <node>value</node>
  ```

- Markers must not overlap—they must be *properly nested*, as in the first line below (the second line is not correct):

  ```
  <node>xx <nested> yy</nested> </node>  // OK
  <node>xx <nested> yy</node> </nested>  // WRONG
  ```

- If a marker has no content (but its presence is important anyway), you can replace the opening and closing markers with an single marker that includes a final or "trailing" slash: `<node/>`.
- Markers can also have attributes, using multiple attribute names followed by a value enclosed within quotes: `<node attrib1="aaa">`.
- Any XML node can have multiple attributes, multiple embedded tags, and only one block of text, representing the value of the node. If it's technically possible, it is common practice for XML nodes to have either a textual value or embedded tags, and not both. Here is an example of the full syntax of a node:

  ```
  <node attrib1="aaa" attrib2="bbb">
    value1
    <child1>
      value2
    </child1>
  </node>
  ```

- A node can have multiple child nodes with the same tag (tags need not be unique). Attribute names are unique for each node.

Well-Formed XML

If the elements discussed in the previous section define the syntax of an XML document, they are not enough. A XML document is considered syntactically correct, or *well formed*, if it follows a few extra rules. Notice that this type of check doesn't guarantee that the content of the document is meaningful, but only the tags are properly laid out.

One of the rules is that each document should have a prologue, indicating that is it indeed an XML document, which version of XML it complies with, and the possibly the type of character encoding. Here is an example:

```
<?xml version="1.0" encoding="UTF-8"?>
```

Possible encodings include various Unicode character sets (such as UTF-8, UTF-16, and UTF-32) or some ISO encodings (such as ISO-10646-xxx or ISO-8859-xxx). The prologue can also include external declarations, the schema used to validate the document, namespace declarations, an associated XSL file, and some internal entity declarations. Refer to XML documentation or books for more information on these topics.

An XML document is well formed if it has a prologue, has a proper syntax (see the rules in the previous section), and has a tree of nodes with a single root. Most tools (including Internet Explorer) check whether a document is well formed when loading it.

NOTE As you can see, XML is more formal and precise than HTML. The W3C is coming along with an XHTML standard that will make HTML documents XML-compliant, for better processing with XML tools. This implies many changes in a typical HTML document, such as avoiding attributes with no values, adding all the closing markers (as `</p>` and `</li>`), adding the slash to stand-alone markers (as `<hr/>` and `<br/>`), proper nesting, and more. An HTML-to-XHTML converter, called HTML Tidy, is hosted by the W3C Web site at `www.w3.org/People/Raggett/tidy/`.

Working with XML

To get acquainted with the format of XML, you can use one of the existing XML editors available on the market. You can also simply type your XML code into Notepad and then try to load it into Internet Explorer to see whether it is correct. In this case, you'll see it within the browser in a tree-like structure.

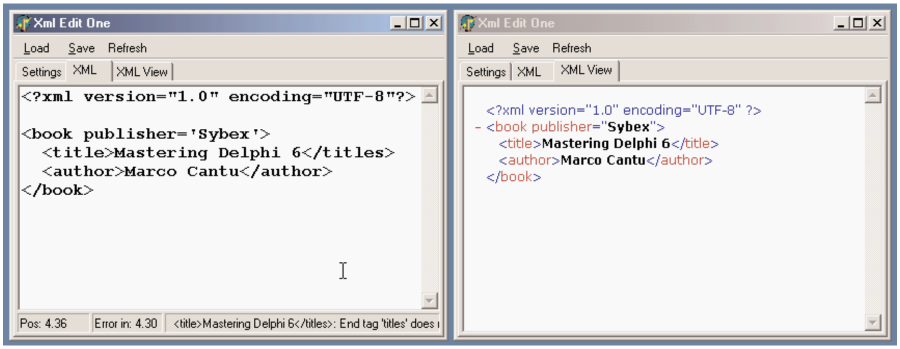
To speed up this type of operation, I've build the simplest XML editor I could come up with—basically Notepad with some XML syntax-checking and a browser attached to it. The XmlEditOne example has a PageControl with three pages. The first page, Settings, hosts a couple of components where you can insert the path and the name of the file and you want to work with. (The reason for not using a standard dialog will become clear when I show you an extension of the program.) The edit box hosting the complete filename is automatically updated with the path and filename, provided the AutoUpdate check box is selected.

The second page hosts a Memo control, with the text of the XML file, loaded and saved by clicking the two toolbar buttons. As soon as you load the file, or each time you modify its text, its content is loaded into a DOM to let a parser check for its correctness (something that would be quite complex to do with your own code). To parse the code, I've used the XMLDocument component available in Delphi 6, which is basically a wrapper around a DOM available on the computer and indicated by its `DOMVendor` property. I'll discuss the use of this component in a little more detail in the next section. For the moment, suffice to say you can assign a string list to its `XML` property and activate it to let it parse the XML text and eventually report an error with an exception.

For this specific example, though, this behavior is far from good, because while typing the XML code you'll have temporarily incorrect XML. Still, I prefer not to ask the user to click a button to do the validation, but let it run continuously. As it is not possible to disable the parse exception raised by the XMLDocument component, I had to work at a lower level, extracting the `DOMPersist` property (referring to the persistency interface of the DOM) after extracting the `IXMLDocumentAccess` interface from the XMLDocument component (called `XmlDoc` in this code). At this point, I can also extract the IDOMParseError interface from the document component, to display any error message in the status bar:

```
procedure TFormXmlEdit.MemoXmlChange(Sender: TObject);
var
  eParse: IDOMParseError;
begin
  XmlDoc.Active := True;
  xmlBar.Panels[1].Text := 'OK';
  xmlBar.Panels[2].Text := '';
  (XmlDoc as IXMLDocumentAccess).DOMPersist.loadxml(MemoXml.Text);
  eParse := (XmlDoc.DOMDocument as IDOMParseError);
  if eParse.errorCode <> 0 then
    with eParse do
    begin
      xmlBar.Panels[1].Text := 'Error in: ' + IntToStr (Line) + '.' +
        IntToStr (LinePos);
      xmlBar.Panels[2].Text := SrcText + ': ' + Reason;
    end;
end;
```

You can see an example of the output of the program in Figure 23.1, alongside the XML tree view provided by the third page (for a correct document). The third page of the program is built using the WebBrowser component, which embeds the ActiveX control of Internet Explorer. Unfortunately, there is no direct way to assign a string with the XML text to this control, so you'll have to save the file first and then move to its page to trigger the loading of the XML in the browser (or manually click the Refresh button).



```
<?xml version="1.0" encoding="UTF-8"?>

```

FIGURE 23.1:

The XmlEditOne example allows you to enter XML text in a memo, indicating errors as you type, and shows the result in the embedded browser.

WARNING Unicode support in Internet Explorer 5 is quite limited, even on Windows 2000 (which has, in general, rather good Unicode support). If you change the final letter in my last name to an accented letter, as it should be, you won't see any problem when checking the document with the DOM, but you'll see an error when viewing it in the browser. The same happens if you change the format to UTF-16.

Managing XML Documents

Now that you know the core elements of XML, we can start discussing how to manage XML documents in Delphi programs (or in programs in general, as some of the techniques discussed here go beyond the language used). There are two typical techniques for manipulating XML documents, using a Document Object Model (DOM) interface or using the Simple API for XML (SAX). The two approaches are quite different:

- The DOM loads the entire document into a hierarchical tree of nodes, allowing you to read them and manipulate them to change the document. For this reason, the DOM is suited when you want to navigate the XML structure in memory and edit it, or even for creating new documents from scratch.
- The SAX parses the document firing an event for each element of the document, without building any structure in memory. Once parsed by the SAX, the document is lost, but this operation is generally much faster than the construction of the DOM tree. Using the SAX is good for reading a document once, possibly looking for portion of its data.

There is a third classic way to manipulate (and specifically create) XML documents: string management. Creating a document by adding strings is certainly the fastest operation, particularly if you can do a single pass (and don't need to modify nodes already generated). Even reading documents by means of string functions is very fast, but this can become quite difficult for complex structures.

Finally, Delphi 6 provides two more techniques you should consider. The first is the definition of interfaces mapping the document structure and used to access the document instead of the generic DOM interface. As we'll see, this approach makes for faster coding and more robust applications. Another technique is the development of transformations that allow you to read a generic XML document into a ClientDataSet component or save the dataset into an XML file of a given structure (not the specific XML structure natively supported by the ClientDataSet, or MyBase).

I won't try to fully assess which option is better suited for each type of document and manipulation, but I will try to highlight some of the advantages and disadvantages while discussing examples of each approach in the next sections.

Programming with the DOM

Since an XML document has a tree-like structure, loading an XML document into a tree in memory is quite a natural fit. This is what the Document Object Model does. The DOM is a standard interface, so that when you have written code that uses a DOM, you can switch DOM implementations without changing your source code (at least, if you haven't used any non-custom extensions).

In Delphi, you can install several DOM implementations, available as COM servers, and use their interfaces. One of the most commonly used DOMs on Windows is the one provided by Microsoft as part of the MSXML SDK. That DOM is also used by Internet Explorer (even if generally in an older version), but the SDK contains some rather detailed documentation, which will probably help you. Other frequently used DOMs are available from IBM and Apache (this one is called Xerces).

TIP There are also a couple of native Object Pascal DOM components. One is the open source OpenXML, available at `www.philo.de/xml`. Another native Delphi DOM is offered by TurboPower. The advantage of these solutions is that they don't require an external library for the program to execute, because the DOM component gets compiled into your application.

Delphi 6 embeds the DOM implementations into a wrapper component, called XMLDocument. I've just used this component in the preceding example, but here I want to examine its role in a more general way. The idea behind using this component is that, instead of the actual DOM interface, you remain even more independent from the implementations and can work with some simplified methods, or helpers.

The DOM interface, in fact, is quite complex to use. A document is a collection of nodes, each having a name, a text element, a collection of attributes, and a collection of child nodes. Each collection of nodes allows accessing elements by position or searching them by name. Notice that the text within the tags of a node, if any, is rendered as a child of the node and listed in its collection of child nodes. The root node has some extra methods for creating new nodes, values, or attributes.

With Delphi's XMLDocument, you can actually work at two different levels:

- At a lower level, you can use the `DOMDocument` property (of the `IDOMDocument` interface type) to access a standard W3C Document Object Model interface. The official DOM is defined in the xmldom unit, and includes interfaces like `IDOMNode`, `IDOMNodeList`, IDOMAttr, IDOMElement, and IDOMText. With the official DOM interfaces, Delphi supports a lower-level but standard programming model. Notice that the actual DOM implementation will be the one indicated by the XMLDocument component.

- As a higher-level alternative, the XMLDocument component implements also the IXMLDocument interface. This is a custom DOM-like interface defined by Borland in the XMLIntf unit and comprising interfaces like IXMLNode, IXMLNodeList, and IXMLNodeCollection. This Borland interface simplifies some of the DOM operations by replacing multiple method calls, which are repeated quite often in sequence, with a single property or method.

In the following examples (particularly the DomCreate demo), I'll use both approaches so you can have a better idea of the practical differences among the two approaches.

An XML Document in a TreeView

The starting point is generally loading a document from a file or creating it from a string, but you can also start with a brand new document. As a first example of the use of the DOM, I've built a program that can load an XML document into a DOM and show its structure in a TreeView control. I've also added to the program, called XmlDomTree on the companion CD, a few buttons with sample code used to access to the elements of a sample file, as an example of accessing the DOM data. Loading the document is actually quite simple, while showing it in a tree requires a recursive function that navigates the nodes and subnodes. Here is the code of the two methods:

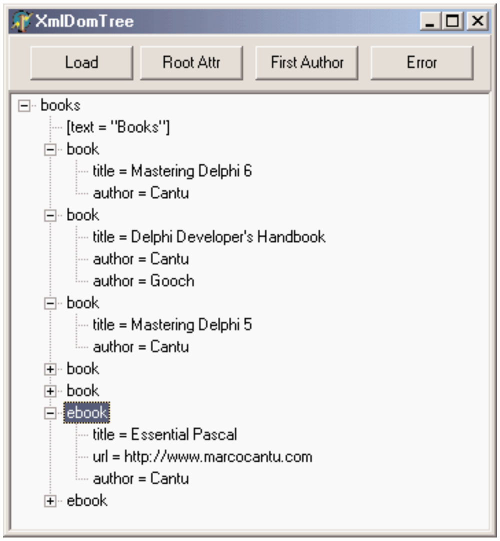
```
procedure TFormXmlTree.btnLoadClick(Sender: TObject);
begin
  OpenDialog1.InitialDir := ExtractFilePath (Application.ExeName);
  if OpenDialog1.Execute then
  begin
    XMLDocument1.LoadFromFile(OpenDialog1.FileName);
    Treeview1.Items.Clear;
    DomToTree (XMLDocument1.DocumentElement, nil);
    TreeView1.FullExpand;
  end;
end;

procedure TFormXmlTree.DomToTree (XmlNode: IXMLNode; TreeNode: TTreeNode);
var
  I: Integer;
  NewTreeNode: TTreeNode;
  NodeText: string;
  AttrNode: IXMLNode;
begin
  // skip text nodes and other special cases
  if not (XmlNode.NodeType = ntElement) then
    Exit;
  // add the node itself
  NodeText := XmlNode.NodeName;
  if XmlNode.IsTextElement then
    NodeText := NodeText + ' = ' + XmlNode.NodeValue;
  NewTreeNode := TreeView1.Items.AddChild(TreeNode, NodeText);
  // add attributes
  for I := 0 to xmlNode.AttributeNodes.Count - 1 do
  begin
    AttrNode := xmlNode.AttributeNodes.Nodes[I];
    TreeView1.Items.AddChild(NewTreeNode,
      '[' + AttrNode.NodeName + ' = "' + AttrNode.Text + '"]');
  end;
  // add each child node
  if XmlNode.HasChildNodes then
    for I := 0 to xmlNode.ChildNodes.Count - 1 do
      DomToTree (xmlNode.ChildNodes.Nodes [I], NewTreeNode);
end;
```

This code is quite interesting, as it highlights some of the operations you can do with a DOM. First of all, each node has a `NodeType` property that you can use to determine whether the node is an element, attribute, text node, or special entity (such as CDATA and others). Another aspect is that you cannot access the textual representation of the node, its `NodeValue`, unless it has a text element (notice that the text node will be skipped, as per the initial test). After displaying the name of the item, and then the text value if available, the program (Figure 23.2) shows the content of each attribute directly and of each subnode calling the `DomToTree` method recursively.

FIGURE 23.2:

The XmlDomTree example can open a generic XML document and show it inside a TreeView common control.



```

Once you have loaded the sample document that accompanies the XmlDomTree program (and shown in Listing 23.1) into the XMLDocument component, you can use the various methods to access generic nodes, as in tree-building code above, or fetch specific elements. For example, you can grab the value of the attribute *text* of the root node by writing:

```
XMLDocument1.DocumentElement.Attributes ['text']
```

Notice that if there is no attribute called *text*, the call will fail with a rather generic error message, "Invalid variant type conversion," which helps neither you nor the end user to understand what's wrong. If you need to access to the first attribute of the root without knowing its name, you can use the following more generic code:

```
XMLDocument1.DocumentElement.AttributeNodes.Nodes[0].NodeValue
```

To access the actual nodes, you use a similar technique, possibly taking advantage of the `ChildValues` array. This is a Delphi extension to the DOM, which allows you to pass as parameter either the name of the element or its numeric position:

```
XMLDocument1.DocumentElement.ChildNodes.Nodes[1].ChildValues['author']
```

This code gets the (first) author of the second book. I cannot use the `ChildValues['book']` expression, as there are multiple nodes with the same name under the root node.

Listing 23.1: The sample XML document used by examples in this chapter

Creating Documents Using the DOM

Although I mentioned earlier that you can create an XML document by chaining together some strings, this is far from a robust technique. Using a DOM to create a document ensures that the XML will be well formed. Also, if the DOM has a schema definition attached, you can validate the structure of the document while adding data to it.

To highlight different cases of document creation, I've built the DomCreate example (a program I originally created with the Xerces DOM from the Apache group and changed slightly for supporting Delphi's XMLDocument). This program can create XML documents within the DOM, showing the text of them on a memo and optionally in a TreeView.

TIP The XMLDocument component uses the `doAutoIndent` option to improve the output of the XML text to the memo by formatting the XML in a slightly better way. You can choose the type of indentation by setting the `NodeIndentStr` property. For formatting a generic XML text, you can also use the global `FormatXMLData` function using the default setting (2 spaces) as indentation. Oddly, there doesn't seem a way to pass a different parameter to the function.

The first button of the form, Simple, creates some simple XML text using the low-level, official DOM interfaces. The program calls the `createElement` method of the document for each node, adding them as children of other nodes:

```
procedure TForm1.btnSimpleClick(Sender: TObject);
var
  iXml: IDOMDocument;
  iRoot, iNode, iNode2, iChild, iAttribute: IDOMNode;
begin
  // empty the document
  XMLDoc.Active := False;
  XMLDoc.XML.Text := '';
  XMLDoc.Active := True;

  // root
  iXml := XmlDoc.DOMDocument;
  iRoot := iXml.appendChild (iXml.createElement ('xml'));
  // node "test"
  iNode := iRoot.appendChild (iXml.createElement ('test'));
  iNode.appendChild (iXml.createElement ('test2'));
  iChild := iNode.appendChild (iXml.createElement ('test3'));
  iChild.appendChild (iXml.createTextNode('simple value'));
  iNode.insertBefore (iXml.createElement ('test4'), iChild);

  // node replication
  iNode2 := iNode.cloneNode (True);
  iRoot.appendChild (iNode2);

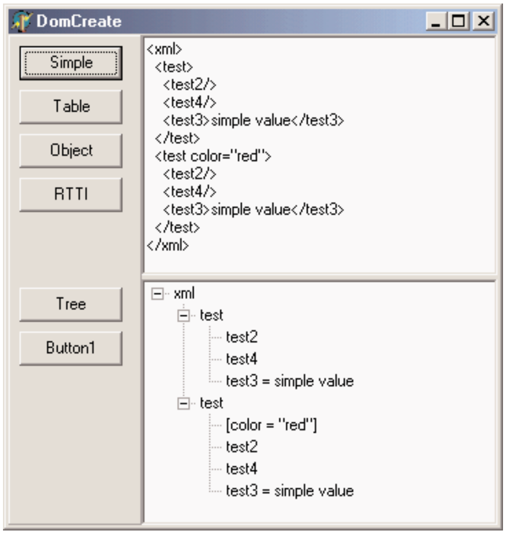
  // add an attribute
  iAttribute := iXml.createAttribute ('color');
  iAttribute.nodeValue := 'red';
  iNode2.attributes.setNamedItem (iAttribute);

  // show XML in memo
  Memo1.Lines.Text := FormatXMLData (XMLDoc.XML.Text);
end;
```

Notice that text nodes are added explicitly, attributes are created with a specific create call, and that the code uses `cloneNode` to replicate an entire branch of the tree. Overall, the code is quite cumbersome to write, but after a while you might get used to this style. The effect of the program is visible (formatted in the memo and in the tree) in Figure 23.3.

FIGURE 23.3:

The DomCreate example can generate various types of XML documents using a DOM.



```
<xml>
 <test>
  <test2/>
  <test4/>
  <test3>simple value</test3>
 </test>
 <test color="red">
  <test2/>
  <test4/>
  <test3>simple value</test3>
 </test>
</xml>
```

```
⊟ xml
  ⊟ test
      test2
      test4
      test3 = simple value
  ⊟ test
      [color = "red"]
      test2
      test4
      test3 = simple value
```

The second example of DOM creation relates to a dataset. I've added to the form a BDE Table component (but any other dataset would have done) and added to a button the call to my custom `DataSetToDOM` procedure, like this:

```
DataSetToDOM ('customers', 'customer', XMLDoc, Table1);
```

The DataSetToDOM procedure creates a root node with the text of the first parameter, then grabs each record of the dataset, defines a node with the second parameter, and adds a subnode for each field of the record, all using extremely generic code:

```
procedure DataSetToDOM (RootName, RecordName: string; XMLDoc: TXMLDocument;
  DataSet: TDataSet);
var
  iNode, iChild: IXMLNode;
  i: Integer;
begin
  DataSet.Open;
  DataSet.First;
  // root
  XMLDoc.DocumentElement := XMLDoc.CreateNode (RootName);

  // add table data
  while not DataSet.EOF do
  begin
    // add a node for each record
    iNode := XMLDoc.DocumentElement.AddChild (RecordName);
    for I := 0 to DataSet.FieldCount - 1 do
    begin
      // add an element for each field
      iChild := iNode.AddChild (DataSet.Fields[i].FieldName);
      iChild.Text := DataSet.Fields[i].AsString;
    end;
    DataSet.Next;
  end;
end;
```

The preceding code uses the simplified DOM access interfaces provided by Borland, which include an AddChild node that creates the subnode, and the direct access to the Text property for defining a child node with textual content. This apparently simple routine extracts an XML representation of your dataset, also opening up a lot of opportunities for Web publishing, as I'll discuss later in the section on XSL.

Another interesting opportunity is the generation of XML documents describing Delphi objects. The DomCreate program has a button used to describe a few selected properties of an object, again using the low-level DOM:

```
procedure AddAttr (iNode: IDOMNode; Name, Value: string);
var
  iAttr: IDOMNode;
begin
  iAttr := iNode.ownerDocument.createAttribute (name);
  iAttr.nodeValue := Value;
  iNode.attributes.setNamedItem (iAttr);
end;
```

```
procedure TForm1.btnObjectClick(Sender: TObject);
var
  iXml: IDOMDocument;
  iRoot: IDOMNode;
begin
  // empty the document
  XMLDoc.Active := False;
  XMLDoc.XML.Text := '';
  XMLDoc.Active := True;

  // root
  iXml := XmlDoc.DOMDocument;
  iRoot := iXml.appendChild (iXml.createElement ('Button1'));

  // a few properties as attributes (might also be nodes)
  AddAttr (iRoot, 'Name', Button1.Name);
  AddAttr (iRoot, 'Caption', Button1.Caption);
  AddAttr (iRoot, 'Font.Name', Button1.Font.Name);
  AddAttr (iRoot, 'Left', IntToStr (Button1.Left));
  AddAttr (iRoot, 'Hint', Button1.Hint);

  // show XML in memo
  Memo1.Lines := XmlDoc.XML;
end;
```

Of course, it is more interesting to have a generic technique capable of saving the properties of each Delphi component (or persistent object, to be more precise), recursing on persistent subobjects and indicating the names of referenced components. This is what I've done in the ComponentToDOM procedure, which uses the low-level RTTI information provided by the TypInfo unit, including the extraction of the list of the properties of a component. Once more, the program uses the simplified Delphi XML interfaces:

```
procedure ComponentToDOM (iNode: IXmlNode; Comp: TPersistent);
var
  nProps, i: Integer;
  PropList: PPropList;
  Value: Variant;
  newNode: IXmlNode;
begin
  // get list of properties
  nProps := GetTypeData (Comp.ClassInfo)^.PropCount;
  GetMem (PropList, nProps * SizeOf(Pointer));
  try
    GetPropInfos (Comp.ClassInfo, PropList);
    for i := 0 to nProps - 1 do
    begin
      Value := GetPropValue (Comp, PropList [i].Name);
      NewNode := iNode.AddChild(PropList [i].Name);
      NewNode.Text := Value;
      if (PropList [i].PropType^.Kind = tkClass) and (Value <> 0) then
        if TObject (Integer(Value)) is TComponent then
          NewNode.Text := TComponent (Integer(Value)).Name
        else
          // TPersistent but not TComponent: recurse
          ComponentToDOM (newNode, TObject (Integer(Value)) as TPersistent);
    end;
  finally
    FreeMem (PropList);
  end;
end;
```

These two lines of code, in this case, trigger the creation of the XML document (visible in Figure 23.4):

```
XMLDoc.DocumentElement := XMLDoc.CreateNode(self.ClassName);
ComponentToDOM (XMLDoc.DocumentElement, self);
```

FIGURE 23.4:

The XML generated to describe the form of the DomCreate program. Notice (in the tree and in the memo text) that properties of class types are further expanded.

XML Data Binding Interfaces

We have seen that working with the DOM to access or generate a document is rather tedious, because you must use positional information and not logical access to the data. Also, handling series of repeated nodes of different possible types (as in the XML sample of Listing 23.1, describing books) is far from simple. Moreover, using a DOM, you can create any well-formed document, but (unless you use a validating DOM) you can add any subnode to any node, coming up with almost useless documents, as no one else will be able to manage them.

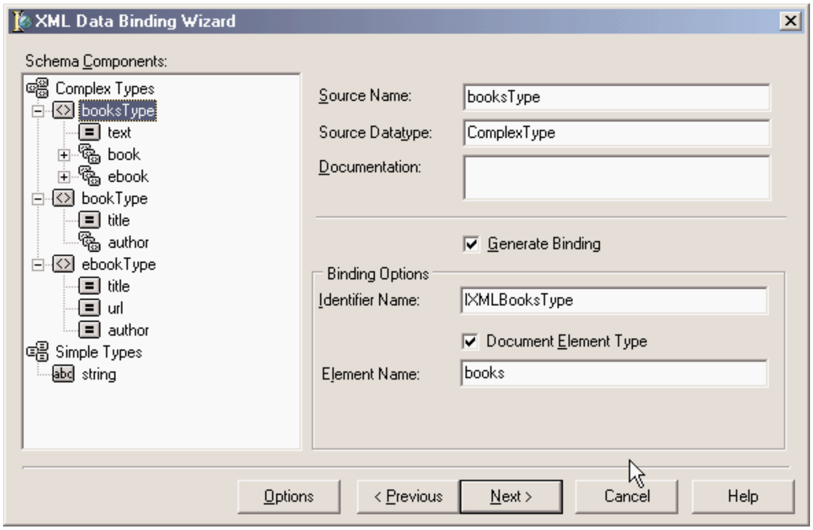
To solve these issues, Borland has added to Delphi 6 an XML Data Binding Wizard, which can examine an XML document or a document definition (a schema, a DTD, or another type of definition) and generate a set of interfaces for manipulating the document. These interfaces are specific to the document and its structure, and allow you to have more readable code, but are certainly less generic as far as the types of documents you can handle with them (and this is far more positive than it might sound at first).

You can activate the XML Data Binding Wizard by using the corresponding icon in the first page of the New Items dialog box of the IDE or by double-clicking directly on the XMLDocument component. (What is quite odd is that the corresponding command is not in the local menu of the component.)

After a first page where you can select a input file, this wizard shows you the structure of the document graphically, as you can see in Figure 23.5 for the sample XML file from Listing 23.1. In this page, you can give a name to each entity of the generated interfaces, in case you don't like the defaults suggested by the wizard. You can actually also change the rules used by the wizard to generate the names, an extended flexibility I'd like to have in other areas of the Delphi IDE. The final page gives you a preview of the generated interfaces and offers options for generating schemas and other definition files.

FIGURE 23.5:

Delphi's XML Data Binding Wizard can examine the structure of a document or a schema (or another document definition) to create a set of interfaces for simplified and direct access to the DOM data.



Source Name: booksType

Source Datatype: ComplexType

Documentation:

☑ Generate Binding

Binding Options

Identifier Name: IXMLBooksType

☑ Document Element Type

Element Name: books

For the sample XML file with the author names, the XML Data Binding Wizard generates an interface of the root node, and four interfaces for the two lists of different elements and the actual elements (books and e-books). These are a few excerpts of the generated code, available in the XmlIntfDefinition unit of the XmlInterface example:

```
type
  IXMLBooksType = interface(IXMLNode)
    ['{C9A9FB63-47ED-4F27-8ABA-E71F30BA7F11}']
    { Property Accessors }
    function Get_Text: WideString;
    function Get_Book: IXMLBookTypeList;
    function Get_Ebook: IXMLEbookTypeList;
    procedure Set_Text(Value: WideString);
    { Methods & Properties }
    property Text: WideString read Get_Text write Set_Text;
    property Book: IXMLBookTypeList read Get_Book;
    property Ebook: IXMLEbookTypeList read Get_Ebook;
  end;

  IXMLBookTypeList = interface(IXMLNodeCollection)
    ['{3449E8C4-3222-47B8-B2B2-38EE504790B6}']
    { Methods & Properties }
    function Add: IXMLBookType;
    function Insert(const Index: Integer): IXMLBookType;
    function Get_Item(Index: Integer): IXMLBookType;
    property Items[Index: Integer]: IXMLBookType read Get_Item; default;
  end;

  IXMLBookType = interface(IXMLNode)
    ['{26BF5C51-9247-4D1A-8584-24AE68969935}']
    { Property Accessors }
    function Get_Title: WideString;
    function Get_Author: IXMLString_List;
    procedure Set_Title(Value: WideString);
    { Methods & Properties }
    property Title: WideString read Get_Title write Set_Title;
    property Author: IXMLString_List read Get_Author;
  end;
```

For each interface, the XML Data Binding Wizard also generates an implementation class that provides the code for the interface methods by translating the requests into DOM calls. The unit includes three initialization functions, which can return the interface of the root node from a document loaded in an XMLDocument component (or a component providing a generic IXMLDocument interface), or return one from a file, or create a brand new DOM:

```
function Getbooks(Doc: IXMLDocument): IXMLBooksType;
function Loadbooks(const FileName: WideString): IXMLBooksType;
function Newbooks: IXMLBooksType;
```

After generating these interfaces using the wizard, in the XmlInterface example, I've repeated XML document access code similar to the XmlDomTree example, but much simpler to write (and to read). For example, you can get the attribute of the root node by writing:

```
procedure TForm1.btnAttrClick(Sender: TObject);
var
  Books: IXMLBooksType;
begin
  Books := Getbooks (XmlDocument1);
  ShowMessage (Books.Text);
end;
```

Simple, isn't it? It is even simpler if you recall that while typing this code, Delphi's code insight can help by listing the available properties of each node, thanks to the fact that the parser can read in the interface definitions (while it cannot understand the format of a generic XML document). Accessing a node of one of the sublists is a matter of writing one of the following statements (possibly the second with the default array property):

```
Books.Book.Items[1].Title  // full
Books.Book[1].Title        // further simplified
```

Similarly simplified code can be used to generate new documents or add new elements, also thanks to the customized Add method is available in each list-based interface. Again, if you don't have a predefined structure for the XML document, as in the dataset-based and RTTI-based examples of the previous demonstration, you won't be able to use this approach.

Validation and Schemas in Short

The XML Data Binding Wizard can work from existing schemas or generate one for an XML document (and eventually save it in a file with the .XDB extension). But what is a schema for, and what does it look like? An XML document describes some data, but to exchange this data among companies it has to stick to some agreed structure. A schema is a document definition, against which a document can be checked for correctness, an operation usually indicated with the term *validation*.

The first—and still very widespread—type of validation available for XML was *document type definitions (DTDs)*. These documents describe the structure of the XML but cannot really define the possible content of each node. Also, DTDs are not XML document themselves but use a different, very awkward notation.

At the end of year 2000, the W3C approved the first official draft of XML *schemas* (already available in an incompatible version called XML-Data within Microsoft's DOM). An XML schema is itself a XML document, one that can validate both the structure of the XML tree and the content of the node. A schema is based on the use and definition of simple and complex data types, similar to what happens in an OOP programming language.

A schema defines complex types, indicating for each the possible nodes, their optional sequence (sequence, all), the number of occurrences for each subnode (minOccurs, maxOccurs), and the data type of each specific element. Here is the schema defined by the XML Data Binding Wizard for the usual sample books file:

```
<?xml version="1.0"?>
<xs:schema xmlns:xs="http://www.w3.org/2001/XMLSchema"
  xmlns:xdb="http://www.borland.com/schemas/delphi/6.0/XMLDataBinding">
  <xs:element name="books" type="booksType"/>
  <xs:complexType name="booksType">
    <xs:annotation>
      <xs:appinfo xdb:docElement="books"/>
    </xs:annotation>
    <xs:sequence>
      <xs:element name="book" type="bookType" maxOccurs="unbounded"/>
      <xs:element name="ebook" type="ebookType" maxOccurs="unbounded"/>
    </xs:sequence>
    <xs:attribute name="text" type="xs:string"/>
  </xs:complexType>
  <xs:complexType name="bookType">
    <xs:annotation>
      <xs:appinfo xdb:repeated="True"/>
    </xs:annotation>
    <xs:sequence>
      <xs:element name="title" type="xs:string"/>
      <xs:element name="author" type="xs:string" maxOccurs="unbounded"/>
    </xs:sequence>
  </xs:complexType>
  <xs:complexType name="ebookType">
    <xs:annotation>
      <xs:appinfo xdb:repeated="True"/>
    </xs:annotation>
    <xs:sequence>
      <xs:element name="title" type="xs:string"/>
      <xs:element name="url" type="xs:string"/>
      <xs:element name="author" type="xs:string"/>
    </xs:sequence>
  </xs:complexType>
</xs:schema>
```

NOTE As I write, there are still very few DOM implementations that can be used to validate a document against an XML schema. Apache Xerces DOM has good support for schemas. Another tool I've used for validation is XSV (XML Schema Validator), an open source attempt at a conformant schema-aware processor, which can be used either directly via the Web or after downloading a command-line executable.

Using the SAX API

The Simple API for XML, or SAX, doesn't create a tree for the XML nodes, but simply parses the node-firing events for each node, attribute, value, and so on. Because it doesn't keep the document in memory, using the SAX allows managing much larger documents. Its approach is also very useful for one-time examination of a document, or retrieval of specific information. This is a list of events fired by the SAX:

- `StartDocument` and `EndDocument` for the entire document
- `StartElement` and `EndElement` for each node
- `Characters` for the text within the nodes

It is quite common to use a stack to handle the current path within the nodes tree, and push and pop elements to and from the stack for every `StartElement` and `EndElement` event.

Delphi 6 does not include specific support for the SAX interface, but this can be easily obtained by importing Microsoft's XML support (the MSXML library). In particular for the SaxDemo1 example I've used version 2 of MSXML: the Pascal version of its type library is available within the source code of the program, but you must have the COM library registered on your computer to run the program successfully.

To use the SAX, you have to install a SAX event handler within a SAX reader, then load a file and parse it. I've used the SAX reader interface provided by MSXML for VB programmers. In fact, the official (C++) interface had a few errors in its type library that prevented Delphi from importing it properly (the newer MSXML 3 might have fixed this issue by the time you read this).

In the main form of the SaxDemo1 example, I've declared:

```
sax: IVBSAXXMLReader;
```

In the `FormCreate` method, this is initialized with the actual COM object:

```
sax := CreateComObject (CLASS_SAXXMLReader) as IVBSAXXMLReader;
sax.ErrorHandler := TMySaxErrorHandler.Create;
```

The code also sets an error handler, which is a class implementing a specific interface, `IVBSAXErrorHandler`, with three methods that are called depending on the severity of the problem: `error`, `fatalError`, and `ignorableWarning`.

Simplifying the code a little, the SAX parser is activated by calling the `parseURL` method after assigning a content handler to it:

```
sax.ContentHandler := TMySaxHandler.Create;
sax.parseURL (filename)
```

So the code ultimately resides in the `TMySaxHandler` class, which has the SAX events. Because I have multiple SAX content handlers in this example, I've written a base class with the core code and a few specialized versions for specific processing; this is the code of the base class, which implements both the `IDispatch` and `IVBSAXContentHandler` interfaces:

```
type
  TMySaxHandler = class (TInterfacedObject, IVBSAXContentHandler)
  protected
    stack: TStringList;
  public
    constructor Create;
    destructor Destroy; override;
    // IDispatch
    function GetTypeInfoCount(out Count: Integer): HResult; stdcall;
    function GetTypeInfo(Index, LocaleID: Integer; out TypeInfo):
      HResult; stdcall;
    function GetIDsOfNames(const IID: TGUID; Names: Pointer;
      NameCount, LocaleID: Integer; DispIDs: Pointer): HResult; stdcall;
    function Invoke(DispID: Integer; const IID: TGUID; LocaleID: Integer;
      Flags: Word; var Params; VarResult, ExcepInfo, ArgErr: Pointer):
      HResult; stdcall;
    // IVBSAXContentHandler
    procedure Set_documentLocator(const Param1: IVBSAXLocator);
      virtual; safecall;
    procedure startDocument; virtual; safecall;
    procedure endDocument; virtual; safecall;
    procedure startPrefixMapping(var strPrefix: WideString;
      var strURI: WideString); virtual; safecall;
    procedure endPrefixMapping(var strPrefix: WideString); virtual; safecall;
    procedure startElement(var strNamespaceURI: WideString;
      var strLocalName: WideString; var strQName: WideString;
      const oAttributes: IVBSAXAttributes); virtual; safecall;
    procedure endElement(var strNamespaceURI: WideString;
      var strLocalName: WideString; var strQName: WideString);
      virtual; safecall;
    procedure characters(var strChars: WideString); virtual; safecall;
    procedure ignorableWhitespace(var strChars: WideString);
      virtual; safecall;
    procedure processingInstruction(var strTarget: WideString;
      var strData: WideString); virtual; safecall;
    procedure skippedEntity(var strName: WideString); virtual; safecall;
  end;
```

The most interesting portion, of course, is the final list of SAX events. All this base class does is emit information to a log when the parser starts (`startDocument`) and finishes (`endDocument`) and keep track of the current node and all of its parent nodes with a stack:

```
// TMySaxHandler.startElement
stack.Add (strLocalName);
// TMySaxHandler.endElement
```

```
stack.Delete (stack.Count - 1);
```

An actual implementation is provided by the `TMySimpleSaxHandler` class, which overrides the `startElement` event triggered for any new node to output the current position in the tree with the statement:

```
Log.Add (strLocalName + '(' + stack.CommaText + ')');
```

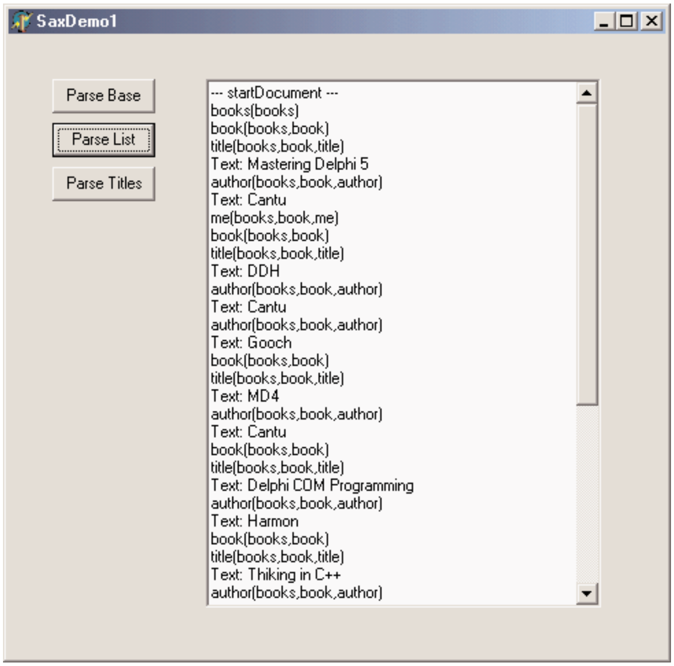
The second method of the class is the `characters` event, triggered when a node value (or a test node) is encountered, to output its content:

```
procedure TMySimpleSaxHandler.characters(var strChars: WideString);
var
  str: WideString;
begin
  inherited;
  str := RemoveWhites (strChars);
  if (str <> '') then
    Log.Add ('Text: ' + str);
end;
```

The two methods produce the combined effect of Figure 23.6.

FIGURE 23.6:

The log produced by reading an XML document with the SAX in the SaxDemo1 example



```
--- startDocument ---
books(books)
book(books,book)
title(books,book,title)
Text: Mastering Delphi 5

Text: Harmon
book(books,book)
title(books,book,title)
Text: Thiking in C++
author(books,book,author)
```

This is still a generic parsing operation affecting the entire XML file. The second derived SAX content handler class, instead, refers to the specific structure of the XML document, extracting only nodes of a give type. In particular, the program looks for nodes of the *title* type. When a node has this type (in `startElement`), the class sets the `isbook` Boolean variable. The text value of the node is considered only right after a node of this type is encountered:

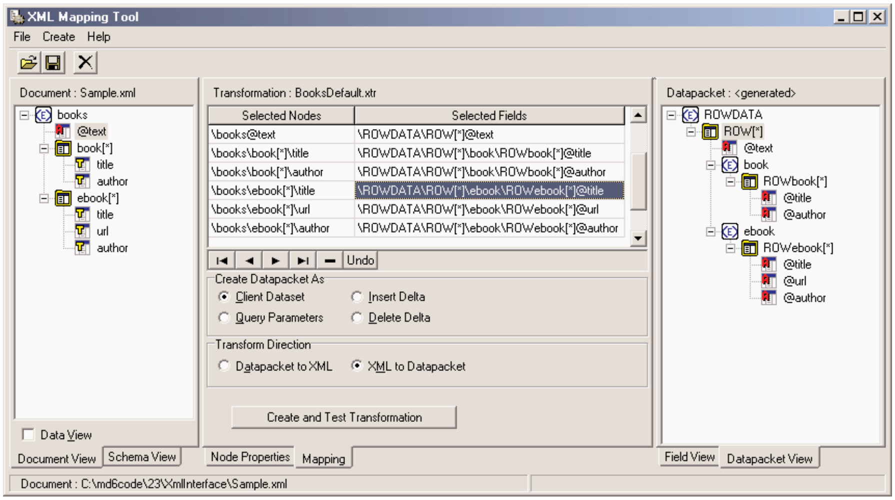
```
procedure TMyBooksListSaxHandler.startElement(var strNamespaceURI,
  strLocalName, strQName: WideString; const oAttributes: IVBSAXAttributes);
begin
  inherited;
  isbook := (strLocalName = 'title');
end;

procedure TMyBooksListSaxHandler.characters(var strChars: WideString);
var
  str: string;
begin
  inherited;
  if isbook then
  begin
    str := RemoveWhites (strChars);
    if (str <> '') then
      Log.Add (stack.CommaText + ': ' + str);
  end;
end;
```

Mapping XML with Transformations

There is one more technique you can use in Delphi 6 to handle at least some XML documents. You can create a *transformation* to translate the XML of a generic document into the format used natively by the ClientDataSet component when saving data to a MyBase XML file. In the reverse direction, another transformation can turn a dataset available within a ClientDataSet (through a DataSetProvider component) into a XML file of a required format (or schema).

Delphi 6 includes a wizard to generate such transformations. Called XML Mapping Tool, or XML Mapper for short, it is invokable from the Tools menu of the IDE or executed as a stand-alone application. The XML Mapper, visible in Figure 23.7, is a design-time helper that assists you in defining transformation rules between the nodes of a generic XML document and fields of the data packet of the ClientDataSet.



Selected Nodes	Selected Fields
\books@text	\ROWDATA\ROW[*]@text
\books\book[*]\title	\ROWDATA\ROW[*]\book\ROWbook[*]@title
\books\book[*]\author	\ROWDATA\ROW[*]\book\ROWbook[*]@author
\books\ebook[*]\title	\ROWDATA\ROW[*]\ebook\ROWebook[*]@title
\books\ebook[*]\url	\ROWDATA\ROW[*]\ebook\ROWebook[*]@url
\books\ebook[*]\author	\ROWDATA\ROW[*]\ebook\ROWebook[*]@author

Create Datapacket As

● Client Dataset ○ Insert Delta

○ Query Parameters ○ Delete Delta

Transform Direction

○ Datapacket to XML ● XML to Datapacket

Document : C:\md6code\23\XmlInterface\Sample.xml

FIGURE 23.7:

The XML Mapper shows the two sides of a transformation to define a mapping among them (with the rules indicated in the central portion).

The XML Mapper windows has three areas:

- On the left is the XML document section, which displays information about the structure of the XML document (and eventually its data, if the related check box is active) in the Document View or an XML schema in the Schema View, depending on the selected tab.
- On the right is the data packet section, which displays information about the metadata in the data packet, either in the Field View indicating the dataset structure or in the Datapacket View reporting the XML structure. Notice, in fact, that the XML Mapper can also open files in the native ClientDataSet format.
- The central portion of the windows is used by the mapping section. This contains two pages as well: one for Mapping, where you can see the correspondences between selected elements of the two sides that will be part of the mapping, and one for Node Properties, where you can modify the data types and other details of each of the possible mappings.

The Mapping page of the central pane also hosts the local menu used to generate the transformation, while each other pane and view has specific local menus you can use to perform the various actions (beside the few commands in the main menu).

You can use XML Mapper to map an existing schema (or extract it from a document) to a brand new data packet, an existing data packet to a new schema or document, or an existing data packet into an existing XML document (if a match is reasonable). Besides converting the data of an XML file into a data packet, you can also convert to a delta packet of the ClientDataSet. This is useful for merging a document to an existing table, as if a user had inserted them. In particular, you can transform an XML document into a delta packet for records to be modified, deleted, or inserted.

The result of using the XML Mapper is one or more transformation files, each representing a one-way conversion (so you need at least two transformation files to convert data back and forth). These transformation files are then used at design time and at run time by the XMLTransform, XMLTransformProvider, and XMLTransformClient components.

As an example, I've tried opening the usual "books" XML, which has a structure that doesn't easily match a table, since there are two lists of values of different types (I've skipped easier examples in which the XML has a plain rectangular structure). After opening the `Sample.XML` file in the XML Document section, I've used its local menu to select all of its elements (Select All) and to create the data packet (Create Datapacket From XML). This automatically fills the right pane with the data packet and the central portion with the proposed transformation. You can also immediately view its effect in a sample program by selecting the Create And Test Transformation button. This opens a generic application that can load a document into the dataset using the transformation you've just created, as you can see in Figure 23.8.

FIGURE 23.8:

The Create and Test Transformation button of the XML Mapper tool allows you to immediately verify the effect of the transformations you are building

Document : C:\md6code\23\XmlInterface\Sample.xml

In this specific case, you can see that the XML Mapper generates a table with two dataset fields, one of each possible list of subelements. This was the only possible standard solution, as the two sublists have different structures, and is the only solution that allows you to edit the data in a DBGrid attached to the ClientDataSet and save it back to a complete XML file, as demonstrated by the XmlMapping example. This program is basically a Windows-based editor of a complex XML document.

It uses a TransformProvider component, with two transformation files attached, to read in an XML document and make it available to a ClientDataSet. As the name suggests, in fact, this component is a dataset provider. To build the user interface, I haven't connected the

ClientDataSet directly to a grid, as it has a single record with a text field plus two detailed datasets. For this reason, I've added to the program two more ClientDataSet components, attached to the dataset fields and connected to two DBGrid controls. This is probably easier to understand by looking at its DFM source code in the following excerpt and at its output in Figure 23.9.

FIGURE 23.9:

The XmlMapping example uses a TransformProvider component to make a complex XML document available for editing within multiple ClientDataSet components.

    DataSetField = ClientDataSet1ebook
  end
  object DataSource3: TDataSource
    DataSet = ClientDataSet3
    Left = 232
    Top = 224
  end
  object DBGrid2: TDBGrid
    Align = alClient
    DataSource = DataSource3
  end
end
```

This program allows you to edit the data of the various sublists of nodes, within the grids, modifying them but also adding or deleting records. As you apply the changes to the dataset (clicking the Save button, which calls `ApplyUdpates`), the transform provider saves an updated version of the file to disk.

As an alternative approach, you can also create transformations that map only portions of the XML document into a dataset. As an example, see the `BooksOnly.xtr` file in the folder of the XmlMapping example. This can be useful for viewing the data, but the modified XML document you'll generate will have a different structure and content from the original, including only the portion you've selected. So this can be useful for viewing the data, but not for editing it.

NOTE It is not surprising that the transformation files are themselves XML documents, as you can see by opening one in the editor. This XML document uses a custom format.

At the opposite side, we can see how a transformation can be used to take a database table or the result of a query and produce an XML file with a more readable format than the one provided by default by the ClientDataSet persistence mechanism. To build the MapTable example, I've placed a table component on a form and attached a DataSetProvider to it and a ClientDataSet to the provider. After opening the table and the client dataset, I saved its content to an XML file.

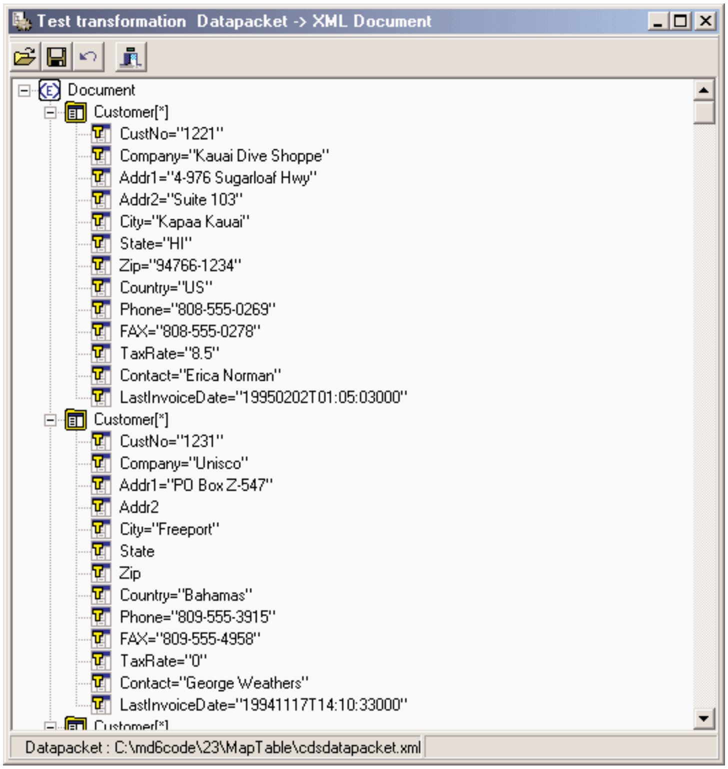
At that point, I opened the XML Mapper, loaded the data packet file into it, selected all of the data packet nodes (with the Select All command of its local menu) and invoked the Create XML From Datapacket command. In the following dialog box, I accepted the default name mappings for fields and only changed the suggested name for record nodes (*ROW*) into something more readable (*Customer*). If you now test the transformation, the XML Mapper will display the contents of the resulting XML document in a custom tree view, as you can see in Figure 23.10.

After saving the transformation file, I was ready to resume developing the program, adding to it another provider that takes the data from the ClientDataSet (as a user might edit in on an attached DBGrid before transforming it) and makes it available to an XMLTransform-Client component. This component has the transformation file connected to it, but not an XML file. In fact, clicking the button shows the XML document within a memo (after a formatting it) instead of saving it to a file, something you can do by calling the `GetDataAsXml` method (even if the Help file is far from clear about this):

```
procedure TForm1.btnMapClick(Sender: TObject);
begin
  Memo1.Lines.Text := FormatXmlData(XMLTransformClient1.GetDataAsXml(''));
end;
```

FIGURE 23.10:

When you convert from a data packet to an XML document, the XML Mapper can preview the document in a tree structure.



Test transformation Datapacket -> XML Document

Datapacket : C:\md6code\23\MapTable\cdsdatapacket.xml

This is the only code of the program visible at run time in Figure 23.11. The application has much simpler code than the DomCreate example I used to generate a similar XML document, but requires the design-time definition of the transformation. The DomCreate example, instead, could work on any dataset at run time, without any connection to a specific table, as it had some rather generic code. In theory, it is possible to produce similar dynamic mappings by using the events of the generic XMLTransform component, but I find it much easier to use the DOM-based approach discussed earlier. Notice also that the `FormatXmlData` call produces much nicer output but slows down the program, because it involves loading the XML into a DOM.

FIGURE 23.11:

The MapTable example can generate an XML document from a database table using a custom transformation file. You can see the original dataset in the DBGrid above and the resulting XML document in the memo control below

XML and Internet Express

Once you have defined the structure of an XML document, you might want to let users see and edit the data in a Windows application or over the Web. This second case is rather interesting, as Delphi provides specific support for it. Delphi 5 already included an architecture called Internet Express, which is now available in Delphi 6 as part of the WebSnap platform. WebSnap offers also support for XSL, which I'll discuss later.

In Chapter 17, "Multitier Database Applications with DataSnap," I discussed the development of DataSnap applications (formerly known as Midas applications). Internet Express provides a client component for this architecture, called XMLBroker, which can be used in place of a client dataset to retrieve data from a middle-tier DataSnap program and make it available to a specific type of page producer, called InetXpageProducer. You can use these components in a standard WebBroker application or in a WebSnap program. The idea behind Internet Express is that you write a Web server extension (CGI or ISAPI or Apache modules, as discussed in the preceding chapter), which in turn produces Web pages hooked to your DataSnap server. Your custom application acts as a DataSnap client and produces pages for a browser client. Internet Express offers the services required to build this custom application easily.

I know this sounds confusing, but Internet Express is a four-tier architecture: SQL server, application server (the DataSnap server), Web server with a custom application, and finally Web browser. Of course, you can place the database access components within the same application handling the HTTP request and generating the resulting HTML, as in a client/server solution. You can even access a local database or an XML file, in a single-tier structure.

In other words, Internet Express is a technology for building clients based on a browser, which lets you send the entire dataset to the client computer along with the HTML and some JavaScript for manipulating the XML and showing it into the user interface defined by the HTML. It is the JavaScript that enables the browser to show the data and manipulate it.

The XMLBroker Component

Internet Express uses multiple technologies to accomplish this. The DataSnap data packets are converted into the XML format, to let the program embed this data right into the HTML page for Web client-side manipulation. Actually, the Delta data packet is also represented in XML. These operations are performed by the XMLBroker component, which can handle XML and provide data to the new JavaScript components. Like the ClientDataSet, the XMLBroker has

- A `MaxRecords` property indicating the number of records to add to a single page
- A `Params` property hosting the parameters that components will forward to the remote query through the provider
- A `WebDispatch` property indicating the update request the broker responds to

The InetXPageProducer allows you to generate HTML forms from datasets, in a visual way similar to the development of an AdapterPageProducer user interface. Actually, the Internet Express architecture, the interfaces it uses internally, and some of its IDE editor can together be considered the parent of the WebSnap architecture. With the notable difference of generating scripts to be executed on the server side and on the client side, they both provide an editor for placing visual components and generating such scripts. A notable difference I'm personally not terribly happy about, though, is that the older Internet Express is more XML-oriented than newer WebSnap.

TIP Another common feature of the InetXPageProducer and the AdapterPageProducer is the support for Cascading Style Sheets (CSS). These components have the two alternative `Style` and `StylesFile` properties for defining the CSS, and each visual element has a `StyleRule` property where you can select the style name.

JavaScript Support

To make the editing operations on the client side powerful, the InetXPageProducer uses special JavaScript components and code. Delphi embeds a rather large JavaScript library, which the browser will have to download. This might seem a nuisance, but it is the only way the browser interface (which is based on dynamic HTML) can be rich enough to support field constraints and other business rules with the browser. This is really impossible with plain HTML. The JavaScript files provided by Borland, and that you should make available on the Web site hosting the application, are the following:

File	Description
`Xmldom.js`	DOM-compatible XML parser (for browsers lacking native XML DOM support)
`Xmldb.js`	JavaScript classes for the HTML controls
`Xmldisp.js`	JavaScript classes for binding XML data with the HTML controls
`Xmlerrdisp.js`	Classes for reconciling errors
`XmlShow.js`	JavaScript functions to display data and delta packets (for debugging purposes)

HTML pages generated by Internet Express usually include references to these JavaScript files, such as:

```
<script language=Javascript type="text/javascript"
  src="IncludePathURL/xmldb.js"></script>
```

You can customize the JavaScript by adding code directly into the HTML pages or by creating a new Delphi components, written to fit with the Internet Express architecture that “emits” JavaScript code (possibly along with HTML). As an example, the sample `TPromptQueryButton` class of INetXCustom generates the following HTML and JavaScript code:

```
<script language=javascript type="text/javascript">
  function PromptSetField(input, msg) {
    var v = prompt(msg);
    if (v == null || v == "")
      return false;
    input.value = v
    return true;
  }
  var QueryForm3 = document.forms['QueryForm3'];
</script>
<input type=button value="Prompt..."
  onclick="if (PromptSetField(PromptResult, 'Enter some text\n'))
    QueryForm3.submit();">
```

TIP If you plan on using Internet Express, have a look at the INetXCustom extra demo components, available in the `\Demos\Midas\InternetExpress\INetXCustom` folder. Follow the detailed instructions in the `readme.txt` file for the installation of these components, which are provided by Borland with no support but allow you to add many more features to your Internet Express applications with little extra effort.

Of course, to deploy this architecture you don't need anything special on the client side, as any browser up to the HTML 4 standard can be used, on any operating system. The Web server, instead, must be a Win32 server (we're waiting for this technology to be available in Kylix) and you must deploy the DataSnap libraries on it (after paying the proper license fee to Borland, still not disclosed at this time).

Building a First Example

To better understand what I'm talking about, and as a way to cover some more technical details, let me try out a simple demo, called IeFirst. To avoid configuration issues, this is a CGI application accessing a dataset directly—in this case, a local table retrieved via the BDE. Later I'll show you how to turn an existing DataSnap Windows client to a browser-based interface. To build IeFirst, I've created a new CGI application and added to its data module a Table and a DataSetProvider. The next step is to add an XMLBroker component and connect it to the provider:

```
object Table1: TTable
  DatabaseName = 'DBDEMOS'
  TableName = 'employee.db'
end
object DataSetProvider1: TDataSetProvider
  DataSet = Table1
end
object XMLBroker1: TXMLBroker
  ProviderName = 'DataSetProvider1'
  WebDispatch.MethodType = mtAny
  WebDispatch.PathInfo = 'XMLBroker1'
  ReconcileProducer = PageProducer1
  OnGetResponse = XMLBroker1GetResponse
end
```

The `ReconcileProducer` property is required to show a proper error message in case of an update conflict. As we'll see later, one of the Delphi demos includes some custom code, but in this simple example I've simply connected a traditional PageProducer component with a generic HTML error message. After setting up the XML broker, you can add an InetXPageProducer to the Web data module. This component has a standard HTML skeleton; I've customized to add a title to it, without touching the special tags:

```
<HTML><HEAD>
  <title>IeFirst</title>
</HEAD><BODY>
  <h1>Internet Express First Demo (IeFirst.exe)</h1>
  <#INCLUDES><#STYLES><#WARNINGS><#FORMS><#SCRIPT>
</BODY>
```

The special tags are automatically expanded using the JavaScript files of the directory specified by the `IncludePathURL` property. You *must* set this property to refer to the Web server directory where these files reside. You can find them in the `\Delphi6\Source\WebMidas` directory. The five tags have the following effect:

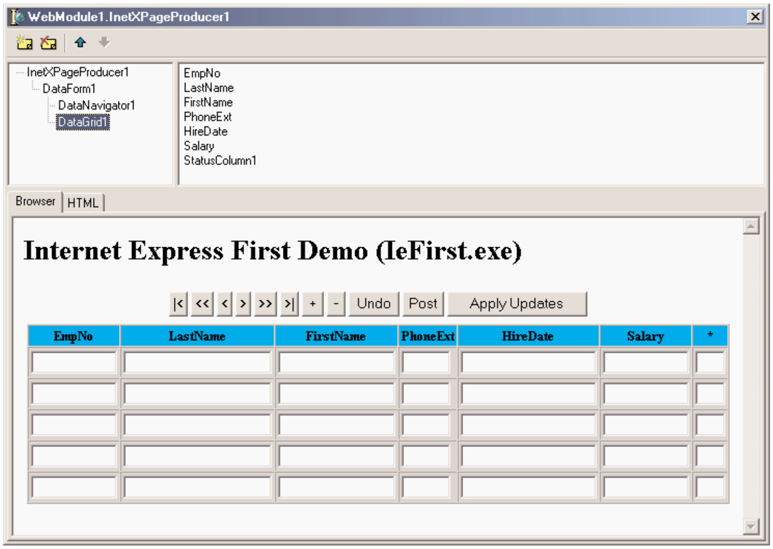
Tag	Effect
`<#INCLUDES>`	Generates the instructions to include the JavaScript libraries
`<#STYLES>`	Adds the embedded style sheet definition
`<#WARNINGS>`	Used at design time to show errors in the InetXPageProducer editor
`<#FORMS>`	Generates the HTML code produced by the components of the Web page
`<#SCRIPT>`	Adds a JavaScript block used to start up the client-side script

NOTE The InetXPageProducer component handles also a few more internal tags. `<#BODYELEMENTS>` corresponds to all of the five tags of the predefined template. `<#COMPONENT Name=WebComponentName>` is part of the generated HTML code used to declare the components generated visually. `<#DATAPACKET XMLBroker=BrokerName>` is replaced with the actual XML of the data packet.

To customize the resulting HTML of the InetXPageProducer, you can use its editor, which again is similar to the one for WebSnap server-side scripting. Just double-click the InetXPageProducer component, and Delphi opens up a window like the one in Figure 23.12 (with the final settings of the example). In this editor, you can create complex structures, starting with a query form, data form, or generic layout group. In the data form of my simple example, I've added a DataGrid and a DataNavigator component, without customizing them any further (an operation you do by adding child buttons, columns, and other objects, which fully replace the default ones).

FIGURE 23.12:

The InetXPageProducer editor allows you to build complex HTML forms visually, similarly to the AdapterPageProducer.



Internet Express First Demo (IeFirst.exe)

EmpNo	LastName	FirstName	PhoneExt	HireDate	Salary	*

The DFM code for the InetXPageProducer and its internal components in my example is the following, where you can seen the core settings plus some limited graphical customizations:

```
object InetXPageProducer1: TInetXPageProducer
  IncludePathURL = '/jssource/'
  HTMLDoc.Strings = (...)
  object DataForm1: TDataForm
    object DataNavigator1: TDataNavigator
      XMLComponent = DataGrid1
      Custom = 'align="center"'
    end
    object DataGrid1: TDataGrid
      XMLBroker = XMLBroker1
      DisplayRows = 5
      TableAttributes.BgColor = 'Silver'
      TableAttributes.CellSpacing = 0
      TableAttributes.CellPadding = 2
      HeadingAttributes.BgColor = 'Aqua'
      object EmpNo: TTextColumn...
      object LastName: TTextColumn...
      object FirstName: TTextColumn...
      object PhoneExt: TTextColumn...
      object HireDate: TTextColumn...
      object Salary: TTextColumn...
      object StatusColumn1: TStatusColumn...
    end
  end
end
```

But the value of these components is in the HTML (and JavaScript) code they generate, which you can preview by selecting the HTML tab of the InetXPageProducer editor. Here are a few portions of the definitions in the HTML, for the buttons, the data grid heading, and one if its cells:

```
// buttons
<table align="center">
  <tr><td colspan="2">
    <input type="button" value="|<"
      onclick='if (xml_ready) DataGrid1_Disp.first();'>
    <input type="button" value="<<"
      onclick='if (xml_ready) DataGrid1_Disp.pgup();'>
...
// data grid heading
<table cellspacing="0" cellpadding="2" border="1" bgcolor="silver">
  <tr bgcolor="aqua">
    <th>EmpNo</th>
    <th>LastName</th>
  ...
  </tr>
  <tr>
    // a data cell
    <td><div>
      <input type="text" name="EmpNo" size="10"
        onfocus='if(xml_ready)DataGrid1_Disp.xfocus(this);'
        onkeydown='if(xml_ready)DataGrid1_Disp.keys(this);'>
    </div></td>...
```

When the HTML generator is set up, you can go back to the Web data module, add an action to it, and connect the action with the InetXPageProducer via the `Producer` property. This should be enough to make the program work through a browser, as you can see in Figure 23.13.

If you look at the HTML file received by the browser, you'll find the table mentioned in the preceding definition, some JavaScript code here and there, and the database data in the data packet XML format. This data is assembled by the XML broker and passed to the producer component to be embedded in the HTML file. Notice that the number of records sent to the client depends on the XMLBroker, not on the number of lines in the grid. Once the XML data is sent to the browser, in fact, you can use the buttons of the navigator component to move around in the data without requiring further access to the server to fetch more. This is quite different from the paging behavior of WebSnap. Not that one is better than the other; this depends on the specific application you are building.

FIGURE 23.13:

The IeFirst application sends to the browser some HTML components, an entire XML document, and the JavaScript code to show the data in the visual components.

Internet Express First Demo (IeFirst.exe)

EmpNo	LastName	FirstName	PhoneExt	HireDate	Salary	*
2	Nelson	Roberto	250	12/28/1988 00:00:00	40000	
4	Young	Bruce	233	12/28/1988 00:00:00	55500	
5	Lambert	Kim	22	02/06/1989 00:00:00	25000	
8	Johnson	Leslie	410	04/05/1989 00:00:00	25050	
9	Forest	Phil	229	04/17/1989 00:00:00	25050	

At the same time, the JavaScript classes in the system allow the user to type in new data, following the rules imposed by the JavaScript code hooked to dynamic HTML events. Notice that the grid, by default, has an extra asterisk column, indicating which records have been modified. The update data is collected in an XML data packet in the browser, and sent back to the server when the user clicks the Apply Updates button. At this point, the browser activates the action specified by the `WebDispath.PathInfo` property of the XMLBroker. There is no need to export this action from the Web data module, as this operation is automatic (although you can disable it by setting `WebDispath.Enable` to False).

The XMLBroker applies the changes to the server, returning the content of the provider connected to the `ReconcileProvider` property (or raising an exception if this is not defined). When everything works fine, the XMLBroker redirects the control to the main page that contains the data. However, I've experienced some problems with this technique, so the IeFirst example handles the `OnGetReponse`, indicating this is an update view:

```
procedure TWebModule1.XMLBroker1GetResponse(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
begin
  Response.Content := '<h1>Updated</h1><p>' + InetXPageProducer1.Content;
  Handled := True;
end;
```

Master/Detail in Internet Express

My second Internet Express example goes a little beyond the basics by providing a master/detail data packet for Web browsing obtained through a DataSnap connection. The program uses the AppPlus server of Chapter 17, which defines the master/detail relationship between two tables. The dataset field embedded in the table will be transformed into a nested XML structure, delivering the same information.

The program uses a combination of XMLBroker, InetXPageProducer, and DCOMConnection. This time, I've customized the Web components, by adding a LayoutGroup component to obtain multiple columns, and I've also created fields to select the information to display. In Listing 23.2 are some snippets of the DFM file of this Web module: I've removed a lot of extra information, but I think it is worth looking at it.

Listing 23.2: Portions of the DFM file for the IeMd example's Web module

```
object DCOMConnection1: TDCOMConnection
  Connected = False
  ServerName = 'AppSPlus.AppServerPlus'
end
object XMLBroker1: TXMLBroker
  ProviderName = 'ProviderCustomer'
  RemoteServer = DCOMConnection1
  WebDispatch.PathInfo = 'XMLBroker1'
end
object InetXPageProducer1: TInetXPageProducer
  IncludePathURL = '/jssource/'
  object DataForm1: TDataForm
    object LayoutGroup1: TLayoutGroup
      DisplayColumns = 2
      object DataNavigator1: TDataNavigator
        XMLComponent = FieldGroup1
        object FirstButton1: TFirstButton
          XMLComponent = FieldGroup1
          Caption = '|<'
        end
        object PriorButton1: TPriorButton
          XMLComponent = FieldGroup1
          Caption = '<'
        end
        object NextButton1: TNextButton
          XMLComponent = FieldGroup1
          Caption = '>'
        end
        ...
        object ApplyUpdatesButton1: TApplyUpdatesButton
          Caption = 'Apply Updates'
          XMLBroker = XMLBroker1
          XMLUseParent = True
        end
      end
      object FieldGroup1: TFieldGroup
        XMLBroker = XMLBroker1
        object CustNo: TFieldText
          DisplayWidth = 10
          Caption = 'CustNo'
          FieldName = 'CustNo'
        end
        object Company: TFieldText
          DisplayWidth = 30
          Caption = 'Company'
          FieldName = 'Company'
        end
        ...
      end
      object DataNavigator2: TDataNavigator
        XMLComponent = DataGrid1
        object FirstButton2: TFirstButton
          XMLComponent = DataGrid1
          Caption = '|<'
        end
        object PriorPageButton1: TPriorPageButton
          XMLComponent = DataGrid1
          Caption = '<<'
        end
        ...
      end
      object DataGrid1: TDataGrid
        XMLBroker = XMLBroker1
        XMLDataSetField = 'TableOrders'
        DisplayRows = 8
        object OrderNo: TTextColumn
          DisplayWidth = 10
          Caption = 'OrderNo'
          FieldName = 'OrderNo'
        end
        object SaleDate: TTextColumn
          DisplayWidth = 18
          Caption = 'SaleDate'
          FieldName = 'SaleDate'
        end
        ...
      end
    end
  end
end
```

Once the structure is set up, you can deploy the CGI executable on the Web server and see the effect illustrated in Figure 23.14 directly in a browser. Notice that the HTML you receive is rather large, as it includes the entire master/detail structure. Once you've received it, however, you can browse the master table and the detail grid without having to ask the server for any more data.

FIGURE 23.14:

A master/detail relationship displayed in a browser by the IeMd example

Obviously, much more could be said about the capabilities of the Internet Express to build a Web front end for a DataSnap server, as a possible alternative to the server-side scripting offered by WebSnap. Server-side scripting certainly allows for wider support of browsers, although most browsers have the minimal JavaScript required by Internet Express. Also, you should consider cases in which you prefer to have immediate feedback on the server for every action of the user or when you prefer to let the user prepare a large delta packet, even working in a disconnected situation, and then receive the entire batch of updates at once.

Using XSLT

Another approach for generating HTML starting from an XML document is the use of the Extensible Stylesheet Language (XSL) or, to be more precise, its XSL Transformations (XSLT) subset. XSLT uses other XML technologies, notably XPath and XPointer to identify portions of documents.

XPath defines a set of rules to locate one or more nodes within a document. The rules are based on a path-lie structure of the node within the XML tree, so that /books/book identifies any *book* node under the *books* document root. XPath uses a few special symbols to identify nodes:

- An asterisk (*) stands for any node; for example, book/* indicates any subnode under a *book* node.
- A dot (.) stands for the current node.
- The pipe symbol (|) indicates alternatives, as in book|ebook.
- A double slash (//) stands for any path, so that //title indicates all of the title nodes, whatever their parent nodes, and books//author indicates any author node under a books node regardless of the nodes in between.
- The at sign (@) indicates an attribute instead of a node, as in the hypothetical author/@lastname. A similar notation can be used to choose only nodes having a given value for an attribute—for example, all authors with a given first name: author[@name="marco"].

There are many other cases, but this short introduction to the rules of XPath should at least get you started and help you understand the following examples. An XSTL document is an XML document that works on the structure of a source XML document and generates in output another XML document, possibly an XHTML document you can view within a Web browser.

NOTE Commonly used XSLT processors include MS-XML, Xalan from the Apache XML project (xml.apache.org), and the Java-based Xt of James Clarke.

The structure of an XSL file is quite simple, although its content can become extremely complex to understand. At the root should be a node like:

```
<xsl:stylesheet version="1.0" xmlns:xsl="...">
```

This node is followed by some of the base commands, such as the definition of a template to operate on a given type of nodes (xsl:template match), the activation of a template for a given node (xsl:apply-templates select), or the extraction of a value from an XML document (xsl:value-of select). There are also specific instructions you can use, including xsl:for-each, xsl:if, xsl:choose, xsl:sort (not available in MSXML the last time I checked), and xsl:number.

XSTL in Practice

After this short and probably unclear explanation, let me discuss a couple of examples. As a starting point, you should study XSL by itself, and then focus on its activation from within a Delphi application.

For your initial tests, you can connect an XSL file directly into an XML file. As you load the XML file in Internet Explorer, this will show you the resulting transformation, usually the HTML. The connection is indicated in the heading of the XML document with a command like:

```
<?xml-stylesheet type="text/xsl" href="sample1embedded.xsl"?>
```

This is what I've done in the `sample1embedded.xml` file available in the XslEmbed project. The related XSL embeds various XSL snippets that I cannot discuss in detail. For example, it grabs the entire list of authors or filters a specific group of them with this code:

```
<h2>All Authors</h2>
<ul>
  <xsl:for-each select="books//author">
    <li><xsl:value-of select="."/></li>
  </xsl:for-each>
</ul>
<h3>E-Authors</h3>
<ul>
  <xsl:for-each select="books/ebook/author">
    <li><xsl:value-of select="."/></li>
  </xsl:for-each>
</ul>
```

Some rather more complex code is used to extract nodes only when a specific value is present in a subnode or attribute, regardless of the higher-level nodes. This final XSL snippet also has an `if` statement and produces an attribute in the resulting node, as a way to build an `href` hyperlink in the HTML:

```
<h3>Marco's works (books + ebooks)</h3>
<ul>
  <xsl:for-each select="books/*[author = 'Cantu']">
    <li> <xsl:value-of select="title"/>
        <xsl:if test="url">
           (<a><xsl:attribute name="href"><xsl:value-of select="url"/>
               </xsl:attribute>Jump to document</a>)
        </xsl:if>
     </li>
  </xsl:for-each>
</ul>
```

Again, I suggest you get some more documentation on the topic, but these examples should at least get you started.

XSLT with WebSnap

Within the code of a program, you can execute the `TransformNode` method of a DOM node, passing to it another DOM hosting the XSL document. Instead of using this low-level approach, however, we can let WebSnap help us to create an XSL-based example. In fact, you can create a new WebSnap application (I've built a CGI program called XslCust in this case) and choose an XSLPageProducer component for its main page, to let Delphi help you start with the application code. Actually, Delphi also includes a skeleton XSL file for manipulating a ClientDataSet data packet and adds to the editor many new views. The XSL Text replaces the HTML file; the XML Tree shows the data, if any; the XSL tree shows the XSL within the Internet Explorer ActiveX; the HTML result shows the code produced by the transformation; and (finally) the Preview page shows what a user will see in a browser.

To make this actually work, you must provide some data to the XSLPageProducer component, via its `XMLData` property. This property can be hooked up to an XMLDocument but also directly to an XMLBroker component, as I've done in this case. The broker takes its data from a provider connected to a local table, attached to the Customers table of the classic DBDEMOS.

The effect is that, with the following Delphi-generated XSL, you get (even at design time) the output of Figure 23.15.

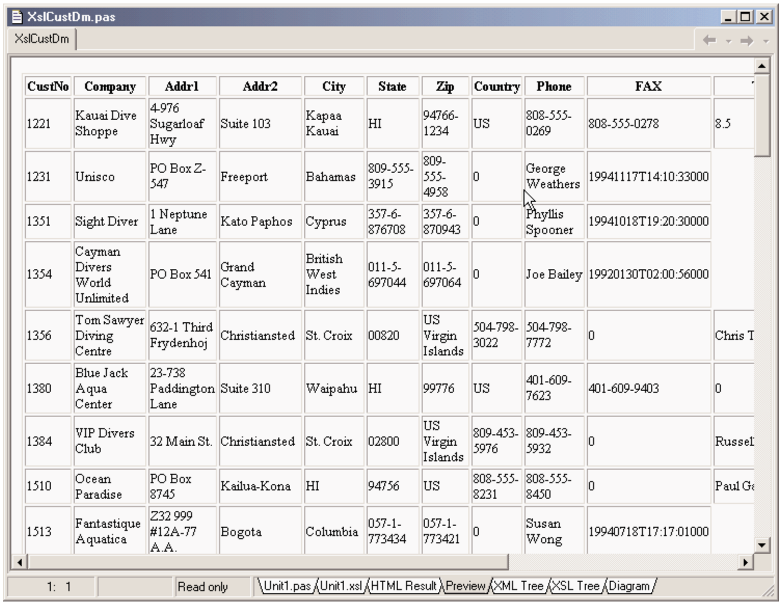

FIGURE 23.15:

The result of an XSTL transformation generated (even at design time) by the XSLPageProducer component in the XslCust example

```
<?xml version="1.0"?>
<xsl:stylesheet xmlns:xsl="http://www.w3.org/TR/WD-xsl">
  <xsl:template match="/">
    <html><body>
      <xsl:apply-templates/>
    </body></html>
  </xsl:template>

  <xsl:template match="DATAPACKET">
    <table border="1">
    <xsl:apply-templates select="METADATA/FIELDS"/>
    <xsl:apply-templates select="ROWDATA/ROW"/>
    </table>
  </xsl:template>

  <xsl:template match="FIELDS">
    <tr><xsl:apply-templates/></tr>
  </xsl:template>

  <xsl:template match="FIELD">
    <th><xsl:value-of select="@attrname"/></th>
  </xsl:template>

  <xsl:template match="ROWDATA/ROW">
    <tr><xsl:for-each select="@*">
      <td><xsl:value-of/></td>
    </xsl:for-each></tr>
  </xsl:template>
</xsl:stylesheet>
```

This code, based heavily on XSL templates, generates an HTML table made of the expansion of field metadata and row data. The fields are used to generate the table heading, with a `<th>` cell for each entry in a single row. The row data is used to fill in the other rows of the table with the value of each attribute (`select="@*"`). At this point, you should be able to modify this XSL file and change the output of the program.

Direct XSL Transformations with the DOM

Using the XSLPageProducer can certainly be handy, but generating multiple pages based on the same data just to handle different possible XSL styles with WebSnap doesn't seem to be the best approach. I've rather built a plain CGI application, called CdsXstl, that can transform a ClientDataSet data packet into different types of HTML, depending on the name of the XSL file passed as parameter to it. The advantage is that I can not only modify but even add new XSL files to the system without having to recompile the program.

To obtain the XSL transformation, the program loads both the XML and the XSL files into two XMLDocument components, called `xmlDom` and `XslDom`. Then it invokes the `transformNode` method of the XML document, passing the XSL document as parameter and filling in a third XMLDocument component, called `HtmlDom`:

```
procedure TWebModule1.WebModule1WebActionItem1Action(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
var
  xslfile: string;
  attr: IDOMAttr;
begin
  // open the client dataset and load its XML in a DOM
  ClientDataSet1.Open;
  XmlDom.Xml.Text := ClientDataSet1.XMLData;
  XmlDom.Active := True;
  // load the requested xsl file
  xslfile := Request.QueryFields.Values ['style'];
  if xslfile = '' then
    xslfile := 'customer.xsl';
  xslDom.LoadFromFile ('c:\websites\xsl\' + xslfile);
  XSLDom.Active := True;
  if xslfile = 'single.xsl' then
  begin
    attr := xslDom.DOMDocument.createAttribute('select');
    attr.value := '//ROW[@CustNo="' + Request.QueryFields.Values ['id'] + '"]';
    xslDom.DOMDocument.getElementsByTagName ('xsl:apply-templates').
      item[0].attributes.setNamedItem(attr);
  end;
  // do the transformation
  HTMLDom.Active := True;
  xmlDom.DocumentElement.transformNode (xslDom.DocumentElement, HTMLDom);
  Response.Content := HTMLDom.XML.Text;
end;
```

The code uses the DOM to modify the XSL document for displaying a single record, adding the XPath statement for selecting the record indicated by the `id` query field. This `id` is added to the hyperlink by the XSL with the list of records, but here I'd rather skip listing more XSL files. You can study them, as they are available in the XSL subfolder of the folder for this example.

WARNING To run this program, the XSL files should be deployed to the folder `c:\websites\xsl\`, or anywhere you like after fixing the source code accordingly.

Web Services

Of all of the new features of Delphi 6, one stands out quite clearly: the support for Web services built into the product. The fact I'm discussing it at the end of the book has nothing to do with its importance, but only with the logical flow of the text, and with the fact that this is indeed not the starting point to learn Delphi programming.

But what is a Web service? It is a rapidly emerging technology that has the potential to change the way the Internet works for businesses. Browsing Web pages to enter your orders is fine for individuals (so-called B2C or business-to-consumer applications) but not for companies (so-called B2B or business-to-business applications). If you want to buy a few books, going to a book vendor Web site and punching in your requests is probably fine. But if you run a bookstore and want to place hundreds of orders a day, this is far from a good approach, particularly if you have a program that helps you track your sales and determine reorders. Grabbing the output of this program and reentering it into another application is really ridiculous.

The idea of Web services is to solve this issue: The program used to track sales can automatically create a request and send it to a Web service, which can immediately return information about the order. The next step might be to ask for a tracking number for the shipment. At this point, your program can use another Web service to track the shipment until it is at its destination, so you can tell your customers how long they have to wait. As the shipment arrives, your program can send a reminder via SMS or pager to the people with pending orders, issue a payment with a bank Web service, and … I could continue but I think I've given you an idea. Web services are for computer interoperability as much as the Web and email let people interact.

SOAP and WSDL

If the idea of Web services should be clear by now, what makes them possible is the Simple Object Access Protocol (SOAP). SOAP is built over standard HTTP, so that a Web server can handle the SOAP requests and the related data packets can pass though firewalls. SOAP defines an XML-based notation for requesting the execution of a method by an object on the server, passing parameters to it, and a notation to define the format of a response.

NOTE SOAP was originally developed by DevelopMentor (the training company of COM expert Don Box) and Microsoft, to overcome weaknesses of using DCOM inside Web servers. Submitted to the W3C for standardization, it is being embraced by many companies, with a particular push from IBM. It is too early to see whether there will be a real standardization to let software programs from Microsoft, IBM, Sun, Oracle, and many others truly interoperate or whether some of these vendors will try to push a private version of the standard. In any case, SOAP is a cornerstone of Microsoft's dotNet architecture but also of the current proposals by Sun and Oracle.

SOAP is going to replace COM invocation, at least between different types of computers. Similarly, the definition of a SOAP service in the Web Services Description Language (WSDL) format is going to replace the IDL and type libraries used by COM and COM+. WSDL documents are another type of XML document that provides the metadata definition of a SOAP request. As you get a file in this format (generally published to define a service), you'll be able to create a program to call it.

Specifically, Delphi 6 provides a bidirectional mapping between WSDL and interfaces. This means you can grab a WSDL file and generate an interface for it. At this point, you can create a client program embedding SOAP requests via these interfaces and use a special Delphi component that allows you to convert your local interface requests into SOAP calls (as I doubt you want to manually generate the XML required for a SOAP request).

The other way around, you can define an interface (or use an existing one) and let a Delphi component generate a WSDL description for it. Another component provides you with a SOAP-to-Pascal mapping, so that by embedding this component and an object implementing the interface within a server-side program, you can have your Web service up and running in matter of minutes.

BabelFish Translations

As a first example of the use of Web service, I'm going to build a simple client for the BabelFish translation service offered by AltaVista. Because this is an experimental service, like most others, there is no guarantee that the service will be working by the time you read this. You can find this and other services for experiments on the XMethods Web site (`www.xmethods.com`) and also look for sample Web services provided by my own site (`www.marcocantu.com`).

After downloading the WSDL description of this service from XMethods (also available on the CD-ROM), I invoked Delphi's Web Services Importer in the Web Services page of the New items dialog box and selected the file. Delphi generated an Object Pascal interface for the Web service, as follows:

```
unit babelintf;

interface

uses
  Types, XSBuiltIns;

type
  BabelFishPortType = interface(IInvokable)
    ['{DF96B8F8-DD8E-43A1-9276-4F821D9EA3FA}']
    function BabelFish(const translationmode: String;
      const sourcedata: String): String; stdcall;
  end;

implementation

uses InvokeRegistry;

initialization
  InvRegistry.RegisterInterface(TypeInfo(BabelFishPortType), '', '');
end.
```

Notice first that the interface inherits from the IInvokable interface. This doesn't add anything in terms of methods to the IInterface base interface of Delphi, but is compiled with the flag used to enable RTTI generation, {$M+}, like the TPersistent class. In this code, you can also see that the interface is registered in the global invocation registry (or InvRegistry), passing the type information reference of the interface type.

NOTE Having RTTI information for interfaces is actually the most important technological advance underlying SOAP invocation. Not that SOAP-to-Pascal mapping isn't important, as it is crucial to simplify the process, but having RTTI for an interface is what makes the entire architecture powerful and robust.

Once you have converted a WSDL definition into an easy-to-use interface, you need a component translating from interface call to SOAP call, and also handling the response and possible errors. This role can be played by the HTTPRio component, which implements the idea of a Remote Invocation Object (RIO) over HTTP. Delphi 6 was built opening up the road for SOAP, but also keeping it open for other remote invocation mechanisms.

In the BabelFish example, the HTTPRio component has the following settings, obtained by choosing the WSDL file first and then selecting the only available service and port from it, directly in the drop-down lists of the Object Inspector:

```
object HTTPRIO1: THTTPRIO
  WSDLLocation = 'C:\md6code\23\BabelFish\BabelFishService.xml'
  Service = 'BabelFish'
  Port = 'BabelFishPort'
  HTTPWebNode.Agent = 'Borland SOAP 1.1'
  Converter.Options = [soSendMultiRefObj, soTryAllSchema]
end
```

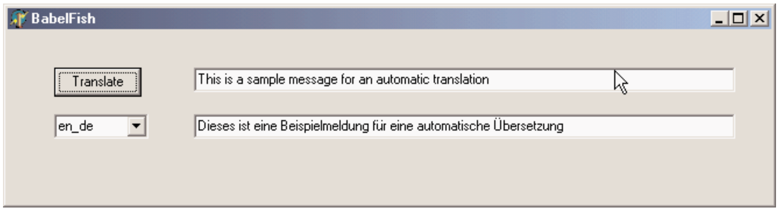
At this point, there is very little left to do. We have information about the service that can be used for its invocation, and we know the parameters required by the only available method. The two elements are merged by extracting the interface you want to call directly from the HTTPRio component, with an expression like HTTPRIO1 as BabelFishPortType. It might seem rather astonishing at first, but it is also outrageously simple. This is the Web service call done by the example:

```
EditTarget.Text := (HTTPRIO1 as BabelFishPortType).
  BabelFish(ComboBoxType.Text, EditSource.Text);
```

The resulting output of the program, depicted in Figure 23.16, allows you to learn foreign languages (although the teacher here has its shortcomings!). I haven't replicated the same example with stock options, currencies, weather forecasts, and the many other services available, as they would look much the same.

FIGURE 23.16:

An example of a translation from English to German obtained by AltaVista's BabelFish via a Web service



This is a sample message for an automatic translation

Building a Web Service

If calling a Web service in Delphi 6 is very straightforward, the same can be said of the development of an actual service. If you go into the Web Services page of the New items dialog box, you can see the SOAP Server Application option. Selecting it, Delphi presents you a list quite similar to selection of a WebBroker application. A Web service, in fact, is typically hosted by a Web server, using one of the available Web server extension technologies (CGI, ISAPI, Apache modules, etc.). After completing this step, Delphi will add three components to the resulting Web module, which is just a plain Web module, with no special additions:

- The HTTPSoapDispatcher component has the role of receiving the Web request, as any other HTTP dispatcher does.
- The HTTPSoapPascalInvoker component does the reverse operation of the HTTPRio component, as it can translate SOAP requests into calls of Pascal interfaces (instead of shifting interface method calls into SOAP requests).
- The WSDLHTMLPublish component can be used to extract the WSDL definition of the service from the interfaces it support, and performs the opposite role of the Web Services Importer Wizard. Technically, this is another HTTP dispatcher.

Once this framework is in place—something you can also do by adding the three components above to an existing Web module—we can start writing a service. As an example I've taken the euro conversion example of Chapter 4, "The Run-Time Library," and transformed it into a Web service called ConvertService. First of all, I've added to the program a unit defining the interface of the service, as follows:

```
type
  IConvert = interface(IInvokable)
  ['{FF1EAA45-0B94-4630-9A18-E768A91A78E2}']
    function ConvertCurrency (Source, Dest: string; Amount: Double): Double;
      stdcall;
    function ToEuro (Source: string; Amount: Double): Double; stdcall;
    function FromEuro (Dest: string; Amount: Double): Double; stdcall;
    function TypesList: string; stdcall;
  end;
```

Defining an interface directly in code, without having to use a tool such as the Type Library Editor, provides a great advantage. Notice that I've given a GUID to the interface, as usual, and used the `stdcall` calling convention, as the SOAP converter does not support the default `register` calling convention.

In the same unit defining the interface of the service, we should also register it, an operation which will be useful on both the client and server sides of the program, as we will be able to include this interface definition unit in both.

```
uses InvokeRegistry;

initialization
  InvRegistry.RegisterInterface(TypeInfo(IConvert));
```

Now that we have an interface we can expose to the public, we have to provide an implementation for it, again by means of the standard Pascal code (and with the help of the predefined `TInvokableClass` class:

```
type
  TConvert = class (TInvokableClass, IConvert)
  protected
    function ConvertCurrency (Source, Dest: string; Amount: Double): Double;
      stdcall;
    function ToEuro (Source: string; Amount: Double): Double; stdcall;
    function FromEuro (Dest: string; Amount: Double): Double; stdcall;
    function TypesList: string; stdcall;
  end;
```

The implementation of these functions, which call in the code of the euro conversion system of Chapter 4, is not discussed here as it has little to do with the development of the service itself. What is important to notice, instead, is that this implementation unit also has a registration call in its initialization section:

```
InvRegistry.RegisterInvokableClass (TConvert);
```

This is basically all. By registering the interface, we'll make it possible for the program to generate a WSDL description, as you can see in Figure 23.17, where I've used a browser to connect to the *wsdl* action of the service, implemented by the WSDLHTMLPublish component.

  - <message name="FromEuroResponse">
      <part name="return" type="double" />
    </message>
    <message name="TypesListRequest" />
  - <message name="TypesListResponse">
```

Of course, you cannot call the service from a browser, as the role of a Web service is not to display data on the Web but rather to let applications interoperate (still, you can reasonably have a Web application calling a service). Before I discuss the client application, though, let me cover another interesting element. For debugging purposes, I've added to the Web module an actual action, connected with code to generate information about the registered interfaces and servers:

```
Response.Content :=
  '<h3>GetMethExternalName - ToEuro</h3><p>' +
  InvRegistry.GetMethExternalName(TypeInfo(IConvert), 'ToEuro</p>') +
  '<h3>GetInterfaceExternalName - IConvert</h3><p>' +
  InvRegistry.GetInterfaceExternalName(TypeInfo(IConvert)) + '</p>' +
  '<h3>GetNamespaceByGUID - IConvert</h3><p>' +
  InvRegistry.GetNamespaceByGUID (IConvert) + '</p>';
```

The first call verifies whether a given method is properly registered and really exists, by calling the `GetMethExternalName` of the invocation registry. The result, unsurprisingly, is the same string passed as parameter, ToEuro. The second call, `GetInterfaceExternalName`, should return the external name of the interface, but I haven't been able to make it work properly (I left it in anyway, as it is supposed to work). The last call, GetNamespaceByGUID, returns the XML namespace of the interface, urn:ConvertIntf-IConvert. There are other similar calls you can make against the registry, which are quite interesting and demonstrate the power of this approach and of RTTI for interfaces.

Having said this, let me move to the client application, calling the service. This time I don't really need to start from the WSDL file, as I already have the Pascal interface. This time the form doesn't even have the HTTPRio component, which is created in code:

```
private
  Invoker: THTTPRio;

procedure TForm1.FormCreate(Sender: TObject);
begin
  Invoker := THTTPRio.Create(nil);
  Invoker.URL := 'http://localhost/scripts/ConvertService.exe/soap/iconvert';
  ConvIntf := Invoker as IConvert;
end;
```

As an alternative to using a WSDL file, the SOAP invoker component can be associated with an URL. Once this association has been done and the required interface has been extracted from the component, you can start writing straight Pascal code to invoke the service, as we saw earlier.

A user can fill the two combo boxes, calling the TypesList method, which returns a list of available currencies within a string (separated by semicolons). This list is extracted by replacing any semicolon with a line break and then assigning the multiline string directly to the combo items:

```
procedure TForm1.Button2Click(Sender: TObject);
var
  TypeNames: string;
begin
  TypeNames := ConvIntf.TypesList;
  ComboBoxFrom.Items.Text := StringReplace (TypeNames, ';', sLineBreak,
    [rfReplaceAll]);
  ComboBoxTo.Items := ComboBoxFrom.Items;
end;
```

At this point, after selecting two currencies, you can perform the conversion, with this code and the result of Figure 23.18:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  LabelResult.Caption := Format ('%n', [(ConvIntf.ConvertCurrency(
    ComboBoxFrom.Text, ComboBoxTo.Text, StrToFloat(EditAmount.Text)))]);
end;
```

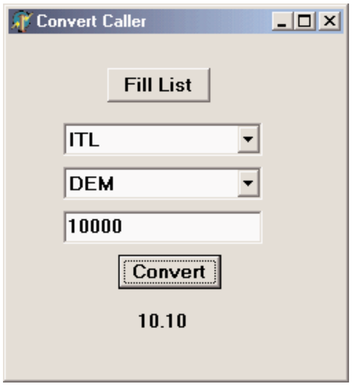

FIGURE 23.18:

The ConvertCaller client of the ConvertService Web service shows how few German marks you used to get for so many Italian liras, before the euro changed all this.

DataSnap over SOAP

Now that we have a reasonably good idea of how to build a SOAP server and a SOAP client, we can have a look at how to use this technology in building a multitier DataSnap application. We'll use a Soap Server Data Module to create the new Web service and the SoapConnection component to connect a client application to it.

Let's look at the server side first. You have to move to the Web Services page of the New Items dialog box and use the Soap Server Application icon first to create a new Web service, and then use the Soap Server Data Module icon to add a DataSnap server-side data module to the SOAP server. This is what I've done in the SoapDataServer example (which uses the Web App Debugger architecture for testing purposes). From this point on, all you do is write a *normal* DataSnap server (or actually a middle-tier DataSnap application) as discussed in Chapter 17. In this specific case, I've added to the program InterBase access by means of dbExpress, resulting in the following structure:

```
object SoapTestDm: TSoapTestDm
  object SQLConnection1: TSQLConnection
    ConnectionName = 'IBLocal'
  end
  object SQLDataSet1: TSQLDataSet
    SQLConnection = SQLConnection1
    CommandText = 'select * from EMPLOYEE'
  end
  object DataSetProvider1: TDataSetProvider
    DataSet = SQLDataSet1
  end
end
```

The data module built for a SOAP-based DataSnap server defines a custom interface (so you can add methods to it) inheriting from `IAppServer`, which is now defined as a published interface (even though it doesn't inherit from `IInvokable`). The implementation class, `TSoapTestDm`, is the data module itself, as in other DataSnap types of servers. This is the code Delphi generated for me:

```
type
  ISoapTestDm = interface(IAppServer)
    ['{1F109687-6D8B-4F85-9BF5-EFFC87A9F10F}']
  end;

  TSoapTestDm = class(TSoapDataModule, ISoapTestDm, IAppServer)
    DataSetProvider1: TDataSetProvider;
    SQLConnection1: TSQLConnection;
    SQLDataSet1: TSQLDataSet;
  end;
```

The base `TSoapDataModule` doesn't inherit from `TInvokableClass`. This is not a problem as long as you provide an extra procedure to create the object (which is what `TInvokableClass` does for you) and add it to the registration code:

```
procedure TSoapTestDmCreateInstance(out obj: TObject);
begin
  obj := TSoapTestDm.Create(nil);
end;

initialization
  InvRegistry.RegisterInvokableClass(TSoapTestDm, TSoapTestDmCreateInstance);
  InvRegistry.RegisterInterface(TypeInfo(ISoapTestDm));
```

The server application actually also publishes the `IAppServer` interface, thanks to the only line of code in the SOAPMidas unit.

WARNING Web service applications should not include more than one SOAP Data Module, as the registration cannot distinguish between multiple implementations of the same `IAppServer` interface.

To build the client application, called SoapDataClient, I've started with a plain program and added a SoapConnection component to it (from the Web Services page of the palette), hooking it to the URL of the DataSnap Web service, referring to the specific interface we are looking for:

```
object SoapConnection1: TSoapConnection
  Agent = 'Borland SOAP 1.1'
  URL = 'http://localhost:1024/SoapDataServer.SoapDataServer/Soap/ISoapTestDm'
end
```

From this point on, I've proceeded as usual, adding a ClientDataSet component, a DataSource, and a DBGrid to the program, choosing the only available provider for the client dataset, and hooking the rest as usual. Not surprisingly, for this simple example, the client application has little custom code: a single call to open the connection when a button is clicked (to avoid startup errors) and an `ApplyUpdates` call to send changes back to the database.

Regardless of the apparent similarity of this program to all of the other DataSnap client and server programs built in Chapter 17, there is a very important difference worth underlining: The SoapDataServer and SoapDataClient programs do not use COM for exposing or calling the `IAppServer` interface. Quite the opposite—the socket- and HTTP-based connections of DataSnap still rely on local COM objects and a registration of the server in the Windows Registry. The native SOAP-based support provided by Delphi 6, instead, allows for a totally custom solution independent from COM and with many more chances to be ported to other operating systems (Linux being certainly the first, with a future release of Kylix).

What's Next?

In this final chapter of the book, I've covered XML and related technologies, including XSLT, SOAP, WSDL, XML schemas, XPath, and a few more. We've seen how Delphi 6 provides simplified DOM programming, XML access using interfaces, and XML transformations. I've also covered Internet Express and the development of Web services.

Besides tracking what goes on in the area of SOAP and WSDL, particularly in terms of standards conformance by the major players, there are a few interesting initiatives you should probably keep track of if you're interested in the development in business-to-business services. One of them is the UDDI proposal (`www.uddi.org`), pushed by Microsoft, IBM, Ariba, and many other companies, to create a universal registry of services. Another is ebXML (`www.ebxml.org`), a proposal by the U.N. office that defined the EDI standards for an XML-based global business exchange.

Of course, I don't want to delve too much into these nontechnical issues, but I thought it was worth mentioning them at the end of this book, as I try to give a few hints at a sort of "what's next" for Delphi programmers. Delphi is indeed a strong player in both the Windows and Linux client markets, in the client/server and enterprise application markets, and now takes a bold step in the areas of Web development and Web services.

Just as Borland wants to provide the best tools to developers, I hope this book has helped you master Delphi, the most successful tool Borland has brought to the market in the last few years. Remember to check from time to time the reference, foundations, and advanced material I've collected on my Web site (`www.marcocantu.com`). Check my site also for eventual updates and integration of the material in the book, and feel free to use the newsgroups hosted there for your questions about the book and about Delphi in general. Much of this material could not be included in the book, simply because of space constraints. Some of this extra material is actually already available on the companion CD, where you can continue reading about other aspects of Delphi programming.

Introduction

The *Developer's Guide* describes intermediate and advanced development topics, such as building client/server database applications, writing custom components, and creating Internet Web server applications. It allows you to build applications that meet many industry-standard specifications such as SOAP, TCP/IP, COM+, and ActiveX. Many of the advanced features that support Web development, advanced XML technologies, and database development require components or wizards that are not available in all versions of Delphi.

The *Developer's Guide* assumes you are familiar with using Delphi and understand fundamental Delphi programming techniques. For an introduction to Delphi programming and the integrated development environment (IDE), see the Quick Start manual or the online Help.

What's in this manual?

This manual contains five parts, as follows:

- **Part I, "Programming with Delphi,"** describes how to build general-purpose Delphi applications. This part provides details on programming techniques you can use in any Delphi application. For example, it describes how to use common Visual Component Library (VCL) or Component Library for Cross-platform (CLX) objects that make user interface programming easy. Objects are available for handling strings, manipulating text, implementing common dialogs, and so on. This section also includes chapters on working with graphics, error and exception handling, using DLLs, OLE automation, and writing international applications.

  A chapter describes how to use objects in the Borland Component Library for Cross-Platform (CLX) to develop applications that can be compiled and run on either Windows or Linux platforms.

The chapter on deployment details the tasks involved in deploying your application to your application users. For example, it includes information on effective compiler options, using InstallShield Express, licensing issues, and how to determine which packages, DLLs, and other libraries to use when building the production-quality version of your application.

- **Part II, "Developing database applications,"** describes how to build database applications using database tools and components. Delphi lets you access many types of databases, including local databases such as Paradox and dBASE, and network SQL server databases like InterBase, Oracle, and Sybase. You can choose from a variety of data access mechanisms, including dbExpress, the Borland Database Engine, InterbaseExpress, and ADO. To implement the more advanced database applications, you need the Delphi features that are not available in all versions.
- **Part III, "Writing Internet applications,"** describes how to create applications that are distributed over the internet. Delphi includes a wide array of tools for writing Web server applications, including the Web Broker architecture, which lets you create cross-platform server applications, WebSnap, which lets you design Web pages in a GUI environment, support for working with XML documents, and an architecture for using SOAP-based Web Services. For lower-level support that underlies much of the messaging in Internet applications, this section also describes how to work with socket components. The components that implement many of these features are not available in all versions of Delphi.
- **Part IV, "Developing COM-based applications,"** describes how to build applications that can interoperate with other COM-based API objects on the system such as Windows Shell extensions or multimedia applications. Delphi contains components that support the ActiveX, COM+, and a COM-based library for COM controls that can be used for general-purpose and Web-based applications. Support for COM controls is not available in all editions of Delphi. To create ActiveX controls, you need the Professional or Enterprise edition.
- **Part V, "Creating custom components,"** describes how to design and implement your own components, and how to make them available on the Component palette of the IDE. A component can be almost any program element that you want to manipulate at design time. Implementing custom components entails deriving a new class from an existing class type in the VCL or CLX class libraries.

Manual conventions

This manual uses the typefaces and symbols described in Table 1.1 to indicate special text.

Table 1.1 Typefaces and symbols

Typeface or symbol	Meaning
`Monospace type`	Monospaced text represents text as it appears on screen or in Object Pascal code. It also represents anything you must type.
[ ]	Square brackets in text or syntax listings enclose optional items. Text of this sort should not be typed verbatim.
Boldface	Boldfaced words in text or code listings represent Object Pascal keywords or compiler options.
Italics	Italicized words in text represent Object Pascal identifiers, such as variable or type names. Italics are also used to emphasize certain words, such as new terms.
Keycaps	This typeface indicates a key on your keyboard. For example, "Press *Esc* to exit a menu."

Developer support services

Inprise also offers a variety of support options to meet the needs of its diverse developer community. To find out about support offerings for Delphi, refer to http://www.borland.com/devsupport/delphi.

Additional Delphi Technical Information documents and answers to Frequently Asked Questions (FAQs) are also available at this Web site.

From the Web site, you can access many newsgroups where Delphi developers exchange information, tips, and techniques. The site also includes a list of books about Delphi.

Ordering printed documentation

For information about ordering additional documentation, refer to the Web site at shop.borland.com.

Part

I

Programming with Delphi

The chapters in “Programming with Delphi” introduce concepts and skills necessary for creating Delphi applications using any edition of the product. They also introduce the concepts discussed in later sections of the *Developer’s Guide*.

Chapter

2

Developing applications with Delphi

Borland Delphi is an object-oriented, visual programming environment for rapid development of 32-bit applications for deployment on Windows and Linux. Using Delphi, you can create highly efficient applications with a minimum of manual coding.

Delphi provides a comprehensive class library called the *Visual Component Library* (VCL), Borland Component Library for Cross Platform (CLX), and a suite of Rapid Application Development (RAD) design tools, including application and form templates, and programming wizards. Delphi supports truly object-oriented programming:

- the VCL class library includes objects that encapsulate the Windows API as well as other useful programming techniques (Windows)
- the CLX class library includes objects that encapsulate the Qt library (Windows or Linux)

This chapter briefly describes the Delphi development environment and how it fits into the development life cycle. The rest of this manual provides technical details on developing general-purpose, database, Internet and Intranet applications, and includes information on creating ActiveX and COM controls and writing your own components.

Integrated development environment

When you start Delphi, you are immediately placed within the integrated development environment, also called the IDE. This environment provides all the tools you need to design, develop, test, debug, and deploy applications.

Delphi's development environment includes a visual form designer, Object Inspector, Object TreeView, Component palette, Project Manager, source code editor, and debugger among other tools. Some tools may not be included in all versions of the product. You can move freely from the visual representation of an object (in the form designer), to the Object Inspector to edit the initial runtime state of the object, to the source code editor to edit the execution logic of the object. Changing code-related properties, such as the name of an event handler, in the Object Inspector automatically changes the corresponding source code. In addition, changes to the source code, such as renaming an event handler method in a form class declaration, is immediately reflected in the Object Inspector.

The IDE supports application development throughout the stages of the product life cycle—from design to deployment. Using the tools in the IDE allows for rapid prototyping and shortens development time.

A more complete overview of the development environment is presented in the *Quick Start* manual included with the product. In addition, the online Help system provides help on all menus, dialogs, and windows.

Designing applications

Delphi includes all the tools necessary to start designing applications:

- A blank window, known as a *form*, on which to design the UI for your application.
- Extensive class libraries with many reusable objects.
- An Object Inspector for examining and changing object traits.
- A Code editor that provides direct access to the underlying program logic.
- A Project Manager for managing the files that make up one or more projects.
- Many other tools such as an image editor on the toolbar and an integrated debugger on menus to support application development in the IDE.
- Command-line tools including compilers, linkers, and other utilities.

You can use Delphi to design any kind of 32-bit application—from general-purpose utilities to sophisticated data access programs or distributed applications. Delphi's database tools and data-aware components let you quickly develop powerful desktop database and client/server applications. Using Delphi's data-aware controls, you can view live data while you design your application and immediately see the results of database queries and changes to the application interface.

Chapter 5, "Building applications, components, and libraries" introduces Delphi's support for different types of applications.

Many of the objects provided in the class library are accessible in the IDE from the Component palette. The Component palette shows all of the controls, both visual and nonvisual, that you can place on a form. Each tab contains components grouped by functionality. By convention, the names of objects in the class library begin with a T, such as *TStatusBar*.

One of the revolutionary things about Delphi is that you can create your own components using Object Pascal. Most of the components provided are written in Object Pascal. You can add components that you write to the Component palette and customize the palette for your use by including new tabs if needed.

You can also use Delphi for cross platform development on both Linux and Windows by using CLX. CLX contains a set of classes that, if used instead of those in the VCL, allow your program to port between Windows and Linux.

Developing applications

As you visually design the user interface for your application, Delphi generates the underlying Object Pascal code to support the application. As you select and modify the properties of components and forms, the results of those changes appear automatically in the source code, and vice versa. You can modify the source files directly with any text editor, including the built-in Code editor. The changes you make are immediately reflected in the visual environment as well.

Creating projects

All of Delphi's application development revolves around projects. When you create an application in Delphi you are creating a project. A project is a collection of files that make up an application. Some of these files are created at design time. Others are generated automatically when you compile the project source code.

You can view the contents of a project in a project management tool called the Project Manager. The Project Manager lists, in a hierarchical view, the unit names, the forms contained in the unit (if there is one), and shows the paths to the files in the project. Although you can edit many of these files directly, it is often easier and more reliable to use the visual tools in Delphi.

At the top of the project hierarchy, is a group file. You can combine multiple projects into a project group. This allows you to open more than one project at a time in the Project Manager. Project groups let you organize and work on related projects, such as applications that function together or parts of a multi-tiered application. If you are only working on one project, you do not need a project group file to create an application.

Project files, which describe individual projects, files, and associated options, have a .dpr extension. Project files contain directions for building an application or shared object. When you add and remove files using the Project Manager, the project file is updated. You specify project options using a Project Options dialog which has tabs for various aspects of your project such as forms, application, compiler. These project options are stored in the project file with the project.

Units and forms are the basic building blocks of a Delphi application. A project can share any existing form and unit file including those that reside outside the project directory tree. This includes custom procedures and functions that have been written as standalone routines.

If you add a shared file to a project, realize that the file is not copied into the current project directory; it remains in its current location. Adding the shared file to the current project registers the file name and path in the **uses** clause of the project file. Delphi automatically handles this as you add units to a project.

When you compile a project, it does not matter where the files that make up the project reside. The compiler treats shared files the same as those created by the project itself.

Editing code

The Delphi Code editor is a full-featured ASCII editor. If using the visual programming environment, a form is automatically displayed as part of a new project. You can start designing your application interface by placing objects on the form and modifying how they work in the Object Inspector. But other programming tasks, such as writing event handlers for objects, must be done by typing the code.

The contents of the form, all of its properties, its components, and their properties can be viewed and edited as text in the Code editor. You can adjust the generated code in the Code editor and add more components within the editor by typing code. As you type code into the editor, the compiler is constantly scanning for changed and updating the form with the new layout. You can then go back to the form, view and test the changes you made in the editor and continue adjusting the form from there.

The Delphi code generation and property streaming systems are completely open to inspection. The source code for everything that is included in your final executable file—all of the VCL objects, CLX objects, RTL sources, all of the Delphi project files can be viewed and edited in the Code editor.

Compiling applications

When you have finished designing your application interface on the form, writing additional code so it does what you want, you can compile the project from the IDE or from the command line.

All projects have as a target a single distributable executable file. You can view or test your application at various stages of development by compiling, building, or running it:

- When you compile, only units that have changed since the last compile are recompiled.
- When you build, all units in the project are compiled, regardless of whether or not they have changed since the last compile. This technique is useful when you are unsure of exactly which files have or have not been changed, or when you simply want to ensure that all files are current and synchronized. It's also important to use Build when you've changed global compiler directives, to ensure that all code compiles in the proper state. You can also test the validity of your source code without attempting to compile the project.
- When you run, you compile and then execute your application. If you modified the source code since the last compilation, the compiler recompiles those changed modules and relinks your application.

If you have grouped several projects together, you can compile or build all projects in a single project group at once. Choose Project | Compile All Projects or Project | Build All Projects with the project group selected in the Project Manager.

Debugging applications

Delphi provides an integrated debugger that helps you find and fix errors in your applications. The integrated debugger lets you control program execution, monitor variable values and items in data structures, and modify data values while debugging.

The integrated debugger can track down both runtime errors and logic errors. By running to specific program locations and viewing the values of variables, the functions on the call stack, and the program output, you can monitor how your program behaves and find the areas where it is not behaving as designed. The debugger is described in online Help.

You can also use exception handling to recognize, locate, and deal with errors. Exceptions in Delphi are classes, like other classes in Delphi, except, by convention, they begin with an E rather than the initial T for other classes.

Deploying applications

Delphi includes add-on tools to help with application deployment. For example, InstallShield Express (not available in all versions) helps you to create an installation package for your application that includes all of the files needed for running a distributed application. Refer to Chapter 13, “Deploying applications” for specific information on deployment.

Note Not all versions of Delphi have deployment capabilities.

TeamSource software (not available in all versions) is also available for tracking application updates.

Chapter

3

Using the component libraries

This chapter presents an overview of the component libraries and introduces some of the components that you can use while developing applications. Delphi includes both the Visual Component Library (VCL) and the Borland Component Library for Cross-Platform (CLX). The VCL is for Windows development and CLX is for cross-platform development on Windows and Linux. They are two different class libraries but they have many similarities. Objects, properties, methods, and events that are not in CLX are marked “VCL only.”

Understanding the component libraries

VCL and CLX are class libraries made up of objects, some of which are also components or controls, that you use when developing applications. Both libraries look very similar and contain many of the same objects. Some objects in the VCL implement features that are available on Windows only such as objects that appear on the ADO, BDE, QReport, COM+, Web Services, and Servers tabs on the Component palette. Virtually all CLX objects are available on both Windows and Linux.

VCL and CLX objects are active entities that contain all necessary data and the “methods” (code) that modify the data. The data is stored in the fields and properties of the objects, and the code is made up of methods that act upon the field and property values. Each object is declared as a “class.” All VCL and CLX objects descend from the ancestor object *TObject* including objects that you develop in Object Pascal.

A subset of objects are components. Components are objects that you can place on a form or data module and manipulate at design time. Components appear on the Component palette. You can specify their properties without writing code. All VCL or CLX components descend from the *TComponent* object.

Components are objects in the true object-oriented programming (OOP) sense because they

- Encapsulate a set of data and data-access functions
- Inherit data and behavior from the objects they are derived from
- Operate interchangeably with other objects derived from a common ancestor, through a concept called *polymorphism*

Unlike most components, objects do not appear on the Component palette. Instead, a default instance variable is declared in the unit of the object, or you have to declare one yourself.

Controls are a special kind of component that is visible to users at runtime. Controls are a subset of components. Controls are visual components that you can see when your application is running. All controls have properties in common that specify their visual attributes, such as *Height* and *Width.* The properties, methods, and events that all controls have in common are inherited from *TControl*.

Refer to Chapter 10, “Using CLX for cross-platform development” for details about cross-platform programming and the differences between the Windows and Linux environments. Detailed reference material on all of the objects in the VCL or CLX is accessible using online Help while you are programming. From within the code editor, place the cursor anywhere on the object and press F1 to display help on VCL or CLX components.

If you are using Kylix while developing cross-platform applications, Kylix also includes a *Developer’s Guide* that is tailored for the Linux environment. You can refer to the manual both in the Kylix online Help or the printed manual provided with the Kylix product.

Properties, methods, and events

Both the VCL and CLX form hierarchies of objects that are tied to the Delphi IDE, where you can develop applications quickly. The objects in both component libraries are based on properties, methods, and events. Each object includes data members (properties), functions that operate on the data (methods), and a way to interact with users of the class (events). The VCL is written in Object Pascal, whereas CLX is based on Qt, a C++ class library.

Properties

Properties are characteristics of an object that influence either the visible behavior or the operations of the object. For example, the *Visible* property determines whether an object can be seen or not in an application interface. Well-designed properties make your components easier for others to use and easier for you to maintain.

Here are some of the useful features of properties:

- Unlike methods, which are only available at runtime, you can see and change properties at design time and get immediate feedback as the components change in the IDE.

- Properties can be accessed in the Object Inspector where you can modify the values of your object visually. Setting properties at design time is easier than writing code and makes your code easier to maintain.
- Because the data is encapsulated, it is protected and private to the actual object.
- The actual calls to get and set the values are methods, so special processing can be done that is invisible to the user of the object. For example, data could reside in a table, but could appear as a normal data member to the programmer.
- You can implement logic that triggers events or modifies other data during the access of the property. For example, changing the value of one property may require the modification of another. You can make the change in the methods created for the property.
- Properties can be virtual.
- A property is not restricted to a single object. Changing a one property on one object could effect several objects. For example, setting the *Checked* property on a radio button effects all of the radio buttons in the group.

Methods

A *method* is a procedure that is always associated with a class. Methods define the behavior of an object. Class methods can access all the *public*, *protected,* and *private* properties and data members of the class and are commonly referred to as member functions.

Events

An *event i*s an action or occurrence detected by a program. Most modern applications are said to be event-driven, because they are designed to respond to events. In a program, the programmer has no way of predicting the exact sequence of actions a user will perform next. They may choose a menu item, click a button, or mark some text. You can write code to handle the events you're interested in, rather than writing code that always executes in the same restricted order.

Regardless of how an event is called, Delphi looks to see if you have written any code to handle that event. If you have, that code is executed; otherwise, the default event handling behavior takes place.

The kinds of events that can occur can be divided into two main categories:

- User events
- System events

Regardless of how the event was called, Delphi looks to see if you have assigned any code to handle that event. If you have, then that code is executed; otherwise, nothing is done.

User events

User events are actions that are initiated by the user. Examples of user events are *OnClick* (the user clicked the mouse), *OnKeyPress* (the user pressed a key on the keyboard), and *OnDblClick* (the user double-clicked a mouse button). These events are always tied to a user's actions.

System events

System events are events that the operating system fires for you. For example, the *OnTimer* event (the Timer component issues one of these events whenever a predefined interval has elapsed), the *OnCreate* event (the component is being created), the *OnPaint* event (a component or window needs to be redrawn), and so on. Usually, system events are not directly initiated by a user action.

Object Pascal and the class libraries

Object Pascal, a set of object-oriented extensions to standard Pascal, is the language of Delphi. Using Delphi's Component palette and Object Inspector, you can place VCL or CLX components on forms and manipulate their properties without writing code.

All objects descend from *TObject*, an abstract class whose methods encapsulate fundamental behavior like construction, destruction, and message handling. *TObject* is the immediate ancestor of many simple classes.

Components in the VCL or CLX descend from the abstract class *TComponent*. Components are objects that you can manipulate on forms at design time. Visual components—that is, components like *TForm* and *TSpeedButton* that appear on the screen at runtime—are called *controls*, and they descend from *TControl*.

In addition to the visual components, the component libraries contain many nonvisual objects. The IDE allows you to add many nonvisual components to your programs by dropping them onto forms. For example, if you were writing an application that connects to a database, you might place a *TDataSource* component on a form. Although *TDataSource* is nonvisual, it is represented on the form by an icon (which doesn't appear at runtime). You can manipulate the properties and events of *TDataSource* in the Object Inspector just as you would those of a visual control.

When you write classes of your own in Object Pascal, they should descend from *TObject* in the class library that you plan to use. Use VCL if you're writing a Windows application or CLX if writing a cross-platform application. By deriving new classes from the appropriate base class (or one of its descendants), you provide your classes with essential functionality and ensure that they work with the other classes in the class library.

Using the object model

Object-oriented programming is an extension of structured programming that emphasizes code reuse and encapsulation of data with functionality. Once you create an object (or, more formally, a class), you and other programmers can use it in different applications, thus reducing development time and increasing productivity.

If you want to create new components and put them on the Component palette, see Chapter 40, "Overview of component creation."

What is an object?

An object, or *class*, is a data type that encapsulates *data* and *operations on data* in a single unit. Before object-oriented programming, data and operations (functions) were treated as separate elements.

You can begin to understand objects if you understand Object Pascal *records* or *structures* in C. Records are made of up fields that contain data, where each field has its own type. Records make it easy to refer to a collection of varied data elements.

Objects are also collections of data elements. But objects—unlike records—contain procedures and functions that operate on their data. These procedures and functions are called *methods*.

An object's data elements are accessed through *properties*. The properties of VCL and CLX objects have values that you can change at design time without writing code. If you want a property value to change at runtime, you need to write only a small amount of code.

The combination of data and functionality in a single unit is called *encapsulation*. In addition to encapsulation, object-oriented programming is characterized by *inheritance* and *polymorphism*. Inheritance means that objects derive functionality from other objects (called *ancestors*); objects can modify their inherited behavior. Polymorphism means that different objects derived from the same ancestor support the same method and property interfaces, which often can be called interchangeably.

Examining a Delphi object

When you create a new project, Delphi displays a new form for you to customize. In the Code editor, Delphi declares a new class type for the form and produces the code that creates the new form instance. The code generated for a new Windows application looks like this:

```
unit Unit1;
interface

uses Windows, Classes, Graphics, Forms, Controls, Dialogs;

type
  TForm1 = class(TForm){ The type declaration of the form begins here }
  private
    { Private declarations }
  public
    { Public declarations }
  end;{ The type declaration of the form ends here }

var
  Form1: TForm1;

implementation{ Beginning of implementation part }
{$R *.DFM}
end.{ End of implementation part and unit}
```

The new class type is *TForm1*, and it is derived from type *TForm*, which is also a class.

A class is like a record in that they both contain data fields, but a class also contains methods—code that acts on the object's data. So far, *TForm1* appears to contain no fields or methods, because you haven't added to the form any components (the fields of the new object) and you haven't created any event handlers (the methods of the new object). *TForm1* does contain inherited fields and methods, even though you don't see them in the type declaration.

This variable declaration declares a variable named *Form1* of the new type *TForm1*.

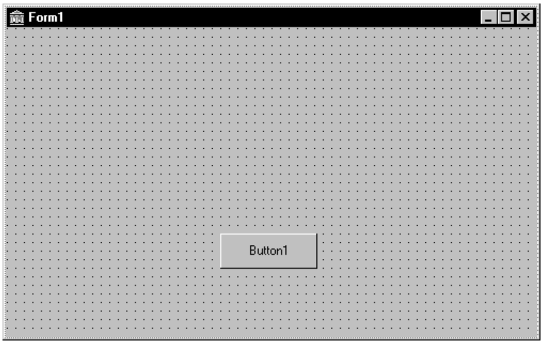
```
var
  Form1: TForm1;
```

Form1 represents an instance, or object, of the class type *TForm1*. You can declare more than one instance of a class type; you might want to do this, for example, to create multiple child windows in a Multiple Document Interface (MDI) application. Each instance maintains its own data, but all instances use the same code to execute methods.

Although you haven't added any components to the form or written any code, you already have a complete Delphi application that you can compile and run. All it does is display a blank form.

Suppose you add a button component to this form and write an *OnClick* event handler that changes the color of the form when the user clicks the button. The result might look like this:

Figure 3.1 A simple form



When the user clicks the button, the form's color changes to green. This is the event-handler code for the button's *OnClick* event:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Form1.Color := clGreen;
end;
```

Objects can contain other objects as data fields. Each time you place a component on a form, a new field appears in the form's type declaration. If you create the application described above and look at the code in the Code editor, this is what you see:

```
unit Unit1;

interface

uses Windows, Classes, Graphics, Forms, Controls;
```

```
type
  TForm1 = class(TForm)
    Button1: TButton;{ New data field }
    procedure Button1Click(Sender: TObject);{ New method declaration }
  private
    { Private declarations }
  public
    { Public declarations }
  end;

var
  Form1: TForm1;

implementation

{$R *.DFM}

procedure TForm1.Button1Click(Sender: TObject);{ The code of the new method }
begin
  Form1.Color := clGreen;
end;

end.
```

TForm1 has a *Button1* field that corresponds to the button you added to the form. *TButton* is a class type, so *Button1* refers to an object.

All the event handlers you write in Delphi are methods of the form object. Each time you create an event handler, a method is declared in the form object type. The *TForm1* type now contains a new method, the *Button1Click* procedure, declared within the *TForm1* type declaration. The code that implements the *Button1Click* method appears in the **implementation** part of the unit.

Changing the name of a component

You should always use the Object Inspector to change the name of a component. For example, suppose you want to change a form's name from the default *Form1* to a more descriptive name, such as *ColorBox*. When you change the form's *Name* property in the Object Inspector, the new name is automatically reflected in the form's .dfm or .xfm file (which you usually don't edit manually) and in the Object Pascal source code that Delphi generates:

```
unit Unit1;

interface

uses Windows, Classes, Graphics, Forms, Controls;

type
  TColorBox = class(TForm){ Changed from TForm1 to TColorBox }
    Button1: TButton;
    procedure Button1Click(Sender: TObject);
  private
    { Private declarations }
  public
    { Public declarations }
  end;

var
```

```
  ColorBox: TColorBox;{ Changed from Form1 to ColorBox }

implementation

{$R *.DFM}

procedure TColorBox.Button1Click(Sender: TObject);
begin
  Form1.Color := clGreen;{ The reference to Form1 didn't change! }
end;

end.
```

Note that the code in the *OnClick* event handler for the button hasn't changed. Because you wrote the code, you have to update it yourself and correct any references to the form:

```
procedure TColorBox.Button1Click(Sender: TObject);
begin
  ColorBox.Color := clGreen;
end;
```

Inheriting data and code from an object

The *TForm1* object described seems simple. *TForm1* appears to contain one field (*Button1*), one method (*Button1Click*), and no properties. Yet you can show, hide, or resize of the form, add or delete standard border icons, and set up the form to become part of a Multiple Document Interface (MDI) application. You can do these things because the form has *inherited* all the properties and methods of the component *TForm*. When you add a new form to your project, you start with *TForm* and customize it by adding components, changing property values, and writing event handlers. To customize any object, you first derive a new object from the existing one; when you add a new form to your project, Delphi automatically derives a new form from the *TForm* type:

```
TForm1 = class(TForm)
```

A derived object inherits all the properties, events, and methods of the object it derives from. The derived object is called a *descendant* and the object it derives from is called an *ancestor*. If you look up *TForm* in the online Help, you'll see lists of its properties, events, and methods, including the ones that *TForm* inherits from *its* ancestors. An object can have only one immediate ancestor, but it can have many direct descendants.

Scope and qualifiers

Scope determines the accessibility of an object's fields, properties, and methods. All members declared within an object are available to that object and its descendants. Although a method's implementation code appears outside of the object declaration, the method is still within the scope of the object because it is declared within the object's declaration.

When you write code to implement a method that refers to properties, methods, or fields of the object where the method is declared, you don't need to preface those identifiers with the name of the object. For example, if you put a button on a new form, you could write this event handler for the button's *OnClick* event:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Color := clFuchsia;
  Button1.Color := clLime;
end;
```

The first statement is equivalent to

```
Form1.Color := clFuchsia
```

You don't need to qualify *Color* with *Form1* because the *Button1Click* method is part of *TForm1*; identifiers in the method body therefore fall within the scope of the *TForm1* instance where the method is called. The second statement, in contrast, refers to the color of the button object (not of the form where the event handler is declared), so it requires qualification.

Delphi creates a separate unit (source code) file for each form. If you want to access one form's components from another form's unit file, you need to qualify the component names, like this:

```
Form2.Edit1.Color := clLime;
```

In the same way, you can access a component's methods from another form. For example,

```
Form2.Edit1.Clear;
```

To access *Form2*'s components from *Form1*'s unit file, you must also add *Form2*'s unit to the **uses** clause of *Form1*'s unit.

The scope of an object extends to the object's descendants. You can, however, redeclare a field, property, or method within a descendant object. Such redeclarations either hide or override the inherited member.

For more information about scope, inheritance, and the **uses** clause, see the *Object Pascal Language Guide*.

Private, protected, public, and published declarations

When you declare a field, property, or method, the new member has a *visibility* indicated by one of the keywords **private**, **protected**, **public**, or **published**. The visibility of a member determines its accessibility to other objects and units.

- A private member is accessible only within the unit where it is declared. Private members are often used within a class to implement other (public or published) methods and properties.
- A protected member is accessible within the unit where its class is declared and within any descendant class, regardless of the descendant class's unit.
- A public member is accessible from wherever the object it belongs to is accessible—that is, from the unit where the class is declared and from any unit that uses that unit.

- A published member has the same visibility as a public member, but the compiler generates runtime type information for published members. Published properties appear in the Object Inspector at design time.

For more information about visibility, see the *Object Pascal Language Guide*.

Using object variables

You can assign one object variable to another object variable if the variables are of the same type or assignment compatible. In particular, you can assign an object variable to another object variable if the type of the variable you are assigning to is an ancestor of the type of the variable being assigned. For example, here is a *TDataForm* type declaration (VCL only) and a variable declaration section declaring two variables, *AForm* and *DataForm*:

```
type
  TDataForm = class(TForm)
  Button1: TButton;
    Edit1: TEdit;
    DataGrid1: TDataGrid;
    Database1: TDatabase;
  private
    { Private declarations }
  public
    { Public declarations }
  end;

var
  AForm: TForm;
  DataForm: TDataForm;
```

AForm is of type *TForm*, and *DataForm* is of type *TDataForm*. Because *TDataForm* is a descendant of *TForm*, this assignment statement is legal:

```
AForm := DataForm;
```

Suppose you write an event handler for the *OnClick* event of a button. When the button is clicked, the event handler for the *OnClick* event is called. Each event handler has a *Sender* parameter of type *TObject*:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
⋮
end;
```

Because *Sender* is of type *TObject*, any object can be assigned to *Sender*. The value of *Sender* is always the control or component that responds to the event. You can test *Sender* to find the type of component or control that called the event handler using the reserved word **is**. For example,

```
if Sender is TEdit then
  DoSomething
else
  DoSomethingElse;
```

Creating, instantiating, and destroying objects

Many of the objects you use in Delphi, such as buttons and edit boxes, are visible at both design time and runtime. Some, such as common dialog boxes, appear only at runtime. Still others, such as timers and datasource components, have no visual representation at runtime.

You may want to create your own objects. For example, you could create a *TEmployee* object that contains *Name*, *Title*, and *HourlyPayRate* properties. You could then add a *CalculatePay* method that uses the data in *HourlyPayRate* to compute a paycheck amount. The *TEmployee* type declaration might look like this:

```
type
  TEmployee = class(TObject)
  private
    FName: string;
    FTitle: string;
    FHourlyPayRate: Double;
  public
    property Name: string read FName write FName;
    property Title: string read FTitle write FTitle;
    property HourlyPayRate: Double read FHourlyPayRate write FHourlyPayRate;
    function CalculatePay: Double;
  end;
```

In addition to the fields, properties, and methods you've defined, *TEmployee* inherits all the methods of *TObject*. You can place a type declaration like this one in either the **interface** or **implementation** part of a unit, and then create instances of the new class by calling the *Create* method that *TEmployee* inherits from *TObject*:

```
var
  Employee: TEmployee;
begin
  Employee := TEmployee.Create;
end;
```

The *Create* method is called a *constructor*. It allocates memory for a new instance object and returns a reference to the object.

Components on a form are created and destroyed automatically by Delphi. But if you write your own code to instantiate objects, you are responsible for disposing of them as well. Every object inherits a *Destroy* method (called a *destructor*) from *TObject*. To destroy an object, however, you should call the *Free* method (also inherited from *TObject*), because *Free* checks for a **nil** reference before calling *Destroy*. For example,

```
Employee.Free
```

destroys the *Employee* object and deallocates its memory.

Components and ownership

Delphi has a built-in memory-management mechanism that allows one component to assume responsibility for freeing another. The former component is said to *own* the latter. The memory for an owned component is automatically freed when its owner's memory is freed. The owner of a component—the value of its *Owner* property—is determined by a parameter passed to the constructor when the component is created. By default, a form owns all components on it and is in turn owned by the application. Thus, when the application shuts down, the memory for all forms and the components on them is freed.

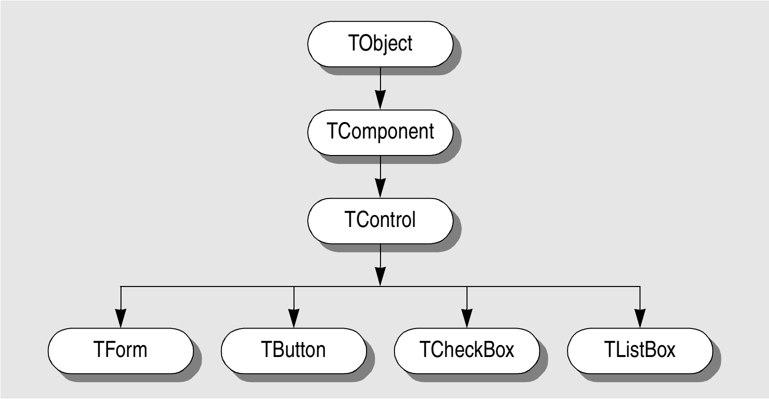
Ownership applies only to *TComponent* and its descendants. If you create, for example, a *TStringList* or *TCollection* object (even if it is associated with a form), you are responsible for freeing the object.

Note Don't confuse a component's *owner* with its *parent*. See "Parent properties" on page 3-19".

Objects, components, and controls

Figure 3.2 is a greatly simplified view of the inheritance hierarchy that illustrates the relationship between objects, components, and controls.

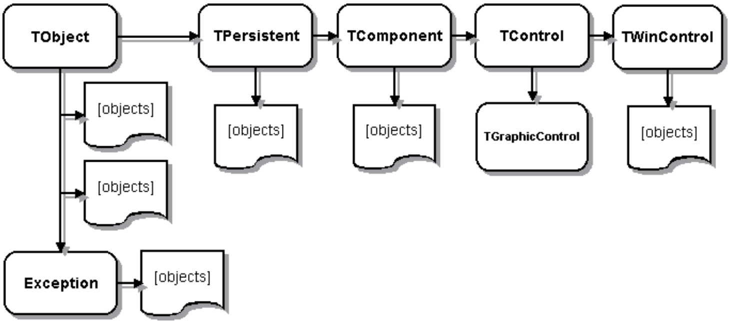
Figure 3.2 Objects, components, and controls



Every object inherits from *TObject*, and many objects inherit from *TComponent*. Controls, which inherit from *TControl*, have the ability to display themselves at runtime. A control like *TCheckBox* inherits all the functionality of *TObject*, *TComponent*, and *TControl*, and adds specialized capabilities of its own.

Figure 3.3 is an overview of the Visual Component Library (VCL) that shows the major branches of the inheritance tree. The Borland Component Library for Cross-Platform (CLX) look very much the same at this level but *TWinControl* is replaced by *TWidgetControl*.

Figure 3.3 A simplified hierarchy diagram



Several important base classes are shown in the figure, and they are described in the following table:

Table 3.1 Important base classes

Class	Description
TObject	Signifies the base class and ultimate ancestor of everything in the VCL or CLX. *TObject* encapsulates the fundamental behavior common to all VCL/CLX objects by introducing methods that perform basic functions such as creating, maintaining, and destroying an instance of an object.
Exception	Specifies the base class of all classes that relate to exceptions. *Exception* provides a consistent interface for error conditions, and enables applications to handle error conditions gracefully.
TPersistent	Specifies the base class for all objects that implement properties. Classes under *TPersistent* deal with sending data to streams and allow for the assignment of classes.
TComponent	Specifies the base class for all nonvisual components such as *TApplication*. *TComponent* is the common ancestor of all components. This class allows a component to be displayed on the Component palette, lets the component own other components, and allows the component to be manipulated directly on a form.
TControl	Represents the base class for all controls that are visible at runtime. *TControl* is the common ancestor of all visual components and provides standard visual controls like position and cursor. This class also provides events that respond to mouse actions.
TWinControl	Specifies the base class of all user interface objects also called widgets. Controls under *TWinControl* are windowed controls that can capture keyboard input. (In CLX, *TWidgetControl* replaces *TWinControl*.)

The next few sections present a general description of the types of classes that each branch contains. For a complete overview of the VCL object hierarchy, refer to the VCL Object Hierarchy wall chart that is included with this product. For details on CLX, refer to the CLX Object Hierarchy wall chart included with the product and the Kylix documentation.

TObject branch

The *TObject* branch includes all objects that descend from *TObject* but not from *TPersistent*. All VCL or CLX objects descend from *TObject*, an abstract class whose methods define fundamental behavior like construction, destruction, and message or system event handling. Much of the powerful capability of VCL and CLX objects are established by the methods that *TObject* introduces. *TObject* encapsulates the fundamental behavior common to all objects in the VCL and CLX by introducing methods that provide:

- The ability to respond when object instances are created or destroyed.
- Class type and instance information on an object, and runtime type information (RTTI) about its published properties.
- Support for message-handling (VCL only).

TObject is the immediate ancestor of many simple classes. Classes that are contained within this branch have one common, important characteristic: they are transitory. What this means is that these classes do not have a method to save the state that they are in prior to destruction; they are not persistent.

One of the main groups of classes in this branch is the *Exception* class. This class provides a large set of built-in exception classes for automatically handling divide-by-zero errors, file I/O errors, invalid typecasts, and many other exception conditions.

Another type of group in the *TObject* branch are classes that encapsulate data structures, such as:

- *TBits,* a class that stores an "array" of Boolean values
- *TList,* a linked list class
- *TStack,* a class that maintains a last-in first-out array of pointers
- *TQueue,* a class that maintains a first-in first-out array of pointers

In the VCL, you can also find wrappers for external objects like *TPrinter*, which encapsulates the Windows printer interface, and *TRegistry,* a low-level wrapper for the system registry and functions that operate on the registry. These are specific to the Windows environment.

TStream is good example of another type of class in this branch. *TStream* is the base class type for stream objects that can read from or write to various kinds of storage media, such as disk files, dynamic memory, and so on.

So you can see, this branch includes many different types of classes that are very useful to you as a developer.

TPersistent branch

Objects in this branch of the VCL and CLX descend from *TPersistent* but not from *TComponent*. *TPersistent* adds persistence to objects. Persistence determines what gets saved with a form file or data module and what gets loaded into the form or data module when it is retrieved from memory.

Objects in this branch implement properties for components. Properties are only loaded and saved with a form if they have an owner. The owner must be some component. This branch introduces the *GetOwner* function which lets you determine the owner of the property.

Objects in this branch are also the first to include a published section where properties can be automatically loaded and saved. A *DefineProperties* method also allows you to indicate how to load and save properties.

Following are some of the other classes in the TPersistent branch of the hierarchy:

- *TGraphicsObject,* an abstract base class for graphics objects such as: *TBrush*, *TFont*, and *TPen*.
- *TGraphic,* an abstract base class for objects such as icons and bitmaps that can store and display visual images: *TBitmap* and *TIcon* (and for Windows development only: *TMetafile).*
- *TStrings,* a base class for objects that represent a list of strings.
- *TClipboard,* a class that contains text or graphics that have been cut or copied from an application.
- *TCollection*, *TOwnedCollection*, and *TCollectionItem,* classes that maintain indexed collections of specially defined items.

TComponent branch

TComponent branch contains objects that descend from *TComponent* but not *TControl*. Objects in this branch are components that you can manipulate on forms at design time. They are persistent objects that can do the following:

- Appear on the Component palette and can be changed in the form designer.
- Own and manage other components.
- Load and save themselves.

Several methods in *TComponent* dictate how components act during design time and what information gets saved with the component. Streaming is introduced in this branch of the VCL and CLX. Delphi handles most streaming chores automatically. Properties are persistent if they are published and published properties are automatically streamed.

The *TComponent* class also introduces the concept of ownership that is propagated throughout the VCL and CLX. Two properties support ownership: *Owner* and *Components*. Every component has an *Owner* property that references another component as its owner. A component may own other components. In this case, all owned components are referenced in the component's *Array* property.

A component's constructor takes a single parameter that is used to specify the new component's owner. If the passed-in owner exists, the new component is added to the owner's Components list. Aside from using the Components list to reference owned components, this property also provides for the automatic destruction of owned components. As long as the component has an owner, it will be destroyed when the owner is destroyed. For example, since *TForm* is a descendant of *TComponent*, all components owned by the form are destroyed and their memory freed when the form is destroyed. This assumes that all of the components on the form clean themselves up properly when their destructors are called.

If a property type is a *TComponent* or a descendant, the streaming system creates an instance of that type when reading it in. If a property type is *TPersistent* but not *TComponent*, the streaming system uses the existing instance available through the property and read values for that instance's properties.

When creating a form file (a file used to store information about the components on the form), the form designer loops through its components array and saves all the components on the form. Each component "knows" how to write its changed properties out to a stream (in this case, a text file). Conversely, when loading the properties of components in the form file, the form designer loops through the components array and loads each component.

The types of classes you'll find in this branch include:

- *TMainMenu,* a class that provides a menu bar and its accompanying drop-down menus for a form.
- *TTimer,* a class that includes the timer functions.
- *TOpenDialog*, *TSaveDialog*, *TFontDialog*, *TFindDialog*, *TColorDialog*, and so on, provide commonly used dialog boxes.
- *TActionList,* a class that maintains a list of actions used with components and controls, such as menu items and buttons.
- *TScreen,* a class that keeps track of what forms and data modules have been instantiated by the application, the active form, and the active control within that form, the size and resolution of the screen, and the cursors and fonts available for the application to use.

Components that do not need a visual interface can be derived directly from *TComponent*. To make a tool such as a *TTimer* device, you can derive from *TComponent*. This type of component resides on the Component palette but performs internal functions that are accessed through code rather than appearing in the user interface at runtime.

In CLX, the *TComponent* branch also includes *THandleComponent*. This is the base class for nonvisual components that require a handle to an underlying Qt object such as dialogs and menus.

TControl branch

The *TControl* branch consists of components that descend from *TControl* but not *TWinControl* (*TWidgetControl* in CLX). Objects in this branch are controls that are visual objects which the application user can see and manipulate at runtime. All controls have properties, methods, and events in common that relate to how the control looks, such as its position, the cursor associated with the control's window (or widget in CLX), methods to paint or move the control, and events to respond to mouse actions. Controls can never receive keyboard input.

Whereas *TComponent* defines behavior for all components, *TControl* defines behavior for all visual controls. This includes drawing routines, standard events, and containership.

There are two basic types of control:

- Those that have a window (or widget) of their own
- Those that use the window (or widget) of their "parent"

Controls that have their own window are called "windowed" controls (VCL) or "widget-based" controls (CLX) and descend from *TWinControl* (*TWidgetControl* in CLX). Buttons and check boxes fall into this class.

Controls that use a parent window (or widget) are called "graphic" controls and descend from *TGraphicControl*. Image and label controls fall into this class. In the VCL, the main difference between these types of components is that graphic controls do not maintain a window handle, and thus cannot receive the input focus. In CLX, the main difference between these types of components is that graphic controls do not have an associated widget, and thus cannot receive the input focus nor can they contain other controls. Because a graphic control does not need a handle, its demand on system resources is lessened, and painting a graphic control is quicker than painting a widget-based control.

TGraphicControl controls must draw themselves and include controls such as:

Table 3.2 Graphic controls

Control	Description
TImage	Displays graphical images.
TLabel	Displays text on a form.
TBevel	Represents a beveled outline.
TPaintBox	Provides a canvas that applications can use for drawing or rendering an image.

Notice that these include common paint routines (*Repaint*, *Invalidate*, and so on) that never need to receive focus.

TWinControl/TWidgetControl branch

The *TWinControl* branch(*TWidgetControl* replaces *TWinControl* in CLX) includes all controls that descend from *TWinControl*. *TWinControl* is the base class for all windowed controls, including many of the items that you will use in the user interface of an application.

TWidgetControl is the base class for all widget-based controls or *widgets*. The term widget comes from combining "window" and "gadget." A widget is almost anything you use in the user interface of an application. Examples of widgets are buttons, labels, and scroll bars.

The following are features of windowed and widget-based controls:

- Both can receive focus while an application is running.
- Other controls may display data, but the user can use the keyboard to interact with windowed or widget-based controls.
- Windowed or widget-based controls can contain other controls.

- A control that contains other controls is called a parent. Only a windowed or widget-based control can be a parent of one or more child controls.
- Windowed controls have a window handle. Widget-based controls have an associated widget.

Descendants of *TWinControl* (*TWidgetControl* in CLX) are controls that can receive focus, meaning they can receive keyboard input from the application user. This implies that many more standard events apply to them.

This branch includes both controls that are drawn automatically (including *TEdit*, *TListBox*, *TComboBox*, *TPageControl*, and so on) and custom controls that Delphi must draw (such as *TDBNavigator*, *TMediaPlayer* (VCL only), *TGauge* (VCL only), and so on). Direct descendants of *TWinControl* (*TWidgetControl* in CLX) typically implement standard controls, like an edit field, a combo box, list box, or page control, and, therefore, already know how to paint themselves.

The *TCustomControl* class is provided for components that require a window handle but do not encapsulate a standard control that includes the ability to repaint itself. You never have to worry about how the controls render themselves or how they respond to events—Delphi completely encapsulates this behavior for you.

The following sections provide an overview of controls. Refer to Chapter 7, “Working with controls” for more information on using controls.

Properties common to TControl

All visual controls (descendants of *TControl*) share certain properties including:

- Action properties
- Position, size, and alignment properties
- Display properties
- Parent properties
- A navigation property
- Drag-and-drop properties
- Drag-and-dock properties (VCL only)

While these properties are inherited from *TControl*, they are published—and hence appear in the Object Inspector—only for components to which they are applicable. For example, *TImage* does not publish the *Color* property, since its color is determined by the graphic it displays.

Action properties

Actions let you share common code for performing actions (for example, when a tool bar button and menu item do the same thing), as well as providing a single, centralized way to enable and disable actions depending on the state of your application.

- *Action* designates the action associated with the control.
- *ActionLink* contains the action link object associated with the control.

Position, size, and alignment properties

This set of properties defines the position and size of a control on the parent control:

- *Height* sets the vertical size.
- *Width* sets the horizontal size.
- *Top* positions the top edge.
- *Left* positions the left edge.
- *AutoSize* specifies whether the control sizes itself automatically to accommodate its contents.
- *Align* determines how the control aligns within its container (parent control).
- *Anchor* specifies how the control is anchored to its parent (VCL only).

This set of properties determine the height, width, and overall size of the control's client area:

- *ClientHeight* specifies the height of the control's client area in pixels.
- *ClientWidth* specifies the width of the control's client area in pixels.

These properties aren't accessible in nonvisual components, but Delphi does keep track of where you place the component icons on your forms. Most of the time you'll set and alter these properties by manipulating the control's image on the form or using the Alignment palette. You can, however, alter them at runtime.

Display properties

The following properties govern the general appearance of a control:

- *Color* changes the background color of a control.
- *Font* changes the color, type family, style, or size of text.
- *Cursor* specifies the image used to represent the mouse pointer when it passes into the region covered by the control.
- *DesktopFont* specifies whether the control uses the Windows icon font when writing text (VCL only).

Parent properties

To maintain a consistent appearance across your application, you can make any control look like its container—called its *parent*—by setting the parent properties to *True*.

- *ParentColor* determines where a control looks for its color information.
- *ParentFont* determines where a control looks for its font information.
- *ParentShowHint* determines where a control looks to find out if its Help Hint should be shown.

A navigation property

The following property determines how users navigate among the controls in a form:

- *Caption* contains the text string that labels a component. To underline a character in a string, include an ampersand (&) before the character. This type of character is called an accelerator key. The user can then select the control or menu item by pressing *Alt* while typing the underlined character.

Drag-and-drop properties

Two component properties affect drag-and-drop behavior:

- *DragMode* determines how dragging starts. By default, *DragMode* is *dmManual*, and the application must call the *BeginDrag* method to start dragging. When *DragMode* is *dmAutomatic*, dragging starts as soon as the mouse button goes down.
- *DragCursor* determines the shape of the mouse pointer when it is over a draggable component (VCL only).

Drag-and-dock properties (VCL only)

The following properties control drag-and-dock behavior:

- *Floating* indicates whether the control is floating.
- *DragKind* specifies whether the control is being dragged normally or for docking.
- *DragMode* determines how the control initiates drag-and-drop or drag-and-dock operations.
- *FloatingDockSiteClass* specifies the class of the temporary control that hosts the control when it is floating.
- *DragCursor* is the cursor that is shown while dragging.
- *DockOrientation* specifies how the control is docked relative to other controls docked in the same parent.
- *HostDockSite* specifies the control in which the control is docked.

For more information, see “Implementing drag-and-dock in controls” on page 7-4.

Standard events common to TControl

The VCL defines a set of standard events for its controls. The following events are declared as part of the *TControl* class, and are therefore available for all classes derived from *TControl*:

- *OnClick* occurs when the user clicks the control.
- *OnContextPopup* occurs when the user right-clicks the control or otherwise invokes the popup menu (such as using the keyboard).
- *OnCanResize* occurs when an attempt is made to resize the control.
- *OnResize* occurs immediately after the control is resized.
- *OnConstrainedResize* occurs immediately after OnCanResize.
- *OnStartDock* occurs when the user begins to drag a control with a DragKind of dkDock (VCL only).
- *OnEndDock* occurs when the dragging of an object ends, either by docking the object or by canceling the dragging (VCL only).
- *OnStartDrag* occurs when the user begins to drag the control or an object it contains by left-clicking on the control and holding the mouse button down.

- *OnEndDrag* occurs when the dragging of an object ends, either by dropping the object or by canceling the dragging.
- *OnDragDrop* occurs when the user drops an object being dragged.
- *OnMouseMove* occurs when the user moves the mouse pointer while the mouse pointer is over a control.
- *OnDblClick* occurs when the user double-clicks the primary mouse button when the mouse pointer is over the control.
- *OnDragOver* occurs when the user drags an object over a control (VCL only).
- *OnMouseDown* occurs when the user presses a mouse button with the mouse pointer over a control.
- *OnMouseUp* occurs when the user releases a mouse button that was pressed with the mouse pointer over a component.

Properties common to TWinControl and TWidgetControl

All windowed controls (descendants of *TWinControl* in the VCL and *TWidgetControl* in CLX) share certain properties including:

- Information about the control
- Border style display properties
- Navigation properties
- Drag-and-dock properties (VCL only)

While these properties are inherited from *TWinControl* and *TWidgetControl*, they are published—and hence appear in the Object Inspector—only for controls to which they are applicable.

General information properties

The general information properties contain information about the appearance of the *TWinControl* and *TWidgetControl*, client area size and origin, windows assigned information, and help context information.

- *ClientOrigin* specifies the screen coordinates (in pixels) of the top left corner of a control’s client area. The screen coordinates of a control that is descended from *TControl* and not *TWinControl* are the screen coordinates of the control’s parent added to its *Left* and *Top* properties.
- *ClientRect* returns a rectangle with its *Top* and *Left* properties set to zero, and its *Bottom* and *Right* properties set to the control's *Height* and *Width*, respectively. *ClientRect* is equivalent to Rect(0, 0, *ClientWidth*, *ClientHeight*).
- *Brush* determines the color and pattern used for painting the background of the control.
- *HelpContext* provides a context number for use in calling context-sensitive online Help.
- *Handle* provides access to the window or widget handle of the control.

Border style display properties

The bevel properties control the appearance of the beveled lines, boxes, or frames on the forms and windowed controls in your application.

Many more objects in the VCL publish these properties; they are not all available in CLX and the border style properties are published on fewer objects.

- *InnerBevel* specifies whether the inner bevel has a raised, lowered, or flat look (VCL only).
- *BevelKind* specifies the type of bevel if the control has beveled edges (VCL only).
- *BevelOuter* specifies whether the outer bevel has a raised, lowered, or flat look.
- *BevelWidth* specifies the width, in pixels, of the inner and outer bevels.
- *BorderWidth* is used to get or set the width of the control's border.
- *BevelEdges* is used to get or set which edges of the control are beveled.

Navigation properties

Two additional properties determine how users navigate among the controls on a form:

- *TabOrder* indicates the position of the control in its parent's tab order, the order in which controls receive focus when the user presses the *Tab* key. Initially, tab order is the order in which the components are added to the form, but you can change this by changing *TabOrder*. *TabOrder* is meaningful only if *TabStop* is *True*.
- *TabStop* determines whether the user can tab to a control. If *TabStop* is *True*, the control is in the tab order.

Drag-and-dock properties (VCL only)

The following properties manage drag-and-dock behavior in VCL objects:

- *UseDockManager* specifies whether the dock manager is used in drag-and-dock operations.
- *VisibleDockClientCount* specifies the number of visible controls that are docked on the windowed control.
- *DockManager* specifies the control's dock manager interface.
- *DockClients* lists the controls that are docked to the windowed control.
- *DockSite* specifies whether the control can be the target of drag-and-dock operations.

For more information, see "Implementing drag-and-dock in controls" on page 7-4.

Events common to TWinControl and TWidgetControl

The following events exist for all controls derived from *TWinControl* in the VCL (this also includes all the controls that Windows defines) and in *TWidgetControl* in CLX. These events are in addition to those that exist in all controls.

- *OnEnter* occurs when the control is about to receive focus.
- *OnKeyDown* occurs on the down stroke of a key press.
- *OnKeyPress* occurs when a user presses a single character key.
- *OnKeyUp* occurs when the user releases a key that has been pressed.

- *OnExit* occurs when the input focus shifts away from one control to another.
- *OnMouseWheel* occurs when the mouse wheel is rotated.
- *OnMouseWheelDown* occurs when the mouse wheel is rotated downward.
- *OnMouseWheelUp* occurs when the mouse wheel is rotated upward.

The following events relate to docking and are available in the VCL only:

- *OnUnDock* occurs when the application tries to undock a control that is docked to a windowed control (VCL only).
- *OnDockDrop* occurs when another control is docked to the control (VCL only).
- *OnDockOver* occurs when another control is dragged over the control (VCL only).
- *OnGetSiteInfo* returns the control's docking information (VCL only).

Creating the application user interface

All visual design work in Delphi takes place on forms. When you open Delphi or create a new project, a blank form is displayed on the screen. You can use it to start building your application interface including windows, menus, and common dialogs.

You design the look and feel of the graphical user interface for an application by placing and arranging visual components such as buttons and list boxes on the form. Delphi takes care of the underlying programming details. You can also place invisible components on forms to capture information from databases, perform calculations, and manage other interactions.

Chapter 6, "Developing the application user interface" provides details on using forms such as creating modal forms dynamically, passing parameters to forms, and retrieving data from forms.

Using Delphi components

Many visual components are provided in the development environment itself on the Component palette. All visual design work in Delphi takes place on forms. When you open Kylix or create a new project, a blank form is displayed on the screen. You select components from the Component palette and drop them onto the form. You design the look and feel of the application's user interface by arranging the visual components such as buttons and list boxes on the form. Once a visual component is on the form, you can adjust its position, size, and other design-time properties. Delphi takes care of the underlying programming details.

Delphi components are grouped functionally on different pages of the Component palette. For example, commonly used components such as those to create menus, edit boxes, or buttons are located on the Standard page of the Component palette. Handy VCL controls such as a timer, paint box, media player, and OLE container are on the System page.

At first glance, Delphi's components appear to be just like any other classes. But there are differences between components in Delphi and the standard class hierarchies that many programmers work with. Some differences are described here:

- All Delphi components descend from *TComponent*.
- Components are most often used as is and are changed through their properties, rather than serving as "base classes" to be subclassed to add or change functionality. When a component is inherited, it is usually to add specific code to existing event handling member functions.
- Components can only be allocated on the heap, not on the stack.
- Properties of components intrinsically contain runtime type information.
- Components can be added to the Component palette in the Delphi user interface and manipulated on a form.

Components often achieve a better degree of encapsulation than is usually found in standard classes. For example, consider the use of a dialog containing a push button. In a Windows program developed using VCL components, when a user clicks on the button, the system generates a WM_LBUTTONDOWN message. The program must catch this message (typically in a **switch** statement, a message map, or a response table) and dispatch it to a routine that will execute in response to the message.

Most Windows messages (VCL) or system events (CLX) are handled by Delphi components. When you want to respond to a message, you only need to provide an event handler.

Setting component properties

Published properties can be set at design time in the Object Inspector and, in some cases, with special property editors.

To set properties at runtime, assign them new values in your application source code.

For information about the properties of each component, see the online Help.

Using the Object Inspector

When you select a component on a form, the Object Inspector displays its published properties and (when appropriate) allows you to edit them. Use the *Tab* key to toggle between the Value column and the Property column. When the cursor is in the Property column, you can navigate to any property by typing the first letters of its name. For properties of Boolean or enumerated types, you can choose values from a drop-down list or toggle their settings by double-clicking in Value column.

If a plus (+) symbol appears next to a property name, clicking the plus symbol or typing '+' when the property has focus displays a list of subvalues for the property. Similarly, if a minus (-) symbol appears next to the property name, clicking the minus symbol or typing '-' hides the subvalues.

By default, properties in the Legacy category are not shown; to change the display filters, right-click in the Object Inspector and choose View. For more information, see “property categories” in the online Help.

When more than one component is selected, the Object Inspector displays all properties—except *Name*—that are shared by the selected components. If the value for a shared property differs among the selected components, the Object Inspector displays either the default value or the value from the first component selected. When you change a shared property, the change applies to all selected components.

Using property editors

Some properties, such as *Font*, have special property editors. Such properties appear with ellipsis marks (...) next to their values when the property is selected in the Object Inspector. To open the property editor, double-click in the Value column, click the ellipsis mark, or type *Ctrl+Enter* when focus is on the property or its value. With some components, double-clicking the component on the form also opens a property editor.

Property editors let you set complex properties from a single dialog box. They provide input validation and often let you preview the results of an assignment.

Setting properties at runtime

Any writable property can be set at runtime in your source code. For example, you can dynamically assign a caption to a form:

```
Form1.Caption := MyString;
```

Calling methods

Methods are called just like ordinary procedures and functions. For example, visual controls have a *Repaint* method that refreshes the control’s image on the screen. You could call the *Repaint* method in a draw-grid object like this:

```
DrawGrid1.Repaint;
```

As with properties, the scope of a method name determines the need for qualifiers. If you want, for example, to repaint a form within an event handler of one of the form’s child controls, you don’t have to prepend the name of the form to the method call:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Repaint;
end;
```

For more information about scope, see “Scope and qualifiers” on page 3-8.

Working with events and event handlers

In Delphi, almost all the code you write is executed, directly or indirectly, in response to *events*. An event is a special kind of property that represents a runtime occurrence, often a user action. The code that responds directly to an event—called an *event handler*—is an Object Pascal procedure. The sections that follow show how to

- Generate a new event handler
- Generate a handler for a component’s default event
- Locate event handlers
- Associate an event with an existing event handler
- Associate menu events with event handlers
- Delete event handlers

Generating a new event handler

Delphi can generate skeleton event handlers for forms and other components. To create an event handler,

1 Select a component.

2 Click the Events tab in the Object Inspector. The Events page of the Object Inspector displays all events defined for the component.

3 Select the event you want, then double-click the Value column or press *Ctrl+Enter*. Delphi generates the event handler in the Code editor and places the cursor inside the **begin...end** block.

4 Inside the **begin...end** block, type the code that you want to execute when the event occurs.

Generating a handler for a component’s default event

Some components have a *default* event, which is the event the component most commonly needs to handle. For example, a button’s default event is *OnClick*. To create a default event handler, double-click the component in the Form Designer; this generates a skeleton event-handling procedure and opens the Code editor with the cursor in the body of the procedure, where you can easily add code.

Not all components have a default event. Some components, such as *TBevel*, don’t respond to any events. Other components respond differently when you double-click on them in the Form Designer. For example, many components open a default property editor or other dialog when they are double-clicked at design time.

Locating event handlers

If you generated a default event handler for a component by double-clicking it in the Form Designer, you can locate that event handler in the same way. Double-click the component, and the Code editor opens with the cursor at the beginning of the event-handler body.

To locate an event handler that’s not the default,

1 In the form, select the component whose event handler you want to locate.

2 In the Object Inspector, click the Events tab.

3 Select the event whose handler you want to view and double-click in the Value column. The Code editor opens with the cursor at the beginning of the event-handler body.

Associating an event with an existing event handler

You can reuse code by writing event handlers that respond to more than one event. For example, many applications provide speed buttons that are equivalent to drop-down menu commands. When a button initiates the same action as a menu command, you can write a single event handler and assign it to both the button's and the menu item's *OnClick* event.

To associate an event with an existing event handler,

1. On the form, select the component whose event you want to handle.
2. On the Events page of the Object Inspector, select the event to which you want to attach a handler.
3. Click the down arrow in the Value column next to the event to open a list of previously written event handlers. (The list includes only event handlers written for events of the same name on the same form.) Select from the list by clicking an event-handler name.

The procedure above is an easy way to reuse event handlers. *Action lists* and in the VCL, *action bands*, however, provide powerful tools for centrally organizing the code that responds to user commands. Action lists can be used in cross-platform applications, whereas action bands cannot. For more information about action lists and action bands, see "Organizing actions for toolbars and menus" on page 6-16.

Using the Sender parameter

In an event handler, the *Sender* parameter indicates which component received the event and therefore called the handler. Sometimes it is useful to have several components share an event handler that behaves differently depending on which component calls it. You can do this by using the *Sender* parameter in an **if...then...else** statement. For example, the following code displays the title of the application in the caption of a dialog box only if the *OnClick* event was received by *Button1*.

```
procedure TMainForm.Button1Click(Sender: TObject);
begin
if Sender = Button1 then
  AboutBox.Caption := 'About ' + Application.Title
else
  AboutBox.Caption := '';
AboutBox.ShowModal;
end;
```

Displaying and coding shared events

When components share events, you can display their shared events in the Object Inspector. First, select the components by holding down the *Shift* key and clicking on them in the Form Designer; then choose the Events tab in the Object Inspector. From the Value column in the Object Inspector, you can now create a new event handler for, or assign an existing event handler to, any of the shared events.

Associating menu events with event handlers

The Menu Designer, along with the *MainMenu* and *PopupMenu* components, make it easy to supply your application with drop-down and pop-up menus. For the menus to work, however, each menu item must respond to the *OnClick* event, which occurs whenever the user chooses the menu item or presses its accelerator or shortcut key. This section explains how to associate event handlers with menu items. For information about the Menu Designer and related components, see "Creating and managing menus" on page 6-29.

To create an event handler for a menu item,

1. Open the Menu Designer by double-clicking on a *MainMenu* or *PopupMenu* object.
2. Select a menu item in the Menu Designer. In the Object Inspector, make sure that a value is assigned to the item's *Name* property.
3. From the Menu Designer, double-click the menu item. Delphi generates an event handler in the Code editor and places the cursor inside the **begin...end** block.
4. Inside the **begin...end** block, type the code that you want to execute when the user selects the menu command.

To associate a menu item with an existing *OnClick* event handler,

1. Open the Menu Designer by double-clicking on a *MainMenu* or *PopupMenu* object.
2. Select a menu item in the Menu Designer. In the Object Inspector, make sure that a value is assigned to the item's *Name* property.
3. On the Events page of the Object Inspector, click the down arrow in the Value column next to *OnClick* to open a list of previously written event handlers. (The list includes only event handlers written for *OnClick* events on this form.) Select from the list by clicking an event handler name.

Deleting event handlers

When you delete a component from a form using the Form Designer, Delphi removes the component from the form's type declaration. It does not, however, delete any associated methods from the unit file, since these methods may still be called by other components on the form. You can manually delete a method—such as an event handler—but if you do so, be sure to delete both the method's forward declaration (in the **interface** section of the unit) and its implementation (in the **implementation** section); otherwise you'll get a compiler error when you build your project.

VCL and CLX components

The Component palette contains a selection of components that handle a wide variety of programming tasks. You can add, remove, and rearrange components on the palette, and you can create component *templates* and *frames* that group several components.

The components on the palette are arranged in pages according to their purpose and functionality. Which pages appear in the default configuration depends on the version of Delphi you are running. Table 3.3 lists typical default pages and components available for creating applications. Some of the tabs and components are not cross platform and the table points them out. You can use some VCL-specific nonvisual components in Windows-only CLX applications, however, the applications will not be cross-platform unless you isolate these portions of the code.

Table 3.3 Component palette pages

Page name	Description	Cross platform?
Standard	Standard controls, menus	Yes
Additional	Specialized controls	Yes except ApplicationEvents and CustomizeDlg
Win32	Windows common controls	Many of the same components are on the Common Controls tab that appears instead when creating CLX applications; RichEdit, UpDown, HotKey, Animate, DataTimePicker, MonthCalendar, Coolbar, PageScroller, and ComboBoxEx are not cross-platform
System	Components and controls for system-level access, including timers, multimedia, and DDE	Timer is but PaintBox, MediaPlayer, OleContainer, and the Dde components are not
Data Access	Components for working with database data that are not tied to any particular data access mechanism	Yes
Data Controls	Visual, data-aware controls	Yes except for DBRichEdit, DBCtrlGrid, and DBChart
dbExpress	Database controls that use dbExpress, a cross-platform, database-independent layer that provides methods for dynamic SQL processing. It defines a common interface for accessing SQL servers.	Yes
DataSnap	Components used for creating multi-tiered database applications	No but can be used in Windows CLX applications
BDE	Components that provide data access through the Borland Database Engine	No but can be used in Windows CLX applications
ADO	Components that provide data access through the ADO framework	No but can be used in Windows CLX applications
InterBase	Components that provide direct access to InterBase	Yes
InternetExpress	Components that are simultaneously a Web Server application and the client of a multi-tiered database application	No but can be used in Windows CLX applications
Internet	Components for Internet communication protocols and Web applications	Yes except for ClientSocket, ServerSocket, QueryTableProducer, XMLDoc, and WebBrowser
WebSnap	Components for building Web server applications	No but can be used in Windows CLX applications
FastNet	NetMasters Internet controls	No but can be used in Windows CLX applications

Table 3.3 Component palette pages (continued)

Page name	Description	Cross platform?
QReport	QuickReport components for creating embedded reports	No but can be used in Windows CLX applications
Dialogs	Commonly used dialog boxes	Yes except for OpenPictureDialog, SavePictureDialog, PrinterSetup-Dialog, and PageSetupDialog
Win 3.1	Old style Win 3.1 components	No
Samples	Sample custom components	No
ActiveX	Sample ActiveX controls; see Microsoft documentation (msdn.microsoft.com)	No
COM+	Component for handling COM+ events	No but can be used in Windows CLX applications
WebServices	Components for writing applications that implement or use SOAP-based Web services	No but can be used in Windows CLX applications
Servers	COM Server examples for Microsoft Excel, Word, and so on (see Microsoft MSDN documentation)	No but can be used in Windows CLX applications
Indy Clients	Cross-platform Internet components for the client (open source Winshoes Internet components)	Yes
Indy Servers	Cross-platform Internet components for the server (open source Winshoes Internet components)	Yes
Indy Misc	Additional cross-platform Internet components (open source Winshoes Internet components)	Yes

The online Help provides information about the components on the Component palette. Some of the components on the ActiveX, Servers, and Samples pages, however, are provided as examples only and are not documented.

Adding custom components to the Component palette

You can install custom components—written by yourself or third parties—on the Component palette and use them in your applications. To write a component, see Part V, “Creating custom components”. To install an existing component, see “Installing component packages” on page 11-5.

Text controls

Many applications present text to the user or allow the user to enter text. The type of control used for this purpose depends on the size and format of the information.

Use this component:	When you want users to do this:
TEdit	Edit a single line of text
TMemo	Edit multiple lines of text
TMaskEdit	Adhere to a particular format, such as a postal code or phone number
TRichEdit	Edit multiple lines of text using rich text format (VCL only)

TEdit and *TMaskEdit* are simple text controls that include a single line text edit box in which you can type information. When the edit box has focus, a blinking insertion point appears.

You can include text in the edit box by assigning a string value to its *Text* property. You control the appearance of the text in the edit box by assigning values to its *Font* property. You can specify the typeface, size, color, and attributes of the font. The attributes affect all of the text in the edit box and cannot be applied to individual characters.

An edit box can be designed to change its size depending on the size of the font it contains. You do this by setting the *AutoSize* property to True. You can limit the number of characters an edit box can contain by assigning a value to the *MaxLength* property.

TMaskEdit is a special edit control that validates the text entered against a mask that encodes the valid forms the text can take. The mask can also format the text that is displayed to the user.

TMemo is for adding several lines of text.

Text control properties

Following are some of the important properties of text controls:

Table 3.4 Text control properties

Property	Description
Text	Determines the text that appears in the edit box or memo control.
Font	Controls the attributes of text written in the edit box or memo control.
AutoSize	Enables the edit box to dynamically change its height depending on the currently selected font.
ReadOnly	Specifies whether the user is allowed to change the text.
MaxLength	Limits the number of characters in simple text controls.

Properties of memo and rich text controls

Memo and rich text controls, which handle multiple lines of text, have several properties in common. Note that rich text controls are not cross-platform.

TMemo is another type of edit box, which handles multiple lines of text. The lines in a memo control can extend beyond the right boundary of the edit box, or they can wrap onto the next line. You control whether the lines wrap using the *WordWrap* property.

Memo and rich text controls include other properties such as the following:

- *Alignment* specifies how text is aligned (left, right, or center) in the component.
- The *Text* property contains the text in the control. Your application can tell if the text changes by checking the *Modified* property.
- *Lines* contains the text as a list of strings.
- *OEMConvert* determines whether the text is temporarily converted from ANSI to OEM as it is entered. This is useful for validating file names (VCL only).
- *WordWrap* determines whether the text will wrap at the right margin.
- *WantReturns* determines whether the user can insert hard returns in the text.
- *WantTabs* determines whether the user can insert tabs in the text.
- *AutoSelect* determines whether the text is automatically selected (highlighted) when the control becomes active.
- *SelText* contains the currently selected (highlighted) part of the text.
- *SelStart* and *SelLength* indicate the position and length of the selected part of the text.

At runtime, you can select all the text in the memo with the *SelectAll* method.

Rich text controls (VCL only)

The rich edit (*TRichEdit*) component is a memo control that supports rich text formatting, printing, searching, and drag-and-drop of text. It allows you to specify font properties, alignment, tabs, indentation, and numbering.

Specialized input controls

The following components provide additional ways of capturing input.

Use this component:	When you want users to do this:
TScrollBar	Select values on a continuous range
TTrackBar	Select values on a continuous range (more visually effective than a scroll bar)
TUpDown	Select a value from a spinner attached to an edit component (VCL only)
THotKey	Enter *Ctrl*/*Shift*/*Alt* keyboard sequences (VCL only)
TSpinEdit	Select a value from a spinner widget (CLX only)

Scroll bars

The scroll bar component creates a scroll bar that you can use to scroll the contents of a window, form, or other control. In the *OnScroll* event handler, you write code that determines how the control behaves when the user moves the scroll bar.

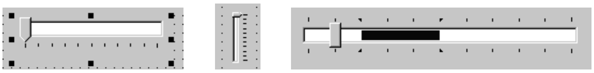
The scroll bar component is not used very often, because many visual components include scroll bars of their own and thus don’t require additional coding. For example, *TForm* has *VertScrollBar* and *HorzScrollBar* properties that automatically configure scroll bars on the form. To create a scrollable region within a form, use *TScrollBox*.

Track bars

A track bar can set integer values on a continuous range. It is useful for adjusting properties like color, volume and brightness. The user moves the slide indicator by dragging it to a particular location or clicking within the bar.

- Use the *Max* and *Min* properties to set the upper and lower range of the track bar.
- Use *SelEnd* and *SelStart* to highlight a selection range. See Figure 3.4.
- The *Orientation* property determines whether the track bar is vertical or horizontal.
- By default, a track bar has one row of ticks along the bottom. Use the *TickMarks* property to change their location. To control the intervals between ticks, use the *TickStyle* property and *SetTick* method.

Figure 3.4 Three views of the track bar component



- *Position* sets a default position for the track bar and tracks the position at runtime.
- By default, users can move one tick up or down by pressing the up and down arrow keys. Set *LineSize* to change that increment.
- Set *PageSize* to determine the number of ticks moved when the user presses *Page Up* and *Page Down*.

Up-down controls (VCL only)

An up-down control (*TUpDown*) consists of a pair of arrow buttons that allow users to change an integer value in fixed increments. The current value is given by the *Position* property; the increment, which defaults to 1, is specified by the *Increment* property. Use the *Associate* property to attach another component (such as an edit control) to the up-down control.

Spin edit controls (CLX only)

A spin edit control (*TSpinEdit*) is also called an up-down widget, little arrows widget, or spin button. This control lets the application user change an integer value in fixed increments, either by clicking the up or down arrow buttons to increase or decrease the value currently displayed, or by typing the value directly into the spin box.

The current value is given by the *Value* property; the increment, which defaults to 1, is specified by the *Increment* property.

Hot key controls (VCL only)

Use the hot key component (*THotKey*) to assign a keyboard shortcut that transfers focus to any control. The *HotKey* property contains the current key combination and the *Modifiers* property determines which keys are available for *HotKey*.

The hot key component can be assigned as the *ShortCut* property of a menu item. Then, when a user enters the key combination specified by the *HotKey* and *Modifiers* properties, Windows activates the menu item.

Splitter controls

A splitter (*TSplitter*) placed between aligned controls allows users to resize the controls. Used with components like panels and group boxes, splitters let you divide a form into several panes with multiple controls on each pane.

After placing a panel or other control on a form, add a splitter with the same alignment as the control. The last control should be client-aligned, so that it fills up the remaining space when the others are resized. For example, you can place a panel at the left edge of a form, set its *Alignment* to *alLeft*, then place a splitter (also aligned to *alLeft*) to the right of the panel, and finally place another panel (aligned to *alLeft* or *alClient*) to the right of the splitter.

Set *MinSize* to specify a minimum size the splitter must leave when resizing its neighboring control. Set *Beveled* to *True* to give the splitter's edge a 3D look.

Buttons and similar controls

Aside from menus, buttons provide the most common way to invoke a command in an application. Delphi offers several button-like controls:

Use this component:	To do this:
TButton	Present command choices on buttons with text
TBitBtn	Present command choices on buttons with text and glyphs
TSpeedButton	Create grouped toolbar buttons
TCheckBox	Present on/off options
TRadioButton	Present a set of mutually exclusive choices
TToolBar	Arrange tool buttons and other controls in rows and automatically adjust their sizes and positions
TCoolBar	Display a collection of windowed controls within movable, resizable bands (VCL only)

Button controls

Users click button controls with the mouse to initiate actions. Buttons are labeled with text that represent the action. The text is specified by assigning a string value to the *Caption* property. Most buttons can also be selected by pressing a key on the keyboard as a keyboard shortcut. The shortcut is shown as an underlined letter on the button.

Users click button controls to initiate actions. You can assign an action to a *TButto*n component by creating an *OnClick* event handler for it. Double-clicking a button at design time takes you to the button's *OnClick* event handler in the Code editor.

- Set *Cancel* to *True* if you want the button to trigger its *OnClick* event when the user presses Esc.
- Set *Default* to *True* if you want the Enter key to trigger the button's *OnClick* event.

Bitmap buttons

A bitmap button (*BitBtn*) is a button control that presents a bitmap image on its face.

- To choose a bitmap for your button, set the *Glyph* property.
- Use *Kind* to automatically configure a button with a glyph and default behavior.
- By default, the glyph is to the left of any text. To move it, use the *Layout* property.
- The glyph and text are automatically centered in the button. To move their position, use the *Margin* property. *Margin* determines the number of pixels between the edge of the image and the edge of the button.
- By default, the image and the text are separated by 4 pixels. Use *Spacing* to increase or decrease the distance.
- Bitmap buttons can have 3 states: up, down, and held down. Set the *NumGlyphs* property to 3 to show a different bitmap for each state.

Speed buttons

Speed buttons, which usually have images on their faces, can function in groups. They are commonly used with panels to create toolbars.

- To make speed buttons act as a group, give the *GroupIndex* property of all the buttons the same nonzero value.
- By default, speed buttons appear in an up (unselected) state. To initially display a speed button as selected, set the *Down* property to *True*.
- If *AllowAllUp* is *True*, all of the speed buttons in a group can be unselected. Set *AllowAllUp* to *False* if you want a group of buttons to act like a radio group.

For more information on speed buttons, refer to subtopics in the section “Adding a toolbar using a panel component” on page 6-43.

Check boxes

A check box is a toggle that lets the user select an on or off state. When the choice is turned on, the check box is checked. Otherwise, the check box is blank. You create check boxes using *TCheckBox*.

- Set *Checked* to *True* to make the box appear checked by default.
- Set *AllowGrayed* to *True* to give the check box three possible states: checked, unchecked, and grayed.
- The *State* property indicates whether the check box is checked (*cbChecked*), unchecked (*cbUnchecked*), or grayed (*cbGrayed*).

Note Check box controls display one of two binary states. The indeterminate state is used when other settings make it impossible to determine the current value for the check box.

Radio buttons

Radio buttons present a set of mutually exclusive choices. You can create individual radio buttons using *TRadioButton* or use the *radio group* component (*TRadioGroup*) to arrange radio buttons into groups automatically. You can group radio buttons to let the user select one from a limited set of choices. See “Grouping components” on page 3-39 for more information.

A selected radio button is displayed as a circle filled in the middle. When not selected, the radio button shows an empty circle. Assign the value True or False to the Checked property to change the radio button's visual state.

Toolbars

Toolbars provide an easy way to arrange and manage visual controls. You can create a toolbar out of a panel component and speed buttons, or you can use the *ToolBar* component, then right-click and choose New Button to add buttons to the toolbar.

The *TToolBar* component has several advantages: buttons on a toolbar automatically maintain uniform dimensions and spacing; other controls maintain their relative position and height; controls can automatically wrap around to start a new row when they do not fit horizontally; and *TToolBar* offers display options like transparency, pop-up borders, and spaces and dividers to group controls.

You can use a centralized set of actions on toolbars and menus, by using *action lists* or *action bands*. See "Using action lists" on page 6-23 for details on how to use action lists with buttons and toolbars.

Toolbars can also parent other controls such as edit boxes, combo boxes, and so on.

Cool bars (VCL only)

A cool bar contains child controls that can be moved and resized independently. Each control resides on an individual band. The user positions the controls by dragging the sizing grip to the left of each band.

The cool bar requires version 4.70 or later of COMCTL32.DLL (usually located in the Windows\System or Windows\System32 directory) at both design time and runtime. Cool bars cannot be used in cross-platform applications.

- The *Bands* property holds a collection of *TCoolBand* objects. At design time, you can add, remove, or modify bands with the Bands editor. To open the Bands editor, select the *Bands* property in the Object Inspector, then double-click in the Value column to the right, or click the ellipsis (...) button. You can also create bands by adding new windowed controls from the palette.
- The *FixedOrder* property determines whether users can reorder the bands.
- The *FixedSize* property determines whether the bands maintain a uniform height.

Handling lists

Lists present the user with a collection of items to select from. Several components display lists:

Use this component:	To display:
TListBox	A list of text strings
TCheckListBox	A list with a check box in front of each item
TComboBox	An edit box with a scrollable drop-down list
TTreeView	A hierarchical list

Use this component:	To display:
TListView	A list of (draggable) items with optional icons, columns, and headings
TDateTimePicker	A list box for entering dates or times (VCL only)
TMonthCalendar	A calendar for selecting dates (VCL only)

Use the nonvisual *TStringList* and *TImageList* components to manage sets of strings and images. For more information about string lists, see "Working with string lists" on page 3-47.

List boxes and check-list boxes

List boxes (*TListBox*) and check-list boxes display lists from which users can select items.

- *Items* uses a *TStrings* object to fill the control with values.
- *ItemIndex* indicates which item in the list is selected.
- *MultiSelect* specifies whether a user can select more than one item at a time.
- *Sorted* determines whether the list is arranged alphabetically.
- *Columns* specifies the number of columns in the list control.
- *IntegralHeight* specifies whether the list box shows only entries that fit completely in the vertical space (VCL only).
- *ItemHeight* specifies the height of each item in pixels. The *Style* property can cause *ItemHeight* to be ignored.
- The *Style* property determines how a list control displays its items. By default, items are displayed as strings. By changing the value of *Style*, you can create *owner-draw* list boxes that display items graphically or in varying heights. For information on owner-draw controls, see "Adding graphics to controls" on page 7-11.

To create a simple list box,

1. Within your project, drop a list box component from the Component palette onto a form.
2. Size the list box and set its alignment as needed.
3. Double-click the right side of the *Items* property or choose the ellipsis button to display the String List Editor.
4. Use the editor to enter free form text arranged in lines for the contents of the list box.
5. Then choose OK.

To let users select multiple items in the list box, you can use the *ExtendedSelect* and *MultiSelect* properties.

Combo boxes

A combo box (*TComboBox*) combines an edit box with a scrollable list. When users enter data into the control—by typing or selecting from the list—the value of the *Text* property changes. If *AutoComplete* is enabled, the application looks for and displays the closest match in the list as the user types the data.

Three types of combo boxes are: standard, drop-down (the default), and drop-down list.

- Use the *Style* property to select the type of combo box you need.
- Use *csDropDown* if you want an edit box with a drop-down list. Use *csDropDownList* to make the edit box read-only (forcing users to choose from the list). Set the *DropDownCount* property to change the number of items displayed in the list.
- Use *csSimple* to create a combo box with a fixed list that does not close. Be sure to resize the combo box so that the list items are displayed.
- Use *csOwnerDrawFixed* or *csOwnerDrawVariable* to create *owner-draw* combo boxes that display items graphically or in varying heights. For information on owner-draw controls, see “Adding graphics to controls” on page 7-11.

At runtime, CLX combo boxes work differently than VCL combo boxes. In CLX (but not in the VCL combo box), you can add a item to a drop down by entering text and pressing Enter in the edit field of a combo box. You can turn this feature off by setting *InsertMode* to ciNone. It is also possible to add empty (no string) items to the list in the combo box. Also, if you keep pressing the down arrow key, it does not stop at the last item of the combo box list. It cycles around to the top again.

Tree views

A tree view *(TTreeView)* displays items in an indented outline. The control provides buttons that allow nodes to be expanded and collapsed. You can include icons with items’ text labels and display different icons to indicate whether a node is expanded or collapsed. You can also include graphics, such as check boxes, that reflect state information about the items.

- *Indent* sets the number of pixels horizontally separating items from their parents.
- *ShowButtons* enables the display of '+' and '–' buttons to indicate whether an item can be expanded.
- *ShowLines* enables display of connecting lines to show hierarchical relationships (VCL only).
- *ShowRoot* determines whether lines connecting the top-level items are displayed (VCL only).

To add items to a tree view control at design time, double-click on the control to display the TreeView Items editor. The items you add become the value of the *Items* property. You can change the items at runtime by using the methods of the *Items* property, which is an object of type *TTreeNodes*. *TTreeNodes* has methods for adding, deleting, and navigating the items in the tree view.

Tree views can display columns and subitems similar to list views in vsReport mode.

List views

List views, created using *TListView*, display lists in various formats. Use the *ViewStyle* property to choose the kind of list you want:

- *vsIcon* and *vsSmallIcon* display each item as an icon with a label. Users can drag items within the list view window (VCL only).
- *vsList* displays items as labeled icons that cannot be dragged.

- *vsReport* displays items on separate lines with information arranged in columns. The leftmost column contains a small icon and label, and subsequent columns contain subitems specified by the application. Use the *ShowColumnHeaders* property to display headers for the columns.

Date-time pickers and month calendars (VCL only)

The DateTimePicker component displays a list box for entering dates or times, while the MonthCalendar component presents a calendar for entering dates or ranges of dates. To use these components, you must have version 4.70 or later of COMCTL32.DLL (usually located in the Windows\System or Windows\System32 directory) at both design time and runtime. They are not available for use in cross-platform applications.

Grouping components

A graphical interface is easier to use when related controls and information are presented in groups. Delphi provides several components for grouping components:

Use this component:	When you want this:
TGroupBox	A standard group box with a title
TRadioGroup	A simple group of radio buttons
TPanel	A more visually flexible group of controls
TScrollBox	A scrollable region containing controls
TTabControl	A set of mutually exclusive notebook-style tabs
TPageControl	A set of mutually exclusive notebook-style tabs with corresponding pages, each of which may contain other controls
THeaderControl	Resizable column headers

Group boxes and radio groups

A group box (*TGroupBox*) arranges related controls on a form. The most commonly grouped controls are radio buttons. After placing a group box on a form, select components from the Component palette and place them in the group box. The *Caption* property contains text that labels the group box at runtime.

The radio group component (*TRadioGroup*) simplifies the task of assembling radio buttons and making them work together. To add radio buttons to a radio group, edit the *Items* property in the Object Inspector; each string in *Items* makes a radio button appear in the group box with the string as its caption. The value of the *ItemIndex* property determines which radio button is currently selected. Display the radio buttons in a single column or in multiple columns by setting the value of the *Columns* property. To respace the buttons, resize the radio group component.

Panels

The *TPanel* component provides a generic container for other controls. Panels are typically used to visually group components together on a form. Panels can be aligned with the form to maintain the same relative position when the form is resized. The *BorderWidth* property determines the width, in pixels, of the border around a panel.

You can also place other controls onto a panel and use the *Align* property to ensure proper positioning of all the controls in the group on the form. You can make a panel alTop aligned so that its position will remain in place even if the form is resized.

The look of the panel can be changed to a raised or lowered look by using the *BevelOuter* and *BevelInner* properties. You can vary the values of these properties to create different visual 3-D effects. Note that if you merely want a raised or lowered bevel, you can use the less resource intensive *TBevel* control instead.

You can also use one or more panels to build various status bars or information display areas.

Scroll boxes

Scroll boxes (*TScrollBox*) create scrolling areas within a form. Applications often need to display more information than will fit in a particular area. Some controls—such as list boxes, memos, and forms themselves—can automatically scroll their contents.

Another use of scroll boxes is to create multiple scrolling areas (views) in a window. Views are common in commercial word-processor, spreadsheet, and project management applications. Scroll boxes give you the additional flexibility to define arbitrary scrolling subregions of a form.

Like panels and group boxes, scroll boxes contain other controls, such as *TButton* and *TCheckBox* objects. But a scroll box is normally invisible. If the controls in the scroll box cannot fit in its visible area, the scroll box automatically displays scroll bars.

Another use of a scroll box is to restrict scrolling in areas of a window, such as a toolbar or status bar (*TPanel* components). To prevent a toolbar and status bar from scrolling, hide the scroll bars, and then position a scroll box in the client area of the window between the toolbar and status bar. The scroll bars associated with the scroll box will appear to belong to the window, but will scroll only the area inside the scroll box.

Tab controls

The tab control component (*TTabControl*) creates a set of tabs that look like notebook dividers. You can create tabs by editing the *Tabs* property in the Object Inspector; each string in *Tabs* represents a tab. The tab control is a single panel with one set of components on it. To change the appearance of the control when the tabs are clicked, you need to write an *OnChange* event handler. To create a multipage dialog box, use a page control instead.

Page controls

The page control component (*TPageControl*) is a page set suitable for multipage dialog boxes. A page control displays multiple overlapping pages that are *TTabSheet* objects. A page is selected in the user interface by clicking a tab on top of the control.

To create a new page in a page control at design time, right-click the control and choose New Page. At runtime, you add new pages by creating the object for the page and setting its *PageControl* property:

```
NewTabSheet = TTabSheet.Create(PageControl1);
NewTabSheet.PageControl := PageControl1;
```

To access the active page, use the *ActivePage* property. To change the active page, you can set either the *ActivePage* or the *ActivePageIndex* property.

Header controls

A header control (*THeaderControl*) is a is a set of column headers that the user can select or resize at runtime. Edit the control's *Sections* property to add or modify headers. You can place the header sections above columns or fields. For example, header sections might be placed over a list box (*TListBox*).

Providing visual feedback

There are many ways to provide users with information about the state of an application. For example, some components—including *TForm*—have a *Caption* property that can be set at runtime. You can also create dialog boxes to display messages. In addition, the following components are especially useful for providing visual feedback at runtime.

Use this component or property:	To do this:
TLabel and *TStaticText*	Display non-editable text
TStatusBar	Display a status region (usually at the bottom of a window)
TProgressBar	Show the amount of work completed for a particular task
Hint and *ShowHint*	Activate fly-by or "tooltip" help
HelpContext and *HelpFile*	Link context-sensitive online Help

Labels and static text components

Labels (*TLabel*) display text and are usually placed next to other controls. You place a label on a form when you need to identify or annotate another component such as an edit box or when you want to include text on a form. The standard label component, *TLabel*, is a non-windowed control (not widget-based in CLX), so it cannot receive focus; when you need a label with a window handle, use *TStaticText* instead.

Label properties include the following:

- *Caption* contains the text string for the label.
- *Font*, *Color*, and other properties determine the appearance of the label. Each label can use only one typeface, size, and color.
- *FocusControl* links the label to another control on the form. If *Caption* includes an accelerator key, the control specified by *FocusControl* receives focus when the user presses the accelerator key.

- *ShowAccelChar* determines whether the label can display an underlined accelerator character. If *ShowAccelChar* is *True*, any character preceded by an ampersand (&) appears underlined and enables an accelerator key.
- *Transparent* determines whether items under the label (such as graphics) are visible.

Labels usually display read-only static text that cannot be changed by the application user. The application can change the text while it is executing by assigning a new value to the *Caption* property. To add a text object to a form that a user can scroll or edit, use *TEdit*.

Status bars

Although you can use a panel to make a status bar, it is simpler to use the status bar component. By default, the status bar's *Align* property is set to *alBottom*, which takes care of both position and size.

If you only want to display one text string at a time in the status bar, set its *SimplePanel* property to *True* and use the *SimpleText* property to control the text displayed in the status bar.

You can also divide a status bar into several text areas, called panels. To create panels, edit the *Panels* property in the Object Inspector, setting each panel's *Width*, *Alignment*, and *Text* properties from the Panels editor. Each panel's *Text* property contains the text displayed in the panel.

Progress bars

When your application performs a time-consuming operation, you can use a progress bar to show how much of the task is completed. A progress bar displays a dotted line that grows from left to right.

Figure 3.5 A progress bar

The *Position* property tracks the length of the dotted line. *Max* and *Min* determine the range of *Position*. To make the line grow, increment *Position* by calling the *StepBy* or *StepIt* method. The *Step* property determines the increment used by *StepIt*.

Help and hint properties

Most visual controls can display context-sensitive Help as well as fly-by hints at runtime. The *HelpContext* and *HelpFile* properties establish a Help context number and Help file for the control.

The *Hint* property contains the text string that appears when the user moves the mouse pointer over a control or menu item. To enable hints, set *ShowHint* to *True*; setting *ParentShowHint* to *True* causes the control's *ShowHint* property to have the same value as its parent's.

Grids

Grids display information in rows and columns. If you're writing a database application, use the *TDBGrid* or *TDBCtrlGrid* component described in Chapter 15, "Using data controls." Otherwise, use a standard draw grid or string grid.

Draw grids

A draw grid (*TDrawGrid*) displays arbitrary data in tabular format. Write an *OnDrawCell* event handler to fill in the cells of the grid.

- The *CellRect* method returns the screen coordinates of a specified cell, while the *MouseToCell* method returns the column and row of the cell at specified screen coordinates. The *Selection* property indicates the boundaries of the currently selected cells.
- The *TopRow* property determines which row is currently at the top of the grid. The *LeftCol* property determines the first visible column on the left. *VisibleColCount* and *VisibleRowCount* are the number of columns and rows visible in the grid.
- You can change the width or height of a column or row with the *ColWidths* and *RowHeights* properties. Set the width of the grid lines with the *GridLineWidth* property. Add scroll bars to the grid with the *ScrollBars* property.
- You can choose to have fixed or non-scrolling columns and rows with the *FixedCols* and *FixedRows* properties. Assign a color to the fixed columns and rows with the *FixedColor* property.
- The *Options*, *DefaultColWidth*, and *DefaultRowHeight* properties also affect the appearance and behavior of the grid.

String grids

The string grid component is a descendant of *TDrawGrid* that adds specialized functionality to simplify the display of strings. The *Cells* property lists the strings for each cell in the grid; the *Objects* property lists objects associated with each string. All the strings and associated objects for a particular column or row can be accessed through the *Cols* or *Rows* property.

Value list editors (VCL only)

TValueListEditor is a specialized grid for editing string lists that contain name/value pairs in the form Name=Value. The names and values are stored as a *TStrings* descendant that is the value of the *Strings* property. You can look up the value for any name using the *Values* property. *TValueListEditor* is not available for cross-platform programming.

The grid contains two columns, one for the names and one for the values. By default, the Name column is named "Key" and the Value column is named "Value". You can change these defaults by setting the *TitleCaptions* property. You can omit these titles using the *DisplayOptions* property (which also controls resize when you resize the control.)

You can control whether users can edit the Name column using the *KeyOptions* property. *KeyOptions* contains separate options to allow editing, adding new names, deleting names, and controlling whether new names must be unique.

You can control how users edit the entries in the Value column using the *ItemProps* property. Each item has a separate *TItemProp* object that lets you

- Supply an edit mask to limit the valid input.
- Specify a maximum length for values.
- Mark the value as read-only.
- Specify that the value list editor displays a drop-down arrow that opens a pick list of values from which the user can choose or an ellipsis button that triggers an event you can use for displaying a dialog in which users enter values.

  If you specify that there is a drop-down arrow, you must supply the list of values from which the user chooses. These can be a static list (the *PickList* property of the *TItemProp* object) or they can be dynamically added at runtime using the value list editor's *OnGetPickList* event. You can also combine these approaches and have a static list that the *OnGetPickList* event handler modifies.

  If you specify that there is an ellipsis button, you must supply the response that occurs when the user clicks that button (including the setting of a value, if appropriate). You provide this response by writing an *OnEditButtonClick* event handler.

Displaying graphics

The following components make it easy to incorporate graphics into an application.

Use this component:	To display:
TImage	Graphics files
TShape	Geometric shapes
TBevel	3-D lines and frames
TPaintBox	Graphics drawn by your program at runtime
TAnimate	AVI files (VCL only)

Images

The image component displays a graphical image, like a bitmap, icon, or metafile. The *Picture* property determines the graphic to be displayed. Use *Center*, *AutoSize*, *Stretch*, and *Transparent* to set display options. For more information, see "Overview of graphics programming" on page 8-1.

Shapes

The shape component displays a geometric shape. It is a nonwindowed control (not widget-based in CLX) and therefore, cannot receive user input. The *Shape* property determines which shape the control assumes. To change the shape's color or add a pattern, use the *Brush* property, which holds a *TBrush* object. How the shape is painted depends on the *Color* and *Style* properties of *TBrush*.

Bevels

The bevel component (*TBevel*) is a line that can appear raised or lowered. Some components, such as *TPanel*, have built-in properties to create beveled borders. When such properties are unavailable, use *TBevel* to create beveled outlines, boxes, or frames.

Paint boxes

The paint box (*TPaintBox*) allows your application to draw on a form. Write an *OnPaint* event handler to render an image directly on the paint box's *Canvas*. Drawing outside the boundaries of the paint box is prevented. For more information, see"Overview of graphics programming" on page 8-1.

Animation control (VCL only)

The animation component is a window that silently displays an Audio Video Interleaved (AVI) clip. An AVI clip is a series of bitmap frames, like a movie. Although AVI clips can have sound, animation controls work only with silent AVI clips. The files you use must be either uncompressed AVI files or AVI clips compressed using run-length encoding (RLE). Animation control cannot be used in cross-platform programming.

Following are some of the properties of an animation component:

- *ResHandle* is the Windows handle for the module that contains the AVI clip as a resource. Set *ResHandle* at runtime to the instance handle or module handle of the module that includes the animation resource. After setting *ResHandle*, set the *ResID* or *ResName* property to specify which resource in the indicated module is the AVI clip that should be displayed by the animation control.
- Set *AutoSize* to *True* to have the animation control adjust its size to the size of the frames in the AVI clip.
- *StartFrame* and *StopFrame* specify in which frames to start and stop the clip.
- Set *CommonAVI* to display one of the common Windows AVI clips provided in Shell32.DLL.
- Specify when to start and interrupt the animation by setting the *Active* property to *True* and *False*, respectively, and how many repetitions to play by setting the *Repetitions* property.
- The *Timers* property lets you display the frames using a timer. This is useful for synchronizing the animation sequence with other actions, such as playing a sound track.

Developing dialog boxes

The dialog box components on the Dialogs page of the Component palette make various dialog boxes available to your applications. These dialog boxes provide applications with a familiar, consistent interface that enables the user to perform common file operations such as opening, saving, and printing files. Dialog boxes display and/or obtain data.

Each dialog box opens when its *Execute* method is called. *Execute* returns a Boolean value: if the user chooses OK to accept any changes made in the dialog box, *Execute* returns *True*; if the user chooses Cancel to escape from the dialog box without making or saving changes, *Execute* returns *False*.

If you are developing cross-platform applications, you can use the dialogs provided with CLX in the QDialogs unit. For operating systems that have native dialog box types for common tasks, such as for opening or saving a file or for changing font or color, you can use the *UseNativeDialog* property. Set *UseNativeDialog* to *True* if your application will run in such an environment, and if you want it to use the native dialogs instead of the Qt dialogs.

Using open dialog boxes

One of the commonly used dialog box components is *TOpenDialog*. This component is usually invoked by a New or Open menu item under the File option on the main menu bar of a form. The dialog box contains controls that let you select groups of files using a wildcard character and navigate through directories.

The *TOpenDialog* component makes an Open dialog box available to your application. The purpose of this dialog box is to let a user specify a file to open. You use the *Execute* method to display the dialog box.

When the user chooses OK in the dialog box, the user's file is stored in the *TOpenDialog FileName* property, which you can then process as you want.

The following code snippet can be placed in an *Action* and linked to the *Action* property of a *TMainMenu* subitem or be placed in the subitem's *OnClick* event:

```
if OpenDialog1.Execute then
  filename := OpenDialog1.FileName;
```

This code will show the dialog box and if the user presses the OK button, it will copy the name of the file into a previously declared *AnsiString* variable named `filename`.

Using helper objects

The VCL and CLX include a variety of nonvisual objects that simplify common programming tasks. This section describes a few Helper objects that make it easier to perform the following tasks:

- Working with lists
- Working with string lists
- Changing the Windows registry and .INI files
- Using streams

Working with lists

The following objects provide functionality for creating and managing lists:

Table 3.5 Components for creating and managing lists

Object	Maintains
TList	A list of pointers
TObjectList	A memory-managed list of instance objects
TComponentList	A memory-managed list of components (that is, instances of classes descended from *TComponent*)
TQueue	A first-in first-out list of pointers
TStack	A last-in first-out list of pointers
TObjectQueue	A first-in first-out list of objects
TObjectStack	A last-in first-out list of objects
TClassList	A list of class types
TCollection, *TOwnedCollection*, and *TCollectionItem*	Indexed collections of specially defined items
TStringList	A list of strings

For more information about these objects, see the online reference.

Working with string lists

Applications often need to manage lists of character strings. Examples include items in a combo box, lines in a memo, names of fonts, and names of rows and columns in a string grid. The VCL and CLX provide a common interface to any list of strings through an object called *TStrings* and its descendant *TStringList*. *TStringList* implements the abstract properties and methods introduced by *TStrings*, and introduces properties, events, and methods to

- Sort the strings in the list.
- Prohibit duplicate strings in sorted lists.
- Respond to changes in the contents of the list.

In addition to providing functionality for maintaining string lists, these objects allow easy interoperability; for example, you can edit the lines of a memo (which are an instance of *TStrings*) and then use these lines as items in a combo box (also an instance of *TStrings*).

A string-list property appears in the Object Inspector with *TStrings* in the Value column. Double-click *TStrings* to open the String List editor, where you can edit, add, or delete lines.

You can also work with string-list objects at runtime to perform such tasks as

- Loading and saving string lists
- Creating a new string list
- Manipulating strings in a list
- Associating objects with a string list

Loading and saving string lists

String-list objects provide *SaveToFile* and *LoadFromFile* methods that let you store a string list in a text file and load a text file into a string list. Each line in the text file corresponds to a string in the list. Using these methods, you could, for example, create a simple text editor by loading a file into a memo component, or save lists of items for combo boxes.

The following example loads a copy of the WIN.INI file into a memo field and makes a backup copy called WIN.BAK.

```
procedure EditWinIni;
var
  FileName: string;{ storage for file name }
begin
  FileName := 'C:\WINDOWS\WIN.INI';{ set the file name }
  with Form1.Memo1.Lines do
  begin
    LoadFromFile(FileName);{ load from file }
    SaveToFile(ChangeFileExt(FileName, '.BAK'));{ save into backup file }
  end;
end;
```

Creating a new string list

A string list is typically part of a component. There are times, however, when it is convenient to create independent string lists, for example to store strings for a lookup table. The way you create and manage a string list depends on whether the list is short-term (constructed, used, and destroyed in a single routine) or long-term (available until the application shuts down). Whichever type of string list you create, remember that you are responsible for freeing the list when you finish with it.

Short-term string lists

If you use a string list only for the duration of a single routine, you can create it, use it, and destroy it all in one place. This is the safest way to work with string lists. Because the string-list object allocates memory for itself and its strings, you should use a **try...finally** block to ensure that the memory is freed even if an exception occurs.

1. Construct the string-list object.
2. In the **try** part of a **try...finally** block, use the string list.
3. In the **finally** part, free the string-list object.

The following event handler responds to a button click by constructing a string list, using it, and then destroying it.

```
procedure TForm1.Button1Click(Sender: TObject);
var
  TempList: TStrings;{ declare the list }
begin
  TempList := TStringList.Create;{ construct the list object }
  try
    { use the string list }
  finally
    TempList.Free;{ destroy the list object }
  end;
end;
```

Long-term string lists

If a string list must be available at any time while your application runs, construct the list at start-up and destroy it before the application terminates.

1 In the unit file for your application's main form, add a field of type *TStrings* to the form's declaration.

2 Write an event handler for the main form's *constructor*, which executes before the form appears. It should create a string list and assign it to the field you declared in the first step.

3 Write an event handler that frees the string list for the form's *OnClose* event.

This example uses a long-term string list to record the user's mouse clicks on the main form, then saves the list to a file before the application terminates.

```
unit Unit1;
interface
uses Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs;
{For CLX: uses SysUtils, Classes, QGraphics, QControls, QForms, Qialogs;}

type
  TForm1 = class(TForm)
    procedure FormCreate(Sender: TObject);
    procedure FormDestroy(Sender: TObject);
    procedure FormMouseDown(Sender: TObject; Button: TMouseButton;
      Shift: TShiftState; X, Y: Integer);
  private
    { Private declarations }
  public
    { Public declarations }
    ClickList: TStrings;{ declare the field }
  end;

var
  Form1: TForm1;

implementation

{$R *.DFM}

procedure TForm1.FormCreate(Sender: TObject);
begin
  ClickList := TStringList.Create;{ construct the list }
end;

procedure TForm1.FormDestroy(Sender: TObject);
begin
  ClickList.SaveToFile(ChangeFileExt(Application.ExeName, '.LOG'));{ save the list }
  ClickList.Free;{ destroy the list object }
end;

procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  ClickList.Add(Format('Click at (%d, %d)', [X, Y]));{ add a string to the list }
end;

end.
```

Manipulating strings in a list

Operations commonly performed on string lists include:

- Counting the strings in a list
- Accessing a particular string
- Finding the position of a string in the list
- Iterating through strings in a list
- Adding a string to a list
- Moving a string within a list
- Deleting a string from a list
- Copying a complete string list

Counting the strings in a list

The read-only *Count* property returns the number of strings in the list. Since string lists use zero-based indexes, *Count* is one more than the index of the last string.

Accessing a particular string

The *Strings* array property contains the strings in the list, referenced by a zero-based index. Because *Strings* is the default property for string lists, you can omit the *Strings* identifier when accessing the list; thus

```
StringList1.Strings[0] := 'This is the first string.';
```

is equivalent to

```
StringList1[0] := 'This is the first string.';
```

Locating items in a string list

To locate a string in a string list, use the *IndexOf* method. *IndexOf* returns the index of the first string in the list that matches the parameter passed to it, and returns –1 if the parameter string is not found. *IndexOf* finds exact matches only; if you want to match partial strings, you must iterate through the string list yourself.

For example, you could use *IndexOf* to determine whether a given file name is found among the *Items* of a list box:

```
if FileListBox1.Items.IndexOf('WIN.INI') > -1 ...
```

Iterating through strings in a list

To iterate through the strings in a list, use a **for** loop that runs from zero to *Count* – 1.

This example converts each string in a list box to uppercase characters.

```
procedure TForm1.Button1Click(Sender: TObject);
var
  Index: Integer;
begin
  for Index := 0 to ListBox1.Items.Count - 1 do
    ListBox1.Items[Index] := UpperCase(ListBox1.Items[Index]);
end;
```

Adding a string to a list

To add a string to the end of a string list, call the *Add* method, passing the new string as the parameter. To insert a string into the list, call the *Insert* method, passing two parameters: the string and the index of the position where you want it placed. For example, to make the string “Three” the third string in a list, you would use:

```
Insert(2, 'Three');
```

To append the strings from one list onto another, call *AddStrings*:

```
StringList1.AddStrings(StringList2);  { append the strings from StringList2 to StringList1 }
```

Moving a string within a list

To move a string in a string list, call the *Move* method, passing two parameters: the current index of the string and the index you want assigned to it. For example, to move the third string in a list to the fifth position, you would use:

```
Move(2, 4)
```

Deleting a string from a list

To delete a string from a string list, call the list’s *Delete* method, passing the index of the string you want to delete. If you don’t know the index of the string you want to delete, use the *IndexOf* method to locate it. To delete all the strings in a string list, use the *Clear* method.

This example uses *IndexOf* and *Delete* to find and delete a string:

```
with ListBox1.Items do
begin
  BIndex := IndexOf('bureaucracy');
  if BIndex > -1 then
    Delete(BIndex);
end;
```

Copying a complete string list

You can use the *Assign* method to copy strings from a source list to a destination list, overwriting the contents of the destination list. To append strings without overwriting the destination list, use *AddStrings*. For example,

```
Memo1.Lines.Assign(ComboBox1.Items);    { overwrites original strings }
```

copies the lines from a combo box into a memo (overwriting the memo), while

```
Memo1.Lines.AddStrings(ComboBox1.Items);   { appends strings to end }
```

appends the lines from the combo box to the memo.

When making local copies of a string list, use the *Assign* method. If you assign one string-list variable to another—

```
StringList1 := StringList2;
```

—the original string-list object will be lost, often with unpredictable results.

Associating objects with a string list

In addition to the strings stored in its *Strings* property, a string list can maintain references to objects, which it stores in its *Objects* property. Like *Strings*, *Objects* is an array with a zero-based index. The most common use for *Objects* is to associate bitmaps with strings for owner-draw controls.

Use the *AddObject* or *InsertObject* method to add a string and an associated object to the list in a single step. *IndexOfObject* returns the index of the first string in the list associated with a specified object. Methods like *Delete*, *Clear*, and *Move* operate on both strings and objects; for example, deleting a string removes the corresponding object (if there is one).

To associate an object with an existing string, assign the object to the *Objects* property at the same index. You cannot add an object without adding a corresponding string.

Windows registry and INI files

The Windows system registry is a hierarchical database where applications store configuration information. The VCL class *TRegistry* supplies methods that read and write to the registry.

Until Windows 95, most applications stored configuration information in initialization files, usually named with the extension .INI. The VCL provides the following classes to facilitate maintenance and migration of programs that use INI files:

- *TRegistry* to work with the registry (VCL only).
- *TIniFile* (VCL only) or *TMemIniFile* to work with INI files.
- *TRegistryIniFile* when you want to work with both the registry and INI files (VCL only). *TRegistryIniFile* has properties and methods similar to those of *TIniFile*, but it reads and writes to the system registry. By using a variable of type *TCustomIniFile* (the common ancestor of *TIniFile*, *TMemIniFile*, and *TRegistryIniFile*), you can write generic code that accesses either the registry or an INI file, depending on where it is called.

Only *TMemIniFile* can be used in cross-platform programming.

Using TIniFile (VCL only)

The INI file format is still popular, many of the Delphi configuration files (such as the DSK Desktop settings file) are in this format. Because this file format was and is prevalent, VCL provides a class to make reading and writing these files very easy. *TIniFile* is not available for cross-platform programming.

When you instantiate the *TIniFile* object, you pass as a parameter to the constructor the name of the INI file. If the file does not exist, it is automatically created. You are then free to read values using *ReadString*, *ReadInteger*, or *ReadBool*. Alternatively, if you want to read an entire section of the INI file, you can use the *ReadSection* method. Similarly, you can write values using *WriteBool*, *WriteInteger*, or *WriteString*.

Each of the Read routines takes three parameters. The first parameter identifies the section of the INI file. The second parameter identifies the value you want to read, and the third is a default value in case the section or value doesn't exist in the INI file. Similarly, the Write routines will create the section and/or value if they do not exist. The example code creates an INI file the first time it is run that looks like this:

```
[Form]
Top=185
Left=280
Caption=Default Caption
InitMax=0
```

On subsequent execution of this application, the INI values are read in during creation of the form and written back out in the *OnClose* event.

Using TRegistry

Most 32-bit applications store their information in the registry instead of INI files because the registry is hierarchical, more robust, and doesn't suffer from the size limitations of INI files. The *TRegistry* object contains methods to open, close, save, move, copy, and delete keys.

TRegistry is not available for cross-platform programming.

For more information, see the *TRegistry* topic in the online help.

Using TRegIniFile

If you are accustomed to using INI files and want to move your configuration information to the registry instead, you can use the *TRegIniFile* class. *TRegIniFile* is designed to make registry entries look like INI file entries. All the methods from *TIniFile* (read and write) exist in *TRegIniFile*.

When you construct a *TRegIniFile* object, the parameter you pass (the filename for an *IniFile* object) becomes a key value under the user key in the registry, and all sections and values branch from that root. In fact, this object simplifies the registry interface considerably, so you may want to use it instead of the *TRegistry* component even if you aren't porting existing code.

TRegIniFile is not available for cross-platform programming.

For more information, see the *TRegIniFile* topic in the VCL online reference.

Creating drawing spaces

The *TCanvas* encapsulates a Windows device context in the VCL and a paint device (Qt painter) in CLX. which handles all drawing for both forms, visual containers (such as panels) and the printer object (covered in"Printing" on page 3-54 ").

Using the canvas object, you no longer have to worry about allocating pens, brushes, palettes, and so on—all the allocation and deallocation are handled for you.

TCanvas includes a large number of primitive graphics routines to draw lines, shapes, polygons, fonts, etc. onto any control that contains a canvas. For example, here is a button event handler that draws a line from the upper left corner to the middle of the form and outputs some raw text onto the form:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Canvas.Pen.Color := clBlue;
  Canvas.MoveTo( 10, 10 );
  Canvas.LineTo( 100, 100 );
  Canvas.Brush.Color := clBtnFace;
  Canvas.Font.Name := 'Arial';
  Canvas.TextOut( Canvas.PenPos.x, Canvas.PenPos.y,'This is the end of the line' );
end;
```

In Windows applications, the *TCanvas* object also protects you against common Windows graphics errors, such as restoring device contexts, pens, brushes, and so on to the value they had before the drawing operation. *TCanvas* is used everywhere in Delphi that drawing is required or possible, and makes drawing graphics both fail-safe and easy.

See *TCanvas* in the online help reference for a complete listing of properties and methods.

Printing

The VCL *TPrinter* object encapsulates details of Windows printers. To get a list of installed and available printers, use the *Printers* property. The CLX *TPrinter* object is a paint device that paints on a printer. It generates postscript and sends that to lpr, lp, or another print command.

Both printer objects use a *TCanvas* (which is identical to the form's *TCanvas*) which means that anything that can be drawn on a form can be printed as well. To print an image, call the *BeginDoc* method followed by whatever canvas graphics you want to print (including text through the *TextOut* method) and send the job to the printer by calling the *EndDoc* method.

This example uses a button and a memo on a form. When the user clicks the button, the content of the memo is printed with a 200-pixel border around the page.

To run this example successfully, add Printers to your **uses** clause.

```
procedure TForm1.Button1Click(Sender: TObject);
var
  r: TRect;
  i: Integer;
begin
  with Printer do
    begin
      r := Rect(200,200,(Pagewidth - 200),(PageHeight - 200));
      BeginDoc;
      for i := 0 to Memo1.Lines.Count do
       Canvas.TextOut(200,200 + (i *
Canvas.TextHeight(Memo1.Lines.Strings[i])),
                                   Memo1.Lines.Strings[i]);
      Canvas.Brush.Color := clBlack;
      Canvas.FrameRect(r);
      EndDoc;
    end;
end;
```

For more information on the use of the *TPrinter* object, look in the online help under *TPrinter*.

Using streams

Streams are just ways of reading and writing data. Steams provide a common interface for reading and writing to different media such as memory, strings, sockets, and blob streams.

In the following streaming example, one file is copied to another one using streams. The application includes two edit controls (From and To) and a Copy File button.

```
procedure TForm1.CopyFileClick(Sender: TObject);
var
  stream1, stream2:TStream;
begin
  stream1:=TFileStream.Create(From.Text,fmOpenRead or fmShareDenyWrite);
  try
    stream2 := TFileStream.Create(To.Text fmOpenCreate or fmShareDenyRead);
    try
      stream2.CopyFrom(Stream1,Stream1.Size);
    finally
      stream2.Free;
  finally
    stream1.Free
end;
```

Use specialized stream objects to read or write to storage media. Each descendant of *TStream* implements methods for accessing a particular medium, such as disk files, dynamic memory, and so on. *TStream* descendants include *TFileStream*, *TStringStream*, and *TMemoryStream*. In addition to methods for reading and writing, these objects permit applications to seek to an arbitrary position in the stream. Properties of *TStream* provide information about the stream, such as size and current position.

Chapter

4

Common programming tasks

This chapter discusses how to perform some of the common programming tasks in Delphi:

- Understanding classes
- Defining classes
- Handling exceptions
- Using interfaces
- Defining custom variants
- Working with strings
- Working with files
- Converting measurements

Understanding classes

A *class* is an abstract definition of properties, methods, events, and class members (such as variables local to the class). When you create an instance of a class, this instance is called an object. The term object is often used more loosely in the Delphi documentation and where the distinction between a class and an instance of the class is not important, the term "object" may also refer to a class.

Although Delphi includes many classes in its object hierarchy, you are likely to need to create additional classes if you are writing object-oriented programs. The classes you write must descend from *TObject* or one of its descendants. A class type declaration contains three possible sections that control the accessibility of its fields and methods:

```
Type
  TClassName = Class(TObject)
    public
      {public fields}
      {public methods}
    protected
      {protected fields}
      {protected methods}
    private
      {private fields}
      {private methods}
end;
```

- The public section declares fields and methods with no access restrictions; class instances and descendant classes can access these fields and methods.
- The protected section includes fields and methods with some access restrictions; descendant classes can access these fields and methods.
- The private section declares fields and methods that have rigorous access restrictions; they cannot be accessed by class instances or descendant classes.

The advantage of using classes comes from being able to create new classes as descendants of existing ones. Each descendant class inherits the fields and methods of its parent and ancestor classes. You can also declare methods in the new class that override inherited ones, introducing new, more specialized behavior.

The general syntax of a descendant class is as follows:

```
Type
  TClassName = Class (TParentClass)
    public
      {public fields}
      {public methods}
    protected
      {protected fields}
      {protected methods}
    private
      {private fields}
      {private methods}
end;
```

If no parent class name is specified, the class inherits directly from *TObject*. *TObject* defines only a handful of methods, including a basic constructor and destructor.

For more information about the syntax, language definitions, and rules for classes, see the *Object Pascal Language Guide* online Help on Class types.

Defining classes

Delphi allows you to declare classes that implement the programming features you need to use in your application. Some versions of Delphi include a feature called class completion that simplifies the work of defining and implementing new classes by generating skeleton code for the class members you declare.

To define a class,

1 In the IDE, start with a project open and choose File | New | Unit to create a new unit where you can define the new class.

2 Add the **uses** clause and **type** section to the **interface** section.

3 In the **type** section, write the class declaration. You need to declare all the member variables, properties, methods, and events.

```
TMyClass = class; {This implicitly descends from TObject}
public
  .
  .
  .
  .
  .
  .
private
  .
  .
  .
published {If descended from TPersistent or below}
  .
  .
  .
```

Note The object that holds the custom variant's data must be compiled with RTTI. This means it must be compiled using the {$M+} compiler directive, or descend from *TPersistent* or below.

If you want the class to descend from a specific class, you need to indicate that class in the definition:

```
TMyClass = class(TParentClass); {This descends from TParentClass}
```

For example:

```
type TMyButton = class(TButton)
  property Size: Integer;
  procedure DoSomething;
end;
```

If your version of Delphi includes class completion: place the cursor within a method definition in the **interface** section and press Ctrl+Shift+C (or right-click and select Complete Class at Cursor). Delphi completes any unfinished property declarations and creates the empty methods you need in the **implementation** section. (If you do not have class completion, you'll need to write the code yourself, completing property declarations and writing the methods.)

Given the example above, if you have class completion, Delphi adds **read** and **write** specifiers to your interface declaration, including any supporting fields or methods:

```
type TMyButton = class(TButton)
  property Size: Integer read FSize write SetSize;
  procedure DoSomething;
private
  FSize: Integer;
  procedure SetSize(const Value: Integer);
```

It also adds the following code to the **implementation** section of the unit.

```
{ TMyButton }
procedure TMyButton.DoSomething;
begin
```

```
end;
procedure TMyButton.SetSize(const Value: Integer);
begin
   FSize := Value;
end;
```

4 Fill in the methods. For example, to make it so the button beeps when you call the DoSomething method, add the Beep between **begin** and **end**.

```
{ TMyButton }
procedure TMyButton.DoSomething;
begin
  Beep;
end;

procedure TMyButton.SetSize(const Value: Integer);
begin
  if fsize < > value then
  begin
    FSize := Value;
    DoSomething;
  end;
end;
```

Note that the button also beeps when you call SetSize to change the size of the button.

For more information about the syntax, language definitions, and rules for classes and methods, see the *Object Pascal Language Guide* online Help on Class types and methods.

Handling exceptions

Delphi provides a mechanism to handle errors in a consistent manner. Exception handling allows the application to recover from errors if possible and to shut down if need be, without losing data or resources. Error conditions in Delphi are indicated by exceptions. This section describes the following tasks for using exceptions to create safe applications:

- Protecting blocks of code
- Protecting resource allocations
- Handling RTL exceptions
- Handling component exceptions
- Exception handling with external sources
- Silent exceptions
- Defining your own exceptions

Protecting blocks of code

To make your applications robust, your code needs to recognize exceptions when they occur and respond to them. If you don't specify a response, the application will present a message box describing the error. Your job, then, is to recognize places where errors might happen, and define responses, particularly in areas where errors could cause the loss of data or system resources.

When you create a response to an exception, you do so on blocks of code. When you have a series of statements that all require the same kind of response to errors, you can group them into a block and define error responses that apply to the whole block.

Blocks with specific responses to exceptions are called protected blocks because they can guard against errors that might otherwise either terminate the application or damage data.

To protect blocks of code you need to understand

- Responding to exceptions
- Exceptions and the flow of control
- Nesting exception responses

Responding to exceptions

When an error condition occurs, the application raises an exception, meaning it creates an exception object. Once an exception is raised, your application can execute cleanup code, handle the exception, or both.

Executing cleanup code

The simplest way to respond to an exception is to guarantee that some cleanup code is executed. This kind of response doesn't correct the condition that caused the error but lets you ensure that your application doesn't leave its environment in an unstable state. You typically use this kind of response to ensure that the application frees allocated resources, regardless of whether errors occur.

Handling an exception

This is a specific response to a specific kind of exception. Handling an exception clears the error condition and destroys the exception object, which allows the application to continue execution. You typically define exception handlers to allow your applications to recover from errors and continue running. Types of exceptions you might handle include attempts to open files that don't exist, writing to full disks, or calculations that exceed legal bounds. Some of these, such as “File not found,” are easy to correct and retry, while others, such as running out of memory, might be more difficult for the application or the user to correct.

To handle exceptions effectively, you need to understand the following:

- Creating an exception handler
- Exception handling statements
- Using the exception instance
- Scope of exception handlers
- Providing default exception handlers
- Handling classes of exceptions
- Reraising the exception

Exceptions and the flow of control

Object Pascal makes it easy to incorporate error handling into your applications because exceptions don't get in the way of the normal flow of your code. In fact, by moving error checking and error handling out of the main flow of your algorithms, exceptions can simplify the code you write.

When you declare a protected block, you define specific responses to exceptions that might occur within that block. When an exception occurs in that block, execution immediately jumps to the response you defined, then leaves the block.

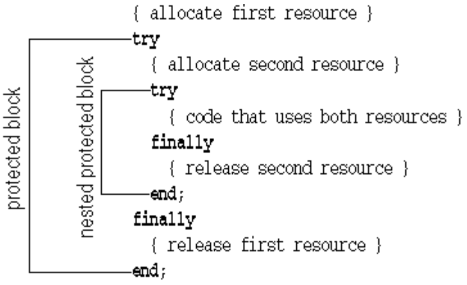
Example The following code that includes a protected block. If any exception occurs in the protected block, execution jumps to the exception-handling part, which beeps. Execution resumes outside the block.

```
try
  AssignFile(F, FileName);
  Reset(F);
  ⋮
except
  on Exception do Beep;
end;
  ⋮ { execution resumes here, outside the protected block }
```

Nesting exception responses

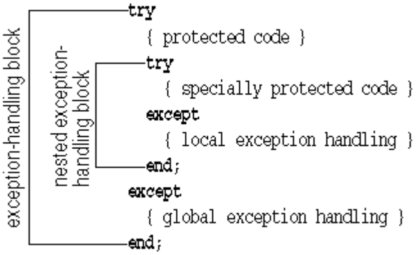
Your code defines responses to exceptions that occur within blocks. Because Pascal allows you to nest blocks of code inside other blocks, you can customize responses even within blocks that already contain customized responses.

In the simplest case, for example, you can protect a resource allocation, and within that protected block, define blocks that allocate and protect other resources. Conceptually, that might look something like this:



```
{ allocate first resource }
try
  { allocate second resource }
  try
    { code that uses both resources }
  finally
    { release second resource }
  end;
finally
  { release first resource }
end;
```

You can also use nested blocks to define local handling for specific exceptions that overrides the handling in the surrounding block. Conceptually, that looks something like this:



```
try
  { protected code }
  try
    { specially protected code }
  except
    { local exception handling }
  end;
except
  { global exception handling }
end;
```

You can also mix different kinds of exception-response blocks, nesting resource protections within exception handling blocks and vice versa.

Protecting resource allocations

One key to having a robust application is ensuring that if it allocates resources, it also releases them, even if an exception occurs. For example, if your application allocates memory, you need to make sure it eventually releases the memory, too. If it opens a file, you need to make sure it closes the file later.

Keep in mind that exceptions don't come just from your code. A call to an RTL routine, for example, or another component in your application might raise an exception. Your code needs to ensure that if these conditions occur, you release allocated resources.

To protect resources effectively, you need to understand the following:

- What kind of resources need protection?
- Creating a resource protection block

What kind of resources need protection?

Under normal circumstances, you can ensure that an application frees allocated resources by including code for both allocating and freeing. When exceptions occur, however, you need to ensure that the application still executes the resource-freeing code.

Some common resources that you should always be sure to release are:

- Files
- Memory
- Windows resources (VCL only)
- Objects

Example The following event handler allocates memory, then generates an error, so it never executes the code to free the memory:

```
procedure TForm1.Button1Click(Sender: TComponent);
var
  APointer: Pointer;
  AnInteger, ADividend: Integer;
begin
  ADividend := 0;
  GetMem(APointer, 1024);{ allocate 1K of memory }
  AnInteger := 10 div ADividend;{ this generates an error }
  FreeMem(APointer, 1024);{ it never gets here }
end;
```

Although most errors are not that obvious, the example illustrates an important point: When the division-by-zero error occurs, execution jumps out of the block, so the *FreeMem* statement never gets to free the memory.

To guarantee that the *FreeMem* gets to free the memory allocated by *GetMem*, you need to put the code in a resource-protection block.

Creating a resource protection block

To ensure that you free allocated resources, even in case of an exception, you embed the resource-using code in a protected block, with the resource-freeing code in a special part of the block. Here's an outline of a typical protected resource allocation:

```
{ allocate the resource }
try
  { statements that use the resource }
finally
  { free the resource }
end;
```

The key to the **try..finally** block is that the application always executes any statements in the **finally** part of the block, even if an exception occurs in the protected block. When any code in the **try** part of the block (or any routine called by code in the **try** part) raises an exception, execution halts at that point. Once an exception handler is found, execution jumps to the **finally** part, which is called the cleanup code. After the finally part is executed, the exception handler is called. If no exception occurs, the cleanup code is executed in the normal order, after all the statements in the **try** part.

Example The following code illustrates an event handler that allocates memory and generates an error, but still frees the allocated memory:

```
procedure TForm1.Button1Click(Sender: TComponent);
var
  APointer: Pointer;
  AnInteger, ADividend: Integer;

begin
  ADividend := 0;
  GetMem(APointer, 1024);{ allocate 1K of memory }
  try
    AnInteger := 10 div ADividend;{ this generates an error }
    finally
      FreeMem(APointer, 1024);{ execution resumes here, despite the error }
    end;
  end;
```

The statements in the **finally** block do not depend on an exception occurring. If no statement in the **try** part raises an exception, execution continues through the **finally** block.

Handling RTL exceptions

When you write code that calls routines in the runtime library (RTL), such as mathematical functions or file-handling procedures, the RTL reports errors back to your application in the form of exceptions. By default, RTL exceptions generate a message that the application displays to the user. You can define your own exception handlers to handle RTL exceptions in other ways.

There are also silent exceptions that do not, by default, display a message.

RTL exceptions are handled like any other exceptions. To handle RTL exceptions effectively, you need to understand the following:

- What are RTL exceptions?
- Creating an exception handler
- Exception handling statements
- Using the exception instance
- Scope of exception handlers
- Providing default exception handlers
- Handling classes of exceptions
- Reraising the exception

What are RTL exceptions?

The runtime library's exceptions are defined in the *SysUtils* unit, and they all descend from a generic exception-object type called Exception. Exception provides the string for the message that RTL exceptions display by default.

Several kinds of exceptions can be raised by the RTL, as described in the following table.

Table 4.1 RTL exceptions

Error type	Cause	Meaning
Input/output	Error accessing a file or I/O device	Most I/O exceptions are related to error codes returned when accessing a file.
Heap	Error using dynamic memory	Heap errors can occur when there is insufficient memory available, or when an application disposes of a pointer that points outside the heap.
Integer math	Illegal operation on integer-type expressions	Errors include division by zero, numbers or expressions out of range, and overflows.

Table 4.1 RTL exceptions (continued)

Error type	Cause	Meaning
Floating-point math	Illegal operation on real-type expressions	Floating-point errors can come from either a hardware coprocessor or the software emulator. Errors include invalid instructions, division by zero, and overflow or underflow.
Typecast	Invalid typecasting with the **as** operator	Objects can only be typecast to compatible types.
Conversion	Invalid type conversion	Type-conversion functions such as IntToStr, StrToInt, and StrToFloat raise conversion exceptions when the parameter cannot be converted to the desired type.
Hardware	System condition	Hardware exceptions indicate that either the processor or the user generated some kind of error condition or interruption, such as an access violation, stack overflow, or keyboard interrupt.
Variant	Illegal type coercion	Errors can occur when referring to variants in expressions where the variant cannot be coerced into a compatible type.

For a list of the RTL exception types, see the code in the *SysUtils* unit.

Creating an exception handler

An exception handler is code that handles a specific exception or exceptions that occur within a protected block of code. In cross-platform programming, it is very rare that you will need to write an exception handler. Most exceptions can be handled using **try..finally** blocks as described in "Protecting blocks of code" on page 4-4 and "Protecting resource allocations" on page 4-7.

To define an exception handler, embed the code you want to protect in an exception-handling block and specify the exception handling statements in the **except** part of the block. Here is an outline of a typical exception-handling block:

```
try
  { statements you want to protect }
except
  { exception-handling statements }
end;
```

The application executes the statements in the **except** part only if an exception occurs during execution of the statements in the **try** part. Execution of the **try** part statements includes routines called by code in the **try** part. That is, if code in the **try** part calls a routine that doesn't define its own exception handler, execution returns to the exception-handling block, which handles the exception.

When a statement in the **try** part raises an exception, execution immediately jumps to the **except** part, where it steps through the specified exception-handling statements, or exception handlers, until it finds a handler that applies to the current exception.

Once the application locates an exception handler that handles the exception, it executes the statement, then automatically destroys the exception object. Execution continues at the end of the current block.

Exception handling statements

Each **on** statement in the **except** part of a **try..except** block defines code for handling a particular kind of exception. The form of these exception-handling statements is as follows:

```
on <type of exception> do <statement>;
```

Example You can define an exception handler for division by zero to provide a default result:

```
function GetAverage(Sum, NumberOfItems: Integer): Integer;
begin
  try
    Result := Sum div NumberOfItems;{ handle the normal case }
  except
    on EDivByZero do Result := 0;{ handle the exception only if needed }
  end;
end;
```

Note that this is clearer than having to test for zero every time you call the function. Here's an equivalent function that doesn't take advantage of exceptions:

```
function GetAverage(Sum, NumberOfItems: Integer): Integer;
begin
  if NumberOfItems <> 0 then{ always test }
    Result := Sum div NumberOfItems{ use normal calculation }
  else Result := 0;{ handle exceptional case }
end;
```

The difference between these two functions really defines the difference between programming with exceptions and programming without them. This example is quite simple, but you can imagine a more complex calculation involving hundreds of steps, any one of which could fail if one of dozens of inputs were invalid.

By using exceptions, you can spell out the “normal” expression of your algorithm, then provide for those exceptional cases when it doesn't apply. Without exceptions, you have to test every single time to make sure you're allowed to proceed with each step in the calculation.

Using the exception instance

Most of the time, an exception handler doesn't need any information about an exception other than its type, so the statements following on..do are specific only to the type of exception. In some cases, however, you might need some of the information contained in the exception instance.

To read specific information about an exception instance in an exception handler, you use a special variation of on..do that gives you access to the exception instance. The special form requires that you provide a temporary variable to hold the instance.

Example If you create a new project that contains a single form, you can add a scroll bar and a command button to the form. Double-click the button and add the following line to its click-event handler:

```
ScrollBar1.Max := ScrollBar1.Min - 1;
```

That line raises an exception because the maximum value of a scroll bar must always exceed the minimum value. The default exception handler for the application opens a dialog box containing the message in the exception object. You can override the exception handling in this handler and create your own message box containing the exception's message string:

```
try
  ScrollBar1.Max := ScrollBar1.Min - 1;
except
  on E: EInvalidOperation do
    MessageDlg('Ignoring exception: ' + E.Message, mtInformation, [mbOK], 0);
end;
```

The temporary variable (E in this example) is of the type specified after the colon (*EInvalidOperation* in this example). You can use the as operator to typecast the exception into a more specific type if needed.

Note Never destroy the temporary exception object. Handling an exception automatically destroys the exception object. If you destroy the object yourself, the application attempts to destroy the object again, generating an access violation.

Scope of exception handlers

You do not need to provide handlers for every kind of exception in every block. In fact, you only need handlers for exceptions that you want to handle specially within a particular block.

If a block does not handle a particular exception, execution leaves that block and returns to the block that contains the block (or returns to the code that called the block), with the exception still raised. This process repeats with increasingly broad scope until either execution reaches the outermost scope of the application or a block at some level handles the exception.

Providing default exception handlers

You can provide a single default exception handler to handle any exceptions you haven't provided specific handlers for. To do that, you add an else part to the **except** part of the exception-handling block:

```
try
  { statements }
except
  on ESomething do
    { specific exception-handling code };
  else
    { default exception-handling code };
end;
```

Adding default exception handling to a block guarantees that the block handles every exception in some way, thereby overriding all handling from the containing block.

Caution It is not advisable to use this all-encompassing default exception handler. The **else** clause handles all exceptions, including those you know nothing about. In general, your code should handle only exceptions you actually know how to handle. If you want to handle cleanup and leave the exception handling to code that has more information about the exception and how to handle it, then you can do so use an enclosing **try..finally** block:

```
try
  try
  { statements }
  except
    on ESomething do { specific exception-handling code };
  end;
finally
  {cleanup code };
end;
```

For another approach to augmenting exception handling, see Reraising the exception.

Handling classes of exceptions

Because exception objects are part of a hierarchy, you can specify handlers for entire parts of the hierarchy by providing a handler for the exception class from which that part of the hierarchy descends.

Example The following block outlines an example that handles all integer math exceptions specially:

```
try
  { statements that perform integer math operations }
except
  on EIntError do { special handling for integer math errors };
end;
```

You can still specify specific handlers for more specific exceptions, but you need to place those handlers above the generic handler, because the application searches the handlers in the order they appear in, and executes the first applicable handler it finds. For example, this block provides special handling for range errors, and other handling for all other integer math errors:

```
try
  { statements performing integer math }
except
  on ERangeError do { out-of-range handling };
  on EIntError do { handling for other integer math errors };
end;
```

Note that if the handler for *EIntError* came before the handler for *ERangeError*, execution would never reach the specific handler for *ERangeError*.

Reraising the exception

Sometimes when you handle an exception locally, you actually want to augment the handling in the enclosing block, rather than replacing it. Of course, when your local handler finishes its handling, it destroys the exception instance, so the enclosing block's handler never gets to act. You can, however, prevent the handler from destroying the exception, giving the enclosing handler a chance to respond.

Example When an exception occurs, you might want to display a message to the user or record the error in a log file, then proceed with the standard handling. To do that, you declare a local exception handler that displays the message then calls the reserved word raise. This is called reraising the exception, as shown in this example:

```
try
  { statements }
  try
    { special statements }
  except
    on ESomething do
    begin
      { handling for only the special statements }
      raise;{ reraise the exception }
    end;
  end;
except
  on ESomething do ...;{ handling you want in all cases }
end;
```

If code in the { statements } part raises an *ESomething* exception, only the handler in the outer **except** part executes. However, if code in the { special statements } part raises *ESomething*, the handling in the inner **except** part is executed, followed by the more general handling in the outer **except** part.

By reraising exceptions, you can easily provide special handling for exceptions in special cases without losing (or duplicating) the existing handlers.

Handling component exceptions

Delphi's components raise exceptions to indicate error conditions. Most component exceptions indicate programming errors that would otherwise generate a runtime error. The mechanics of handling component exceptions are no different than handling RTL exceptions.

Example A common source of errors in components is range errors in indexed properties. For example, if a list box has three items in its list (0..2) and your application attempts to access item number 3, the list box raises a “List index out of bounds” exception.

The following event handler contains an exception handler to notify the user of invalid index access in a list box:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  ListBox1.Items.Add('a string');{ add a string to list box }
  ListBox1.Items.Add('another string');{ add another string... }
  ListBox1.Items.Add('still another string');{ ...and a third string }
  try
    Caption := ListBox1.Items[3];{ set form caption to fourth string in list box }
  except
    on EStringListError do
      MessageDlg('List box contains fewer than four strings', mtWarning, [mbOK], 0);
  end;
end;
```

If you click the button once, the list box has only three strings, so accessing the fourth string (Items[3]) raises an exception. Clicking a second time adds more strings to the list, so it no longer causes the exception.

Exception handling with external sources

HandleException provides default handling of exceptions for the application. Normally when developing cross-platform applications, you do not need to call *TApplication.HandleException*. However, you may need it when writing shared object files or callback functions. You can use *TApplication.HandleException* to block an exception from escaping from your code particularly when the code is being called from an external source that does not support exceptions.

For example, if an exception passes through all the **try** blocks in the application code, the application automatically calls the *HandleException* method, which displays a dialog box indicating that an error has occurred. You can use *HandleException* in this fashion:

```
try
  { statements }
except
  Application.HandleException(Self);
end;
```

For all exceptions but *EAbort*, *HandleException* calls the *OnException* event handler, if one exists. Therefore, if you want to both handle the exception, and provide this default behavior as the built-in components do, you can add a call to *HandleException* to your code:

```
try
  { special statements }
except
  on ESomething do
  begin
    { handling for only the special statements }
    Application.HandleException(Self);{ call HandleException }
  end;
end;
```

Note Do not call *HandleException* from within a thread's exception handling code.

For more information, search for exception handling routines in the Help index.

Silent exceptions

Delphi applications handle most exceptions that your code doesn't specifically handle by displaying a message box that shows the message string from the exception object. You can also define "silent" exceptions that do not, by default, cause the application to show the error message.

Silent exceptions are useful when you don't intend to report an exception to the user, but you want to abort an operation. Aborting an operation is similar to using the

Break or *Exit* procedures to break out of a block, but can break out of several nested levels of blocks.

Silent exceptions all descend from the standard exception type *EAbort*. The default exception handler for Delphi VCL and CLX applications displays the error-message dialog box for all exceptions that reach it except those descended from *EAbort*.

Note For console applications, an error-message dialog is displayed on any unhandled *EAbort* exceptions.

There is a shortcut for raising silent exceptions. Instead of manually constructing the object, you can call the *Abort* procedure. *Abort* automatically raises an *EAbort* exception, which will break out of the current operation without displaying an error message.

Example The following code shows a simple example of aborting an operation. On a form containing an empty list box and a button, attach the following code to the button's *OnClick* event:

```
procedure TForm1.Button1Click(Sender: TObject);
var
  I: Integer;
begin
  for I := 1 to 10 do{ loop ten times }
  begin
    ListBox1.Items.Add(IntToStr(I));{ add a numeral to the list }
    if I = 7 then Abort;{ abort after the seventh one }
  end;
end;
```

Defining your own exceptions

In addition to protecting your code from exceptions generated by the runtime library and various components, you can use the same mechanism to manage exception conditions in your own code.

To use exceptions in your code, you need to complete these steps:

- Declaring an exception object type
- Raising an exception

Declaring an exception object type

Because exceptions are objects, defining a new kind of exception is as simple as declaring a new object type. Although you can raise any object instance as an exception, the standard exception handlers handle only exceptions descended from Exception.

As a convention, new exception types should be derived from *Exception* or one of the other standard exceptions. That way, if you raise your new exception in a block of code that isn't protected by a specific exception handler for that exception, one of the standard handlers will handle it instead.

Example For example, consider the following declaration:

```
type
  EMyException = class(Exception);
```

If you raise *EMyException* but don't provide a specific handler for it, a handler for *Exception* (or a default exception handler) will still handle it. Because the standard handling for *Exception* displays the name of the exception raised, you can see that it is your new exception that is raised.

Raising an exception

To indicate a disruptive error condition in an application, you can raise an exception that involves constructing an instance of that type and calling the reserved word **raise**.

To raise an exception, call the reserved word raise, followed by an instance of an exception object. This allows you to establish an exception as coming from a particular address. When an exception handler actually handles the exception, it finishes by destroying the exception instance, so you never need to do that yourself.

Raising an exception address set the *ErrorAddr* variable in the *System* unit to the address where the application raised the exception. You can refer to *ErrorAddr* in your exception handlers, for example, to notify the user where the error occurred. You can also specify a value in the raise clause which will appear in *ErrorAddr* when an exception occurs.

Warning Do not assign a value to *ErrorAddr* yourself. It is intended as read-only.

To specify an error address for an exception, add the reserved word **at** after the exception instance, followed by an address expression such as an identifier.

For example, given the following declaration,

```
type
  EPasswordInvalid = class(Exception);
```

you can raise a “password invalid” exception at any time by calling raise with an instance of *EPasswordInvalid*, like this:

```
if Password <> CorrectPassword then
  raise EPasswordInvalid.Create('Incorrect password entered');
```

Using interfaces

Delphi’s **interface** keyword allows you to create and use interfaces in your application. Interfaces are a way extending the single-inheritance model of Object Pascal by allowing a single class to implement more than one interface, and by allowing several classes descended from different bases to share the same interface. Interfaces are useful when the same sets of operations, such as streaming, are used across a broad range of objects. Interfaces are also a fundamental aspect of the COM (the Component Object Model) and CORBA (Common Object Request Broker Architecture) distributed object models.

Interfaces as a language feature

An interface is like a class that contains only abstract methods and a clear definition of their functionality. Strictly speaking, interface method definitions include the number and types of their parameters, their return type, and their expected behavior. Interface methods are usually named to indicate the purpose of the interface. It is the convention to name interfaces according to their behavior and to preface them with a capital *I*. For example, an *IMalloc* interface would allocate, free, and manage memory. Similarly, an *IPersist* interface could be used as a general base interface for descendants, each of which defines specific method prototypes for loading and saving the state of an object to a storage, stream, or file.

An interface has the following syntax:

```
IMyObject = interface
  procedure MyProcedure;
end;
```

A simple example of declaring an interface is:

```
type
IEdit = interface
  procedure Copy; stdcall;
  procedure Cut; stdcall;
  procedure Paste; stdcall;
  function Undo: Boolean; stdcall;
end;
```

Like abstract classes, interfaces themselves can never be instantiated. To use an interface, you need to obtain it from an implementing class.

To implement an interface, you must define a class that declares the interface in its ancestor list, indicating that it will implement all of the methods of that interface:

```
TEditor = class(TInterfacedObject, IEdit)
  procedure Copy; stdcall;
  procedure Cut; stdcall;
  procedure Paste; stdcall;
  function Undo: Boolean; stdcall;
end;
```

While interfaces define the behavior and signature of their methods, they do not define the implementations. As long as the class's implementation conforms to the interface definition, the interface is fully polymorphic, meaning that accessing and using the interface is the same for any implementation of it.

Implementing interfaces across the hierarchy

Using interfaces offers a design approach to separating the way a class is used from the way it is implemented. Two classes can implement the same interface without requiring that they descend from the same base class. This polymorphic invocation of the same methods on unrelated objects is possible as long as the objects implement the same interface. For example, consider the interface,

```
IPaint = interface
  procedure Paint;
end;
```

and the two classes,

```
TSquare = class(TPolygonObject, IPaint)
  procedure Paint;
end;

TCircle = class(TCustomShape, IPaint)
  procedure Paint;
end;
```

Whether or not the two classes share a common ancestor, they are still assignment compatible with a variable of *IPaint* as in

```
var
  Painter: IPaint;
begin
  Painter := TSquare.Create;
  Painter.Paint;
  Painter := TCircle.Create;
  Painter.Paint;
end;
```

This could have been accomplished by having *TCircle* and *TSquare* descend from say, *TFigure* which implemented a virtual method *Paint*. Both *TCircle* and *TSquare* would then have overridden the *Paint* method. The above *IPaint* would be replaced by *TFigure*. However, consider the following interface:

```
IRotate = interface
  procedure Rotate(Degrees: Integer);
end;
```

which makes sense for the rectangle to support but not the circle. The classes would look like

```
TSquare = class(TRectangularObject, IPaint, IRotate)
  procedure Paint;
  procedure Rotate(Degrees: Integer);
end;

TCircle = class(TCustomShape, IPaint)
  procedure Paint;
end;
```

Later, you could create a class *TFilledCircle* that implements the *IRotate* interface to allow rotation of a pattern used to fill the circle without having to add rotation to the simple circle.

Note For these examples, the immediate base class or an ancestor class is assumed to have implemented the methods of *IInterface* that manage reference counting. For more information, see “Implementing IInterface” on page 4-20 and “Memory management of interface objects” on page 4-24.

Using interfaces with procedures

Interfaces also allow you to write generic procedures that can handle objects without requiring the objects to descend from a particular base class. Using the above *IPaint* and *IRotate* interfaces you can write the following procedures,

```
procedure PaintObjects(Painters: array of IPaint);
var
  I: Integer;
begin
  for I := Low(Painters) to High(Painters) do
    Painters[I].Paint;
end;

procedure RotateObjects(Degrees: Integer; Rotaters: array of IRotate);
var
  I: Integer;
begin
  for I := Low(Rotaters) to High(Rotaters) do
    Rotaters[I].Rotate(Degrees);
end;
```

RotateObjects does not require that the objects know how to paint themselves and *PaintObjects* does not require the objects know how to rotate. This allows the above generic procedures to be used more often than if they were written to only work against a *TFigure* class.

For details about the syntax, language definitions and rules for interfaces, see the *Object Pascal Language Guide* online Help section on Object interfaces.

Implementing IInterface

All interfaces derive either directly or indirectly from the *IInterface* interface. This interface provides the essential functionality of an interface, that is, dynamic querying and lifetime management. This functionality is established in the three *IInterface* methods:

- *QueryInterface* provides a method for dynamically querying a given object and obtaining interface references for the interfaces the object supports.
- *_AddRef* is a reference counting method that increments the count each time the call to *QueryInterface* succeeds. While the reference count is nonzero the object must remain in memory.
- *_Release* is used with *_AddRef* to enable an object to track its own lifetime and to determine when it is safe to delete itself. Once the reference count reaches zero, the object is freed from memory.

Every class that implements interfaces must implement the three *IInterface* methods, as well as all of the methods declared by any other ancestor interfaces, and all of the methods declared by the interface itself. You can, however, inherit the implementations of methods of interfaces declared in your class.

By implementing these methods yourself, you can provide an alternative means of life-time management, disabling reference-counting. This is a powerful technique that lets you decouple interfaces from reference-counting.

TInterfacedObject

Delphi defines a simple class, *TInterfacedObject*, that serves as a convenient base because it implements the methods of *IInterface*. *TInterfacedObject* class is declared in the *System* unit as follows:

```
type
  TInterfacedObject = class(TObject, IInterface)
  protected
    FRefCount: Integer;
    function QueryInterface(const IID: TGUID; out Obj): HResult; stdcall;
    function _AddRef: Integer; stdcall;
    function _Release: Integer; stdcall;
  public
    procedure AfterConstruction; override;
    procedure BeforeDestruction; override;
    class function NewInstance: TObject; override;
    property RefCount: Integer read FRefCount;
  end;
```

Deriving directly from *TInterfacedObject* is straightforward. In the following example declaration, *TDerived* is a direct descendant of *TInterfacedObject* and implements a hypothetical *IPaint* interface.

```
type
  TDerived = class(TInterfacedObject, IPaint)
    ...
  end;
```

Because it implements the methods of *IInterface*, *TInterfacedObject* automatically handles reference counting and memory management of interfaced objects. For more information, see “Memory management of interface objects” on page 4-24, which also discusses writing your own classes that implement interfaces but that do not follow the reference-counting mechanism inherent in *TInterfacedObject*.

Using the as operator

Classes that implement interfaces can use the **as** operator for dynamic binding on the interface. In the following example:

```
procedure PaintObjects(P: TInterfacedObject)
var
  X: IPaint;

begin
  X := P as IPaint;
{ statements }
end;
```

the variable *P* of type *TInterfacedObject*, can be assigned to the variable *X*, which is an *IPaint* interface reference. Dynamic binding makes this assignment possible. For this assignment, the compiler generates code to call the *QueryInterface* method of *P*'s *IInterface* interface. This is because the compiler cannot tell from *P*'s declared type whether *P*'s instance actually supports *IPaint*. At runtime, *P* either resolves to an *IPaint* reference or an exception is raised. In either case, assigning *P* to *X* will not generate a compile-time error as it would if *P* was of a class type that did not implement *IInterface*.

When you use the **as** operator for dynamic binding on an interface, you should be aware of the following requirements:

- Explicitly declaring *IInterface*: Although all interfaces derive from *IInterface*, it is not sufficient, if you want to use the **as** operator, for a class to simply implement the methods of *IInterface*. This is true even if it also implements the interfaces it explicitly declares. The class must explicitly declare *IInterface* in its interface list.
- Using an IID: Interfaces can use an identifier that is based on a GUID (globally unique identifier). GUIDs that are used to identify interfaces are referred to as interface identifiers (IIDs). If you are using the **as** operator with an interface, it must have an associated IID. To create a new GUID in your source code you can use the *Ctrl+Shift+G* editor shortcut key.

Reusing code and delegation

One approach to reusing code with interfaces is to have an object contain, or be contained by another. Using properties that are object types provides an approach to containment and code reuse. To support this design for interfaces, Object Pascal has a keyword **implements**, that makes if easy to write code to delegate all or part of the implementation of an interface to a subobject. Aggregation is another way of reusing code through containment and delegation. In aggregation, an outer object contains an inner object that implements interfaces which are exposed only by the outer object. The VCL and CLX have classes that support aggregation.

Using implements for delegation

Many classes have properties that are subobjects. You can also use interfaces as property types. When a property is of an interface type (or a class type that implements the methods of an interface) you can use the keyword **implements** to specify that the methods of that interface are delegated to the object or interface reference which is the property instance. The delegate only needs to provide implementation for the methods. It does not have to declare the interface support. The class containing the property must include the interface in its ancestor list.

By default using the keyword **implements** delegates all interface methods. However, you can use methods resolution clauses or declare methods in your class that implement some of the interface methods as a way of overriding this default behavior.

The following example uses the implements keyword in the design of a color adapter object that converts an 8-bit RGB color value to a *Color* reference:

```
unit cadapt;

type
IRGB8bit = interface
    ['{1d76360a-f4f5-11d1-87d4-00c04fb17199}']
    function Red: Byte;
    function Green: Byte;
    function Blue: Byte;
  end;

IColorRef = interface
    ['{1d76360b-f4f5-11d1-87d4-00c04fb17199}']
    function Color: Integer;
  end;

{ TRGB8ColorRefAdapter   map an IRGB8bit to an IColorRef }
  TRGB8ColorRefAdapter = class(TInterfacedObject, IRGB8bit, IColorRef)
  private
    FRGB8bit: IRGB8bit;
    FPalRelative: Boolean;
  public
    constructor Create(rgb: IRGB8bit);
    property RGB8Intf: IRGB8bit read FRGB8bit implements IRGB8bit;
    property PalRelative: Boolean read FPalRelative write FPalRelative;
    function Color: Integer;
  end;

implementation

constructor TRGB8ColorRefAdapter.Create(rgb: IRGB8bit);
begin
  FRGB8bit := rgb;
end;

function TRGB8ColorRefAdapter.Color: Integer;
begin
  if FPalRelative then
    Result := PaletteRGB(RGB8Intf.Red, RGB8Intf.Green, RGB8Intf.Blue)
  else
    Result := RGB(RGB8Intf.Red, RGB8Intf.Green, RGB8Intf.Blue);
end;
end.
```

For more information about the syntax, implementation details, and language rules of the **implements** keyword, see the *Object Pascal Language Guide* online Help section on Object interfaces.

Aggregation

Aggregation offers a modular approach to code reuse through sub-objects that define the functionality of a containing object, but that hide the implementation details from that object. In aggregation, an outer object implements one or more interfaces. The only requirement is that it implement *IInterface*. The inner object, or objects, can implement one or more interfaces, however only the outer object exposes the interfaces. These include both the interfaces it implements and the ones implemented by its contained objects. Clients know nothing about inner objects. While the outer object provides access to the inner object interfaces, their implementation is completely transparent. Therefore, the outer object class can exchange the inner object class type for any class that implements the same interface. Correspondingly, the code for the inner object classes can be shared by other classes that want to use it.

The implementation model for aggregation defines explicit rules for implementing *IInterface* using delegation. The inner object must implement an *IInterface* on itself, that controls the inner object's reference count. This implementation of *IInterface* tracks the relationship between the outer and the inner object. For example, when an object of its type (the inner object) is created, the creation succeeds only for a requested interface of type *IInterface*. The inner object also implements a second *IInterface* for all the interfaces it implements. These are the interfaces exposed by the outer object. This second *IInterface* delegates calls to *QueryInterface*, *AddRef*, and *Release* to the outer object. The outer *IInterface* is referred to as the "controlling Unknown."

Refer to the MS online help for the rules about creating an aggregation. When writing your own aggregation classes, you can also refer to the implementation details of *IInterface* in *TComObject*. *TComObject* is a COM class that supports aggregation. If you are writing COM applications, you can also use *TComObject* directly as a base class.

Memory management of interface objects

One of the concepts behind the design of interfaces is ensuring the lifetime management of the objects that implement them. The *_AddRef* and *_Release* methods of *IInterface* provide a way to implement this lifetime management. *_AddRef* and *_Release* track the lifetime of an object by incrementing the reference count on the object when an interface reference is passed to a client, and will destroy the object when that reference count is zero.

If you are creating COM objects for distributed applications (in the Windows environment only), then you should strictly adhere to the reference counting rules. However, if you are using interfaces only internally in your application, then you have a choice that depends upon the nature of your object and how you decide to use it.

Using reference counting

Delphi provides most of the *IInterface* memory management for you by its implementation of interface querying and reference counting. Therefore, if you have an object that lives and dies by its interfaces, you can easily use reference counting by deriving from these classes. *TInterfacedObject* is the non-CoClass that provides this behavior. If you decide to use reference counting, then you must be careful to only hold the object as an interface reference, and to be consistent in your reference counting. For example:

```
procedure beep(x: ITest);

function test_func()
var
```

```
  y: ITest;
begin
  y := TTest.Create; // because y is of type ITest, the reference count is one
  beep(y); // the act of calling the beep function increments the reference count
  // and then decrements it when it returns
  y.something; // object is still here with a reference count of one
end;
```

This is the cleanest and safest approach to memory management; and if you use *TInterfacedObject* it is handled automatically. If you do not follow this rule, your object can unexpectedly disappear, as demonstrated in the following code:

```
function test_func()
var
  x: TTest;
begin
  x := TTest.Create; // no count on the object yet
  beep(x as ITest); // count is incremented by the act of calling beep
  // and decremented when it returns
  x.something; // surprise, the object is gone
end;
```

Note In the examples above, the *beep* procedure, as it is declared, increments the reference count (call *_AddRef*) on the parameter, whereas either of the following declarations do not:

```
procedure beep(const x: ITest);
```

or

```
procedure beep(var x: ITest);
```

These declarations generate smaller, faster code.

One case where you cannot use reference counting, because it cannot be consistently applied, is if your object is a component or a control owned by another component. In that case, you can still use interfaces, but you should not use reference counting because the lifetime of the object is not dictated by its interfaces.

Not using reference counting

If your object is a component or a control that is owned by another component, then your object is part of a different memory management system that is based in *TComponent*. You should not mix the object lifetime management approaches of VCL or CLX components and interface reference counting. If you want to create a component that supports interfaces, you can implement the *IInterface _AddRef* and *_Release* methods as empty functions to bypass the interface reference counting mechanism:

```
function TMyObject._AddRef: Integer;
begin
  Result := -1;
end;

function TMyObject._Release: Integer;
begin
  Result := -1;
end;
```

You would still implement *QueryInterface* as usual to provide dynamic querying on your object.

Note that, because you do implement *QueryInterface*, you can still use the **as** operator for interfaces on components, as long as you create an interface identifier (IID). You can also use aggregation. If the outer object is a component, the inner object implements reference counting as usual, by delegating to the “controlling Unknown.” It is at the level of the outer, component object that the decision is made to circumvent the *_AddRef* and *_Release* methods, and to handle memory management via the component-based approach. In fact, you can use *TInterfacedObject* as a base class for an inner object of an aggregation that has a component as its containing outer object.

Note The “controlling Unknown” is the *IUnknown* implemented by the outer object and the one for which the reference count of the entire object is maintained. *IUnknown* is the same as *IInterface*, but is used instead in COM-based applications (Windows only). For more information distinguishing the various implementations of the *IUnknown* or *IInterface* interface by the inner and outer objects, see “Aggregation” on page 4-23 and the Microsoft online Help topics on the “controlling Unknown.”

Using interfaces in distributed applications (VCL only)

Interfaces are a fundamental element in the COM, SOAP, and CORBA distributed object models. Delphi provides base classes for these technologies that extend the basic interface functionality in *TInterfacedObject*, which simply implements the *IInterface* interface methods.

When using COM, classes and interfaces are defined in terms of *IUnknown* rather than *IInterface*. There is no semantic difference between *IUnknown* and *IInterface*, the use of *IUnknown* is simply a way to adapt Delphi interfaces to the COM definition. COM classes add functionality for using class factories and class identifiers (CLSIDs). Class factories are responsible for creating class instances via CLSIDs. The CLSIDs are used to register and manipulate COM classes. COM classes that have class factories and class identifiers are called CoClasses. CoClasses take advantage of the versioning capabilities of *QueryInterface*, so that when a software module is updated *QueryInterface* can be invoked at runtime to query the current capabilities of an object.

New versions of old interfaces, as well as any new interfaces or features of an object, can become immediately available to new clients. At the same time, objects retain complete compatibility with existing client code; no recompilation is necessary because interface implementations are hidden (while the methods and parameters remain constant). In COM applications, developers can change the implementation to improve performance, or for any internal reason, without breaking any client code that relies on that interface. For more information about COM interfaces, see Chapter 33, “Overview of COM technologies.”

When distributing an application using SOAP, interfaces are required to carry their own runtime type information (RTTI). The compiler only adds RTTI to an interface when it is compiled using the {$M+} switch. Such interfaces are called *invokable interfaces*. The descendant of any invokable interface is also invokable. However, if an invokable interface descends from another interface that is not invokable, client applications can only call the methods defined in the invokable interface and its descendants. Methods inherited from the non-invokable ancestors are not compiled with type information and so can’t be called by clients.

The easiest way to define invokable interfaces is to define your interface so that it descends from *IInvokable*. *IInvokable* is the same as *IInterface*, except that it is compiled using the {$M+} switch. For more information about Web Service applications that are distributed using SOAP, and about invokable interfaces, see Chapter 31, “Using Web Services.”

Another distributed application technology is CORBA. The use of interfaces in CORBA applications is mediated by stub classes on the client and skeleton classes on the server. These stub and skeleton classes handle the details of marshaling interface calls so that parameter values and return values can be transmitted correctly. Applications must use either a stub or skeleton class, or employ the Dynamic Invocation Interface (DII) which converts all parameters to special variants (so that they carry their own type information).

Defining custom variants

One powerful built-in type of the Object Pascal language is the Variant type. Variants represent values whose type is not determined at compile time. Instead, the type of their value can change at runtime. Variants can mix with other variants and with integer, real, string, and boolean values in expressions and assignments; the compiler automatically performs type conversions.

By default, variants can’t hold values that are records, sets, static arrays, files, classes, class references, or pointers. You can, however, extend the Variant type to work with any particular example of these types. All you need to do is create a descendant of the *TCustomVariantType* class that indicates how the Variant type performs standard operations.

To create a Variant type,

1. Map the storage of the variant’s data on to the *TVarData* record.
2. Declare a class that descends from *TCustomVariantType*. Implement all required behavior (including type conversion rules) in the new class.
3. Write utility methods for creating instances of your custom variant and recognizing its type.

The above steps extend the Variant type so that the standard operators work with your new type and the new Variant type can be cast to other data types. You can further enhance your new Variant type so that it supports properties and methods that you define. When creating a Variant type that supports properties or methods, you use *TInvokeableVariantType* or *TPublishableVariantType* as a base class rather than *TCustomVariantType*.

Storing a custom variant type's data

Variants store their data in the *TVarData* record type. This type is a record that contains 16 bytes. The first Word indicates the type of the variant, and the remaining 14 bytes are available to store the data. While your new Variant type can work directly with a *TVarData* record, it is usually easier to define a record type whose members have names that are meaningful for your new type, and cast that new type onto the *TVarData* record type.

For example, the VarConv unit defines a custom variant type that represents a measurement. The data for this type includes the units (*TConvType*) of measurement, as well as the value (a double). The VarConv unit defines its own type to represent such a value:

```
TConvertVarData = packed record
  VType: TVarType;
  VConvType: TConvType;
  Reserved1, Reserved2: Word;
  VValue: Double;
end;
```

This type is exactly the same size as the *TVarData* record. When working with a custom variant of the new type, the variant (or its *TVarData* record) can be cast to *TConvertVarData*, and the custom Variant type simply works with the *TVarData* record as if it were a *TConvertVarData* type.

Note When defining a record that maps onto the *TVarData* record in this way, be sure to define it as a packed record.

If your new custom Variant type needs more than 14 bytes to store its data, you can define a new record type that includes a pointer or object instance. For example, the VarCmplx unit uses an instance of the class *TComplexData* to represent the data in a complex-valued variant. It therefore defines a record type the same size as *TVarData* that includes a reference to a *TComplexData* object:

```
TComplexVarData = packed record
  VType: TVarType;
  Reserved1, Reserved2, Reserved3: Word;
  VComplex: TComplexData;
  Reserved4: LongInt;
end;
```

Object references are actually pointers (two Words), so this type is the same size as the *TVarData* record. As before, a complex custom variant (or its *TVarData* record), can be cast to *TComplexVarData*, and the custom variant type works with the *TVarData* record as if it were a *TComplexVarData* type.

Creating a class to enable the custom variant type

Custom variants work by using a special helper class that indicates how variants of the custom type can perform standard operations. You create this helper class by writing a descendant of *TCustomVariantType*. This involves overriding the appropriate virtual methods of *TCustomVariantType*.

Enabling casting

One of the most important features of the custom variant type for you to implement is typecasting. The flexibility of variants arises, in part, from their implicit typecasts.

There are two methods for you to implement that enable the custom Variant type to perform typecasts: *Cast*, which converts another variant type to your custom variant, and *CastTo*, which converts your custom Variant type to another type of Variant.

When implementing either of these methods, it is relatively easy to perform the logical conversions from the built-in variant types. You must consider, however, the possibility that the variant to or from which you are casting may be another custom Variant type. To handle this situation, you can try casting to one of the built-in Variant types as an intermediate step.

For example, the following *Cast* method, from the *TComplexVariantType* class uses the type Double as an intermediate type:

```
procedure TComplexVariantType.Cast(var Dest: TVarData; const Source: TVarData);
var
  LSource, LTemp: TVarData;
begin
  VarDataInit(LSource);
  try
    VarDataCopyNoInd(LSource, Source);
    if VarDataIsStr(LSource) then
      TComplexVarData(Dest).VComplex := TComplexData.Create(VarDataToStr(LSource))
    else
    begin
      VarDataInit(LTemp);
      try
        VarDataCastTo(LTemp, LSource, varDouble);
        TComplexVarData(Dest).VComplex := TComplexData.Create(LTemp.VDouble, 0);
      finally
        VarDataClear(LTemp);
      end;
    end;
    Dest.VType := VarType;
  finally
    VarDataClear(LSource);
  end;
end;
```

In addition to the use of Double as an intermediate Variant type, there are a few things to note in this implementation:

- The last step of this method sets the *VType* member of the returned *TVarData* record. This member gives the Variant type code. It is set to the *VarType* property of *TComplexVariantType*, which is the Variant type code assigned to the custom variant.
- The custom variant's data (*Dest*) is typecast from *TVarData* to the record type that is actually used to store its data (*TComplexVarData*). This makes the data easier to work with.
- The method makes a local copy of the source variant rather than working directly with its data. This prevents side effects that may affect the source data.

When casting from a complex variant to another type, the *CastTo* method also uses an intermediate type of Double (for any destination type other than a string):

```
procedure TComplexVariantType.CastTo(var Dest: TVarData; const Source: TVarData;
  const AVarType: TVarType);
var
  LTemp: TVarData;
begin
  if Source.VType = VarType then
    case AVarType of
      varOleStr:
        VarDataFromOleStr(Dest, TComplexVarData(Source).VComplex.AsString);
      varString:
        VarDataFromStr(Dest, TComplexVarData(Source).VComplex.AsString);
    else
      VarDataInit(LTemp);
      try
        LTemp.VType := varDouble;
        LTemp.VDouble := TComplexVarData(LTemp).VComplex.Real;
        VarDataCastTo(Dest, LTemp, AVarType);
      finally
        VarDataClear(LTemp);
      end;
    end
  else
    RaiseCastError;
end;
```

Note that the *CastTo* method includes a case where the source variant data does not have a type code that matches the *VarType* property. This case only occurs for empty (unassigned) source variants.

Implementing binary operations

To allow the custom variant type to work with standard binary operators (+, -, *, /, div, mod, shl, shr, and, or, xor listed in the System unit), you must override the *BinaryOp* method. *BinaryOp* has three parameters: the value of the left-hand operand, the value of the right-hand operand, and the operator. Implement this method to perform the operation and return the result using the same variable that contained the left-hand operand.

For example, the following *BinaryOp* method comes from the *TComplexVariantType* defined in the VarCmplx unit:

```
procedure TComplexVariantType.BinaryOp(var Left: TVarData; const Right: TVarData;
  const Operator: TVarOp);
begin
  if Right.VType = VarType then
    case Left.VType of
      varString:
        case Operator of
          opAdd: Variant(Left) := Variant(Left) + TComplexVarData(Right).VComplex.AsString;
        else
          RaiseInvalidOp;
        end;
```

```
          else
            if Left.VType = VarType then
              case Operator of
                opAdd:
                  TComplexVarData(Left).VComplex.DoAdd(TComplexVarData(Right).VComplex);
                opSubtract:
                  TComplexVarData(Left).VComplex.DoSubtract(TComplexVarData(Right).VComplex);
                opMultiply:
                  TComplexVarData(Left).VComplex.DoMultiply(TComplexVarData(Right).VComplex);
                opDivide:
                  TComplexVarData(Left).VComplex.DoDivide(TComplexVarData(Right).VComplex);
                else
                  RaiseInvalidOp;
              end
            else
              RaiseInvalidOp;
        end
      else
        RaiseInvalidOp;
    end;
```

There are several things to note in this implementation:

This method only handles the case where the variant on the right side of the operator is a custom variant that represents a complex number. If the left-hand operand is a complex variant and the right-hand operand is not, the complex variant forces the right-hand operand first to be cast to a complex variant. It does this by overriding the *RightPromotion* method so that it always requires the type in the *VarType* property:

```
function TComplexVariantType.RightPromotion(const V: TVarData;
  const Operator: TVarOp; out RequiredVarType: TVarType): Boolean;
begin
  { Complex Op TypeX }
  RequiredVarType := VarType;
  Result := True;
end;
```

The addition operator is implemented for a string and a complex number (by casting the complex value to a string and concatenating), and the addition, subtraction, multiplication, and division operators are implemented for two complex numbers using the methods of the *TComplexData* object that is stored in the complex variant's data. This is accessed by casting the *TVarData* record to a *TComplexVarData* record and using its *VComplex* member.

Attempting any other operator or combination of types causes the method to call the *RaiseInvalidOp* method, which causes a runtime error. The *TCustomVariantType* class includes a number of utility methods such as *RaiseInvalidOp* that can be used in the implementation of custom variant types.

BinaryOp only deals with a limited number of types: strings and other complex variants. It is possible, however, to perform operations between complex numbers and other numeric types. For the *BinaryOp* method to work, the operands must be cast to complex variants before the values are passed to this method. We have already seen (above) how to use the *RightPromotion* method to force the right-hand operand to be a complex variant if the left-hand operand is complex. A similar method, *LeftPromotion*, forces a cast of the left-hand operand when the right-hand operand is complex:

```
function TComplexVariantType.LeftPromotion(const V: TVarData;
  const Operator: TVarOp; out RequiredVarType: TVarType): Boolean;
begin
  { TypeX Op Complex }
  if (Operator = opAdd) and VarDataIsStr(V) then
    RequiredVarType := varString
  else
    RequiredVarType := VarType;
  Result := True;
end;
```

This *LeftPromotion* method forces the left-hand operand to be cast to another complex variant, unless it is a string and the operation is addition, in which case *LeftPromotion* allows the operand to remain a string.

Implementing comparison operations

There are two ways to enable a custom variant type to support comparison operators (=, <>, <, <=, >, >=). You can override the *Compare* method, or you can override the *CompareOp* method.

The *Compare* method is easiest if your custom variant type supports the full range of comparison operators. *Compare* takes three parameters: the left-hand operand, the right-hand operand, and a var Parameter that returns the relationship between the two. For example, the *TConvertVariantType* object in the VarConv unit implements the following *Compare* method:

```
procedure TConvertVariantType.Compare(const Left, Right: TVarData;
  var Relationship: TVarCompareResult);
const
  CRelationshipToRelationship: array [TValueRelationship] of TVarCompareResult =
    (crLessThan, crEqual, crGreaterThan);
var
  LValue: Double;
  LType: TConvType;
  LRelationship: TValueRelationship;
begin
  // supports...
  //   convvar cmp number
  //     Compare the value of convvar and the given number
  //   convvar1 cmp convvar2
  //     Compare after converting convvar2 to convvar1's unit type
  //  The right can also be a string.  If the string has unit info then it is
  //    treated like a varConvert else it is treated as a double
  LRelationship := EqualsValue;
  case Right.VType of
    varString:
      if TryStrToConvUnit(Variant(Right), LValue, LType) then
        if LType = CIllegalConvType then
          LRelationship := CompareValue(TConvertVarData(Left).VValue, LValue)
        else
          LRelationship := ConvUnitCompareValue(TConvertVarData(Left).VValue,
                                      TConvertVarData(Left).VConvType, LValue, LType)
        else
          RaiseCastError;
      varDouble:
        LRelationship := CompareValue(TConvertVarData(Left).VValue, TVarData(Right).VDouble);
      else
        if Left.VType = VarType then
          LRelationship := ConvUnitCompareValue(TConvertVarData(Left).VValue,
                          TConvertVarData(Left).VConvType, TConvertVarData(Right).VValue,
                          TConvertVarData(Right).VConvType)
        else
          RaiseInvalidOp;
    end;
    Relationship := CRelationshipToRelationship[LRelationship];
  end;
```

If the custom type does not support the concept of "greater than" or "less than," only "equal" or "not equal," however, it is difficult to implement the *Compare* method, because *Compare* must return *crLessThan*, *crEqual*, or *crGreaterThan*. When the only valid response is "not equal," it is impossible to know whether to return *crLessThan* or *crGreaterThan*. Thus, for types that do not support the concept of ordering, you can override the *CompareOp* method instead.

CompareOp has three parameters: the value of the left-hand operand, the value of the right-hand operand, and the comparison operator. Implement this method to perform the operation and return a boolean that indicates whether the comparison is *True*. You can then call the *RaiseInvalidOp* method when the comparison makes no sense.

For example, the following *CompareOp* method comes from the *TComplexVariantType* object in the VarCmplx unit. It supports only a test of equality or inequality:

```
function TComplexVariantType.CompareOp(const Left, Right: TVarData;
  const Operator: Integer): Boolean;
begin
  Result := False;
  if (Left.VType = VarType) and (Right.VType = VarType) then
    case Operator of
      opCmpEQ:
        Result := TComplexVarData(Left).VComplex.Equal(TComplexVarData(Right).VComplex);
      opCmpNE:
        Result := not TComplexVarData(Left).VComplex.Equal(TComplexVarData(Right).VComplex);
    else
      RaiseInvalidOp;
    end
  else
    RaiseInvalidOp;
end;
```

Note that the types of operands that both these implementations support are very limited. As with binary operations, you can use the *RightPromotion* and *LeftPromotion* methods to limit the cases you must consider by forcing a cast before *Compare* or *CompareOp* is called.

Implementing unary operations

To allow the custom variant type to work with standard unary operators (-, not), you must override the *UnaryOp* method. *UnaryOp* has two parameters: the value of the operand and the operator. Implement this method to perform the operation and return the result using the same variable that contained the operand.

For example, the following *UnaryOp* method comes from the *TComplexVariantType* defined in the VarCmplx unit:

```
procedure TComplexVariantType.UnaryOp(var Right: TVarData; const Operator: TVarOp);
begin
  if Right.VType = VarType then
    case Operator of
      opNegate:
        TComplexVarData(Right).VComplex.DoNegate;
    else
      RaiseInvalidOp;
    end
  else
    RaiseInvalidOp;
end;
```

Note that for the logical **not** operator, which does not make sense for complex values, this method calls *RaiseInvalidOp* to cause a runtime error.

Copying and clearing custom variants

In addition to typecasting and the implementation of operators, you must indicate how to copy and clear variants of your custom Variant type.

To indicate how to copy the variant's value, implement the *Copy* method. Typically, this is an easy operation, although you must remember to allocate memory for any classes or structures you use to hold the variant's value:

```
procedure TComplexVariantType.Copy(var Dest: TVarData; const Source: TVarData;
  const Indirect: Boolean);
begin
  if Indirect and VarDataIsByRef(Source) then
    VarDataCopyNoInd(Dest, Source)
  else
    with TComplexVarData(Dest) do
    begin
      VType := VarType;
      VComplex := TComplexData.Create(TComplexVarData(Source).VComplex);
    end;
end;
```

Note The *Indirect* parameter in the *Copy* method signals that the copy must take into account the case when the variant holds only an indirect reference to its data.

Tip If your custom variant type does not allocate any memory to hold its data (if the data fits entirely in the *TVarData* record), your implementation of the Copy method can simply call the *SimplisticCopy* method.

To indicate how to clear the variant's value, implement the *Clear* method. As with the Copy method, the only tricky thing about doing this is ensuring that you free any resources allocated to store the variant's data:

```
procedure TComplexVariantType.Clear(var V: TVarData);
begin
  V.VType := varEmpty;
  FreeAndNil(TComplexVarData(V).VComplex);
end;
```

You will also need to implement the *IsClear* method. This way, you can detect any invalid values or special values that represent "blank" data:

```
function TComplexVariantType.IsClear(const V: TVarData): Boolean;
begin
  Result := (TComplexVarData(V).VComplex = nil) or
            TComplexVarData(V).VComplex.IsZero;
end;
```

Loading and saving custom variant values

By default, when the custom variant is assigned as the value of a published property, it is typecast to a string when that property is saved to a form file, and converted back from a string when the property is read from a form file. You can, however, provide your own mechanism for loading and saving custom variant values in a more natural representation. To do so, the *TCustomVariantType* descendant must implement the *IVarStreamable* interface from Classes.pas.

IVarStreamable defines two methods, *StreamIn* and *StreamOut*, for reading a variant's value from a stream and for writing the variant's value to the stream. For example, *TComplexVariantType*, in the VarCmplx unit, implements the *IVarStreamable* methods as follows:

```
procedure TComplexVariantType.StreamIn(var Dest: TVarData; const Stream: TStream);
begin
  with TReader.Create(Stream, 1024) do
  try
    with TComplexVarData(Dest) do
    begin
      VComplex := TComplexData.Create;
      VComplex.Real := ReadFloat;
      VComplex.Imaginary := ReadFloat;
    end;
  finally
    Free;
  end;
end;

procedure TComplexVariantType.StreamOut(const Source: TVarData; const Stream: TStream);
begin
  with TWriter.Create(Stream, 1024) do
  try
    with TComplexVarData(Source).VComplex do
    begin
      WriteFloat(Real);
      WriteFloat(Imaginary);
      end;
    finally
      Free;
    end;
  end;
```

Note how these methods create a Reader or Writer object for the *Stream* parameter to handle the details of reading or writing values.

Using the TCustomVariantType descendant

In the initialization section of the unit that defines your *TCustomVariantType* descendant, create an instance of your class. When you instantiate your object, it automatically registers itself with the variant-handling system so that the new Variant type is enabled. For example, here is the initialization section of the VarCmplx unit:

```
initialization
  ComplexVariantType := TComplexVariantType.Create;
```

In the finalization section of the unit that defines your *TCustomVariantType* descendant, free the instance of your class. This automatically unregisters the variant type. Here is the finalization section of the VarCmplx unit:

```
finalization
  FreeAndNil(ComplexVariantType);
```

Writing utilities to work with a custom variant type

Once you have created a *TCustomVariantType* descendant to implement your custom variant type, it is possible to use the new Variant type in applications. However, without a few utilities, this is not as easy as it should be.

For example, without a utility function, the only way to create an instance of your custom variant type is to use the global *VarCast* procedure on a source variant of another type. It is a good idea to create a method that creates an instance of your custom variant type from an appropriate value or set of values. This function or set of functions fills out the structure you defined to store your custom variant's data. For example, the following function could be used to create a complex-valued variant:

```
function VarComplexCreate(const AReal, AImaginary: Double): Variant;
begin
  VarClear(Result);
  TComplexVarData(Result).VType := ComplexVariantType.VarType;
  TComplexVarData(ADest).VComplex := TComplexData.Create(ARead, AImaginary);
end;
```

This function does not actually exist in the VarCmplx unit, but is a synthesis of methods that do exist, provided to simplify the example. Note that the returned variant is cast to the record that was defined to map onto the *TVarData* structure (*TComplexVarData*), and then filled out.

Another useful utility to create is one that returns the variant type code for your new Variant type. This type code is not a constant. It is automatically generated when you instantiate your *TCustomVariantType* descendant. It is therefore useful to provide a way to easily determine the type code for your custom variant type. The following function from the VarCmplx unit illustrates how to write one, by simply returning the *VarType* property of the *TCustomVariantType* descendant:

```
function VarComplex: TVarType;
begin
  Result := ComplexVariantType.VarType;
end;
```

Two other standard utilities provided for most custom variants check whether a given variant is of the custom type and cast an arbitrary variant to the new custom type. Here is the implementation of those utilities from the VarCmplx unit:

```
function VarIsComplex(const AValue: Variant): Boolean;
begin
  Result := (TVarData(AValue).VType and varTypeMask) = VarComplex;
end;

function VarAsComplex(const AValue: Variant): Variant;
begin
  if not VarIsComplex(AValue) then
    VarCast(Result, AValue, VarComplex)
  else
    Result := AValue;
end;
```

Note that these use standard features of all variants: the *VType* member of the *TVarData* record and the *VarCast* function, which works because of the methods implemented in the *TCustomVariantType* descendant for casting data.

In addition to the standard utilities mentioned above, you can write any number of utilities specific to your new custom variant type. For example, the VarCmplx unit defines a large number of functions that implement mathematical operations on complex-valued variants.

Supporting properties and methods in custom variants

Some variants have properties and methods. For example, when the value of a variant is an interface, you can use the variant to read or write the values of properties on that interface and call its methods. Even if your custom variant type does not represent an interface, you may want to give it properties and methods that an application can use in the same way.

Using TInvokeableVariantType

To provide support for properties an methods, the class you create to enable the new custom variant type should descend from *TInvokeableVariantType* instead of directly from *TCustomVariantType*.

TInvokeableVariantType defines four methods:

- *DoFunction*
- *DoProcedure*
- *GetProperty*
- *SetProperty*

that you can implement to support properties and methods on your custom variant type.

For example, the VarConv unit uses *TInvokeableVariantType* as the base class for *TConvertVariantType* so that the resulting custom variants can support properties. The following example shows the property getter for these properties:

```
function TConvertVariantType.GetProperty(var Dest: TVarData;
  const V: TVarData; const Name: String): Boolean;
var
  LType: TConvType;
begin
  // supports...
  //   'Value'
  //   'Type'
  //   'TypeName'
  //   'Family'
  //   'FamilyName'
  //   'As[Type]'
  Result := True;
  if Name = 'VALUE' then
    Variant(Dest) := TConvertVarData(V).VValue
  else if Name = 'TYPE' then
    Variant(Dest) := TConvertVarData(V).VConvType
  else if Name = 'TYPENAME' then
    Variant(Dest) := ConvTypeToDescription(TConvertVarData(V).VConvType)
  else if Name = 'FAMILY' then
    Variant(Dest) := ConvTypeToFamily(TConvertVarData(V).VConvType)
  else if Name = 'FAMILYNAME' then
    Variant(Dest) := ConvFamilyToDescription(ConvTypeToFamily(TConvertVarData(V).VConvType))
  else if System.Copy(Name, 1, 2) = 'AS' then
  begin
    if DescriptionToConvType(ConvTypeToFamily(TConvertVarData(V).VConvType),
                             System.Copy(Name, 3, MaxInt), LType) then
      VarConvertCreateInto(Variant(Dest), Convert(TConvertVarData(V).VValue,
                                   TConvertVarData(V).VConvType, LType), LType)
    else
      Result := False;
  end
  else
    Result := False;
end;
```

The *GetProperty* method checks the *Name* parameter to determine what property is wanted. It then retrieves the information from the *TVarData* record of the Variant (*V*), and returns it as a Variant (*Dest*). Note that this method supports properties whose names are dynamically generated at runtime (As[Type]), based on the current value of the custom variant.

Similarly, the *SetProperty*, *DoFunction*, and *DoProcedure* methods are sufficiently generic that you can dynamically generate method names, or respond to variable numbers and types of parameters.

Using TPublishableVariantType

If the custom variant type stores its data using an object instance, then there is an easier way to implement properties, as long as they are also properties of the object that represents the variant's data. If you use *TPublishableVariantType* as the base class for your custom variant type, then you need only implement the *GetInstance* method, and all the published properties of the object that represents the variant's data are automatically implemented for the custom variants.

For example, as was seen in "Storing a custom variant type's data" on page 4-28, *TComplexVariantType* stores the data of a complex-valued variant using an instance of *TComplexData*. *TComplexData* has a number of published properties (*Real*, *Imaginary*, *Radius*, *Theta*, and *FixedTheta*), that provide information about the complex value. *TComplexVariantType* descends from *TPublishableVariantType*, and implements the *GetInstance* method to return the *TComplexData* object (in TypInfo.pas) that is stored in a complex-valued variant's *TVarData* record:

```
function TComplexVariantType.GetInstance(const V: TVarData): TObject;
begin
  Result := TComplexVarData(V).VComplex;
end;
```

TPublishableVariantType does the rest. It overrides the *GetProperty* and *SetProperty* methods to use the runtime type information (RTTI) of the *TComplexData* object for getting and setting property values.

Note For *TPublishableVariantType* to work, the object that holds the custom variant's data must be compiled with RTTI. This means it must be compiled using the {$M+} compiler directive, or descend from *TPersistent*.

Working with strings

Delphi has a number of different character and string types that have been introduced throughout the development of the Object Pascal language. This section is an overview of these types, their purpose, and usage. For language details, see the Object Pascal Language online Help on String types.

Character types

Delphi has three character types: *Char*, *AnsiChar*, and *WideChar*.

The *Char* character type came from standard Pascal, and was used in Turbo Pascal and then in Object Pascal. Later Object Pascal added *AnsiChar* and *WideChar* as specific character types that were used to support standards for character representation on the Windows operating system. *AnsiChar* was introduced to support an 8-bit character ANSI standard, and *WideChar* was introduced to support a 16-bit Unicode standard. The name *WideChar* is used because Unicode characters are also known as wide characters. Wide characters are two bytes instead of one, so that the character set can represent many more different characters. When *AnsiChar* and *WideChar* were implemented, *Char* became the default character type representing the currently recommended implementation. If you use *Char* in your application, remember that its implementation is subject to change in future versions of Delphi.

Note For cross-platform programming: The Linux wchar_t widechar is 32 bits per character. The 16-bit Unicode standard that Object Pascal widechars support is a subset of the 32-bit UCS standard supported by Linux and the GNU libraries. Pascal widechar data must be widened to 32 bits per character before it can be passed to an OS function as wchar_t.

The following table summarizes these character types:

Table 4.2 Object Pascal character types

Type	Bytes	Contents	Purpose
Char	1	A single character	Default character type
AnsiChar	1	A single character	8-bit characters
WideChar	2	A single Unicode character	16-bit Unicode standard.

For more information about using these character types, see the *Object Pascal Language Guide* online Help on Character types For more information about Unicode characters, see the *Object Pascal Language Guide* online Help on About extended character sets.

String types

Delphi has three categories of types that you can use when working with strings:

- Character pointers
- String types
- String classes

This section summarizes string types, and discusses using them with character pointers. For information about using string classes, see the online Help on TStrings.

Delphi has three string implementations: short strings, long strings, and wide strings. Several different string types represent these implementations. In addition, there is a reserved word **string** that defaults to the currently recommended string implementation.

Short strings

String was the first string type used in Turbo Pascal. **String** was originally implemented as a short string. Short strings are an allocation of between 1 and 256 bytes, of which the first byte contains the length of the string and the remaining bytes contain the characters in the string:

```
S: string[0..n]// the original string type
```

When long strings were implemented, **string** was changed to a long string implementation by default and *ShortString* was introduced as a backward compatibility type. *ShortString* is a predefined type for a maximum length string:

```
S: string[255]// the ShortString type
```

The size of the memory allocated for a *ShortString* is static, meaning that it is determined at compile time. However, the location of the memory for the *ShortString* can be dynamically allocated, for example if you use a *PShortString*, which is a pointer to a *ShortString*. The number of bytes of storage occupied by a short string type variable is the maximum length of the short string type plus one. For the *ShortString* predefined type the size is 256 bytes.

Both short strings, declared using the syntax **string**[0..n], and the *ShortString* predefined type exist primarily for backward compatibility with earlier versions of Delphi and Borland Pascal.

A compiler directive, $H, controls whether the reserved word **string** represents a short string or a long string. In the default state, {$H+}, **string** represents a long string. You can change it to a *ShortString* by using the {$H-} directive. The {$H-} state is mostly useful for using code from versions of Object Pascal that used short strings by default. However, short strings can be useful in data structures where you need a fixed-size component or in DLLs when you don't want to use the *ShareMem* unit (see also the online Help on Memory Management). You can locally override the meaning of string-type definitions to ensure generation of short strings. You can also change declarations of short string types to string[255] or *ShortString*, which are unambiguous and independent of the $H setting.

For details about short strings and the *ShortString* type, see the *Object Pascal Language Guide* online Help on Short strings.

Long strings

Long strings are dynamically allocated strings with a maximum length of 2 Gigabytes, but the practical limit is usually dependent on the amount of available memory. Like short strings, long strings use 8-bit Ansi characters and have a length indicator. Unlike short strings, long strings have no zeroth element that contains the dynamic string length. To find the length of a long string you must use the *Length* standard function, and to set the length of a long string you must use the *SetLength* standard procedure. Long strings are also reference-counted and, like *PChars*, long strings are null-terminated. For details about the implementation of longs strings, see the *Object Pascal Language Guide* online Help on Long strings.

Long strings are denoted by the reserved word **string** and by the predefined identifier *AnsiString*. For new applications, it is recommended that you use the long string type. All components in the VCL are compiled in this state, typically using **string**. If you write components, they should also use long strings, as should any code that receives data from string-type properties. If you want to write specific code that always uses a long string, then you should use *AnsiString*. If you want to write flexible code that allows you to easily change the type as new string implementations become standard, then you should use **string**.

WideString

The *WideChar* type allows wide character strings to be represented as arrays of *WideChars*. Wide strings are strings composed of 16-bit Unicode characters. As with long strings, wide strings are dynamically allocated with a maximum length of two Gigabytes, but the practical limit is usually dependent on the amount of available memory. In Delphi, wide strings are not reference-counted. Every assignment of a wide string to a wide string var creates a copy of the string data. In Kylix, WideStrings are reference counted.

The dynamically allocated memory that contains the string is deallocated when the wide string goes out of scope. In all other respects wide strings possess the same attributes as long strings. The *WideString* type is denoted by the predefined identifier *WideString*.

Since the 32-bit version of OLE (Windows only) uses Unicode for all strings, strings must be of wide string type in any OLE automated properties and method parameters. Also, most OLE API functions use null-terminated wide strings.

For more information, see the *Object Pascal Language Guide* topic on WideString.

PChar types

A *PChar* is a pointer to a null-terminated string of characters of the type *Char*. Each of the three character types also has a built-in pointer type:

- A *PChar* is a pointer to a null-terminated string of 8-bit characters.
- A *PAnsiChar* is a pointer to a null-terminated string of 8-bit characters.
- A *PWideChar* is a pointer to a null-terminated string of 16-bit characters.

PChars are, with short strings, one of the original Object Pascal string types. They were created primarily as a C language and Windows API compatibility type.

OpenString

An *OpenString* is obsolete, but you may see it in older code. It is for 16-bit compatibility and is allowed only in parameters. *OpenString* was used, before long strings were implemented, to allow a short string of an unspecified length string to be passed as a parameter. For example, this declaration:

```
procedure a(v : openstring);
```

will allow any length string to be passed as a parameter, where normally the string length of the formal and actual parameters must match exactly. You should not have to use *OpenString* in any new applications you write.

Refer also to the {$P+/-} switch in “Compiler directives for strings” on page 4-49.

Runtime library string handling routines

The runtime library provides many specialized string handling routines specific to a string type. These are routines for wide strings, longs strings, and null-terminated strings (meaning *PChars*). Routines that deal with *PChar* types use the null-termination to determine the length of the string. For more details about null-terminated strings, see Working with null-terminated strings in the *Object Pascal Language Guide* or online Help.

The runtime library also includes a category of string formatting routines. There are no categories of routines listed for *ShortString* types. However, some built-in compiler routines deal with the *ShortString* type. These include, for example, the *Low* and *High* standard functions.

Because wide strings and long strings are the commonly used types, the remaining sections discuss these routines.

Wide character routines

When working with strings you should make sure that the code in your application can handle the strings it will encounter in the various target locales. Sometimes you will need to use wide characters and wide strings. In fact, one approach to working with ideographic character sets is to convert all characters to a wide character encoding scheme such as Unicode. The runtime library includes the following wide character string functions for converting between standard single-byte character strings (or MBCS strings) and Unicode strings:

- StringToWideChar
- WideCharLenToString
- WideCharLenToStrVar
- WideCharToString
- WideCharToStrVar

Using a wide character encoding scheme has the advantage that you can make many of the usual assumptions about strings that do not work for MBCS systems. There is a direct relationship between the number of bytes in the string and the number of characters in the string. You do not need to worry about cutting characters in half or mistaking the second half of a character for the start of a different character.

A disadvantage of working with wide characters is that Windows 95 does not support wide character API function calls. Because of this, the VCL components represent all string values as single byte or MBCS strings. Translating between the wide character system and the MBCS system every time you set a string property or read its value would require tremendous amounts of extra code and slow your application down. However, you may want to translate into wide characters for some special string processing algorithms that need to take advantage of the 1:1 mapping between characters and *WideChars*.

Note Typically, CLX components represent string values as wide strings.

Commonly used long string routines

The long string handling routines cover several functional areas. Within these areas, some are used for the same purpose, the differences being whether or not they use a particular criteria in their calculations. The following tables list these routines by these functional areas:

- Comparison
- Case conversion
- Modification
- Sub-string

Where appropriate, the tables also provide columns indicating whether or not a routine satisfies the following criteria.

- Uses case sensitivity: If locale settings are used, it determines the definition of case. If the routine does not use locale settings, analyses are based upon the ordinal values of the characters. If the routine is case-insensitive, there is a logical merging of upper and lower case characters that is determined by a predefined pattern.

- Uses locale settings: Locale settings allow you to customize your application for specific locales, in particular, for Asian language environments. Most locale settings consider lowercase characters to be less than the corresponding uppercase characters. This is in contrast to ASCII order, in which lowercase characters are greater than uppercase characters. Routines that use the Windows locale are typically prefaced with Ansi (that is, Ansi*XXX*).
- Supports the multi-byte character set (MBCS): MBCSs are used when writing code for far eastern locales. Multi-byte characters are represented as a mix of one- and two-byte character codes, so the length in bytes does not necessarily correspond to the length of the string. The routines that support MBCS are written parse one- and two-byte characters.

ByteType and *StrByteType* determine whether a particular byte is the lead byte of a two-byte character. Be careful when using multi-byte characters not to truncate a string by cutting a two-byte character in half. Do not pass characters as a parameter to a function or procedure, since the size of a character cannot be predetermined. Pass, instead, a pointer to a to a character or string. For more information about MBCS, see “Enabling application code” on page 12-2 of Chapter 12, “Creating international applications.”

Table 4.3 String comparison routines

Routine	Case-sensitive	Uses locale settings	Supports MBCS
AnsiCompareStr	yes	yes	yes
AnsiCompareText	no	yes	yes
AnsiCompareFileName	no	yes	yes
CompareStr	yes	no	no
CompareText	no	no	no

Table 4.4 Case conversion routines

Routine	Uses locale settings	Supports MBCS
AnsiLowerCase	yes	yes
AnsiLowerCaseFileName	yes	yes
AnsiUpperCaseFileName	yes	yes
AnsiUpperCase	yes	yes
LowerCase	no	no
UpperCase	no	no

The routines used for string file names: *AnsiCompareFileName*, *AnsiLowerCaseFileName*, and *AnsiUpperCaseFileName* all use the Windows locale. You should always use file names that are portable because the locale (character set) used for file names can and might differ from the default user interface.

Table 4.5 String modification routines

Routine	Case-sensitive	Supports MBCS
AdjustLineBreaks	NA	yes
AnsiQuotedStr	NA	yes
StringReplace	optional by flag	yes
Trim	NA	yes
TrimLeft	NA	yes
TrimRight	NA	yes
WrapText	NA	yes

Table 4.6 Sub-string routines

Routine	Case-sensitive	Supports MBCS
AnsiExtractQuotedStr	NA	yes
AnsiPos	yes	yes
IsDelimiter	yes	yes
IsPathDelimiter	yes	yes
LastDelimiter	yes	yes
QuotedStr	no	no

Table 4.7 String handling routines

Routine	Case-sensitive	Supports MBCS
AnsiContainsText	no	yes
AnsiEndsText	no	no
AnsiIndexText	no	yes
AnsiMatchText	no	yes
AnsiResemblesText	no	no
AnsiStartsText	no	yes
IfThen	NA	yes
LeftStr	yes	no
RightStr	yes	no
SoundEx	NA	no
SoundExInt	NA	no
DecodeSoundExInt	NA	no
SoundExWord	NA	no
DecodeSoundExWord	NA	no
SoundExSimilar	NA	no
SoundExCompare	NA	no

Declaring and initializing strings

When you declare a long string:

```
S: string;
```

you do not need to initialize it. Long strings are automatically initialized to empty. To test a string for empty you can either use the *EmptyStr* variable:

```
S = EmptyStr;
```

or test against an empty string:

```
S = '';
```

An empty string has no valid data. Therefore, trying to index an empty string is like trying to access **nil** and will result in an access violation:

```
var
  S: string;
begin
  S[i];    // this will cause an access violation
  // statements
end;
```

Similarly, if you cast an empty string to a *PChar*, the result is a **nil** pointer. So, if you are passing such a *PChar* to a routine that needs to read or write to it, be sure that the routine can handle **nil**:

```
var
  S: string;   // empty string
begin
  proc(PChar(S));  // be sure that proc can handle nil
  // statements
end;
```

If it cannot, then you can either initialize the string:

```
S := 'No longer nil';
proc(PChar(S));// proc does not need to handle nil now
```

or set the length, using the *SetLength* procedure:

```
SetLength(S, 100);//sets the dynamic length of S to 100
proc(PChar(S));// proc does not need to handle nil now
```

When you use *SetLength*, existing characters in the string are preserved, but the contents of any newly allocated space is undefined. Following a call to *SetLength*, *S* is guaranteed to reference a unique string, that is a string with a reference count of one. To obtain the length of a string, use the *Length* function.

Remember when declaring a **string** that:

```
S: string[n];
```

implicitly declares a short string, not a long string of *n* length. To declare a long string of specifically *n* length, declare a variable of type **string** and use the *SetLength* procedure.

```
S: string;
SetLength(S, n);
```

Mixing and converting string types

Short, long, and wide strings can be mixed in assignments and expressions, and the compiler automatically generates code to perform the necessary string type conversions. However, when assigning a string value to a short string variable, be aware that the string value is truncated if it is longer than the declared maximum length of the short string variable.

Long strings are already dynamically allocated. If you use one of the built-in pointer types, such as *PAnsiString*, *PString*, or *PWideString*, remember that you are introducing another level of indirection. Be sure this is what you intend.

Additional functions (*CopyQStringListToTstrings, Copy TStringsToQStringList, QStringListToTStringList*) are provided for converting underlying Qt string types and CLX string types. These functions are located in Qtypes.pas.

String to PChar conversions

Long string to *PChar* conversions are not automatic. Some of the differences between strings and *PChars* can make conversions problematic:

- Long strings are reference-counted, while *PChars* are not.
- Assigning to a string copies the data, while a *PChar* is a pointer to memory.
- Long strings are null-terminated and also contain the length of the string, while *PChars* are simply null-terminated.

Situations in which these differences can cause subtle errors are discussed in this section.

String dependencies

Sometimes you will need convert a long string to a null-terminated string, for example, if you are using a function that takes a *PChar*. If you must cast a string to a *PChar*, be aware that you are responsible for the lifetime of the resulting *PChar*. Because long strings are reference counted, typecasting a string to a *PChar* increases the dependency on the string by one, without actually incrementing the reference count. When the reference count hits zero, the string will be destroyed, even though there is an extra dependency on it. The cast *PChar* will also disappear, while the routine you passed it to may still be using it. For example:

```
procedure my_func(x: string);
begin
  // do something with x
  some_proc(PChar(x)); // cast the string to a PChar
  // you now need to guarantee that the string remains
  // as long as the some_proc procedure needs to use it
end;
```

Returning a PChar local variable

A common error when working with *PChars* is to store in a data structure, or return as a value, a local variable. When your routine ends, the *PChar* will disappear because it is simply a pointer to memory, and is not a reference counted copy of the string. For example:

```
function title(n: Integer): PChar;
var
  s: string;
begin
  s := Format(‘title - %d’, [n]);
  Result := PChar(s); // DON’T DO THIS
end;
```

This example returns a pointer to string data that is freed when the *title* function returns.

Passing a local variable as a PChar

Consider that you have a local string variable that you need to initialize by calling a function that takes a *PChar*. One approach is to create a local **array of char** and pass it to the function, then assign that variable to the string:

```
// VCL version
// assume MAXSIZE is a predefined constant
var
  i: Integer;
  buf: array[0..MAX_SIZE] of char;
  S: string;
begin
  i := GetModuleFilename(0, @buf, SizeOf(buf));// treats @buf as a PChar
  S := buf;
  //statements
end;
```

Or, for cross-platform programs, the code is nearly identical:

```
// assume FillBuffer is a predefined function
function FillBuffer(Buf:PChar;Count:Integer):Integer
begin
  . . .
end;

// assume MAX_SIZE is a predefined constant
var
  i: Integer;
  buf: array[0..MAX_SIZE] of char;
  S: string;
begin
  i := FillBuffer(0, @buf, SizeOf(buf));// treats @buf as a PChar
  S := buf;
  //statements
end;
```

This approach is useful if the size of the buffer is relatively small, since it is allocated on the stack. It is also safe, since the conversion between an **array of char** and a **string** is automatic. When *GetModuleFilename* (or *FillBuffer* in the cross-platform version) returns, the *Length* of the string correctly indicates the number of bytes written to *buf*.

To eliminate the overhead of copying the buffer, you can cast the string to a *PChar* (if you are certain that the routine does not need the *PChar* to remain in memory). However, synchronizing the length of the string does not happen automatically, as it does when you assign an **array of char** to a **string**. You should reset the string *Length* so that it reflects the actual width of the string. If you are using a function that returns the number of bytes copied, you can do this safely with one line of code:

```
var
  S: string;
begin
  SetLength(S, MAX_SIZE;// when casting to a PChar, be sure the string is not empty
  SetLength(S, GetModuleFilename( 0, PChar(S), Length(S) ) );
  // statements
end;
```

Compiler directives for strings

The following compiler directives affect character and string types.

Table 4.8 Compiler directives for strings

Directive	Description
{$H+/-}	A compiler directive, $H, controls whether the reserved word **string** represents a short string or a long string. In the default state, {$H+}, **string** represents a long string. You can change it to a *ShortString* by using the {$H-} directive.
{$P+/-}	The $P directive is meaningful only for code compiled in the {$H-} state, and is provided for backwards compatibility. $P controls the meaning of variable parameters declared using the string keyword in the {$H-} state. In the {$P-} state, variable parameters declared using the string keyword are normal variable parameters, but in the {$P+} state, they are open string parameters. Regardless of the setting of the $P directive, the OpenString identifier can always be used to declare open string parameters.

{$V+/-}	The $V directive controls type checking on short strings passed as variable parameters. In the {$V+} state, strict type checking is performed, requiring the formal and actual parameters to be of identical string types.
	In the {$V-} (relaxed) state, any short string type variable is allowed as an actual parameter, even if the declared maximum length is not the same as that of the formal parameter. Be aware that this could lead to memory corruption. For example:
	`var S: string[3];`
	`procedure Test(var T: string);`
	`begin`
	`  T := ‘1234’;`
	`end;`
	`begin`
	`  Test(S);`
	`end.`

{$X+/-}	The {$X+} compiler directive enables support for null-terminated strings by activating the special rules that apply to the built-in *PChar* type and zero-based character arrays. (These rules allow zero-based arrays and character pointers to be used with *Write*, *Writeln*, *Val*, *Assign*, and *Rename* from the System unit.)

Strings and characters: related topics

The following *Object Pascal Language Guide* topics discuss strings and character sets. Also see Chapter 12, “Creating international applications.”

- About extended character sets (Discusses international character sets)
- Working with null-terminated strings (Contains information about character arrays)
- Character strings
- Character pointers
- String operators

Working with files

This section describes working with files and distinguishes between manipulating files on disk, and input/output operations such as reading and writing to files. The first section discusses the runtime library and Windows API routines you would use for common programming tasks that involve manipulating files on disk. The next section is an overview of file types used with file I/O. The last section focuses on the recommended approach to working with file I/O, which is to use file streams.

Although the Object Pascal language is not case sensitive, the Linux operating system is. Be attentive to case when working with files in cross-platform applications.

Note Previous versions of the Object Pascal language performed operations on files themselves, rather than on the filename parameters commonly used now. With these file types you had to locate a file and assign it to a file variable before you could, for example, rename the file.

Manipulating files

Several common file operations are built into Object Pascal's runtime library. The procedures and functions for working with files operate at a high level. For most routines, you specify the name of the file and the routine makes the necessary calls to the operating system for you. In some cases, you use file handles instead. Object Pascal provides routines for most file manipulation. When it does not, alternative routines are discussed.

Caution Although the Object Pascal language is not case sensitive, the Linux operating system is. Be attentive to case when working with files in cross-platform applications.

Deleting a file

Deleting a file erases the file from the disk and removes the entry from the disk's directory. There is no corresponding operation to restore a deleted file, so applications should generally allow users to confirm deletions of files. To delete a file, pass the name of the file to the *DeleteFile* function:

```
DeleteFile(FileName);
```

DeleteFile returns *True* if it deleted the file and *False* if it did not (for example, if the file did not exist or if it was read-only). *DeleteFile* erases the file named by *FileName* from the disk.

Finding a file

There are three routines used for finding a file: *FindFirst*, *FindNext*, and *FindClose*. *FindFirst* searches for the first instance of a filename with a given set of attributes in a specified directory. *FindNext* returns the next entry matching the name and attributes specified in a previous call to *FindFirst*. *FindClose* releases memory allocated by *FindFirst*. You should always use *FindClose* to terminates a *FindFirst*/*FindNext* sequence. If you want to know if a file exists, a *FileExists* function returns *True* if the file exists, *False* otherwise.

The three file find routines take a *TSearchRec* as one of the parameters. *TSearchRec* defines the file information searched for by *FindFirst* or *FindNext*. The declaration for *TSearchRec* is:

```
type
  TFileName = string;
  TSearchRec = record
    Time: Integer;//Time contains the time stamp of the file.
    Size: Integer;//Size contains the size of the file in bytes.
    Attr: Integer;//Attr represents the file attributes of the file.
    Name: TFileName;//Name contains the filename and extension.
    ExcludeAttr: Integer;
    FindHandle: THandle;
    FindData: TWin32FindData;//FindData contains additional information such as
    //file creation time, last access time, long and short filenames.
  end;
```

If a file is found, the fields of the *TSearchRec* type parameter are modified to describe the found file. You can test *Attr* against the following attribute constants or values to determine if a file has a specific attribute:

Table 4.9 Attribute constants and values

Constant	Value	Description
faReadOnly	$00000001	Read-only files
faHidden	$00000002	Hidden files
faSysFile	$00000004	System files
faVolumeID	$00000008	Volume ID files
faDirectory	$00000010	Directory files
faArchive	$00000020	Archive files
faAnyFile	$0000003F	Any file

To test for an attribute, combine the value of the *Attr* field with the attribute constant with the **and** operator. If the file has that attribute, the result will be greater than 0. For example, if the found file is a hidden file, the following expression will evaluate to *True*: (*SearchRec.Attr* and *faHidden* > 0). Attributes can be combined by OR'ing their constants or values. For example, to search for read-only and hidden files in addition to normal files, pass (*faReadOnly* or *faHidden*) the *Attr* parameter.

Example: This example uses a label, a button named *Search*, and a button named *Again* on a form. When the user clicks the *Search* button, the first file in the specified path is found, and the name and the number of bytes in the file appear in the label's caption. Each time the user clicks the *Again* button, the next matching filename and size is displayed in the label:

```
var
  SearchRec: TSearchRec;

procedure TForm1.SearchClick(Sender: TObject);
begin
  FindFirst('c:\Program Files\delphi6\bin\*.*', faAnyFile, SearchRec);
  Label1.Caption := SearchRec.Name + ' is ' + IntToStr(SearchRec.Size) + ' bytes in size';
end;

procedure TForm1.AgainClick(Sender: TObject);
begin
  if (FindNext(SearchRec) = 0)
    Label1.Caption := SearchRec.Name + ' is ' + IntToStr(SearchRec.Size) + ' bytes in size';
  else
    FindClose(SearchRec);
end;
```

In cross-platform applications, you should replace any hardcoded pathnames such as c:\Program Files\delphi6\bin\*.* with the correct pathname for the system or use environment variables (on the Environment Variables page when you choose Tools | Environment Options) to represent them.

Renaming a file

To change a filename, simply use the *RenameFile* function:

```
function RenameFile(const OldFileName, NewFileName: string): Boolean;
```

which changes a filename, identified by *OldFileName*, to the name specified by *NewFileName*. If the operation succeeds, *RenameFile* returns *True*. If it cannot rename the file, for example, if a file called *NewFileName* already exists, it returns *False*. For example:

```
if not RenameFile('OLDNAME.TXT','NEWNAME.TXT') then
  ErrorMsg('Error renaming file!');
```

You cannot rename (move) a file across drives using *RenameFile*. You would need to first copy the file and then delete the old one.

Note *RenameFile* in the VCL is a wrapper around the Windows API *MoveFile* function, so *MoveFile* will not work across drives either.

File date-time routines

The *FileAge*, *FileGetDate*, and *FileSetDate* routines operate on operating system date-time values. *FileAge* returns the date-and-time stamp of a file, or -1 if the file does not exist. *FileSetDate* sets the date-and-time stamp for a specified file, and returns zero on success or an error code on failure. *FileGetDate* returns a date-and-time stamp for the specified file or -1 if the handle is invalid.

As with most of the file manipulating routines, *FileAge* uses a string filename. *FileGetDate* and *FileSetDate*, however, take a *Handle* type as a parameter. To get access to a Windows file *Handle* either

- Call the Windows API *CreateFile* function. *CreateFile* is a 32-bit only function that creates or opens a file and returns a *Handle* that can be used to access the file.
- Instantiate *TFileStream* to create or open a file. Then use the *Handle* property as you would a Windows' file *Handle*. See "Using file streams" on page 4-54 for more information.

Copying a file

The runtime library does not provide any routines for copying a file. However, if you are writing Windows-only applications, you can directly call the Windows API *CopyFile* function to copy a file. Like most of the Delphi runtime library file routines, *CopyFile* takes a filename as a parameter, not a *Handle*. When copying a file, be aware that the file attributes for the existing file are copied to the new file, but the security attributes are not. *CopyFile* is also useful when moving files across drives because neither the Delphi *RenameFile* function nor the Windows API *MoveFile* function can rename/move files across drives. For more information, see the Microsoft Windows online Help.

File types with file I/O

You can use three file types when working with file I/O: Pascal file types, file handles, and file stream objects. The following table summarizes these types.

Table 4.10 File types for file I/O

File type	Description
Pascal file types	In the System unit. These types are used with file variables, usually of the format "F: Text:" or "F: File". The files have three types: typed, text, and untyped. A number of file-handling routines, such as *AssignPrn* and *writeln,* use them. These file types are obsolete and are incompatible with Windows file handles. If you need to work with them, see the *Object Pascal Language Guide*.
File handles	In the Sysutils unit. A number of routines use a handle to identify the file. You get the handle when you open or create the file (for example, using FileOpen or FileCreate). Once you have the handle, there are routines to work with the contents of the file given its handle (write a line, read text, and so on). In Windows programming, the Object Pascal file handles are wrappers for the Windows file handle type. The runtime library file-handling routines that use Windows file Handles are typically wrappers around Windows API functions. For example, the FileRead calls the Windows ReadFile function. Because the Delphi functions use Object Pascal syntax, and occasionally provide default parameter values, they are a convenient interface to the Windows API. Using these routines is straightforward, and if you are familiar and comfortable with the Windows API file routines, you may want to use them when working with file I/O.
File streams	File streams are object instances of the *TFileStream* class used to access information in disk files. File streams are a portable and high-level approach to file I/O. *TFileStream* has a *Handle* property that lets you access the file handle. The next section discusses *TFileStream*.

Using file streams

TFileStream is a class that enables applications to read from and write to a file on disk. It is used for high-level object representations of file streams. *TFileStream* offers multiple functionality: persistence, interaction with other streams, and file I/O.

- *TFileStream* is a descendant of the stream classes. As such, one advantage of using file streams is that they inherit the ability to persistently store component properties. The stream classes work with the *TFiler* classes, *TReader,* and *TWriter*, to stream objects out to disk. Therefore, when you have a file stream, you can use that same code for the component streaming mechanism. For more information about using the component streaming system, see the online Help on the *TStream*, *TFiler*, *TReader*, *TWriter*, and *TComponent* classes.
- *TFileStream* can interact easily with other stream classes. For example, if you want to dump a dynamic memory block to disk, you can do so using a *TFileStream* and a *TMemoryStream*.
- *TFileStream* provides the basic methods and properties for file I/O. The remaining sections focus on this aspect of file streams

Creating and opening files

To create or open a file and get access to a handle for the file, you simply instantiate a *TFileStream*. This opens or creates a named file and provides methods to read from or write to it. If the file cannot be opened, *TFileStream* raises an exception.

```
constructor Create(const filename: string; Mode: Word);
```

The *Mode* parameter specifies how the file should be opened when creating the file stream. The *Mode* parameter consists of an open mode and a share mode or'ed together. The open mode must be one of the following values:

Table 4.11 Open modes

Value	Meaning
fmCreate	TFileStream a file with the given name. If a file with the given name exists, open the file in write mode.
fmOpenRead	Open the file for reading only.
fmOpenWrite	Open the file for writing only. Writing to the file completely replaces the current contents.
fmOpenReadWrite	Open the file to modify the current contents rather than replace them.

The share mode can be one of the following values with the restrictions listed below:

Table 4.12 Shared modes

Value	Meaning
fmShareCompat	Sharing is compatible with the way FCBs are opened.
fmShareExclusive	Other applications can not open the file for any reason.
fmShareDenyWrite	Other applications can open the file for reading but not for writing.
fmShareDenyRead	Other applications can open the file for writing but not for reading.
fmShareDenyNone	No attempt is made to prevent other applications from reading from or writing to the file.

Note that which share mode you can use depends on which open mode you used. The following table shows shared modes that are available for each open mode.

Table 4.13 Shared modes available for each open mode

Open Mode	fmShareCompat	fmShareExclusive	fmShareDenyWrite	fmShareDenyRead	fmShareDenyNone
fmOpenRead	Can't use	Can't use	Available	Can't use	Available
fmOpenWrite	Available	Available	Can't use	Available	Available
fmOpenReadWrite	Available	Available	Available	Available	Available

The file open and share mode constants are defined in the SysUtils unit.

Using the file handle

When you instantiate *TFileStream* you get access to the file handle. The file handle is contained in the *Handle* property. *Handle* is read-only and indicates the mode in which the file was opened. If you want to change the attributes of the file *Handle*, you must create a new file stream object.

Some file manipulation routines take a window's file handle as a parameter. Once you have a file stream, you can use the *Handle* property in any situation in which you would use a window's file handle. Be aware that, unlike handle streams, file streams close file handles when the object is destroyed.

Reading and writing to files

TFileStream has several different methods for reading from and writing to files. These are distinguished by whether they perform the following:

- Return the number of bytes read or written.
- Require the number of bytes is known.
- Raise an exception on error.

Read is a function that reads up to *Count* bytes from the file associated with the file stream, starting at the current *Position*, into *Buffer*. *Read* then advances the current position in the file by the number of bytes actually transferred. The prototype for *Read* is

```
function Read(var Buffer; Count: Longint): Longint; override;
```

Read is useful when the number of bytes in the file is not known. *Read* returns the number of bytes actually transferred, which may be less than *Count* if the end of file marker is encountered.

Write is a function that writes *Count* bytes from the *Buffer* to the file associated with the file stream, starting at the current *Position*. The prototype for *Write* is:

```
function Write(const Buffer; Count: Longint): Longint; override;
```

After writing to the file, *Write* advances the current position by the number bytes written, and returns the number of bytes actually written, which may be less than *Count* if the end of the buffer is encountered.

The counterpart procedures are *ReadBuffer* and *WriteBuffer* which, unlike *Read* and *Write*, do not return the number of bytes read or written. These procedures are useful in cases where the number of bytes is known and required, for example when reading in structures. *ReadBuffer* and *WriteBuffer* raise an exception on error (*EReadError* and *EWriteError*) while the *Read* and *Write* methods do not. The prototypes for *ReadBuffer* and *WriteBuffer* are:

```
procedure ReadBuffer(var Buffer; Count: Longint);
```

```
procedure WriteBuffer(const Buffer; Count: Longint);
```

These methods call the *Read* and *Write* methods, to perform the actual reading and writing.

Reading and writing strings

If you are passing a string to a read or write function, you need to be aware of the correct syntax. The *Buffer* parameters for the read and write routines are **var** and **const** types, respectively. These are untyped parameters, so the routine takes the address of a variable.

The most commonly used type when working with strings is a long string. However, passing a long string as the *Buffer* parameter does not produce the correct result. Long strings contain a size, a reference count, and a pointer to the characters in the string. Consequently, dereferencing a long string does not result in only the pointer element. What you need to do is first cast the string to a *Pointer* or *PChar,* and then dereference it. For example:

```
procedure caststring;
var
  fs: TFileStream;
const
  s: string = 'Hello';
begin
  fs := TFileStream.Create('temp.txt', fmCreate or fmOpenWrite);
  fs.Write(s, Length(s));// this will give you garbage
  fs.Write(PChar(s)^, Length(s));// this is the correct way
end;
```

Seeking a file

Most typical file I/O mechanisms have a process of seeking a file in order to read from or write to a particular location within it. For this purpose, *TFileStream* has a *Seek* method. The prototype for *Seek* is:

```
function Seek(Offset: Longint; Origin: Word): Longint; override;
```

The *Origin* parameter indicates how to interpret the *Offset* parameter. *Origin* should be one of the following values:

Value	Meaning
soFromBeginning	Offset is from the beginning of the resource. Seek moves to the position Offset. Offset must be >= 0.
soFromCurrent	Offset is from the current position in the resource. Seek moves to Position + Offset.
soFromEnd	Offset is from the end of the resource. Offset must be <= 0 to indicate a number of bytes before the end of the file.

Seek resets the current *Position* of the stream, moving it by the indicated offset. *Seek* returns the new value of the *Position* property, the new current position in the resource.

File position and size

TFileStream has properties that hold the current position and size of the file. These are used by the *Seek*, read, and write methods.

The *Position* property of *TFileStream* is used to indicate the current offset, in bytes, into the stream (from the beginning of the streamed data). The declaration for *Position* is:

```
property Position: Longint;
```

The *Size* property indicates the size in bytes of the stream. It is used as an end of file marker to truncate the file. The declaration for *Size* is:

```
property Size: Longint;
```

Size is used internally by routines that read and write to and from the stream.

Setting the *Size* property changes the size of the file. If the *Size* of the file cannot be changed, an exception is raised. For example, trying to change the *Size* of a file that was opened in *fmOpenRead* mode raises an exception.

Copying

CopyFrom copies a specified number of bytes from one (file) stream to another.

```
function CopyFrom(Source: TStream; Count: Longint): Longint;
```

Using *CopyFrom* eliminates the need to create, read into, write from, and free a buffer when copying data.

CopyFrom copies *Count* bytes from *Source* into the stream. *CopyFrom* then moves the current position by *Count* bytes, and returns the number of bytes copied. If *Count* is 0, *CopyFrom* sets *Source* position to 0 before reading and then copies the entire contents of *Source* into the stream. If *Count* is greater than or less than 0, *CopyFrom* reads from the current position in *Source*.

Converting measurements

The ConvUtils unit declares a general-purpose *Convert* function that you can use to convert a measurement from one set of units to another. You can perform conversions between compatible units of measurement such as feet and inches or days and weeks. Units that measure the same types of things are said to be in the same *conversion family*. The units you're converting must be in the same conversion family. For information on doing conversions, see the next section Performing conversions and refer to *Convert* in the online Help.

The StdConvs unit defines several conversion families and measurement units within each family. In addition, you can create customized conversion families and associated units using the *RegisterConversionType* and *RegisterConversionFamily* functions. For information on extending conversion and conversion units, see the section Adding new measurement types and refer to Convert in the online Help.

Performing conversions

You can use the *Convert* function to perform both simple and complex conversions. It includes a simple syntax and a second syntax for performing conversions between complex measurement types.

Performing simple conversions

You can use the *Convert* function to convert a measurement from one set of units to another. The *Convert* function converts between units that measure the same type of thing (distance, area, time, temperature, and so on).

To use *Convert*, you must specify the units from which to convert and to which to convert. You use the *TConvType* type to identify the units of measurement.

For example, this converts a temperature from degrees Fahrenheit to degrees Kelvin:

```
TempInKelvin := Convert(StrToFloat(Edit1.Text), tuFahrenheit, tuKelvin);
```

Performing complex conversions

You can also use the *Convert* function to perform more complex conversions between the ratio of two measurement types. Examples of when you might need to use this this are when converting miles per hour to meters per minute for calculating speed or when converting gallons per minute to liters per hour for calculating flow.

For example, the following call converts miles per gallon to kilometers per liter:

```
nKPL := Convert(StrToFloat(Edit1.Text), duMiles, vuGallons, duKilometers, vuLiter);
```

The units you're converting must be in the same conversion family (they must measure the same thing). If the units are not compatible, *Convert* raises an *EConversionError* exception. You can check whether two *TConvType* values are in the same conversion family by calling *CompatibleConversionTypes*.

The StdConvs unit defines several families of *TConvType* values. See Conversion family variables in the online Help for a list of the predefined families of measurement units and the measurement units in each family.

Adding new measurement types

If you want to perform conversions between measurement units not already defined in the StdConvs unit, you need to create a new conversion family to represent the measurement units (*TConvType* values). When two *TConvType* values are registered with the same conversion family, the *Convert* function can convert between measurements made using the units represented by those *TConvType* values.

You first need to obtain *TConvFamily* values by registering a conversion family using the *RegisterConversionFamily* function. After you get a *TConvFamily* value (by registering a new conversion family or using one of the global variables in the StdConvs unit), you can use the *RegisterConversionType* function to add the new units to the conversion family. The following examples show how to do this.

For more examples, refer to the source code for the standard conversions unit (stdconvs.pas). (Note that the source is not included in all versions of Delphi.)

Creating a simple conversion family and adding units

One example of when you could create a new conversion family and add new measurement types might be when performing conversions between long periods of time (such as months to centuries) where a loss of precision can occur.

To explain this further, the *cbTime* family uses a day as its base unit. The base unit is the one that is used when performing all conversions within that family. Therefore, all conversions must be done in terms of days. An inaccuracy can occur when performing conversions using units of months or larger (months, years, decades, centuries, millennia) because there is not an exact conversion between days and months, days and years, and so on. Months have different lengths; years have correction factors for leap years, leap seconds, and so on.

If you are only using units of measurement greater than or equal to months, you can create a more accurate conversion family with years as its base unit. This example creates a new conversion family called *cbLongTime*.

Declare variables

First, you need to declare variables for the identifiers. The identifiers are used in the new LongTime conversion family, and the units of measurement that are its members:

```
var
  cbLongTime: TConvFamily;
  ltMonths: TConvType;
  ltYears: TConvType;
  ltDecades: TConvType;
  ltCenturies: TConvType;
  ltMillennia: TConvType;
```

Register the conversion family

Next, register the conversion family:

```
cbLongTime := RegisterConversionFamily ('Long Times');
```

Although an *UnregisterConversionFamily* procedure is provided, you don't need to unregister conversion families unless the unit that defines them is removed at runtime. They are automatically cleaned up when your application shuts down.

Register measurement units

Next, you need to register the measurement units within the conversion family that you just created. You use the *RegisterConversionType* function, which registers units of measurement within a specified family. You need to define the base unit which in the example is years, and the other units are defined using a factor that indicates their relation to the base unit. So, the factor for *ltMonths* is 1/12 because the base unit for the LongTime family is years. You also include a description of the units to which you are converting.

The code to register the measurement units is shown here:

```
ltMonths:=RegisterConversionType(cbLongTime,'Months',1/12);
ltYears:=RegisterConversionType(cbLongTime,'Years',1);
ltDecades:=RegisterConversionType(cbLongTime,'Decades',10);
ltCenturies:=RegisterConversionType(cbLongTime,'Centuries',100);
ltMillennia:=RegisterConversionType(cbLongTime,'Millennia',1000);
```

Use the new units

You can now use the newly registered units to perform conversions. The global *Convert* function can convert between any of the conversion types that you registered with the *cbLongTime* conversion family.

So instead of using the following *Convert* call,

```
Convert(StrToFloat(Edit1.Text),tuMonths,tuMillennia);
```

you can now use this one for greater accuracy:

```
Convert(StrToFloat(Edit1.Text),ltMonths,ltMillennia);
```

Using a conversion function

For cases when the conversion is more complex, you can use a different syntax to specify a function to perform the conversion instead of using a conversion factor. For example, you can't convert temperature values using a conversion factor, because different temperature scales have a different origins.

This example, which comes from the StdConvs unit, shows how to register a conversion type by providing functions to convert to and from the base units.

Declare variables

First, declare variables for the identifiers. The identifiers are used in the *cbTemperature* conversion family, and the units of measurement are its members:

```
var
   cbTemperature: TConvFamily;
   tuCelsius: TConvType;
   tuKelvin: TConvType;
   tuFahrenheit: TConvType;
```

Note The units of measurement listed here are a subset of the temperature units actually registered in the *StdConvs* unit.

Register the conversion family

Next, register the conversion family:

```
cbTemperature := RegisterConversionFamily ('Temperature');
```

Register the base unit

Next, define and register the base unit of the conversion family, which in the example is degrees Celsius. Note that in the case of the base unit, we can use a simple conversion factor, because there is no actual conversion to make:

```
tuCelsius:=RegisterConversionType(cbTemperature,'Celsius',1);
```

Write methods to convert to and from the base unit

You need to write the code that performs the conversion from each temperature scale to and from degrees Celsius, because these do not rely on a simple conversion factor. These functions are taken from the StdConvs unit:

```
function FahrenheitToCelsius(const AValue: Double): Double;
begin
  Result := ((AValue - 32) * 5) / 9;
end;

function CelsiusToFahrenheit(const AValue: Double): Double;
begin
  Result := ((AValue * 9) / 5) + 32;
end;

function KelvinToCelsius(const AValue: Double): Double;
begin
  Result := AValue - 273.15;
end;

function CelsiusToKelvin(const AValue: Double): Double;
begin
  Result := AValue + 273.15;
end;
```

Register the other units

Now that you have the conversion functions, you can register the other measurement units within the conversion family. You also include a description of the units.

The code to register the other units in the family is shown here:

```
tuKelvin := RegisterConversionType(cbTemperature, 'Kelvin', KelvinToCelsius,
CelsiusToKelvin);
  tuFahrenheit := RegisterConversionType(cbTemperature, 'Fahrenheit', FahrenheitToCelsius,
CelsiusToFahrenheit);
```

Use the new units

You can now use the newly registered units to perform conversions in your applications. The global *Convert* function can convert between any of the conversion types that you registered with the *cbTemperature* conversion family. For example the following code converts a value from degrees Fahrenheit to degrees Kelvin.

```
Convert(StrToFloat(Edit1.Text), tuFahrenheit, tuKelvin);
```

Using a class to manage conversions

You can always use conversion functions to register a conversion unit. There are times, however, when this requires you to create an unnecessarily large number of functions that all do essentially the same thing.

If you can write a set of conversion functions that differ only in the value of a parameter or variable, you can create a class to handle those conversions. For example, there is a set standard techniques for converting between the various European currencies since the introduction of the Euro. Even though the conversion factors remain constant (unlike the conversion factor between, say, dollars and Euros), you can't use a simple conversion factor approach to properly convert between European currencies for two reasons:

- The conversion must round to a currency-specific number of digits.
- The conversion factor approach uses an inverse factor to the one specified by the standard Euro conversions.

However, this can all be handled by the conversion functions such as the following:

```
function FromEuro(const AValue: Double, Factor, FRound): Double;
begin
  Result := RoundTo(AValue * Factor, FRound);
end;

function ToEuro(const AValue: Double, Factor): Double;
begin
  Result := AValue / Factor;
end;
```

The problem is, this approach requires extra parameters on the conversion function, which means you can't simply register the same function with every European currency. In order to avoid having to write two new conversion functions for every European currency, you can make use of the same two functions by making them the members of a class.

Creating the conversion class

The class must be a descendant of *TConvTypeFactor*. *TConvTypeFactor* defines two methods, *ToCommon* and *FromCommon*, for converting to and from the base units of a conversion family (in this case, to and from Euros). Just as with the functions you use directly when registering a conversion unit, these methods have no extra parameters, so you must supply the number of digits to round off and the conversion factor as private members of your conversion class. This is shown in the EuroConv example in the demos\ConvertIt directory (see euroconv.pas):

```
type
  TConvTypeEuroFactor = class(TConvTypeFactor)
  private
    FRound: TRoundToRange;
  public
    constructor Create(const AConvFamily: TConvFamily;
      const ADescription: string; const AFactor: Double;
      const ARound: TRoundToRange);
    function ToCommon(const AValue: Double): Double; override;
    function FromCommon(const AValue: Double): Double; override;
  end;
end;
```

The constructor assigns values to those private members:

```
constructor TConvTypeEuroFactor.Create(const AConvFamily: TConvFamily;
  const ADescription: string; const AFactor: Double;
  const ARound: TRoundToRange);
begin
  inherited Create(AConvFamily, ADescription, AFactor);
  FRound := ARound;
end;
```

The two conversion functions simply use these private members:

```
function TConvTypeEuroFactor.FromCommon(const AValue: Double): Double;
begin
  Result := SimpleRoundTo(AValue * Factor, FRound);
end;

function TConvTypeEuroFactor.ToCommon(const AValue: Double): Double;
begin
  Result := AValue / Factor;
end;
```

Declare variables

Now that you have a conversion class, begin as with any other conversion family, by declaring identifiers:

```
var
  euEUR: TConvType; { EU euro }
  euBEF: TConvType; { Belgian francs }
  euDEM: TConvType; { German marks }
  euGRD: TConvType; { Greek drachmas }
  euESP: TConvType; { Spanish pesetas }
  euFFR: TConvType; { French francs }
  euIEP: TConvType; { Irish pounds }
  euITL: TConvType; { Italian lire }
  euLUF: TConvType; { Luxembourg francs }
  euNLG: TConvType; { Dutch guilders }
```

```
    euATS: TConvType; { Austrian schillings }
    euPTE: TConvType; { Portuguese escudos }
    euFIM: TConvType; { Finnish marks }
    euUSD: TConvType; { US dollars }
    euGBP: TConvType; { British pounds }
    euJPY: TConvType; { Japanese yen }
```

Register the conversion family and the other units

Now you are ready to register the conversion family and the European monetary units, using your new conversion class:

```
cbEuro := RegisterConversionFamily ('European currency');
...
// Euro's various conversion types
euEUR := RegisterEuroConversionType(cbEuro, SEURDescription, EURToEUR, EURSubUnit);
euBEF := RegisterEuroConversionType(cbEuro, SBEFDescription, BEFToEUR, BEFSubUnit);
euDEM := RegisterEuroConversionType(cbEuro, SDEMDescription, DEMToEUR, DEMSubUnit);
euGRD := RegisterEuroConversionType(cbEuro, SGRDDescription, GRDToEUR, GRDSubUnit);
euESP := RegisterEuroConversionType(cbEuro, SESPDescription, ESPToEUR, ESPSubUnit);
euFFR := RegisterEuroConversionType(cbEuro, SFFRDescription, FFRToEUR, FFRSubUnit);
euIEP := RegisterEuroConversionType(cbEuro, SIEPDescription, IEPToEUR, IEPSubUnit);
euITL := RegisterEuroConversionType(cbEuro, SITLDescription, ITLToEUR, ITLSubUnit);
euLUF := RegisterEuroConversionType(cbEuro, SLUFDescription, LUFToEUR, LUFSubUnit);
euNLG := RegisterEuroConversionType(cbEuro, SNLGDescription, NLGToEUR, NLGSubUnit);
euATS := RegisterEuroConversionType(cbEuro, SATSDescription, ATSToEUR, ATSSubUnit);
euPTE := RegisterEuroConversionType(cbEuro, SPTEDescription, PTEToEUR, PTESubUnit);
euFIM := RegisterEuroConversionType(cbEuro, SFIMDescription, FIMToEUR, FIMSubUnit);
euUSD := RegisterEuroConversionType(cbEuro, SUSDDescription,
                                    ConvertUSDToEUR, ConvertEURToUSD);
euGBP := RegisterEuroConversionType(cbEuro, SGBPDescription,
                                    ConvertGBPToEUR, ConvertEURToGBP);
euJPY := RegisterEuroConversionType(cbEuro, SJPYDescription,
                                    ConvertJPYToEUR, ConvertEURToJPY);
```

Note that *RegisterEuroConversionType* is a wrapper function that simplifies the registering of the monetary types. See the example code for details.

Use the new units

You can now use the newly registered units to perform conversions in your applications. The global *Convert* function can convert between any of the European currencies you have registered with the new cbEuro family. For example, the following code converts a value from Italian Lire to German Marks:

```
Edit2.Text = FloatToStr(Convert(StrToFloat(Edit1.Text), euITL, euDEM));
```

Defining data types

Object Pascal has many predefined data types. You can use these predefined types to create new types that meet the specific needs of your application. For an overview of types, see the *Object Pascal Language Guide*.

Chapter 5

Building applications, components, and libraries

This chapter provides an overview of how to use Delphi to create applications, libraries, and components.

Creating applications

The main use of Delphi is designing and building the following types of applications:

- GUI applications
- Console applications
- Service applications (for Windows applications only)
- Packages and DLLs

GUI applications generally have an easy-to-use interface. Console applications run from a console window. Service applications are run as Windows services. These types of applications compile as executables with start-up code.

You can create other types of projects such as packages and DLLs that result in creating packages or dynamically linkable libraries. These applications produce executable code without start-up code. Refer to "Creating packages and DLLs" on page 5-9.

GUI applications

A graphical user interface (GUI) application is one that is designed using graphical features such as windows, menus, dialog boxes, and features that make the application easy to use. When you compile a GUI application, an executable file with start-up code is created. The executable usually provides the basic functionality of your program, and simple programs often consist of only an executable file. You can extend the application by calling DLLs, packages, and other support files from the executable.

Delphi offers two application UI models:

- Single document interface (SDI)
- Multiple document interface (MDI)

In addition to the implementation model of your applications, the design-time behavior of your project and the runtime behavior of your application can be manipulated by setting project options in the IDE.

User interface models

Any form can be implemented as a multiple document interface (MDI) or single document interface (SDI) form. In an MDI application, more than one document or child window can be opened within a single parent window. This is common in applications such as spreadsheets or word processors. An SDI application, in contrast, normally contains a single document view. To make your form an SDI application, set the *FormStyle* property of your *Form* object to *fsNormal*.

For more information on developing the UI for an application, see Chapter 6, "Developing the application user interface."

SDI applications

To create a new SDI application,

1. Select File | New | Other to bring up the New Items dialog.
2. Click on the Projects page and select SDI Application.
3. Click OK.

By default, the *FormStyle* property of your *Form* object is set to *fsNormal*, so Delphi assumes that all new applications are SDI applications.

MDI applications

To create a new MDI application,

1. Select File | New | Other to bring up the New Items dialog.
2. Click on the Projects page and select MDI Application.
3. Click OK.

MDI applications require more planning and are somewhat more complex to design than SDI applications. MDI applications spawn child windows that reside within the client window; the main form contains child forms. Set the *FormStyle* property of the *TForm* object to specify whether a form is a child (*fsMDIForm*) or main form (*fsMDIChild*). It is a good idea to define a base class for your child forms and derive each child form from this class, to avoid having to reset the child form's properties.

Setting IDE, project, and compilation options

Choose Project | Options to specify various options for your project. For more information, see the online Help.

Setting default project options

To change the default options that apply to all future projects, set the options in the Project Options dialog box and check the Default box at the bottom right of the window. All new projects will use the current options selected by default.

Programming templates

Programming templates are commonly used "skeleton" structures that you can add to your source code and then fill in. Some standard code templates such as those for array, class, and function declarations, and many statements, are included with Delphi.

You can also write your own templates for coding structures that you often use. For example, if you want to use a **for** loop in your code, you could insert the following template:

```
for :=  to  do
begin

end;
```

To insert a code template in the Code editor, press *Ctrl-j* and select the template you want to use. You can also add your own templates to this collection. To add a template:

1 Select Tools | Editor Options.

2 Click the Code Insight tab.

3 In the Templates section, click Add.

4 Type a name for the template after Shortcut name and enter a brief description of the new template.

5 Add the template code to the Code text box.

6 Click OK.

Console applications

Console applications are 32-bit programs that run without a graphical interface, usually in a console window. These applications typically don't require much user input and perform a limited set of functions.

To create a new console application,

1 Choose File | New | Other and select Console Application from the New Items dialog box.

Delphi then creates a project file for this type of source file and displays the code editor.

Note When you create a new console application, the IDE does not create a new form. Only the code editor is displayed.

Service applications

Service applications take requests from client applications, process those requests, and return information to the client applications. They typically run in the background, without much user input. A web, FTP, or e-mail server is an example of a service application.

To create an application that implements a Win32 service, Choose File|New, and select Service Application from the New Items page. This adds a global variable named *Application* to your project, which is of type *TServiceApplication*.

Once you have created a service application, you will see a window in the designer that corresponds to a service (*TService*). Implement the service by setting its properties and event handlers in the Object Inspector. You can add additional services to your service application by choosing Service from the new items dialog. Do not add services to an application that is not a service application. While a *TService* object can be added, the application will not generate the requisite events or make the appropriate Windows calls on behalf of the service.

Once your service application is built, you can install its services with the Service Control Manager (SCM). Other applications can then launch your services by sending requests to the SCM.

To install your application's services, run it using the /INSTALL option. The application installs its services and exits, giving a confirmation message if the services are successfully installed. You can suppress the confirmation message by running the service application using the /SILENT option.

To uninstall the services, run it from the command line using the /UNINSTALL option. (You can also use the /SILENT option to suppress the confirmation message when uninstalling).

Example This service has a *TServerSocket* whose port is set to 80. This is the default port for Web Browsers to make requests to Web Servers and for Web Servers to make responses to Web Browsers. This particular example produces a text document in the C:\Temp directory called WebLog*xxx*.log (where *xxx* is the ThreadID). There should be only one Server listening on any given port, so if you have a web server, you should make sure that it is not listening (the service is stopped).

To see the results: open up a web browser on the local machine and for the address, type 'localhost' (with no quotes). The Browser will time out eventually, but you should now have a file called weblog*xxx*.log in the C:\temp directory.

1 To create the example, choose File|New and select Service Application from the New Items dialog. You will see a window appear named Service1. From the Internet page of the Component palette, add a ServerSocket component to the service window (Service1).

2 Next, add a private data member of type *TMemoryStream* to the TService1 class. The interface section of your unit should now look like this:

```
interface

uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, SvcMgr, Dialogs,
  ScktComp;

type
  TService1 = class(TService)
    ServerSocket1: TServerSocket;
    procedure ServerSocket1ClientRead(Sender: TObject;
      Socket: TCustomWinSocket);
    procedure Service1Execute(Sender: TService);
  private
    { Private declarations }
    Stream: TMemoryStream; // Add this line here
  public
    function GetServiceController: PServiceController; override;
    { Public declarations }
  end;

var
  Service1: TService1;
```

3 Next, select ServerSocket1, the component you added in step 1. In the Object Inspector, double click the *OnClientRead* event and add the following event handler:

```
procedure TService1.ServerSocket1ClientRead(Sender: TObject;
  Socket: TCustomWinSocket);
var
  Buffer: PChar;

begin
  Buffer := nil;

while Socket.ReceiveLength > 0 do begin
    Buffer := AllocMem(Socket.ReceiveLength);
    try
      Socket.ReceiveBuf(Buffer^, Socket.ReceiveLength);
      Stream.Write(Buffer^, StrLen(Buffer));
    finally
      FreeMem(Buffer);
    end;

  Stream.Seek(0, soFromBeginning);
  Stream.SaveToFile('c:\Temp\Weblog' + IntToStr(ServiceThread.ThreadID) + '.log');
  end;
end;
```

4 Finally, select Service1 by clicking in the window's client area (but not on the ServiceSocket). In the Object Inspector, double click the *OnExecute* event and add the following event handler:

```
procedure TService1.Service1Execute(Sender: TService);
begin
  Stream := TMemoryStream.Create;
  try
```

```
    ServerSocket1.Port := 80; // WWW port
    ServerSocket1.Active := True;

    while not Terminated do begin
      ServiceThread.ProcessRequests(True);
    end;

    ServerSocket1.Active := False;
  finally
    Stream.Free;
  end;
end;
```

When writing your service application, you should be aware of:

- Service threads
- Service name properties
- Debugging services

Service threads

Each service has its own thread (*TServiceThread*), so if your service application implements more than one service you must ensure that the implementation of your services is thread-safe. *TServiceThread* is designed so that you can implement the service in the *TService OnExecute* event handler. The service thread has its own *Execute* method which contains a loop that calls the service's *OnStart* and *OnExecute* handlers before processing new requests.

Because service requests can take a long time to process and the service application can receive simultaneous requests from more than one client, it is more efficient to spawn a new thread (derived from *TThread*, not *TServiceThread*) for each request and move the implementation of that service to the new thread's *Execute* method. This allows the service thread's *Execute* loop to process new requests continually without having to wait for the service's *OnExecute* handler to finish. The following example demonstrates.

Example This service beeps every 500 milliseconds from within the standard thread. It handles pausing, continuing, and stopping of the thread when the service is told to pause, continue, or stop.

1 Choose File|New|Other and select Service Application from the New Items dialog. You will see a window appear named Service1.

2 In the interface section of your unit, declare a new descendant of *TThread* named TSparkyThread. This is the thread that does the work for your service. The declaration should appear as follows:

```
TSparkyThread = class(TThread)
    public
      procedure Execute; override;
  end;
```

3 Next, in the implementation section of your unit, create a global variable for a TSparkyThread instance:

```
var
  SparkyThread: TSparkyThread;
```

4 Add the following code to the implementation section for the TSparkyThread Execute method (the thread function):

```
procedure TSparkyThread.Execute;
begin
  while not Terminated do
  begin
    Beep;
    Sleep(500);
  end;
end;
```

5 Select the Service window (Service1), and double-click the OnStart event in the Object Inspector. Add the following OnStart event handler:

```
procedure TService1.Service1Start(Sender: TService; var Started: Boolean);
begin
  SparkyThread := TSparkyThread.Create(False);
  Started := True;
end;
```

6 Double-click the OnContinue event in the Object Inspector. Add the following OnContinue event handler:

```
procedure TService1.Service1Continue(Sender: TService; var Continued: Boolean);
begin
  SparkyThread.Resume;
  Continued := True;
end;
```

7 Double-click the OnPause event in the Object Inspector. Add the following OnPause event handler:

```
procedure TService1.Service1Pause(Sender: TService; var Paused: Boolean);
begin
  SparkyThread.Suspend;
  Paused := True;
end;
```

8 Finally, double-click the OnStop event in the Object Inspector and add the following OnStop event handler:

```
procedure TService1.Service1Stop(Sender: TService; var Stopped: Boolean);
begin
  SparkyThread.Terminate;
  Stopped := True;
end;
```

When developing server applications, choosing to spawn a new thread depends on the nature of the service being provided, the anticipated number of connections, and the expected number of processors on the computer running the service.

Service name properties

The VCL provides classes for creating service applications on the Windows platform (not available for cross-platform applications). These include *TService* and *TDependency*. When using these classes, the various name properties can be confusing. This section describes the differences.

Services have user names (called Service start names) that are associated with passwords, display names for display in manager and editor windows, and actual names (the name of the service). Dependencies can be services or they can be load ordering groups. They also have names and display names. And because service objects are derived from *TComponent*, they inherit the *Name* property. The following sections summarize the name properties:

TDependency properties

The *TDependency DisplayName* is both a display name and the actual name of the service. It is nearly always the same as the *TDependency Name* property.

TService name properties

The *TService Name* property is inherited from *TComponent*. It is the name of the component, and is also the name of the service. For dependencies that are services, this property is the same as the *TDependency Name* and *DisplayName* properties.

TService's *DisplayName* is the name displayed in the Service Manager window. This often differs from the actual service name (*TService.Name*, *TDependency.DisplayName*, *TDependency.Name*). Note that the *DisplayName* for the Dependency and the *DisplayName* for the Service usually differ.

Service start names are distinct from both the service display names and the actual service names. A *ServiceStartName* is the user name input on the Start dialog selected from the Service Control Manager.

Debugging services

Debugging service applications can be tricky, because it requires short time intervals:

1. First, launch the application in the debugger. Wait a few seconds until it has finished loading.
2. Quickly start the service from the control panel or from the command line:

   ```
   start MyServ
   ```

You must launch the service quickly (within 15-30 seconds of application startup) because the application will terminate if no service is launched.

Another approach is to attach to the service application process when it is already running. (That is, starting the service first, and then attaching to the debugger). To attach to the service application process, choose Run | Attach To Process, and select the service application in the resulting dialog.

In some cases, this second approach may fail, due to insufficient rights. If that happens, you can use the Service Control Manager to enable your service to work with the debugger:

1. First create a key called **Image File Execution Options** in the following registry location:

   ```
   HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion
   ```

2. Create a subkey with the same name as your service (for example, MYSERV.EXE). To this subkey, add a value of type REG_SZ, named Debugger. Use the full path to Delphi32.exe as the string value.

3 In the Services control panel applet, select your service, click Startup and check Allow Service to Interact with Desktop.

Creating packages and DLLs

Dynamic link libraries (DLLs) are modules of compiled code that work in conjunction with an executable to provide functionality to an application. You can create DLLs in cross-platform programs. However, on Linux, DLLs (and packages) recompile as shared objects.

Packages are special DLLs used by Delphi applications, the IDE, or both. There are two kinds of packages: runtime packages and design-time packages. Runtime packages provide functionality to a program while that program is running. Design-time packages extend the functionality of the IDE.

The following compiler directives can be placed in library project files:

Table 5.1 Compiler directives for libraries

Compiler Directive	Description
{$LIBPREFIX 'string'}	Adds a specified prefix to the output file name. For example, you could specify {$LIBPREFIX 'dcl'} for a design-time package, or use {$LIBPREFIX ' '} to eliminate the prefix entirely.
{$LIBSUFFIX 'string'}	Adds a specified suffix to the output file name before the extension. For example, use {$LIBSUFFIX '-2.1.3'} in something.pas to generate something-2.1.3.bpl.
{$LIBVERSION 'string'}	Adds a second extension to the output file name after the .bpl extension. For example, use {$LIBVERSION '2.1.3'} in something.pas to generate something.bpl.2.1.3.

For more information on packages, see Chapter 11, "Working with packages and components."

When to use packages and DLLs

For most applications written in Delphi, packages provide greater flexibility and are easier to create than DLLs. However, there are several situations where DLLs would be better suited to your projects than packages:

- Your code module will be called from non-Delphi applications.
- You are extending the functionality of a web server.
- You are creating a code module to be used by third-party developers.
- Your project is an OLE container.

You cannot pass runtime type information (RTTI) across DLLs or from a DLL to an executable. That's because DLLs all maintain their own symbol information. If you need to pass a *TStrings* object from a DLL then using an **is** or **as** operator, you need to create a package rather than a DLL. Packages share symbol information.

Writing database applications

Note Not all versions of Delphi include database support.

One of Delphi's strengths is its support for creating advanced database applications. Delphi supports tools that allow you to connect to SQL servers and databases such as Oracle, Sybase, InterBase, MySQL, MS-SQL, Informix, and DB2 while providing transparent data sharing between applications.

Delphi includes many components for accessing databases and representing the information they contain. On the Component palette, the database components are grouped according to the data access mechanism and function.

Table 5.2 Database pages on the Component palette

Palette page	Contents
BDE	Components that use the Borland Database Engine (BDE), a large API for interacting with databases. The BDE supports the broadest range of functions and comes with the most supporting utilities including Database Desktop, Database Explorer, SQL Monitor, and BDE Administrator. See Chapter 20, "Using the Borland Database Engine" for details.
ADO	Components that use ActiveX Data Objects (ADO), developed by Microsoft, to access database information. Many ADO drivers are available for connecting to different database servers. ADO-based components let you integrate your application into an ADO-based environment. See Chapter 21, "Working with ADO components" for details.
dbExpress	Cross-platform components that use dbExpress to access database information. dbExpress drivers provide fast access to databases but need to be used with *TClientDataSet* and *TDataSetProvider* to perform updates. See Chapter 22, "Using unidirectional datasets" for details.
InterBase	Components that access InterBase databases directly, without going through a separate engine layer. For more information about using the InterBase components, see the online Help.
Data Access	Components that can be used with any data access mechanism such as *TClientDataSet* and *TDataSetProvider*. See Chapter 23, "Using client datasets" for information about client datasets. See Chapter 24, "Using provider components"for information about providers.
Data Controls	Data-aware controls that can access information from a data source. See Chapter 15, "Using data controls" for details.

When designing a database application, you must decide which data access mechanism to use. Each data access mechanism differs in its range of functional support, the ease of deployment, and the availability of drivers to support different database servers.

See Part II, "Developing database applications" in this manual for details on how to use Delphi to create both database client applications and application servers. Refer to "Deploying database applications" on page 13-6 for deployment information.

Distributing database applications

Delphi provides support for creating distributed database applications using a coordinated set of components. Distributed database applications can be built on a variety of communications protocols, including DCOM, CORBA, TCP/IP, and SOAP.

For more information about building distributed database applications, see Chapter 25, "Creating multi-tiered applications."

Distributing database applications often requires you to distribute the Borland Database Engine (BDE) in addition to the application files. For information on deploying the BDE, see "Deploying database applications" on page 13-6.

Creating Web server applications

Web server applications are applications that run on servers that deliver Web content such as HTML Web pages or XML documents over the Internet. Examples of Web server applications include those which control access to a Web site, generate purchase orders, or respond to information requests.

You can create several different types of Web server applications using the following Delphi technologies:

- Web Broker
- WebSnap
- InternetExpress
- Web Services

Using Web Broker

You can use Web Broker (also called NetCLX architecture) to create Web server applications such as CGI applications or dynamic-link libraries (DLLs). These Web server applications can contain any nonvisual component. Components on the Internet page of the Component palette enable you to create event handlers, programmatically construct HTML or XML documents, and transfer them to the client.

To create a new Web server application using the Web Broker architecture, select File | New | Other and select Web Server Application in the New Items dialog box. Then select the Web server application type:

Table 5.3 Web server applications

Web server application type	Description
ISAPI and NSAPI Dynamic Link Library	ISAPI and NSAPI Web server applications are DLLs that are loaded by the Web server. Client request information is passed to the DLL as a structure and evaluated by TISAPIApplication. Each request message is handled in a separate execution thread. Selecting this type of application adds the library header of the project files and required entries to the uses list and exports clause of the project file.
CGI Stand-alone executable	CGI Web server applications are console applications that receive requests from clients on standard input, process those requests, and sends back the results to the server on standard output to be sent to the client. Selecting this type of application adds the required entries to the **uses** clause of the project file and adds the appropriate $APPTYPE directive to the source.
Win-CGI Stand-alone executable	Win-CGI Web server applications are Windows applications that receive requests from clients from a configuration settings (INI) file written by the server and writes the results to a file that the server passes back to the client. The INI file is evaluated by TCGIApplication. Each request message is handled by a separate instance of the application. Selecting this type of application adds the required entries to the **uses** clause of the project file and adds the appropriate $APPTYPE directive to the source.
Apache Shared Module (DLL)	Selecting this type of application sets up your project as a DLL. Apache Web server applications are DLLs loaded by the Web server. Information is passed to the DLL, processed, and returned to the client by the Web server.
Web App Debugger Stand-alone executable	Selecting this type of application sets up an environment for developing and testing Web server applications. Web App Debugger applications are executable files loaded by the Web server. This type of application is not intended for deployment.

CGI and Win-CGI applications use more system resources on the server, so complex applications are better created as ISAPI , NSAPI, or Apache DLL applications. If writing cross-platform applications, you should select CGI stand-alone or Apache Shared Module (DLL) for Web server development. These are also the same options you see when creating WebSnap and Web Service applications.

For more information on building Web server applications, see Chapter 27, “Creating Internet applications.”

Creating WebSnap applications

WebSnap provides a set of components and wizards for building advanced Web servers that interact with Web browsers. WebSnap components generate HTML or other mime content for Web pages. WebSnap is for server side development. WebSnap cannot be used in cross-platform applications at this time.

To create a new WebSnap application, select File | New | Other and select the WebSnap tab in the New Items dialog box. Choose WebSnap Application. Then select the Web server application type (ISAPI/NSAPI, CGI, Win-CGI, Apache). See Table 5.3, "Web server applications" for details.

For more information on WebSnap, see Chapter 29, "Using WebSnap."

Using InternetExpress

InternetExpress is a set of components that extends the basic Web server application architecture to act as the client of an application server. You use InternetExpress for applications wherein browser-based clients can fetch data from a provider, resolve updates to the provider, while executing on a client.

InternetExpress applications generate HTML pages that contain a mixture of HTML, XML, and javascript. The HTML determines the layout and appearance of the pages displayed in end-user browsers. The XML encodes the data packets and delta packets that represent database information. The javascript allows the HTML controls to interpret and manipulate the data in the XML data packets on the client machine.

For more information on InternetExpress, see "Building Web applications using InternetExpress" on page 25-33.

Creating Web Services applications

Web Services are self-contained modular applications that can be published and invoked over a network (such as the World Wide Web). Web Services provide well-defined interfaces that describe the services provided. You use Web Services to produce or consume programmable services over the Internet using emerging standards such as XML, XML Schema, SOAP (Simple Object Access Protocol), and WSDL (Web Service Definition Language).

Web Services use SOAP, a standard lightweight protocol for exchanging information in a distributed environment. It uses HTTP as a communications protocol and XML to encode remote procedure calls.

You can use Delphi to build servers to implement Web Services and clients that call on those services. You can write clients for arbitrary servers to implement Web Services that respond to SOAP messages, and Delphi servers to publish Web Services for use by arbitrary clients.

Refer to Chapter 31, "Using Web Services" for more information on Web Services.

Writing applications using COM

COM is the Component Object Model, a Windows-based distributed object architecture designed to provide object interoperability using predefined routines called interfaces. COM applications use objects that are implemented by a different process or, if you use DCOM, on a separate machine. You can also use COM+, ActiveX and Active Server Pages.

COM is a language-independent software component model that enables interaction between software components and applications running on a Windows platform. The key aspect of COM is that it enables communication between components, between applications, and between clients and servers through clearly defined interfaces. Interfaces provide a way for clients to ask a COM component which features it supports at runtime. To provide additional features for your component, you simply add an additional interface for those features.

Using COM and DCOM

Delphi has classes and wizards that make it easy to create COM, OLE, or ActiveX applications. You can create COM clients or servers that implement COM objects, Automation servers (including Active Server Objects), ActiveX controls, or ActiveForms. COM also severs as the basis for other technologies such as Automation, ActiveX controls, Active Documents, and Active Directories.

Using Delphi to create COM-based applications offers a wide range of possibilities, from improving software design by using interfaces internally in an application, to creating objects that can interact with other COM-based API objects on the system, such as the Win9x Shell extensions and DirectX multimedia support. Applications can access the interfaces of COM components that exist on the same computer as the application or that exist on another computer on the network using a mechanism called Distributed COM (DCOM).

For more information on COM and Active X controls, see Chapter 33, “Overview of COM technologies,” Chapter 38, “Creating an ActiveX control,” and “Distributing a client application as an ActiveX control” on page 25-32.

For more information on DCOM, see “Using DCOM connections” on page 25-8.

Using MTS and COM+

COM applications can be augmented with special services for managing objects in a large distributed environment. These services include transaction services, security, and resource management supplied by Microsoft Transaction Server (MTS) on versions of Windows prior to Windows 2000) or COM+ (for Windows 2000 and later).

For more information on MTS and COM+, see Chapter 39, “Creating MTS or COM+ objects” and “Using transactional data modules” on page 25-6.

Using data modules

A data module is like a special form that contains nonvisual components. All the components in a data module *could* be placed on ordinary forms alongside visual controls. But if you plan on reusing groups of database and system objects, or if you want to isolate the parts of your application that handle database connectivity and business rules, then data modules provide a convenient organizational tool.

There are several types of data modules, including standard, remote, Web modules, applet modules, and services, depending on which edition of Delphi you have. Each type of data module serves a special purpose.

- Standard data modules are particularly useful for single- and two-tiered database applications, but can be used to organize the nonvisual components in any application. For more information, see “Creating and editing standard data modules” on page 5-15.
- Remote data modules form the basis of an application server in a multi-tiered database application. They are not available in all editions. In addition to holding the nonvisual components in the application server, remote data modules expose the interface that clients use to communicate with the application server. For more information about using them, see “Adding a remote data module to an application server project” on page 5-19.
- Web modules form the basis of Web server applications. In addition to holding the components that create the content of HTTP response messages, they handle the dispatching of HTTP messages from client applications. See Chapter 27, “Creating Internet applications” for more information about using Web modules.
- Applet modules form the basis of control panel applets. In addition to holding the nonvisual controls that implement the control panel applet, they define the properties that determine how the applet’s icon appears in the control panel and include the events that are called when users execute the applet. For more information about applet modules, see the online Help.
- Services encapsulate individual services in an NT service application. In addition to holding any nonvisual controls used to implement a service, services include the events that are called when the service is started or stopped. For more information about services, see “Service applications” on page 5-4.

Creating and editing standard data modules

To create a standard data module for a project, choose File | New | Data Module. Delphi opens a data module container on the desktop, displays the unit file for the new module in the Code editor, and adds the module to the current project.

At design time a data module looks like a standard Delphi form with a white background and no alignment grid. As with forms, you can place nonvisual components from the Component palette onto a module, and edit their properties in the Object Inspector. You can resize a data module to accommodate the components you add to it.

You can also right-click a module to display a context menu for it. The following table summarizes the context menu options for a data module.

Table 5.4 Context menu options for data modules

Menu item	Purpose
Edit	Displays a context menu with which you can cut, copy, paste, delete, and select the components in the data module.
Position	Aligns nonvisual components to the module's invisible grid (*Align To Grid) or* according to criteria you supply in the Alignment dialog box (*Align*).
Tab Order	Enables you to change the order that the focus jumps from component to component when you press the tab key.
Creation Order	Enables you to change the order that data access components are created at start-up.
Revert to Inherited	Discards changes made to a module inherited from another module in the Object Repository, and reverts to the originally inherited module.
Add to Repository	Stores a link to the data module in the Object Repository.
View as Text	Displays the text representation of the data module's properties.
View DFM	Toggles between the formats (binary or text) in which this particular form file is saved.

For more information about data modules, see the online Help.

Naming a data module and its unit file

The title bar of a data module displays the module's name. The default name for a data module is "DataModule*N*" where *N* is a number representing the lowest unused unit number in a project. For example, if you start a new project, and add a module to it before doing any other application building, the name of the module defaults to "DataModule2." The corresponding unit file for *DataModule2* defaults to "Unit2."

You should rename your data modules and their corresponding unit files at design time to make them more descriptive. You should especially rename data modules you add to the Object Repository to avoid name conflicts with other data modules in the Repository or in applications that use your modules.

To rename a data module:

1 Select the module.

2 Edit the *Name* property for the module in the Object Inspector.

The new name for the module appears in the title bar when the *Name* property in the Object Inspector no longer has focus.

Changing the name of a data module at design time changes its variable name in the interface section of code. It also changes any use of the type name in procedure declarations. You must manually change any references to the data module in code you write.

To rename a unit file for a data module:

1 Select the unit file.

Placing and naming components

You place nonvisual components in a data module just as you place visual components on a form. Click the desired component on the appropriate page of the Component palette, then click in the data module to place the component. You cannot place visual controls, such as grids, on a data module. If you attempt it, you receive an error message.

For ease of use, components are displayed with their names in a data module. When you first place a component, Delphi assigns it a generic name that identifies what kind of component it is, followed by a *1*. For example, the *TDataSource* component adopts the name *DataSource1*. This makes it easy to select specific components whose properties and methods you want to work with.

You may still want to name a component a different name that reflects the type of component and what it is used for.

To change the name of a component in a data module:

1 Select the component.
2 Edit the component's *Name* property in the Object Inspector.

The new name for the component appears under its icon in the data module as soon as the *Name* property in the Object Inspector no longer has focus.

For example, suppose your database application uses the CUSTOMER table. To access the table, you need a minimum of two data access components: a data source component (*TDataSource)* and a table component (*TClientDataSet)*. When you place these components in your data module, Delphi assigns them the names *DataSource1* and *ClientDataSet1*. To reflect the type of component and the database they access, CUSTOMER, you could change these names to *CustomerSource* and *CustomerTabl*e.

Using component properties and events in a data module

Placing components in a data module centralizes their behavior for your entire application. For example, you can use the properties of dataset components, such as *TClientDataSet*, to control the data available to the data source components that use those datasets. Setting the *ReadOnly* property to *True* for a dataset prevents users from editing the data they see in a data-aware visual control on a form. You can also invoke the Fields editor for a dataset, by double-clicking on *ClientDataSet1*, to restrict the fields within a table or query that are available to a data source and therefore to the data-aware controls on forms. The properties you set for components in a data module apply consistently to all forms in your application that use the module.

In addition to properties, you can write event handlers for components. For example, a *TDataSource* component has three possible events: *OnDataChang*e, *OnStateChang*e, and *OnUpdateDat*a. A *TClientDataSet* component has over 20 potential events. You can use these events to create a consistent set of business rules that govern data manipulation throughout your application.

Creating business rules in a data module

Besides writing event handlers for the components in a data module, you can code methods directly in the unit file for a data module. These methods can be applied to the forms that use the data module as business rules. For example, you might write a procedure to perform month-, quarter-, or year-end bookkeeping. You might call the procedure from an event handler for a component in the data module. The prototypes for the procedures and functions you write for a data module should appear in the module's **type** declaration:

```
type
  TCustomerData = class(TDataModule)
    Customers: TClientDataSet;
    Orders: TClientDataSet;
    :
  private
    { Private declarations }
  public
    { Public declarations }
    procedure LineItemsCalcFields(DataSet: TDataSet); { A procedure you add }
  end;

var
  CustomerData: TCustomerData;
```

The procedures and functions you write should follow in the implementation section of the code for the module.

Accessing a data module from a form

To associate visual controls on a form with a data module, you must first add the data module to the form's **uses** clause. You can do this in several ways:

- In the Code editor, open the form's unit file and add the name of the data module to the **uses** clause in the **interface** section.
- Click the form's unit file, choose File | Use Unit, and enter the name of the module or pick it from the list box in the Use Unit dialog.
- For database components, in the data module click a dataset or query component to open the Fields editor and drag any existing fields from the editor onto the form. Delphi prompts you to confirm that you want to add the module to the form's **uses** clause, then creates controls (such as edit boxes) for the fields.

For example, if you've added the *TClientDataSet* component to your data module, double-click it to open the Fields editor. Select a field and drag it to the form. An edit box component appears.

Because the data source is not yet defined, Delphi adds a new data source component, *DataSource1,* to the form and sets the edit box's *DataSource* property to *DataSource1*. The data source automatically sets its *DataSet* property to the dataset component, *ClientDataSet1,* in the data module.

You can define the data source *before* you drag a field to the form by adding a *TDataSource* component to the data module. Set the data source's *DataSet* property to *ClientDataSet1.* After you drag a field to the form, the edit box appears with its *TDataSource* property already set to *DataSource1*. This method keeps your data access model cleaner.

Adding a remote data module to an application server project

Some editions of Delphi allow you to add *remote data modules* to application server projects. A remote data module has an interface that clients in a multi-tiered application can access across networks.

To add a remote data module to a project:

1. Choose File | New | Other.
2. Select the Multitier page in the New Items dialog box.
3. Double-click the desired type of module (CORBA Data Module, Remote Data Module, or Transactional Data Module) to open the Remote Data Module wizard.

Once you add a remote data module to a project, you use it just like a standard data module.

For more information about multi-tiered database applications, see Chapter 25, "Creating multi-tiered applications."

Using the Object Repository

The Object Repository (Tools | Repository) makes it easy share forms, dialog boxes, frames, and data modules. It also provides templates for new projects and wizards that guide the user through the creation of forms and projects. The repository is maintained in DELPHI32.DRO (by default in the BIN directory), a text file that contains references to the items that appear in the Repository and New Items dialogs.

Sharing items within a project

You can share items *within* a project without adding them to the Object Repository. When you open the New Items dialog box (File | New | Other), you'll see a page tab with the name of the current project. This page lists all the forms, dialog boxes, and data modules in the project. You can derive a new item from an existing item and customize it as needed.

Adding items to the Object Repository

You can add your own projects, forms, frames, and data modules to those already available in the Object Repository. To add an item to the Object Repository,

1. If the item is a project or is in a project, open the project.

2 For a project, choose Project | Add To Repository. For a form or data module, right-click the item and choose Add To Repository.

3 Type a description, title, and author.

4 Decide which page you want the item to appear on in the New Items dialog box, then type the name of the page or select it from the Page combo box. If you type the name of a page that doesn't exist, Delphi creates a new page.

5 Choose Browse to select an icon to represent the object in the Object Repository.

6 Choose OK.

Sharing objects in a team environment

You can share objects with your workgroup or development team by making a repository available over a network. To use a shared repository, all team members must select the same Shared Repository directory in the Environment Options dialog:

1 Choose Tools | Environment Options.

2 On the Preferences page, locate the Shared Repository panel. In the Directory edit box, enter the directory where you want to locate the shared repository. Be sure to specify a directory that's accessible to all team members.

The first time an item is added to the repository, Delphi creates a DELPHI32.DRO file in the Shared Repository directory if one doesn't exist already.

Using an Object Repository item in a project

To access items in the Object Repository, choose File | New | Other. The New Items dialog appears, showing all the items available. Depending on the type of item you want to use, you have up to three options for adding the item to your project:

- Copy
- Inherit
- Use

Copying an item

Choose Copy to make an exact copy of the selected item and add the copy to your project. Future changes made to the item in the Object Repository will not be reflected in your copy, and alterations made to your copy will not affect the original Object Repository item.

Copy is the only option available for project templates.

Inheriting an item

Choose Inherit to derive a new class from the selected item in the Object Repository and add the new class to your project. When you recompile your project, any changes that have been made to the item in the Object Repository will be reflected in your derived class, in addition to changes you make to the item in your project. Changes made to your derived class do not affect the shared item in the Object Repository.

Inherit is available for forms, dialog boxes, and data modules, but not for project templates. It is the *only* option available for reusing items within the same project.

Using an item

Choose Use when you want the selected item itself to become part of your project. Changes made to the item in your project will appear in all other projects that have added the item with the Inherit or Use option. Select this option with caution.

The Use option is available for forms, dialog boxes, and data modules.

Using project templates

Templates are predesigned projects that you can use as starting points for your own work. To create a new project from a template,

1. Choose File | New | Other to display the New Items dialog box.
2. Choose the Projects tab.
3. Select the project template you want and choose OK.
4. In the Select Directory dialog, specify a directory for the new project's files.

Delphi copies the template files to the specified directory, where you can modify them. The original project template is unaffected by your changes.

Modifying shared items

If you modify an item in the Object Repository, your changes will affect all future projects that use the item as well as existing projects that have added the item with the Use or Inherit option. To avoid propagating changes to other projects, you have several alternatives:

- Copy the item and modify it in your current project only.
- Copy the item to the current project, modify it, then add it to the Repository under a different name.
- Create a component, DLL, component template, or frame from the item. If you create a component or DLL, you can share it with other developers.

Specifying a default project, new form, and main form

By default, when you choose File | New | Application or File | New | Form, Delphi displays a blank form. You can change this behavior by reconfiguring the Repository:

1. Choose Tools | Repository
2. If you want to specify a default project, select the Projects page and choose an item under Objects. Then select the New Project check box.

3 If you want to specify a default form, select a Repository page (such as Forms), them choose a form under Objects. To specify the default new form (File | New | Form), select the New Form check box. To specify the default main form for new projects, select the Main Form check box.

4 Click OK.

Enabling Help in applications

Both the VCL and CLX support displaying Help from applications using an object-based mechanism that allows Help requests to be passed on to one of multiple external Help viewers. To support this, an application must include a class that implements the *ICustomHelpViewer* interface (and, optionally, one of several interfaces descended from it), and registers itself with the global Help Manager.

The VCL provides to all applications an instance of *TWinHelpViewer*, which implements all of these interfaces and provides a link between applications and WinHelp; CLX requires that application developers provide their own implementation.

The Help Manager maintains a list of registered viewers and passes requests to them in a two-phase process: it first asks each viewer if it can provide support for a particular Help keyword or context, and then it passes the Help request on to the viewer which says it can provide such support. (If more than one viewer supports the keyword, as would be the case in an application which had registered viewers for both Man and Info, the Help Manager can display a selection box through which the user of the application can determine which Help viewer to invoke. Otherwise, it displays the first responding Help system encountered).

Help system interfaces

The Help system allows communication between your application and Help viewers through a series of interfaces. These interfaces are all defined in HelpIntfs.pas, which also contains the implementation of the Help Manager.

ICustomHelpViewer provides support for displaying Help based upon a provided keyword and for displaying a table of contents listing all Help available in a particular viewer.

IExtendedHelpViewer provides support for displaying Help based upon a numeric Help context and for displaying topics; in most Help systems, topics function as high-level keywords (for example, “IntToStr” might be a keyword in the Help system, but “String manipulation routines” could be the name of a topic).

*ISpecialWinHelpViewe*r provides support for responding to specialized WinHelp messages that an application running under Windows may receive and which are not easily generalizable. In general, only applications operating in the Windows environment need to implement this interface, and even then it is only required for applications that make extensive use of non-standard WinHelp messages.

IHelpManager provides a mechanism for the Help viewer to communicate back to the application's Help Manager and request additional information. An *IHelpManager* is obtained at the time the Help viewer registers itself.

IHelpSystem provides a mechanism through which *TApplication* passes Help requests on to the Help system. *TApplication* obtains an instance of an object which implements both *IHelpSystem* and *IHelpManager* at application load time and exports that instance as a property; this allows other code within the application to file Help requests directly when appropriate.

IHelpSelector provides a mechanism through which the Help system can invoke the user interface to ask which Help viewer should be used in cases where more than one viewer is capable of handling a Help request, and to display a Table of Contents. This display capability is not built into the Help Manager directly to allow the Help Manager code to be identical regardless of which widget set or class library is in use.

Implementing ICustomHelpViewer

The *ICustomHelpViewer* interface contains three types of methods: methods used to communicate system-level information (for example, information not related to a particular Help request) with the Help Manager; methods related to showing Help based upon a keyword provided by the Help Manager; and methods for displaying a table of contents.

Communicating with the Help Manager

ICustomHelpViewer provides four functions that can be used to communicate system information with the Help Manager:

- *GetViewerName*
- *NotifyID*
- *ShutDown*
- *SoftShutDown*

The Help Manager calls through these functions in the following circumstances:

- *ICustomHelpViewer.GetViewerName : String* is called when the Help Manager wants to know the name of the viewer (for example, if the application is asked to display a list of all registered viewers). This information is returned via a string, and is required to be logically static (that is, it cannot change during the operation of the application). Multibyte character sets are not supported.
- *ICustomHelpViewer.NotifyID(const ViewerID: Integer)* is called **immediately** following registration to provide the viewer with a unique cookie that identifies it. This information must be stored off for later use; if the viewer shuts down on its own (as opposed to in response to a notification from the Help Manager), it must provide the Help Manager with the identifying cookie so that the Help Manager can release all references to the viewer. (Failing to provide the cookie, or providing the wrong one, causes the Help Manager to potentially release references to the wrong viewer.)

- *ICustomHelpViewer.ShutDown* is called by the Help Manager to notify the Help viewer that the Manager is shutting down and that any resources the Help viewer has allocated should be freed. It is recommended that all resource freeing be delegated to this method.
- *ICustomHelpViewer.SoftShutDown* is called by the Help Manager to ask the Help viewer to close any externally visible manifestations of the help system (for example, windows displaying help information) without unloading the viewer.

Asking the Help Manager for information

Help viewers communicate with the Help Manager through the *IHelpManager* interface, an instance of which is returned to them when they register with the Help Manager. *IHelpManager* allows the Help viewer to communicate four things: a request for the window handle of the currently active control; a request for the name of the Help file which the Help Manager believes should contain help for the currently active control; a request for the path to that Help file; and a notification that the Help viewer is shutting itself down in response to something other than a request from the Help Manager that it do so.

IHelpManager.GetHandle : LongInt is called by the Help viewer if it needs to know the handle of the currently active control; the result is a window handle.

IHelpManager.GetHelpFile: String is called by the Help viewer if it wishes to know the name of the Help file which the currently active control believes contains its help.

IHelpManager.Release is called to notify the Help Manager when a Help viewer is disconnecting. It should *never* be called in response to a request through *ICustomHelpViewer.ShutDown*; it is only used to notify the Help Manager of unexpected disconnects.

Displaying keyword-based Help

Help requests typically come through to the Help viewer as either *keyword-based* Help, in which case the viewer is asked to provide help based upon a particular string, or as *context-based* Help, in which case the viewer is asked to provide help based upon a particular numeric identifier. (Numeric help contexts are the default form of Help requests in applications running under Windows, which use the WinHelp system; while CLX supports them, they are not recommended for use in CLX applications because most Linux Help systems do not understand them.) *ICustomHelpViewer* implementations are required to provide support for keyword-based Help requests, while *IExtendedHelpViewer* implementations are required to support context-based Help requests.

ICustomHelpViewer provides three methods for handling keyword-based Help:

- *UnderstandsKeyword*
- *GetHelpStrings*
- *ShowHelp*

```
ICustomHelpViewer.UnderstandsKeyword(const HelpString: String): Integer
```

is the first of the three methods called by the Help Manager, which will call *each* registered Help viewer with the same string to ask if the viewer provides help for that string; the viewer is expected to respond with an integer indicating how many different Help pages it can display in response to that Help request. The viewer can use any method it wants to determine this — inside the IDE, the HyperHelp viewer maintains its own index and searches it. If the viewer does not support help on this keyword, it should return zero. Negative numbers are currently interpreted as meaning zero, but this behavior is not guaranteed in future releases.

```
ICustomHelpViewer.GetHelpStrings(const HelpString: String): TStringList
```

is called by the Help Manager if more than one viewer can provide help on a topic. The viewer is expected to return a *TStringList*. The strings in the returned list should map to the pages available for that keyword, but the characteristics of that mapping can be determined by the viewer. In the case of the HyperHelp viewer, the string list always contains exactly one entry (HyperHelp provides its own indexing, and duplicating that elsewhere would be pointless duplication); in the case of the Man page viewer, the string list consists of multiple strings, one for each section of the manual which contains a page for that keyword.

```
ICustomHelpViewer.ShowHelp(const HelpString: String)
```

is called by the Help Manager if it needs the Help viewer to display help for a particular keyword. This is the last method call in the operation; it is guaranteed to never be called unless *CanShowKeyword* is invoked first.

Displaying tables of contents

ICustomHelpViewer provides two methods relating to displaying tables of contents:

- *CanShowTableOfContents*
- *ShowTableOfContents*

The theory behind their operation is similar to the operation of the keyword Help request functions: the Help Manager first queries all Help viewers by calling *ICustomHelpViewer.CanShowTableOfContents : Boolean* and then invokes a particular Help viewer by calling *ICustomHelpViewer.ShowTableOfContents*.

It is reasonable for a particular viewer to refuse to allow requests to support a table of contents. The Man page viewer does this, for example, because the concept of a table of contents does not map well to the way Man pages work; the HyperHelp viewer supports a table of contents, on the other hand, by passing the request to display a table of contents directly to HyperHelp. It is *not* reasonable, however, for an implementation of *ICustomHelpViewer* to respond to queries through *CanShowTableOfContents* with the answer *true*, and then ignore requests through *ShowTableOfContents*.

Implementing IExtendedHelpViewer

ICustomHelpViewer only provides direct support for keyword-based Help. Some Help systems (especially WinHelp) work by associating numbers (known as *context IDs*) with keywords in a fashion which is internal to the Help system and therefore not visible to the application. Such systems require that the application support context-based Help in which the application invokes the Help system with that context, rather than with a string, and the Help system translates the number itself.

Applications written in CLX can talk to systems requiring context-based Help by extending the object which implements *ICustomHelpViewer* to also implement *IExtendedHelpViewer*. *IExtendedHelpViewer* also provides support for talking to Help systems that allow you to jump directly to high-level topics instead of using keyword searches.

IExtendedHelpViewer exposes four functions. Two of them — *UnderstandsContext* and *DisplayHelpByContext* — are used to support context-based Help; the other two — *UnderstandsTopic* and *DisplayTopic* — are used to support topics.

When an application user presses F1, the Help Manager calls

```
IExtendedHelpViewer.UnderstandsContext(const ContextID: Integer;
const HelpFileName: String): Boolean
```

and the currently activated control supports context-based, rather than keyword-based Help. As with *ICustomHelpViewer.CanShowKeyword*, the Help Manager queries all registered Help viewers iteratively. Unlike the case with *ICustomHelpViewer.CanShowKeyword*, however, if more than one viewer supports a specified context, the *first* registered viewer with support for a given context is invoked.

The Help Manager calls

```
IExtendedHelpViewer.DisplayHelpByContext(const ContextID: Integer;
const HelpFileName: String)
```

after it has polled the registered Help viewers.

The topic support functions work the same way:

```
IExtendedHelpViewer.UnderstandsTopic(const Topic: String): Boolean
```

is used to poll the Help viewers asking if they support a topic;

```
IExtendedHelpViewer.DisplayTopic(const Topic: String)
```

is used to invoke the first registered viewer which reports that it is able to provide help for that topic.

Implementing IHelpSelector

IHelpSelector is a companion to *ICustomHelpViewer*. When more than one registered viewer claims to provide support for a given keyword, context, or topic, or provides a table of contents, the Help Manager must choose between them. In the case of contexts or topics, the Help Manager *always* selects the first Help viewer that claims to provide support. In the case of keywords or the table of context, the Help Manager will, by default, select the first Help viewer. This behavior can be overridden by an application.

To override the decision of the Help Manager in such cases, an application must register a class that provides an implementation of the *IHelpSelector* interface. *IHelpSelector* exports two functions: *SelectKeyword*, and *TableOfContents*. Both take as arguments a *TStrings* containing, one by one, either the possible keyword matches or the names of the viewers claiming to provide a table of contents. The implementor is required to return the index (in the *TStrings*) that represents the selected string.

Note The Help Manager may get confused if the strings are re-arranged; it is recommended that implementors of *IHelpSelector* refrain from doing this. The Help system only supports *one* HelpSelector; when new selectors are registered, any previously existing selectors are disconnected.

Registering Help system objects

For the Help Manager to communicate with them, objects that implement *ICustomHelpViewer*, *IExtendedHelpViewer*, *ISpecialWinHelpViewer*, and *IHelpSelector* must register with the Help Manager.

To register Help system objects with the Help Manager, you need to

- Register the Help viewer
- Register the Help Selector

Registering Help viewers

The unit that contains the object implementation must use HelpIntfs. An instance of the object must be declared in the **var** section of the implementing unit.

The initialization section of the implementing unit must assign the instance variable and pass it to the function *RegisterViewer*. *RegisterViewer* is a flat function exported by HelpIntfs.pas which takes as an argument an *ICustomHelpViewer* and returns an *IHelpManager*. The *IHelpManager* should be stored for future use.

Registering Help selectors

The unit that contains the object implementation must use HelpIntfs and QForms. An instance of the object must be declared in the **var** section of the implementing unit.

The initialization section of the implementing unit must register the Help selector through the *HelpSystem* property of the global Application object:

```
Application.HelpSystem.AssignHelpSelector(myHelpSelectorInstance)
```

This procedure does not return a value.

Using Help in a VCL Application

The following sections explain how to use Help within a VCL application.

- How TApplication processes VCL Help
- How VCL controls process Help
- Calling a Help system directly
- Using IHelpSystem

How TApplication processes VCL Help

TApplication in the VCL provides four methods that are accessible from application code:

Table 5.5 Help methods in TApplication

HelpCommand	Takes a Windows Help style HELP_COMMAND and passes it off to WinHelp. Help requests forwarded through this mechanism are passed only to implementations of IspecialWinHelpViewer.
HelpContext	Invokes the Help System with a request for context-based Help.
HelpKeyword	Invokes the HelpSystem with a request for keyword-based Help.
HelpJump	Requests the display of a particular topic.

All four functions take the data passed to them and forward it through a data member of *TApplication* which represents the Help System. That data member is directly accessible through the property *HelpSystem*.

How VCL controls process Help

All controls that derive from *TControl* expose three properties which are used by the Help system: *HelpSystem*, *HelpType*, *HelpContext*, and *HelpKeyword*.

The *HelpType* property contains an instance of an enumerated type that determines if the control's designer expects help to be provided via keyword-based Help or context-based Help. If the *HelpType* is set to *htKeyword*, then the Help system expects the control to use keyword-based Help, and the Help system only looks at the contents of the *HelpKeyword* property. Conversely, if the *HelpType* is set to *htContext*, the Help system expects the control to use context-based Help and only looks at the contents of the *HelpContext* property.

In addition to the properties, controls expose a single method, *InvokeHelp*, that can be called to pass a request to the Help system. It takes no parameters and calls the methods in the global Application object, which correspond to the type of Help the control supports.

Help messages are automatically invoked when F1 is pressed because the *KeyDown* method of *TWinControl* calls *InvokeHelp*.

Using Help in a CLX Application

The following sections explain how to use Help within a CLX application.

- How TApplication processes CLX Help
- How CLX controls process Help
- Calling a Help system directly
- Using IHelpSystem

How TApplication processes CLX Help

TApplication in CLX provides two methods that are accessible from application code:

- *ContextHelp*, which invokes the Help system with a request for context-based Help
- *KeywordHelp*, which invokes the Help system with a request for keyword-based Help

Both functions take as an argument the context or keyword being passed and forward the request on through a data member of *TApplication,* which represents the Help system. That data member is directly accessible through the read-only property *HelpSystem*.

How CLX controls process Help

All controls that derive from *TControl* expose four properties which are used by the Help system: *HelpType*, *HelpFile*, *HelpContext*, and *HelpKeyword*. *HelpFile* is supposed to contain the name of the file in which the control's help is located; if the help is located in an external Help system that does not care about file names (say, for example, the Man page system), then the property should be left blank.

The *HelpType* property contains an instance of an enumerated type which determines if the control's designer expects help to be provided via keyword-based Help or context-based Help; the other two properties are linked to it. If the *HelpType* is set to *htKeyword*, then the Help system expects the control to use keyword-based Help, and the Help system only looks at the contents of the *HelpKeyword* property. Conversely, if the *HelpType* is set to *htContext*, the Help system expects the control to use context-based Help and only looks at the contents of the *HelpContext* property.

In addition to the properties, controls expose a single method, *InvokeHelp*, which can be called to pass a request to the Help system. It takes no parameters and calls the methods in the global Application object, which correspond to the type of help the control supports.

Help messages are automatically invoked when F1 is pressed because the *KeyDown* method of *TWidgetControl* calls *InvokeHelp*.

Calling a Help system directly

For additional Help system functionality not provided by the VCL or CLX, *TApplication* provides a read-only property that allows direct access to the Help system. This property is an instance of an implementation of the interface *IHelpSystem*. *IHelpSystem* and *IHelpManager* are implemented by the same object, but one interface is used to allow the application to talk to the Help Manager, and one is used to allow the Help viewers to talk to the Help Manager.

Using IHelpSystem

IHelpSystem allows a VCL or CLX application to do three things:

- Provides path information to the Help Manager
- Provides a new Help selector
- Asks the Help Manager to display help

Assigning a Help selector allows the Help Manager to delegate decision-making in cases where multiple external Help systems can provide help for the same keyword. For more information, see the section “Implementing IHelpSelector” on page 5-26.

IHelpSystem exports four procedures and one function to request the Help Manager to display help:

- *ShowHelp*
- *ShowContextHelp*
- *ShowTopicHelp*
- *ShowTableOfContents*
- *Hook*

Hook is intended entirely for WinHelp compatibility and should not be used in a CLX application; it allows processing of WM_HELP messages that cannot be mapped directly onto requests for keyword-based, context-based, or topic-based Help. The other methods each take two arguments: the keyword, context ID, or topic for which help is being requested, and the Help file in which it is expected that help can be found.

In general, unless you are asking for topic-based help, it is equally effective and more clear to pass help requests to the Help Manager through the *InvokeHelp* method of your control.

Customizing the IDE Help system

The Delphi IDE supports multiple Help viewers in exactly the same way that a VCL or CLX application does: it delegates Help requests to the Help Manager, which forwards them to registered Help viewers. The IDE makes use of the same WinHelpViewer that the VCL uses.

To install a new Help viewer in the IDE, you do exactly what you would do in a CLX application, with one difference. You write an object that implements *ICustomHelpViewer* (and, if desired, *IExtendedHelpViewer*) to forward Help requests to the external viewer of your choice, and you register the *ICustomHelpViewer* with the IDE.

To register a custom Help viewer with the IDE,

1. Make sure that the unit implementing the Help viewer contains HelpIntfs.pas.
2. Build the unit into a design-time package registered with the IDE, and build the package with runtime packages turned on. (This is necessary to ensure that the Help Manager instance used by the unit is the same as the Help Manager instance used by the IDE.)
3. Make sure that the Help viewer exists as a global instance within the unit.
4. In the initialization section of the unit, make sure that the instance is passed to the *RegisterHelpViewer* function.

Chapter

6

Developing the application user interface

With Delphi, you design a user interface (UI) by selecting components from the component palette and dropping them onto forms. You get the components to do what you want by setting their properties and coding their event handlers.

Controlling application behavior

TApplication, *TScreen*, and *TForm* are the classes that form the backbone of all Delphi applications by controlling the behavior of your project. The *TApplication* class forms the foundation of an application by providing properties and methods that encapsulate the behavior of a standard program. *TScreen* is used at runtime to keep track of forms and data modules that have been loaded as well as maintaining system-specific information such as screen resolution and available display fonts. Instances of the *TForm* class are the building blocks of your application's user interface. The windows and dialog boxes in your application are based on *TForm*.

Using the main form

TForm is the key class for creating GUI applications. When you open Delphi displaying a default project or when you create a new project, a form is displayed on which you can begin your UI design.

The first form you create and save in a project becomes, by default, the project's main form, which is the first form created at runtime. As you add forms to your projects, you might decide to designate a different form as your application's main form. Also, specifying a form as the main form is an easy way to test it at runtime, because unless you change the form creation order, the main form is the first form displayed in the running application.

To change the project main form,

1 Choose Project | Options and select the Forms page.

2 In the Main Form combo box, select the form you want to use as the project's main form and choose OK.

Now if you run the application, the form you selected as the main form is displayed.

Adding forms

To add a form to your project, select File | New Form. You can see all your project's forms and their associated units listed in the Project Manager (View | Project Manager) and you can display a list of the forms alone by choosing View | Forms.

Linking forms

Adding a form to a project adds a reference to it in the project file, but not to any other units in the project. Before you can write code that references the new form, you need to add a reference to it in the referencing forms' unit files. This is called *form linking*.

A common reason to link forms is to provide access to the components in that form. For example, you'll often use form linking to enable a form that contains data-aware components to connect to the data-access components in a data module.

To link a form to another form,

1 Select the form that needs to refer to another.
2 Choose File | Use Unit.
3 Select the name of the form unit for the form to be referenced.
4 Choose OK.

Linking a form to another just means that the **uses** clauses of one form unit contains a reference to the other's form unit, meaning that the linked form and its components are now in scope for the linking form.

Avoiding circular unit references

When two forms must reference each other, it's possible to cause a "Circular reference" error when you compile your program. To avoid such an error, do one of the following:

- Place both **uses** clauses, with the unit identifiers, in the **implementation** parts of the respective unit files. (This is what the File | Use Unit command does.)
- Place one **uses** clause in an **interface** part and the other in an **implementation** part. (You rarely need to place another form's unit identifier in this unit's **interface** part.)

Do not place both **uses** clauses in the **interface** parts of their respective unit files. This will generate the "Circular reference" error at compile time.

Hiding the main form

You can prevent the main form from displaying when your application first starts up. To do so, you must use the global *Application* variable (described in the next topic).

To hide the main form at startup,

1 Choose Project | View Source to display the main project file.

2 Add the following lines after the call to `Application.CreateForm` and before the call to `Application.Run`.

```
Application.ShowMainForm := False;
Form1.Visible := False; { the name of your main form may differ }
```

Note You can set the form's *Visible* property to *False* using the Object Inspector at design time rather than setting it at runtime as shown above.

Working at the application level

The global variable *Application*, of type *TApplication*, is in every VCL or CLX based application. *Application* encapsulates your application as well as providing many functions that occur in the background of the program. For instance, *Application* would handle how you would call a help file from the menu of your program. Understanding how *TApplication* works is more important to a component writer than to developers of stand-alone applications, but you should set the options that *Application* handles in the Project | Options Application page when you create a project.

In addition, *Application* receives many events that apply to the application as a whole. For example, the *OnActivate* event lets you perform actions when the application first starts up, the *OnIdle* event lets you perform background processes when the application is not busy, the *OnMessage* event lets you intercept Windows messages (on Windows only), the *OnEvent* event lets you intercept events, and so on. Although you can't use the IDE to examine the properties and events of the global *Application* variable, another component, *TApplicationEvents*, intercepts the events and lets you supply event-handlers using the IDE.

Handling the screen

A global variable of type *TScreen* called *Screen* is created when you create a project. Screen encapsulates the state of the screen on which your application is running. Common tasks performed by *Screen* include specifying

- the look of the cursor
- the size of the window in which your application is running
- a list of fonts available to the screen device
- multiple screen behavior (not available for cross-platform)

If your Windows application runs on multiple monitors, *Screen* maintains a list of monitors and their dimensions so that you can effectively manage the layout of your user interface.

If using CLX for cross-platform programming, the default behavior is that applications create a screen component based on information about the current screen device and assign it to Screen.

Managing layout

At its simplest, you control the layout of your user interface by where you place controls in your forms. The placement choices you make are reflected in the control's *Top*, *Left*, *Width*, and *Height* properties. You can change these values at runtime to change the position and size of the controls in your forms.

Controls have a number of other properties, however, that allow them to automatically adjust to their contents or containers. This allows you to lay out your forms so that the pieces fit together into a unified whole.

Two properties affect how a control is positioned and sized in relation to its parent. The *Align* property lets you force a control to fit perfectly within its parent along a specific edge or filling up the entire client area after any other controls have been aligned. When the parent is resized, the controls aligned to it are automatically resized and remain positioned so that they fit against a particular edge.

If you want to keep a control positioned relative to a particular edge of its parent, but don't want it to necessarily touch that edge or be resized so that it always runs along the entire edge, you can use the *Anchors* property.

If you want to ensure that a control does not grow too big or too small, you can use the *Constraints* property. *Constraints* lets you specify the control's maximum height, minimum height, maximum width, and minimum width. Set these to limit the size (in pixels) of the control's height and width. For example, by setting the *MinWidth* and *MinHeight* of the constraints on a container object, you can ensure that child objects are always visible.

The value of *Constraints* propagates through the parent/child hierarchy so that an object's size can be constrained because it contains aligned children that have size constraints. *Constraints* can also prevent a control from being scaled in a particular dimension when its *ChangeScale* method is called.

TControl introduces a protected event, *OnConstrainedResize*, of type *TConstrainedResizeEvent*:

```
TConstrainedResizeEvent = procedure(Sender: TObject; var MinWidth, MinHeight, MaxWidth,
MaxHeight: Integer) of object;
```

This event allows you to override the size constraints when an attempt is made to resize the control. The values of the constraints are passed as `var` parameters which can be changed inside the event handler. *OnConstrainedResize* is published for container objects (*TForm*, *TScrollBox*, *TControlBar*, and *TPanel*). In addition, component writers can use or publish this event for any descendant of *TControl*.

Controls that have contents that can change in size have an *AutoSize* property that causes the control to adjust its size to its font or contained objects.

Responding to event notification

The operating system will notify your application when an event has occurred (such as a mouse click, keystrokes entered, and so on) while it is running. The underlying way that event notifications are handled by VCL and CLX objects is different, but the way you work with event notifications at the component level is typically the same. Components have events and methods built-in for the most commonly occurring events. You can use the methods provided with the component in most cases. If you need to write additional event handling, you can override an existing method to write your own. Unless you are writing your own components, you do not need to change the underlying event notification schema.

VCL If developing applications for Windows only, you need to understand that Windows is a message-based operating system. System messages are handled by a message handler that translates the message to an event or event handler. The message itself is a record passed to a control by Windows. For instance, when you click a mouse button on a dialog box, Windows sends a message to the active control and the application containing that control reacts to this new event. If the click occurs over a button, the *OnClick* event could be activated upon receipt of the message. If the click occurs just in the form, the application can ignore the message.

The record type passed to the application by Windows is called a *TMsg*. Windows predefines a constant for each message, and these values are stored in the message field of the *TMsg* record. Each of these constants begin with the letters wm.

The VCL automatically handles messages unless you override the message handling system and create your own message handlers. For more information on messages and message handling, see “Understanding the message-handling system” on page 46-1, “Changing message handling” on page 46-3, and “Creating new message handlers” on page 46-5.

CLX For cross-platform programming: The operating system notification that an event occurred is sent to the underlying Qt widget layer where it is translated into an event and eventually into event objects by *HookEvents*. *EventFilter* is called automatically when a CLX control needs to handle a Qt mouse or keyboard event.

EventFilter responds to event notifications by performing the default response. Typically, this involves dispatching the event to the appropriate virtual method (such as the *Click* method, which generates an *OnClick* event).

CLX Note When overriding the *EventFilter* method, you need to call the inherited method so that the default event processing can occur.

Using forms

When you create a form in Delphi from the IDE, Delphi automatically creates the form in memory by including code in the main entry point of your application function. Usually, this is the desired behavior and you don’t have to do anything to change it. That is, the main window persists through the duration of your program, so you would likely not change the default Delphi behavior when creating the form for your main window.

However, you may not want all your application's forms in memory for the duration of the program execution. That is, if you do not want all your application's dialogs in memory at once, you can create the dialogs dynamically when you want them to appear.

Forms can be modal or modeless. Modal forms are forms with which the user must interact before switching to another form (for example, a dialog box requiring user input). Modeless forms are windows that are displayed until they are either obscured by another window or until they are closed or minimized by the user.

Controlling when forms reside in memory

By default, Delphi automatically creates the application's main form in memory by including the following code in the application's main entry point:

```
Application.CreateForm(TForm1, Form1);
```

This function creates a global variable with the same name as the form. So, every form in an application has an associated global variable. This variable is a pointer to an instance of the form's class and is used to reference the form while the application is running. Any unit that includes the form's unit in its **uses** clause can access the form via this variable.

All forms created in this way in the project unit appear when the program is invoked and exist in memory for the duration of the application.

Displaying an auto-created form

If you choose to create a form at startup, and do not want it displayed until sometime later during program execution, the form's event handler uses the *ShowModal* method to display the form that is already loaded in memory:

```
procedure TMainForm.Button1Click(Sender: TObject);
begin
  ResultsForm.ShowModal;
end;
```

In this case, since the form is already in memory, there is no need to create another instance or destroy that instance.

Creating forms dynamically

You may not always want all your application's forms in memory at once. To reduce the amount of memory required at load time, you may want to create some forms only when you need to use them. For example, a dialog box needs to be in memory only during the time a user interacts with it.

To create a form at a different stage during execution using the IDE, you:

1 Select the File | New Form from the main menu to display the new form.

2 Remove the form from the Auto-create forms list of the Project | Options | Forms page.

This removes the form's invocation. As an alternative, you can manually remove the following line from program's main entry point:

```
Application.CreateForm(TResultsForm, ResultsForm);
```

3 Invoke the form when desired by using the form's *Show* method, if the form is modeless, or *ShowModal* method, if the form is modal.

An event handler for the main form must create an instance of the result form and destroy it. One way to invoke the result form is to use the global variable as follows. Note that *ResultsForm* is a modal form so the handler uses the *ShowModal* method.

```
procedure TMainForm.Button1Click(Sender: TObject);
begin
ResultsForm:=TResultForm.Create(self);
try
  ResultsForm.ShowModal;
finally
  ResultsForm.Free;
end;
```

In the above example, note the use of **try..finally**. Putting in the line `ResultsForm.Free;` in the **finally** clause ensures that the memory for the form is freed even if the form raises an exception.

The event handler in the example deletes the form after it is closed, so the form would need to be recreated if you needed to use *ResultsForm* elsewhere in the application. If the form were displayed using *Show* you could not delete the form within the event handler because *Show* returns while the form is still open.

Note If you create a form using its constructor, be sure to check that the form is not in the Auto-create forms list on the Project Options | Forms page. Specifically, if you create the new form without deleting the form of the same name from the list, Delphi creates the form at startup and this event-handler creates a new instance of the form, overwriting the reference to the auto-created instance. The auto-created instance still exists, but the application can no longer access it. After the event-handler terminates, the global variable no longer points to a valid form. Any attempt to use the global variable will likely crash the application.

Creating modeless forms such as windows

You must guarantee that reference variables for modeless forms exist for as long as the form is in use. This means that these variables should have global scope. In most cases, you use the global reference variable that was created when you made the form (the variable name that matches the name property of the form). If your application requires additional instances of the form, declare separate global variables for each instance.

Using a local variable to create a form instance

A safer way to create a unique instance of a *modal form* is to use a local variable in the event handler as a reference to a new instance. If a local variable is used, it does not matter whether *ResultsForm* is auto-created or not. The code in the event handler makes no reference to the global form variable. For example:

```
procedure TMainForm.Button1Click(Sender: TObject);
var
  RF:TResultForm;
begin
  RF:=TResultForm.Create(self)
  RF.ShowModal;
  RF.Free;
end;
```

Notice how the global instance of the form is never used in this version of the event handler.

Typically, applications use the global instances of forms. However, if you need a new instance of a modal form, and you use that form in a limited, discrete section of the application, such as a single function, a local instance is usually the safest and most efficient way of working with the form.

Of course, you cannot use local variables in event handlers for modeless forms because they must have global scope to ensure that the forms exist for as long as the form is in use. *Show* returns as soon as the form opens, so if you used a local variable, the local variable would go out of scope immediately.

Passing additional arguments to forms

Typically, you create forms for your application from within the IDE. When created this way, the forms have a constructor that takes one argument, *Owner*, which is the owner of the form being created. (The owner is the calling application object or form object.) *Owner* can be **nil**.

To pass additional arguments to a form, create a separate constructor and instantiate the form using this new constructor. The example form class below shows an additional constructor, with the extra argument *whichButton*. This new constructor is added to the form class manually.

```
TResultsForm = class(TForm)
  ResultsLabel: TLabel;
  OKButton: TButton;
  procedure OKButtonClick(Sender: TObject);
private
public
  constructor CreateWithButton(whichButton: Integer; Owner: TComponent);
end;
```

Here's the manually coded constructor that passes the additional argument, *whichButton*. This constructor uses the *whichButton* parameter to set the *Caption* property of a *Label* control on the form.

```
constructor CreateWithButton(whichButton: Integer; Owner: TComponent);
begin
  inherited Create(Owner);
  case whichButton of
```

```
      1: ResultsLabel.Caption := 'You picked the first button.';
      2: ResultsLabel.Caption := 'You picked the second button.';
      3: ResultsLabel.Caption := 'You picked the third button.';
    end;
  end;
```

When creating an instance of a form with multiple constructors, you can select the constructor that best suits your purpose. For example, the following *OnClick* handler for a button on a form calls creates an instance of *TResultsForm* that uses the extra parameter:

```
procedure TMainForm.SecondButtonClick(Sender: TObject);
var
  rf: TResultsForm;
begin
  rf := TResultsForm.CreateWithButton(2, self);
  rf.ShowModal;
  rf.Free;
end;
```

Retrieving data from forms

Most real-world applications consist of several forms. Often, information needs to be passed between these forms. Information can be passed to a form by means of parameters to the receiving form's constructor, or by assigning values to the form's properties. The way you get information from a form depends on whether the form is modal or modeless.

Retrieving data from modeless forms

You can easily extract information from modeless forms by calling public member functions of the form or by querying properties of the form. For example, assume an application contains a modeless form called *ColorForm* that contains a listbox called *ColorListBox* with a list of colors ("Red", "Green", "Blue", and so on). The selected color name string in *ColorListBox* is automatically stored in a property called *CurrentColor* each time a user selects a new color. The class declaration for the form is as follows:

```
TColorForm = class(TForm)
  ColorListBox:TListBox;
  procedure ColorListBoxClick(Sender: TObject);
private
  FColor:String;
public
  property CurColor:String read FColor write FColor;
end;
```

The *OnClick* event handler for the listbox, *ColorListBoxClick*, sets the value of the *CurrentColor* property each time a new item in the listbox is selected. The event handler gets the string from the listbox containing the color name and assigns it to *CurrentColor*. The *CurrentColor* property uses the setter function, *SetColor*, to store the actual value for the property in the private data member *FColor*:

```
procedure TColorForm.ColorListBoxClick(Sender: TObject);
var
  Index: Integer;
begin
  Index := ColorListBox.ItemIndex;
  if Index >= 0 then
    CurrentColor := ColorListBox.Items[Index]
  else
    CurrentColor := '';
end;
```

Now suppose that another form within the application, called *ResultsForm*, needs to find out which color is currently selected on *ColorForm* whenever a button (called *UpdateButton)* on *ResultsForm* is clicked. The *OnClick* event handler for *UpdateButton* might look like this:

```
procedure TResultForm.UpdateButtonClick(Sender: TObject);
var
  MainColor: String;
begin
  if Assigned(ColorForm) then
  begin
    MainColor := ColorForm.CurrentColor;
    {do something with the string MainColor}
  end;
end;
```

The event handler first verifies that *ColorForm* exists using the *Assigned* function. It then gets the value of *ColorForm's CurrentColor* property.

Alternatively, if *ColorForm* had a public function named *GetColor*, another form could get the current color without using the *CurrentColor* property (for example, `MainColor := ColorForm.GetColor;`). In fact, there's nothing to prevent another form from getting the *ColorForm's* currently selected color by checking the listbox selection directly:

```
with ColorForm.ColorListBox do
  MainColor := Items[ItemIndex];
```

However, using a property makes the interface to *ColorForm* very straightforward and simple. All a form needs to know about *ColorForm* is to check the value of *CurrentColor*.

Retrieving data from modal forms

Just like modeless forms, modal forms often contain information needed by other forms. The most common example is form A launches modal form B. When form B is closed, form A needs to know what the user did with form B to decide how to proceed with the processing of form A. If form B is still in memory, it can be queried through properties or member functions just as in the modeless forms example above. But how do you handle situations where form B is deleted from memory upon closing? Since a form does not have an explicit return value, you must preserve important information from the form before it is destroyed.

To illustrate, consider a modified version of the *ColorForm* form that is designed to be a modal form. The class declaration is as follows:

```
TColorForm = class(TForm)
  ColorListBox:TListBox;
  SelectButton: TButton;
  CancelButton: TButton;
  procedure CancelButtonClick(Sender: TObject);
  procedure SelectButtonClick(Sender: TObject);
private
  FColor: Pointer;
public
  constructor CreateWithColor(Value: Pointer; Owner: TComponent);
end;
```

The form has a listbox called *ColorListBox* with a list of names of colors. When pressed, the button called *SelectButton* makes note of the currently selected color name in *ColorListBox* then closes the form. *CancelButton* is a button that simply closes the form.

Note that a user-defined constructor was added to the class that takes a *Pointer* argument. Presumably, this *Pointer* points to a string that the form launching *ColorForm* knows about. The implementation of this constructor is as follows:

```
constructor TColorForm(Value: Pointer; Owner: TComponent);
begin
  FColor := Value;
  String(FColor^) := '';
end;
```

The constructor saves the pointer to a private data member *FColor* and initializes the string to an empty string.

Note To use the above user-defined constructor, the form must be explicitly created. It cannot be auto-created when the application is started. For details, see "Controlling when forms reside in memory" on page 6-6.

In the application, the user selects a color from the listbox and presses *SelectButton* to save the choice and close the form. The *OnClick* event handler for *SelectButton* might look like this:

```
procedure TColorForm.SelectButtonClick(Sender: TObject);
begin
  with ColorListBox do
    if ItemIndex >= 0 then
      String(FColor^) := ColorListBox.Items[ItemIndex];
  end;
  Close;
end;
```

Notice that the event handler stores the selected color name in the string referenced by the pointer that was passed to the constructor.

To use *ColorForm* effectively, the calling form must pass the constructor a pointer to an existing string. For example, assume *ColorForm* was instantiated by a form called *ResultsForm* in response to a button called *UpdateButton* on *ResultsForm* being clicked.

The event handler would look as follows:

```
procedure TResultsForm.UpdateButtonClick(Sender: TObject);
var
  MainColor: String;
begin
  GetColor(Addr(MainColor));
  if MainColor <> '' then
    {do something with the MainColor string}
  else
    {do something else because no color was picked}
end;

procedure GetColor(PColor: Pointer);
begin
  ColorForm := TColorForm.CreateWithColor(PColor, Self);
  ColorForm.ShowModal;
  ColorForm.Free;
end;
```

UpdateButtonClick creates a String called MainColor. The address of MainColor is passed to the *GetColor* function which creates *ColorForm*, passing the pointer to MainColor as an argument to the constructor. As soon as *ColorForm* is closed it is deleted, but the color name that was selected is still preserved in MainColor, assuming that a color was selected. Otherwise, MainColor contains an empty string which is a clear indication that the user exited *ColorForm* without selecting a color.

This example uses one string variable to hold information from the modal form. Of course, more complex objects can be used depending on the need. Keep in mind that you should always provide a way to let the calling form know if the modal form was closed without making any changes or selections (such as having MainColor default to an empty string).

Reusing components and groups of components

Delphi offers several ways to save and reuse work you've done with components:

- *Component templates* provide a simple, quick way of configuring and saving groups of components. See "Creating and using component templates" on page 6-13.
- You can save forms, data modules, and projects in the *Repository*. This gives you a central database of reusable elements and lets you use form inheritance to propagate changes. See "Using the Object Repository" on page 5-19.
- You can save *frames* on the component palette or in the repository. Frames use form inheritance and can be embedded into forms or other frames. See "Working with frames" on page 6-13.
- Creating a *custom component* is the most complicated way of reusing code, but it offers the greatest flexibility. See Chapter 40, "Overview of component creation."

Creating and using component templates

You can create templates that are made up of one or more components. After arranging components on a form, setting their properties, and writing code for them, save them as a *component template*. Later, by selecting the template from the component palette, you can place the preconfigured components on a form in a single step; all associated properties and event-handling code are added to your project at the same time.

Once you place a template on a form, you can reposition the components independently, reset their properties, and create or modify event handlers for them just as if you had placed each component in a separate operation.

To create a component template,

1. Place and arrange components on a form. In the Object Inspector, set their properties and events as desired.
2. Select the components. The easiest way to select several components is to drag the mouse over all of them. Gray handles appear at the corners of each selected component.
3. Choose Component | Create Component Template.
4. Specify a name for the component template in the Component Name edit box. The default proposal is the component type of the first component selected in step 2 followed by the word “Template”. For example, if you select a label and then an edit box, the proposed name will be “TLabelTemplate”. You can change this name, but be careful not to duplicate existing component names.
5. In the Palette Page edit box, specify the component palette page where you want the template to reside. If you specify a page that does not exist, a new page is created when you save the template.
6. Under Palette Icon, select a bitmap to represent the template on the palette. The default proposal will be the bitmap used by the component type of the first component selected in step 2. To browse for other bitmaps, click Change. The bitmap you choose must be no larger than 24 pixels by 24 pixels.
7. Click OK.

To remove templates from the component palette, choose Component | Configure Palette.

Working with frames

A frame (*TFrame*), like a form, is a container for other components. It uses the same ownership mechanism as forms for automatic instantiation and destruction of the components on it, and the same parent-child relationships for synchronization of component properties.

In some ways, however, a frame is more like a customized component than a form. Frames can be saved on the component palette for easy reuse, and they can be nested within forms, other frames, or other container objects. After a frame is created and saved, it continues to function as a unit and to inherit changes from the components (including other frames) it contains. When a frame is embedded in another frame or form, it continues to inherit changes made to the frame from which it derives.

Frames are useful to organize groups of controls that are used in multiple places in your application. For example, if you have a bitmap that is used on multiple forms, you can put it in a frame and only one copy of that bitmap is included in the resources of your application. You could also describe a set of edit fields that are intended to edit a table with a frame and use that whenever you want to enter data into the table.

Creating frames

To create an empty frame, choose File | New | Frame, or choose File | New and double-click on Frame. You can then drop components (including other frames) onto your new frame.

It is usually best—though not necessary—to save frames as part of a project. If you want to create a project that contains only frames and no forms, choose File | New | Application, close the new form and unit without saving them, then choose File | New | Frame and save the project.

Note When you save frames, avoid using the default names *Unit1*, *Project1*, and so forth, since these are likely to cause conflicts when you try to use the frames later.

At design time, you can display any frame included in the current project by choosing View | Forms and selecting a frame. As with forms and data modules, you can toggle between the Form Designer and the frame’s form file by right-clicking and choosing View as Form or View as Text.

Adding frames to the component palette

Frames are added to the component palette as component templates. To add a frame to the component palette, open the frame in the Form Designer (you cannot use a frame embedded in another component for this purpose), right-click on the frame, and choose Add to Palette. When the Component Template Information dialog opens, select a name, palette page, and icon for the new template.

Using and modifying frames

To use a frame in an application, you must place it, directly or indirectly, on a form. You can add frames directly to forms, to other frames, or to other container objects such as panels and scroll boxes.

The Form Designer provides two ways to add a frame to an application:

- Select a frame from the component palette and drop it onto a form, another frame, or another container object. If necessary, the Form Designer asks for permission to include the frame’s unit file in your project.

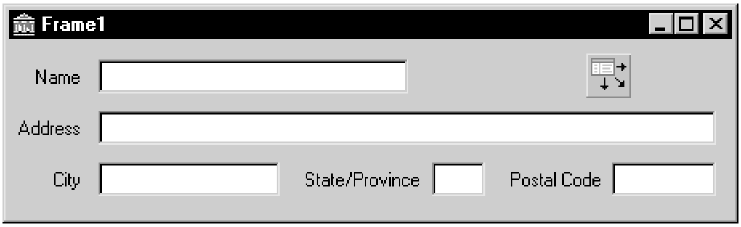
- Select *Frames* from the Standard page of the component palette and click on a form or another frame. A dialog appears with a list of frames that are already included in your project; select one and click OK.

When you drop a frame onto a form or other container, Delphi declares a new class that descends from the frame you selected. (Similarly, when you add a new form to a project, Delphi declares a new class that descends from *TForm*.) This means that changes made later to the original (ancestor) frame propagate to the embedded frame, but changes to the embedded frame do not propagate backward to the ancestor.

Suppose, for example, that you wanted to assemble a group of data-access components and data-aware controls for repeated use, perhaps in more than one application. One way to accomplish this would be to collect the components into a component template; but if you started to use the template and later changed your mind about the arrangement of the controls, you would have to go back and manually alter each project where the template was placed.

If, on the other hand, you put your database components into a frame, later changes would need to be made in only one place; changes to an original frame automatically propagate to its embedded descendants when your projects are recompiled. At the same time, you are free to modify any embedded frame without affecting the original frame or other embedded descendants of it. The only limitation on modifying embedded frames is that you cannot add components to them.

Figure 6.1 A frame with data-aware controls and a data source component



In addition to simplifying maintenance, frames can help you to use resources more efficiently. For example, to use a bitmap or other graphic in an application, you might load the graphic into the *Picture* property of a *TImage* control. If, however, you use the same graphic repeatedly in one application, each *Imag*e object you place on a form will result in another copy of the graphic being added to the form's resource file. (This is true even if you set *TImage.Picture* once and save the *Image* control as a component template.) A better solution is to drop the *Image* object onto a frame, load your graphic into it, then use the frame where you want the graphic to appear. This results in smaller form files and has the added advantage of letting you change the graphic everywhere it occurs simply by modifying the *Image* on the original frame.

Sharing frames

You can share a frame with other developers in two ways:

- Add the frame to the Object Repository.
- Distribute the frame's unit (.pas) and form (.dfm or .xfm) files.

To add a frame to the Repository, open any project that includes the frame, right-click in the Form Designer, and choose Add to Repository For more information, see “Using the Object Repository” on page 5-19.

If you send a frame’s unit and form files to other developers, they can open them and add them to the component palette. If the frame has other frames embedded in it, they will have to open it as part of a project.

Organizing actions for toolbars and menus

Delphi provides several features that simplify the work of creating, customizing, and maintaining menus and toolbars. These features allow you to organize lists of actions that users of your application can initiate by pressing a button on a toolbar, choosing a command on a menu, or pointing and clicking on an icon.

Often a set of actions is used in more than one user interface element. For example, the Cut, Copy, and Paste commands often appear on both an Edit menu and on a toolbar. You only need to add the action once to use it in multiple UI elements in your application.

On the Windows platform, tools are provided to make it easy to define and group actions, create different layouts, and customize menus at design time or runtime. These tools are known collectively as ActionBand tools, and the menus and toolbars you create with them are known as action bands. In general, you can create an ActionBand user interface as follows:

- Build the action list to create a set of actions that will be available for your application (use the Action Manager, *TActionManager*)
- Add the user interface elements to the application (use ActionBand components such as *TActionMainMenuBar* and *TActionToolBar*)
- Drag and drop actions from the Action Manager onto the user interface elements

The following table defines the terminology related to setting up menus and toolbars:

Table 6.1 Action setup terminology

Term	Definition
Action	A response to something a user does, such as clicking a menu item. Many standard actions that are frequently required are provided for you to use in your applications as is. For example, file operations such as File Open, File Save As, File Run, and File Exit are included along with many others for editing, formatting, searches, help, dialogs, and window actions. You can also program custom actions and access them using action lists and the Action Manager.
Action band	A container for a set of actions associated with a customizable menu or toolbar. The ActionBand components for main menus and toolbars (*TActionMainMenuBar* and *TActionToolBar*) are examples of action bands.
Action category	Lets you group actions and drop them as a group onto a menu or toolbar. For example, one of the standard action categories is Search which includes Find, FindFirst, FindNext, and Replace actions all at once.

Table 6.1 Action setup terminology (continued)

Term	Definition
Action classes	Classes that perform the actions used in your application. All of the standard actions are defined in action classes such as *TEditCopy*, *TEditCut*, and *TEditUndo*. You can use these classes by dragging and dropping them from the Customize dialog onto an action band.
Action client	Most often represents a menu item or a button that receives a notification to initiate an action. When the client receives a user command (such as a mouse click), it initiates an associated action.
Action list	Maintains a list of actions that your application can take in response to something a user does.
Action Manager	Groups and organizes logical sets of actions that can be reused on ActionBand components. See *TActionManager*.
Menu	Lists commands that the user of the application can execute by clicking on them. You can create menus by using the ActionBand menu class *TActionMainMenuBar*, or by using cross-platform components such as *TMainMenu* or *TPopupMenu*.
Target	Represents the item an action does something to. The target is usually a control, such as a memo or a data control. Not all actions require a target. For example, the standard help actions ignore the target and simply launch the help system.
Toolbar	Displays a visible row of button icons which, when clicked, cause the program to perform some action, such as printing the current document. You can create toolbars by using the ActionBand toolbar component *TActionToolBar*, or by using the cross-platform component *TToolBar*.

If you are doing cross-platform development, refer to “Using action lists” on page 6-23.

What is an action?

As you are developing your application, you can create a set of actions that you can use on various UI elements. You can organize them into categories that can be dropped onto a menu as a set (for example, Cut, Copy, and Paste) or one at a time (for example, Tools|Customize).

An action corresponds to one or more elements of the user interface, such as menu commands or toolbar buttons. Actions serve two functions: (1) they represent properties common to the user interface elements, such as whether a control is enabled or checked, and (2) they respond when a control fires, for example, when the application user clicks a button or chooses a menu item. You can create a repertoire of actions that are available to your application through menus, through buttons, through toolbars, context menus, and so on.

Actions are associated with other components:

- **Clients:** One or more clients use the action. The client most often represents a menu item or a button (for example, *TToolButton*, *TSpeedButton*, *TMenuItem*, *TButton*, *TCheckBox*, *TRadioButton*, and so on). Actions also reside on ActionBand components such as *TActionMainMenuBar* and *TActionToolBar*. When the client receives a user command (such as a mouse click), it initiates an associated action. Typically, a client’s *OnClick* event is associated with its action’s *Execute* event.

- **Target:** The action acts on the target. The target is usually a control, such as a memo or a data control. Component writers can create actions specific to the needs of the controls they design and use, and then package those units to create more modular applications. Not all actions use a target. For example, the standard help actions ignore the target and simply launch the help system.

  A target can also be a component. For example, data controls change the target to an associated dataset.

The client influences the action—the action responds when a client fires the action. The action also influences the client—action properties dynamically update the client properties. For example, if at runtime an action is disabled (by setting its *Enabled* property to *False*), every client of that action is disabled, appearing grayed.

You can add, delete, and rearrange actions using the Action Manager or the Action List editor (displayed by double-clicking an action list object, *TActionList*). These actions are later connected to client controls.

Setting up action bands

Because actions do not maintain any “layout” (either appearance or positional) information, Delphi provides action bands which are capable of storing this data. Action bands provide a mechanism that allows you to specify layout information and a set of controls. You can render actions as UI elements such as toolbars and menus.

You organize sets of actions using the Action Manager (*TActionManager*). You can use standard actions provided or create new actions of your own.

You then create the action bands:

- Use *TActionMainMenuBar* to create a main menu.
- Use *TActionToolBar* to create a toolbar.

The action bands act as containers that hold and render sets of actions. You can drag and drop items from the Action Manager editor onto the action band at design time. At runtime, application users can also customize the application’s menus or toolbars using a dialog box similar to the Action Manager editor.

Creating toolbars and menus

Note This section describes the recommended method for creating menus and toolbars in Windows applications. For cross-platform development, you need to use *TToolBar* and the menu components, such as *TMainMenu,* organizing them using action lists (*TActionList*). See “Setting up action lists” on page 6-23.

You use the Action Manager to automatically generate toolbars and main menus based on the actions contained in your application. The Action Manager manages standard actions and any custom actions that you have written. You then create UI elements based on these actions and use action bands to render the actions items as either menu items or as buttons on a toolbar.

The general procedure for creating menus, toolbars, and other action bands involves these steps:

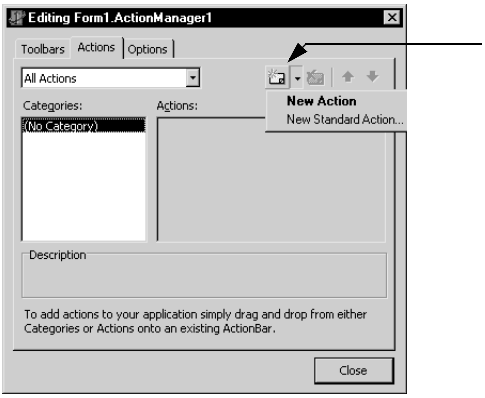
- Drop an Action Manager onto a form.
- Add actions to the Action Manager, which organizes them into appropriate action lists.
- Create the action bands (that is, the menu or the toolbar) for the user interface.
- Drag and drop the actions into the application interface.

The following procedure explains these steps in more detail.

To create menus and toolbars using action bands:

1. From the Additional page of the component palette, drop an Action Manager component (*TActionManager*) onto the form where you want to create the toolbar or menu.
2. If you want images on the menu or toolbar, drop an ImageList component from the Win32 page of the component palette onto a form. (You need to add the images you want to use to the ImageList or use the one provided.)
3. From the Additional page of the component palette, drop one or more of the following action bands onto the form:
   - *TActionMainMenuBar* (for designing main menus)
   - *TActionToolBar* (for designing toolbars)
4. Connect the ImageList to the Action Manager: with focus on the Action Manager and in the Object Inspector, select the name of the ImageList from the Images property.
5. Add actions to the Action Manager editor's action pane:
   - Double-click the Action Manager to display the Action Manager editor.
   - Click the drop-down arrow next to the New Action button (the leftmost button at the top right corner of the Actions tab, as shown in Figure 6.2) and select "New Action..." or "New Standard Action...". A tree view is displayed. Add one or more actions or categories of actions to the Action Manager's actions pane. The Action Manager adds the actions to its action lists.

Figure 6.2 The Action Manager editor.



To add actions to your application simply drag and drop from either Categories or Actions onto an existing ActionBar.

New Action button & dropdown button

6 Drag and drop single actions or categories of actions from the Action Manager editor onto the menu or toolbar you are designing.

To add user-defined actions, create a new *TAction* by pressing the New Action button and writing an event handler that defines how it will respond when fired. See “What happens when an action fires” on page 6-24 for details. Once you’ve defined the actions, you can drag and drop them onto menus or toolbars like the standard actions.

Adding color, patterns, or pictures to menus, buttons, and toolbars

You can use the *Background* and *BackgroundLayout* properties to specify a color, pattern, or bitmap to use on a menu item or button. These properties also let you set up a banner the runs up the left or right side of a menu.

You assign backgrounds and layouts to subitems from their action client objects. If you want to set the background of the items in a menu, in the form designer click on the menu item that contains the items. For example, selecting File lets you change the background of items appearing on the File menu. You can assign a color, pattern, or bitmap in the *Background* property in the Object Inspector.

Use the *BackgroundLayout* property to describe how to place the background on the element. Colors or images can be placed behind the caption normally, stretched to fit the item area, or tiled in small squares to cover the area.

Items with normal (blNormal), stretched (blStretch), or tiled (blTile) backgrounds are rendered with a transparent background. If you create a banner, the full image is placed on the left (blLeftBanner) or the right (blRightBanner) of the item. You need to make sure it is the correct size because it is not stretched or shrunk to fit.

To change the background of an action band (that is, on a main menu or toolbar), select the action band and choose the *TActionClientBar* through the action band collection editor. You can set *Background* and *BackgroundLayout* properties to specify a color, pattern, or bitmap to use on the entire toolbar or menu.

Adding icons to menus and toolbars

You can add icons next to menu items or replace captions on toolbars with icons. You organize bitmaps or icons using an ImageList.

1. Drop an ImageList component from the Win32 page of the component palette onto a form.
2. Add the images you want to use to the ImageList: Double-click the ImageList. Click Add and navigate to the images you want to use and click OK when done. Some sample images are included in Program Files\Common Files\Borland Shared\Images. (The buttons images include two views of each for active and inactive buttons.)
3. From the Additional page of the component palette, drop one or more of the following action bands onto the form:
   - *TActionMainMenuBar* (for designing main menus)
   - *TActionToolBar* (for designing toolbars)
4. Connect the ImageList to the Action Manager. First, set the focus on the Action Manager. Next, in the Object Inspector, select the name of the ImageList from the Images property.
5. Use the Action Manager editor to add actions to the Action Manager. You can associate an image with an action by setting its *ImageIndex* property to its number in the ImageList.
6. Drag and drop single actions or categories of actions from the Action Manager editor onto the menu or toolbar.
7. For toolbars where you only want to display the icon and no caption: select the Toolbar action band and double-click its Items property. In the collection editor, you can select one or more items and set their Caption properties.
8. The images automatically appear on the menu or toolbar.

Creating toolbars and menus that users can customize

You can use action bands with the Action Manager to create customizable toolbars and menus. At runtime, users of your application can customize the toolbars and menus (action bands) in the application user interface using a customization dialog similar to the Action Manager editor.

To allow the user of your application to customize an action band in your application:

1. Drop an Action Manager component onto a form.
2. Drop your action band components (*TActionMainMenuBar*, *TActionToolBar*).
3. Double-click the Action Manager to display the Action Manager editor:
   - Add the actions you want to use in your application. Also add the Customize action, which appears at the bottom of the standard actions list.

- Drop a *TCustomizeDlg* component from the Dialogs tab onto the form, and connect it to the Action Manager using its ActionManager property. You specify a filename for where to stream customizations made by users.
- Drag and drop the actions onto the action band components. (Make sure you add the Customize action to the toolbar or menu.)

4 Complete your application.

When you compile and run the application, users can access a Customize command that displays a customization dialog box similar to the Action Manager editor. They can drag and drop menu items and create toolbars using the same actions you supplied in the Action Manager.

Hiding unused items and categories in action bands

One benefit of using ActionBands is that unused items and categories can be hidden from the user. Over time, the action bands become customized for the application users, showing only the items that they use and hiding the rest from view. Hidden items can become visible again when the user presses a dropdown button. Also, the user can restore the visibility of all action band items by resetting the usage statistics from the customization dialog. Item hiding is the default behavior of action bands, but that behavior can be changed to prevent hiding of individual items, all the items in a particular collection (like the File menu), or all of the items in a given action band.

The action manager keeps track of the number of times an action has been called by the user, which is stored in the associated *TActionClientItem*'s *UsageCount* field. The action manager also records the number of times the application has been run, which we shall call the session number, as well as the session number of the last time an action was used. The value of *UsageCount* is used to look up the maximum number of sessions the item can go unused before it becomes hidden, which is then compared with the difference between the current session number and the session number of the last use of the item. If that difference is greater than the number determined in *PrioritySchedule*, the item is hidden. The default values of *PrioritySchedule* are shown in the table below:

Table 6.2 Default values of the action manager's PrioritySchedule property

Number of sessions in which an action band item was used	Number of sessions an item will remain unhidden after its last use
0, 1	3
2	6
3	9
4, 5	12
6-8	17
9-13	23
14-24	29
25 or more	31

It is possible to disable item hiding at design time. To prevent a specific action (and all the collections containing it) from becoming hidden, find its TActionClientItem object and set its *UsageCount* to -1. To prevent hiding for an entire collection of items, such as the File menu or even the main menu bar, find the *TActionClients* object associated with the collection and set its *HideUnused* property to *False*.

Using action lists

Note The contents of this section apply to setting up toolbars and menus for cross-platform development. For Windows development you can also use the methods described here. However, using action bands instead is simpler and offers more options. The action lists will be handled automatically by the Action Manager. See "Organizing actions for toolbars and menus" on page 6-16 for information on using action bands and the Action Manager.

Action lists maintain a list of actions that your application can take in response to something a user does. By using action objects, you centralize the functions performed by your application from the user interface. This lets you share common code for performing actions (for example, when a toolbar button and menu item do the same thing), as well as providing a single, centralized way to enable and disable actions depending on the state of your application.

Setting up action lists

Setting up action lists is fairly easy once you understand the basic steps involved:

- Create the action list.
- Add actions to the action list.
- Set properties on the actions.
- Attach clients to the action.

Here are the steps in more detail:

1. Drop a *TActionList* object onto your form or data module. (ActionList is on the Standard page of the component palette.)
2. Double-click the *TActionList* object to display the Action List editor.
   a. Use one of the predefined actions listed in the editor: right-click and choose New Standard Action.
   b. The predefined actions are organized into categories (such as Dataset, Edit, Help, and Window) in the Standard Action Classes dialog box. Select all the standard actions you want to add to the action list and click OK.

      or

   c. Create a new action of your own: right-click and choose New Action.

3 Set the properties of each action in the Object Inspector. (The properties you set affect every client of the action.)

The *Name* property identifies the action, and the other properties and events (*Caption*, *Checked*, *Enabled*, *HelpContext*, *Hint*, *ImageIndex*, *ShortCut*, *Visible,* and *Execute*) correspond to the properties and events of its client controls. The client's corresponding properties are typically, but not necessarily, the same name as the corresponding client property. For example, an action's *Enabled* property corresponds to a *TToolButton*'s *Enabled* property. However, an action's *Checked* property corresponds to a *TToolButton*'s *Down* property.

4 If you use the predefined actions, the action includes a standard response that occurs automatically. If creating your own action, you need to write an event handler that defines how the action responds when fired. See "What happens when an action fires" on page 6-24 for details.

5 Attach the actions in the action list to the clients that require them:

- Click on the control (such as the button or menu item) on the form or data module. In the Object Inspector, the *Action* property lists the available actions.
- Select the one you want.

The standard actions, such as *TEditDelete* or *TDataSetPost*, all perform the action you would expect. You can look at the online reference Help for details on how all of the standard actions work if you need to. If writing your own actions, you'll need to understand more about what happens when the action is fired.

What happens when an action fires

When an event fires, a series of events intended primarily for generic actions occurs. Then if the event doesn't handle the action, another sequence of events occurs.

Responding with events

When a client component or control is clicked or otherwise acted on, a series of events occurs to which you can respond. For example, the following code illustrates the event handler for an action that toggles the visibility of a toolbar when the action is executed:

```
procedure TForm1.Action1Execute(Sender: TObject);
begin
  { Toggle Toolbar1's visibility }
  ToolBar1.Visible := not ToolBar1.Visible;
end;
```

Note For general information about events and event handlers, see Working with events and event handlers"Working with events and event handlers" on page 25.

You can supply an event handler that responds at one of three different levels: the action, the action list, or the application. This is only a concern if you are using a new generic action rather than a predefined standard action. You do not have to worry about this if using the standard actions because standard actions have built-in behavior that executes when these events occur.

The order in which the event handlers will respond to events is as follows:

- Action list
- Application
- Action

When the user clicks on a client control, Delphi calls the action's Execute method which defers first to the action list, then the Application object, then the action itself if neither action list nor Application handles it. To explain this in more detail, Delphi follows this dispatching sequence when looking for a way to respond to the user action:

1 If you supply an *OnExecute* event handler for the action list and it handles the action, the application proceeds.

  The action list's event handler has a parameter called *Handled*, that returns *False* by default. If the handler is assigned and it handles the event, it returns *True*, and the processing sequence ends here. For example:

```
procedure TForm1.ActionList1ExecuteAction(Action: TBasicAction; var Handled: Boolean);
begin
  Handled := True;
end;
```

  If you don't set *Handled* to *True* in the action list event handler, then processing continues.

2 If you did not write an *OnExecute* event handler for the action list or if the event handler doesn't handle the action, the application's *OnActionExecute* event handler fires. If it handles the action, the application proceeds.

  The global *Application* object receives an *OnActionExecute* event if any action list in the application fails to handle an event. Like the action list's *OnExecute* event handler, the *OnActionExecute* handler has a parameter *Handled* that returns *False* by default. If an event handler is assigned and handles the event, it returns *True*, and the processing sequence ends here. For example:

```
procedure TForm1.ApplicationExecuteAction(Action: TBasicAction; var Handled: Boolean);
begin
  { Prevent execution of all actions in Application }
  Handled := True;
end;
```

3 If the application's *OnExecute* event handler doesn't handle the action, the action's *OnExecute* event handler fires.

You can use built-in actions or create your own action classes that know how to operate on specific target classes (such as edit controls). When no event handler is found at any level, the application next tries to find a target on which to execute the action. When the application locates a target that the action knows how to address, it invokes the action. See the next section for details on how the application locates a target that can respond to a predefined action class.

How actions find their targets

"What happens when an action fires" on page 6-24 describes the execution cycle that occurs when a user invokes an action. If no event handler is assigned to respond to the action, either at the action list, application, or action level, then the application tries to identify a target object to which the action can apply itself.

The application looks for the target using the following sequence:

1. Active control: The application looks first for an active control as a potential target.
2. Active form: If the application does not find an active control or if the active control can't act as a target, it looks at the screen's *ActiveForm*.
3. Controls on the form: If the active form is not an appropriate target, the application looks at the other controls on the active form for a target.

If no target is located, nothing happens when the event is fired.

Some controls can expand the search to defer the target to an associated component; for example, data-aware controls defer to the associated dataset component. Also, some predefined actions do not use a target; for example, the File Open dialog.

Updating actions

When the application is idle, the *OnUpdate* event occurs for every action that is linked to a control or menu item that is showing. This provides an opportunity for applications to execute centralized code for enabling and disabling, checking and unchecking, and so on. For example, the following code illustrates the *OnUpdate* event handler for an action that is "checked" when the toolbar is visible:

```
procedure TForm1.Action1Update(Sender: TObject);
begin
  { Indicate whether ToolBar1 is currently visible }
  (Sender as TAction).Checked := ToolBar1.Visible;
end;
```

Warning Do not add time-intensive code to the *OnUpdate* event handler. This executes whenever the application is idle. If the event handler takes too much time, it will adversely affect performance of the entire application.

Predefined action classes

You can add predefined actions to your application by right-clicking on the Action Manager and choosing New Standard Action. The New Standard Action Classes dialog box is displayed listing the predefined action classes and the associated standard actions. These are actions that are included with Delphi and they are objects that automatically perform actions. The predefined actions are organized within the following classes:

Table 6.3 Action classes

Class	Description
Edit	Standard edit actions: Used with an edit control target. *TEditAction* is the base class for descendants that each override the *ExecuteTarget* method to implement copy, cut, and paste tasks by using the clipboard.
Format	Standard formatting actions: Used with rich text to apply text formatting options such as bold, italic, underline, strikeout, and so on. *TRichEditAction* is the base class for descendants that each override the *ExecuteTarget* and *UpdateTarget* methods to implement formatting of the target.
Help	Standard Help actions: Used with any target. *THelpAction* is the base class for descendants that each override the *ExecuteTarget* method to pass the command onto a Help system.
Window	Standard window actions: Used with forms as targets in an MDI application. *TWindowAction* is the base class for descendants that each override the *ExecuteTarget* method to implement arranging, cascading, closing, tiling, and minimizing MDI child forms.
File	File actions: Used with operations on files such as File Open, File Run, or File Exit.
Search	Search actions: Used with search options. *TSearchAction* implements the common behavior for actions that display a modeless dialog where the user can enter a search string for searching an edit control.
Tab	Tab control actions: Used to move between tabs on a tab control such as the Prev and Next buttons on a wizard.
List	List control actions: Used for managing items in a list view.
Dialog	Dialog actions: Used with dialog components. *TDialogAction* implements the common behavior for actions that display a dialog when executed. Each descendant class represents a specific dialog.
Internet	Internet actions: Used for functions such as Internet browsing, downloading, and sending mail.
DataSet	DataSet actions: Used with a dataset component target. *TDataSetAction* is the base class for descendants that each override the *ExecuteTarget* and *UpdateTarget* methods to implement navigation and editing of the target. *TDataSetAction* introduces a *DataSource* property that ensures actions are performed on that dataset. If *DataSource* is nil, the currently focused data-aware control is used.
Tools	Tools: Additional tools such as *TCustomizeActionBars* for automatically displaying the customization dialog for action bands.

All of the action objects are described under the action object names in the online reference Help. Refer to the Help for details on how they work.

Writing action components

You can also create your own predefined action classes. When you write your own action classes, you can build in the ability to execute on certain target classes of object. Then, you can use your custom actions in the same way you use pre-defined action classes. That is, when the action can recognize and apply itself to a target class, you can simply assign the action to a client control, and it acts on the target with no need to write an event handler.

Component writers can use the classes in the QStdActns and DBActns units as examples for deriving their own action classes to implement behaviors specific to certain controls or components. The base classes for these specialized actions (*TEditAction*, *TWindowAction*, and so on) generally override *HandlesTarget, UpdateTarget,* and other methods to limit the target for the action to a specific class of objects. The descendant classes typically override *ExecuteTarget* to perform a specialized task. These methods are described here:

Method	Description
HandlesTarget	Called automatically when the user invokes an object (such as a toolbutton or menu item) that is linked to the action. The *HandlesTarget* method lets the action object indicate whether it is appropriate to execute at this time with the object specified by the *Target* parameter as a “target”. See “How actions find their targets” on page 6-26 for details.
UpdateTarget	Called automatically when the application is idle so that actions can update themselves according to current conditions. Use in place of *OnUpdateAction*. See “Updating actions” on page 6-26 for details.
ExecuteTarget	Called automatically when the action fires in response to a user action in place of *OnExecute* (for example, when the user selects a menu item or presses a tool button that is linked to this action). See “What happens when an action fires” on page 6-24 for details.

Registering actions

When you write your own actions, you can register actions to enable them to appear in the Action List editor. You register and unregister actions by using the global routines in the Actnlist unit:

```
procedure RegisterActions(const CategoryName: string; const AClasses: array of
TBasicActionClass; Resource: TComponentClass);

procedure UnRegisterActions(const AClasses: array of TBasicActionClass);
```

When you call *RegisterActions*, the actions you register appear in the Action List editor for use by your applications. You can supply a category name to organize your actions, as well as a *Resource* parameter that lets you supply default property values.

For example, the following code registers the standard actions with the IDE:

```
{ Standard action registration }

RegisterActions('', [TAction], nil);

RegisterActions('Edit', [TEditCut, TEditCopy, TEditPaste], TStandardActions);

RegisterActions('Window', [TWindowClose, TWindowCascade, TWindowTileHorizontal,
TWindowTileVertical, TWindowMinimizeAll, TWindowArrange], TStandardActions);
```

When you call *UnRegisterActions*, the actions no longer appear in the Action List editor.

Creating and managing menus

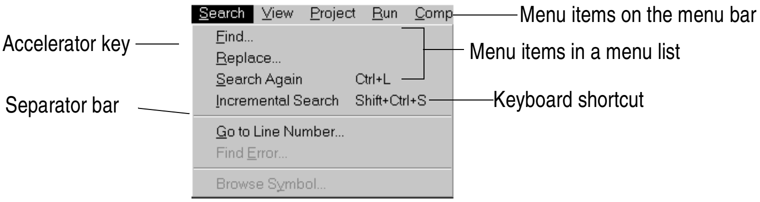
Menus provide an easy way for your users to execute logically grouped commands. The Menu Designer enables you to easily add a menu—either predesigned or custom tailored—to your form. You add a menu component to the form, open the Menu Designer, and type menu items directly into the Menu Designer window. You can add or delete menu items, or drag and drop them to rearrange them during design time.

You don't even need to run your program to see the results—your design is immediately visible in the form, appearing just as it will during runtime. Your code can also change menus at runtime, to provide more information or options to the user.

This chapter explains how to use the Menu Designer to design menu bars and pop-up (local) menus. It discusses the following ways to work with menus at design time and runtime:

- Opening the Menu Designer
- Building menus
- Editing menu items in the Object Inspector
- Using the Menu Designer context menu
- Using menu templates
- Saving a menu as a template
- Adding images to menu items

Figure 6.3 Menu terminology

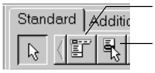


For information about hooking up menu items to the code that executes when they are selected, see “Associating menu events with event handlers” on page 3-28.

Opening the Menu Designer

You design menus for your application using the Menu Designer. Before you can start using the Menu Designer, first add either a MainMenu or PopupMenu component to your form. Both menu components are located on the Standard page of the component palette.

Figure 6.4 MainMenu and PopupMenu components



MainMenu component

PopupMenu component

A MainMenu component creates a menu that's attached to the form's title bar. A PopupMenu component creates a menu that appears when the user right-clicks in the form. Pop-up menus do not have a menu bar.

To open the Menu Designer, select a menu component on the form, and then either:

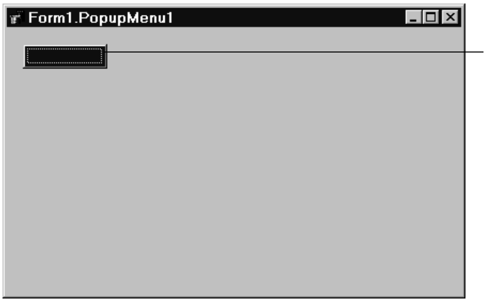
- Double-click the menu component.

  or

- From the Properties page of the Object Inspector, select the *Items* property, and then either double-click [Menu] in the Value column, or click the ellipsis (...) button.

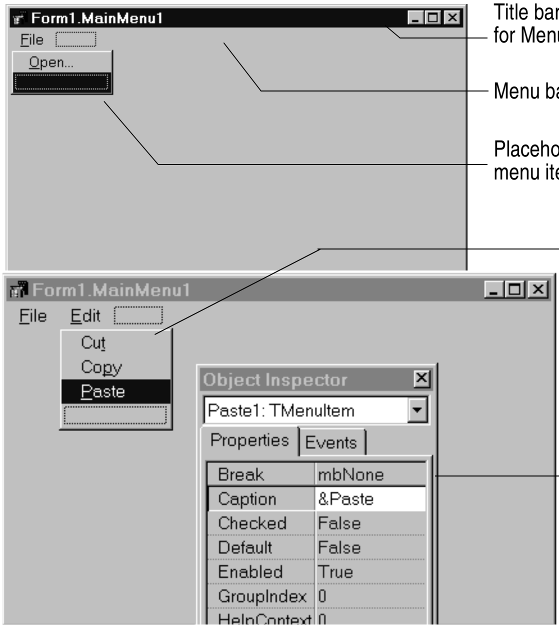
  The Menu Designer appears, with the first (blank) menu item highlighted in the Designer, and the *Caption* property selected in the Object Inspector.

Figure 6.5 Menu Designer for a pop-up menu



Placeholder for first menu item

Figure 6.6 Menu Designer for a main menu



Break	mbNone
Caption	&Paste
Checked	False
Default	False
Enabled	True
GroupIndex	0
HelpContext	0

Title bar (shows *Name* property for Menu component)

Menu bar

Placeholder for menu item

Menu Designer displays WYSIWYG menu items as you build the menu.

A TMenuItem object is created and the *Name* property set to the menu item *Caption* you specify (minus any illegal characters and plus a numeric suffix).

Building menus

You add a menu component to your form, or forms, for every menu you want to include in your application. You can build each menu structure entirely from scratch, or you can start from one of the predesigned menu templates.

This section discusses the basics of creating a menu at design time. For more information about menu templates, see “Using menu templates” on page 6-38.

Naming menus

As with all components, when you add a menu component to the form, Delphi gives it a default name; for example, *MainMenu1*. You can give the menu a more meaningful name that follows Object Pascal naming conventions.

Delphi adds the menu name to the form's type declaration, and the menu name then appears in the Component list.

Naming the menu items

In contrast to the menu component itself, you need to explicitly name menu items as you add them to the form. You can do this in one of two ways:

- Directly type the value for the *Name* property.
- Type the value for the *Caption* property first, and let Delphi derive the *Name* property from the caption.

  For example, if you give a menu item a *Caption* property value of *File*, Delphi assigns the menu item a *Name* property of *File1*. If you fill in the *Name* property before filling in the *Caption* property, Delphi leaves the *Caption* property blank until you type a value.

Note If you enter characters in the *Caption* property that are not valid for Object Pascal identifiers, Delphi modifies the *Name* property accordingly. For example, if you want the caption to start with a number, Delphi precedes the number with a character to derive the *Name* property.

The following table demonstrates some examples of this, assuming all menu items shown appear in the same menu bar.

Table 6.4 Sample captions and their derived names

Component caption	Derived name	Explanation
&File	File1	Removes ampersand
&File (2nd occurrence)	File2	Numerically orders duplicate items
1234	N12341	Adds a preceding letter and numerical order
1234 (2nd occurrence)	N12342	Adds a number to disambiguate the derived name
$@@@#	N1	Removes all non-standard characters, adding preceding letter and numerical order
- (hyphen)	N2	Numerical ordering of second occurrence of caption with no standard characters

As with the menu component, Delphi adds any menu item names to the form's type declaration, and those names then appear in the Component list.

Adding, inserting, and deleting menu items

The following procedures describe how to perform the basic tasks involved in building your menu structure. Each procedure assumes you have the Menu Designer window open.

To add menu items at design time,

1 Select the position where you want to create the menu item.

If you've just opened the Menu Designer, the first position on the menu bar is already selected.

2 Begin typing to enter the caption. Or enter the *Name* property first by specifically placing your cursor in the Object Inspector and entering a value. In this case, you then need to reselect the *Caption* property and enter a value.

3 Press *Enter*.

The next placeholder for a menu item is selected.

If you entered the *Caption* property first, use the arrow keys to return to the menu item you just entered. You'll see that Delphi has filled in the *Name* property based on the value you entered for the caption. (See "Naming the menu items" on page 6-32.)

4 Continue entering values for the *Name* and *Caption* properties for each new item you want to create, or press *Esc* to return to the menu bar.

Use the arrow keys to move from the menu bar into the menu, and to then move between items in the list; press *Enter* to complete an action. To return to the menu bar, press *Esc*.

To insert a new, blank menu item,

1 Place the cursor on a menu item.
2 Press *Ins*.

Menu items are inserted to the left of the selected item on the menu bar, and above the selected item in the menu list.

To delete a menu item or command,

1 Place the cursor on the menu item you want to delete.
2 Press *Del*.

Note You cannot delete the default placeholder that appears below the item last entered in a menu list, or next to the last item on the menu bar. This placeholder does not appear in your menu at runtime.

Adding separator bars

Separator bars insert a line between menu items. You can use separator bars to indicate groupings within the menu list, or simply to provide a visual break in a list.

To make the menu item a separator bar, type a hyphen (-) for the caption.

Specifying accelerator keys and keyboard shortcuts

Accelerator keys enable the user to access a menu command from the keyboard by pressing *Alt+* the appropriate letter, indicated in your code by the preceding ampersand. The letter after the ampersand appears underlined in the menu.

Delphi automatically checks for duplicate accelerators and adjusts them at runtime. This ensures that menus built dynamically at runtime contain no duplicate accelerators and that all menu items have an accelerator. You can turn off this automatic checking by setting the *AutoHotkeys* property of a menu item to *maManual*.

To specify an accelerator,

- Add an ampersand in front of the appropriate letter.

  For example, to add a Save menu command with the *S* as an accelerator key, type `&Save`.

Keyboard shortcuts enable the user to perform the action without using the menu directly, by typing in the shortcut key combination.

To specify a keyboard shortcut,

- Use the Object Inspector to enter a value for the *ShortCut* property, or select a key combination from the drop-down list.

  This list is only a subset of the valid combinations you can type in.

When you add a shortcut, it appears next to the menu item caption.

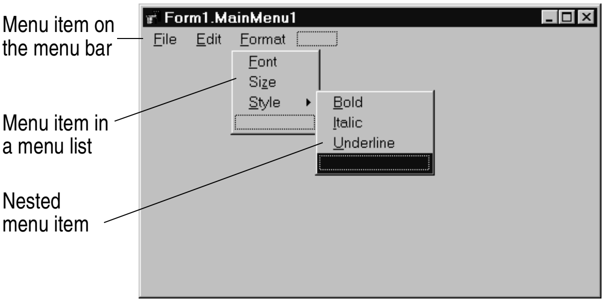
Caution Keyboard shortcuts, unlike accelerator keys, are not checked automatically for duplicates. You must ensure uniqueness yourself.

Creating submenus

Many application menus contain drop-down lists that appear next to a menu item to provide additional, related commands. Such lists are indicated by an arrow to the right of the menu item. Delphi supports as many levels of such submenus as you want to build into your menu.

Organizing your menu structure this way can save vertical screen space. However, for optimal design purposes you probably want to use no more than two or three menu levels in your interface design. (For pop-up menus, you might want to use only one submenu, if any.)

Figure 6.7 Nested menu structures



To create a submenu,

1 Select the menu item under which you want to create a submenu.

2 Press *Ctrl*→ to create the first placeholder, or right-click and choose Create Submenu.

3 Type a name for the submenu item, or drag an existing menu item into this placeholder.

4 Press *Enter*, or ↓, to create the next placeholder.

5 Repeat steps 3 and 4 for each item you want to create in the submenu.

6 Press *Esc* to return to the previous menu level.

Creating submenus by demoting existing menus

You can create a submenu by inserting a menu item from the menu bar (or a menu template) between menu items in a list. When you move a menu into an existing menu structure, all its associated items move with it, creating a fully intact submenu. This pertains to submenus as well—moving a menu item into an existing submenu just creates one more level of nesting.

Moving menu items

During design time, you can move menu items simply by dragging and dropping. You can move menu items along the menu bar, or to a different place in the menu list, or into a different menu entirely.

The only exception to this is hierarchical: you cannot demote a menu item from the menu bar into its own menu; nor can you move a menu item into its own submenu. However, you can move any item into a *different* menu, no matter what its original position is.

While you are dragging, the cursor changes shape to indicate whether you can release the menu item at the new location. When you move a menu item, any items beneath it move as well.

To move a menu item along the menu bar,

1 Drag the menu item along the menu bar until the arrow tip of the drag cursor points to the new location.

2 Release the mouse button to drop the menu item at the new location.

To move a menu item into a menu list,

1 Drag the menu item along the menu bar until the arrow tip of the drag cursor points to the new menu.

   This causes the menu to open, enabling you to drag the item to its new location.

2 Drag the menu item into the list, releasing the mouse button to drop the menu item at the new location.

Adding images to menu items

Images can help users navigate in menus by matching glyphs and images to menu item action, similar to toolbar images. You can add single bitmaps to menu items, or you can organize images for your application into an image list and add them to a menu from the image list. If you're using several bitmaps of the same size in your application, it's useful to put them into an image list.

To add a single image to a menu or menu item, set its *Bitmap* property to reference the name of the bitmap to use on the menu or menu item.

To add an image to a menu item using an image list:

1 Drop a *TMainMenu* or *TPopupMenu* object on a form.

2 Drop a *TImageList* object on the form.

3 Open the ImageList editor by double clicking on the *TImageList* object.

4 Click Add to select the bitmap or bitmap group you want to use in the menu. Click OK.

5 Set the *TMainMenu* or *TPopupMenu* object's *Images* property to the ImageList you just created.

6 Create your menu items and submenu items as described previously.

7 Select the menu item you want to have an image in the Object Inspector and set the *ImageIndex* property to the corresponding number of the image in the *ImageList* (the default value for *ImageIndex* is -1, which doesn't display an image).

Note Use images that are 16 by 16 pixels for proper display in the menu. Although you can use other sizes for the menu images, alignment and consistency problems may result when using images greater than or smaller than 16 by 16 pixels.

Viewing the menu

You can view your menu in the form at design time without first running your program code. (Pop-up menu components are visible in the form at design time, but the pop-up menus themselves are not. Use the Menu Designer to view a pop-up menu at design time.)

To view the menu,

1 If the form is visible, click the form, or from the View menu, choose the form whose menu you want to view.

2 If the form has more than one menu, select the menu you want to view from the form's *Menu* property drop-down list.

   The menu appears in the form exactly as it will when you run the program.

Editing menu items in the Object Inspector

This section has discussed how to set several properties for menu items—for example, the *Name* and *Caption* properties—by using the Menu Designer.

The section has also described how to set menu item properties, such as the *ShortCut* property, directly in the Object Inspector, just as you would for any component selected in the form.

When you edit a menu item by using the Menu Designer, its properties are still displayed in the Object Inspector. You can switch focus to the Object Inspector and continue editing the menu item properties there. Or you can select the menu item from the Component list in the Object Inspector and edit its properties without ever opening the Menu Designer.

To close the Menu Designer window and continue editing menu items,

1 Switch focus from the Menu Designer window to the Object Inspector by clicking the properties page of the Object Inspector.

2 Close the Menu Designer as you normally would.

  The focus remains in the Object Inspector, where you can continue editing properties for the selected menu item. To edit another menu item, select it from the Component list.

Using the Menu Designer context menu

The Menu Designer context menu provides quick access to the most common Menu Designer commands, and to the menu template options. (For more information about menu templates, refer to "Using menu templates" on page 6-38.)

To display the context menu, right-click the Menu Designer window, or press *Alt+F10* when the cursor is in the Menu Designer window.

Commands on the context menu

The following table summarizes the commands on the Menu Designer context menu.

Table 6.5 Menu Designer context menu commands

Menu command	Action
Insert	Inserts a placeholder above or to the left of the cursor.
Delete	Deletes the selected menu item (and all its sub-items, if any).
Create Submenu	Creates a placeholder at a nested level and adds an arrow to the right of the selected menu item.
Select Menu	Opens a list of menus in the current form. Double-clicking a menu name opens the designer window for the menu.
Save As Template	Opens the Save Template dialog box, where you can save a menu for future reuse.
Insert From Template	Opens the Insert Template dialog box, where you can select a template to reuse.
Delete Templates	Opens the Delete Templates dialog box, where you can choose to delete any existing templates.
Insert From Resource	Opens the Insert Menu from Resource file dialog box, where you can choose an .mnu file to open in the current form.

Switching between menus at design time

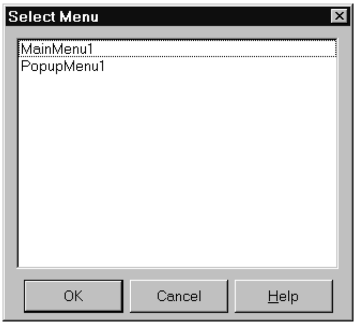
If you're designing several menus for your form, you can use the Menu Designer context menu or the Object Inspector to easily select and move among them.

To use the context menu to switch between menus in a form,

1 Right-click in the Menu Designer and choose Select Menu.

  The Select Menu dialog box appears.

Figure 6.8 Select Menu dialog box



This dialog box lists all the menus associated with the form whose menu is currently open in the Menu Designer.

2 From the list in the Select Menu dialog box, choose the menu you want to view or edit.

To use the Object Inspector to switch between menus in a form,

1 Give focus to the form whose menus you want to choose from.
2 From the Component list, select the menu you want to edit.
3 On the Properties page of the Object Inspector, select the *Items* property for this menu, and then either click the ellipsis button, or double-click [Menu].

Using menu templates

Delphi provides several predesigned menus, or menu templates, that contain frequently used commands. You can use these menus in your applications without modifying them (except to write code), or you can use them as a starting point, customizing them as you would a menu you originally designed yourself. Menu templates do not contain any event handler code.

The menu templates shipped with Delphi are stored in the BIN subdirectory in a default installation. These files have a .DMT (Delphi menu template) extension.

You can also save as a template any menu that you design using the Menu Designer. After saving a menu as a template, you can use it as you would any predesigned menu. If you decide you no longer want a particular menu template, you can delete it from the list.

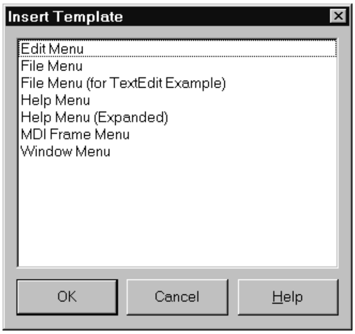
To add a menu template to your application,

1 Right-click the Menu Designer and choose Insert From Template.

(If there are no templates, the Insert From Template option appears dimmed in the context menu.)

The Insert Template dialog box opens, displaying a list of available menu templates.

Figure 6.9 Sample Insert Template dialog box for menus



2 Select the menu template you want to insert, then press *Enter* or choose OK.

This inserts the menu into your form at the cursor's location. For example, if your cursor is on a menu item in a list, the menu template is inserted above the selected item. If your cursor is on the menu bar, the menu template is inserted to the left of the cursor.

To delete a menu template,

1 Right-click the Menu Designer and choose Delete Templates.

(If there are no templates, the Delete Templates option appears dimmed in the context menu.)

The Delete Templates dialog box opens, displaying a list of available templates.

2 Select the menu template you want to delete, and press *Del*.

Delphi deletes the template from the templates list and from your hard disk.

Saving a menu as a template

Any menu you design can be saved as a template so you can use it again. You can use menu templates to provide a consistent look to your applications, or use them as a starting point which you then further customize.

The menu templates you save are stored in your BIN subdirectory as .DMT files.

To save a menu as a template,

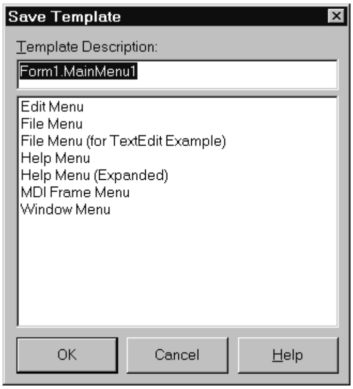
1 Design the menu you want to be able to reuse.

This menu can contain as many items, commands, and submenus as you like; everything in the active Menu Designer window will be saved as one reusable menu.

2 Right-click in the Menu Designer and choose Save As Template.

The Save Template dialog box appears.

Figure 6.10 Save Template dialog box for menus



Save Template

Template Description: Form1.MainMenu1

Edit Menu
File Menu
File Menu (for TextEdit Example)
Help Menu
Help Menu (Expanded)
MDI Frame Menu
Window Menu

3 In the Template Description edit box, type a brief description for this menu, and then choose OK.

The Save Template dialog box closes, saving your menu design and returning you to the Menu Designer window.

Note The description you enter is displayed only in the Save Template, Insert Template, and Delete Templates dialog boxes. It is not related to the *Name* or *Caption* property for the menu.

Naming conventions for template menu items and event handlers

When you save a menu as a template, Delphi does not save its *Name* property, since every menu must have a unique name within the scope of its owner (the form). However, when you insert the menu as a template into a new form by using the Menu Designer, Delphi then generates new names for it and all of its items.

For example, suppose you save a File menu as a template. In the original menu, you name it *MyFile*. If you insert it as a template into a new menu, Delphi names it *File1*. If you insert it into a menu with an existing menu item named *File1*, Delphi names it *File2*.

Delphi also does not save any *OnClick* event handlers associated with a menu saved as a template, since there is no way to test whether the code would be applicable in the new form. When you generate a new event handler for the menu template item, Delphi still generates the event handler name.

You can easily associate items in the menu template with existing *OnClick* event handlers in the form For more information, see “Associating an event with an existing event handler” on page 3-27.

Manipulating menu items at runtime

Sometimes you want to add menu items to an existing menu structure while the application is running, to provide more information or options to the user. You can insert a menu item by using the menu item’s *Add* or *Insert* method, or you can alternately hide and show the items in a menu by changing their *Visible* property. The *Visible* property determines whether the menu item is displayed in the menu. To dim a menu item without hiding it, use the *Enabled* property.

For examples that use the menu item’s *Visible* and *Enabled* properties, see “Disabling menu items” on page 7-10.

In multiple document interface (MDI) and Object Linking and Embedding (OLE) applications, you can also merge menu items into an existing menu bar. The following section discusses this in more detail.

Merging menus

For MDI applications, such as the text editor sample application, and for OLE client applications, your application’s main menu needs to be able to receive menu items either from another form or from the OLE server object. This is often called *merging menus*. Note that OLE technology is limited to Windows applications only and is not available for use in cross-platform programming.

You prepare menus for merging by specifying values for two properties:

- *Menu*, a property of the form
- *GroupIndex*, a property of menu items in the menu

Specifying the active menu: Menu property

The *Menu* property specifies the active menu for the form. Menu-merging operations apply only to the active menu. If the form contains more than one menu component, you can change the active menu at runtime by setting the *Menu* property in code. For example,

```
Form1.Menu := SecondMenu;
```

Determining the order of merged menu items: GroupIndex property

The *GroupIndex* property determines the order in which the merging menu items appear in the shared menu bar. Merging menu items can replace those on the main menu bar, or can be inserted.

The default value for *GroupIndex* is 0. Several rules apply when specifying a value for *GroupIndex*:

- Lower numbers appear first (farther left) in the menu.

  For instance, set the *GroupIndex* property to 0 (zero) for a menu that you always want to appear leftmost, such as a File menu. Similarly, specify a high number (it needn’t be in sequence) for a menu that you always want to appear rightmost, such as a Help menu.

- To replace items in the main menu, give items on the child menu the same *GroupIndex* value.

This can apply to groupings or to single items. For example, if your main form has an Edit menu item with a *GroupIndex* value of 1, you can replace it with one or more items from the child form's menu by giving them a *GroupIndex* value of 1 as well.

Giving multiple items in the child menu the same *GroupIndex* value keeps their order intact when they merge into the main menu.

- To insert items without replacing items in the main menu, leave room in the numeric range of the main menu's items and "plug in" numbers from the child form.

  For example, number the items in the main menu 0 and 5, and insert items from the child menu by numbering them 1, 2, 3, and 4.

Importing resource files

Delphi supports use of menus built with other applications, so long as they are in the standard Windows resource (.RC) file format. You can import such menus directly into your Delphi project, saving you the time and effort of rebuilding menus that you created elsewhere.

To load existing .RC menu files,

1. In the Menu Designer, place your cursor where you want the menu to appear.

   The imported menu can be part of a menu you are designing, or an entire menu in itself.

2. Right-click and choose Insert From Resource.

   The Insert Menu From Resource dialog box appears.

3. In the dialog box, select the resource file you want to load, and choose OK.

   The menu appears in the Menu Designer window.

Note If your resource file contains more than one menu, you first need to save each menu as a separate resource file before importing it.

Designing toolbars and cool bars

A *toolbar* is a panel, usually across the top of a form (under the menu bar), that holds buttons and other controls. A *cool bar* (also called a rebar) is a kind of toolbar that displays controls on movable, resizable bands. If you have multiple panels aligned to the top of the form, they stack vertically in the order added.

Note Cool bars are not available in CLX for cross-platform applications.

You can put controls of any sort on a toolbar. In addition to buttons, you may want to put use color grids, scroll bars, labels, and so on.

You can add a toolbar to a form in several ways:

- Place a panel (*TPanel*) on the form and add controls (typically speed buttons) to it.

- Use a toolbar component (*TToolBar*) instead of *TPanel*, and add controls to it. *TToolBar* manages buttons and other controls, arranging them in rows and automatically adjusting their sizes and positions. If you use tool button (*TToolButton*) controls on the toolbar, *TToolBar* makes it easy to group the buttons functionally and provides other display options.
- Use a cool bar (*TCoolBar*) component and add controls to it. The cool bar displays controls on independently movable and resizable bands.

How you implement your toolbar depends on your application. The advantage of using the Panel component is that you have total control over the look and feel of the toolbar.

By using the toolbar and cool bar components, you are ensuring that your application has the look and feel of a Windows application because you are using the native Windows controls. If these operating system controls change in the future, your application could change as well. Also, since the toolbar and cool bar rely on common components in Windows, your application requires the COMCTL32.DLL. Toolbars and cool bars are not supported in WinNT 3.51 applications.

The following sections describe how to

- Add a toolbar and corresponding speed button controls using the panel component
- Add a toolbar and corresponding tool button controls using the Toolbar component
- Add a cool bar using the cool bar component
- Respond to clicks
- Add hidden toolbars and cool bars
- Hide and show toolbars and cool bars

Adding a toolbar using a panel component

To add a toolbar to a form using the panel component,

1. Add a panel component to the form (from the Standard page of the component palette).
2. Set the panel's *Align* property to *alTop*. When aligned to the top of the form, the panel maintains its height, but matches its width to the full width of the form's client area, even if the window changes size.
3. Add speed buttons or other controls to the panel.

Speed buttons are designed to work on toolbar panels. A speed button usually has no caption, only a small graphic (called a *glyph*), which represents the button's function.

Speed buttons have three possible modes of operation. They can

- Act like regular pushbuttons
- Toggle on and off when clicked

- Act like a set of radio buttons

To implement speed buttons on toolbars, do the following:

- Add a speed button to a toolbar panel
- Assign a speed button's glyph
- Set the initial condition of a speed button
- Create a group of speed buttons
- Allow toggle buttons

Adding a speed button to a panel

To add a speed button to a toolbar panel, place the speed button component (from the Additional page of the component palette) on the panel.

The panel, rather than the form, "owns" the speed button, so moving or hiding the panel also moves or hides the speed button.

The default height of the panel is 41, and the default height of speed buttons is 25. If you set the *Top* property of each button to 8, they'll be vertically centered. The default grid setting snaps the speed button to that vertical position for you.

Assigning a speed button's glyph

Each speed button needs a graphic image called a *glyph* to indicate to the user what the button does. If you supply the speed button only one image, the button manipulates that image to indicate whether the button is pressed, unpressed, selected, or disabled. You can also supply separate, specific images for each state if you prefer.

You normally assign glyphs to speed buttons at design time, although you can assign different glyphs at runtime.

To assign a glyph to a speed button at design time,

1. Select the speed button.
2. In the Object Inspector, select the *Glyph* property.
3. Double-click the Value column beside *Glyph* to open the Picture Editor and select the desired bitmap.

Setting the initial condition of a speed button

Speed buttons use their appearance to give the user clues as to their state and purpose. Because they have no caption, it's important that you use the right visual cues to assist users.

Table 6.6 lists some actions you can set to change a speed button's appearance:

Table 6.6 Setting speed buttons' appearance

To make a speed button:	Set the toolbar's:
Appear pressed	*GroupIndex* property to a value other than zero and its *Down* property to *True*.

Table 6.6 Setting speed buttons' appearance (continued)

To make a speed button:	Set the toolbar's:
Appear disabled	*Enabled* property to *False*.
Have a left margin	*Indent* property to a value greater than 0.

If your application has a default drawing tool, ensure that its button on the toolbar is pressed when the application starts. To do so, set its *GroupIndex* property to a value other than zero and its *Down* property to *True*.

Creating a group of speed buttons

A series of speed buttons often represents a set of mutually exclusive choices. In that case, you need to associate the buttons into a group, so that clicking any button in the group causes the others in the group to pop up.

To associate any number of speed buttons into a group, assign the same number to each speed button's *GroupIndex* property.

The easiest way to do this is to select all the buttons you want in the group, and, with the whole group selected, set *GroupIndex* to a unique value.

Allowing toggle buttons

Sometimes you want to be able to click a button in a group that's already pressed and have it pop up, leaving no button in the group pressed. Such a button is called a *toggle*. Use *AllowAllUp* to create a grouped button that acts as a toggle: click it once, it's down; click it again, it pops up.

To make a grouped speed button a toggle, set its *AllowAllUp* property to *True*.

Setting *AllowAllUp* to *True* for any speed button in a group automatically sets the same property value for all buttons in the group. This enables the group to act as a normal group, with only one button pressed at a time, but also allows every button to be up at the same time.

Adding a toolbar using the toolbar component

The toolbar component (*TToolBar*) offers button management and display features that panel components do not. To add a toolbar to a form using the toolbar component,

1. Add a toolbar component to the form (from the Win32 page of the component palette). The toolbar automatically aligns to the top of the form.
2. Add tool buttons or other controls to the bar.

Tool buttons are designed to work on toolbar components. Like speed buttons, tool buttons can

- Act like regular pushbuttons
- Toggle on and off when clicked
- Act like a set of radio buttons

To implement tool buttons on a toolbar, do the following:

- Add a tool button
- Assign images to tool buttons
- Set the tool buttons' appearance
- Create a group of tool buttons
- Allow toggled tool buttons

Adding a tool button

To add a tool button to a toolbar, right-click on the toolbar and choose New Button.

The toolbar "owns" the tool button, so moving or hiding the toolbar also moves or hides the button. In addition, all tool buttons on the toolbar automatically maintain the same height and width. You can drop other controls from the component palette onto the toolbar, and they will automatically maintain a uniform height. Controls will also wrap around and start a new row when they do not fit horizontally on the toolbar.

Assigning images to tool buttons

Each tool button has an *ImageIndex* property that determines what image appears on it at runtime. If you supply the tool button only one image, the button manipulates that image to indicate whether the button is disabled. To assign images to tool buttons at design time,

1. Select the toolbar on which the buttons appear.
2. In the Object Inspector, assign a *TImageList* object to the toolbar's *Images* property. An image list is a collection of same-sized icons or bitmaps.
3. Select a tool button.
4. In the Object Inspector, assign an integer to the tool button's *ImageIndex* property that corresponds to the image in the image list that you want to assign to the button.

You can also specify separate images to appear on the tool buttons when they are disabled and when they are under the mouse pointer. To do so, assign separate image lists to the toolbar's *DisabledImages* and *HotImages* properties.

Setting tool button appearance and initial conditions

Table 6.7 lists some actions you can set to change a tool button's appearance:

Table 6.7 Setting tool buttons' appearance

To make a tool button:	Set the toolbar's:
Appear pressed	(on tool button) *Style* property to *tbsCheck* and *Down* property to *True*.
Appear disabled	*Enabled* property to *False*.

Table 6.7 Setting tool buttons’ appearance (continued)

To make a tool button:	Set the toolbar’s:
Have a left margin	*Indent* property to a value greater than 0.
Appear to have “pop-up” borders, thus making the toolbar appear transparent	*Flat* property to *True*.

Note Using the *Flat* property of *TToolBar* requires version 4.70 or later of COMCTL32.DLL.

To force a new row of controls after a specific tool button, Select the tool button that you want to appear last in the row and set its *Wrap* property to *True*.

To turn off the auto-wrap feature of the toolbar, set the toolbar’s *Wrapable* property to *False*.

Creating groups of tool buttons

To create a group of tool buttons, select the buttons you want to associate and set their *Style* property to *tbsCheck*; then set their *Grouped* property to *True*. Selecting a grouped tool button causes other buttons in the group to pop up, which is helpful to represent a set of mutually exclusive choices.

Any unbroken sequence of adjacent tool buttons with *Style* set to *tbsCheck* and *Grouped* set to *True* forms a single group. To break up a group of tool buttons, separate the buttons with any of the following:

- A tool button whose *Grouped* property is *False*.
- A tool button whose *Style* property is not set to *tbsCheck*. To create spaces or dividers on the toolbar, add a tool button whose *Style* is *tbsSeparator* or *tbsDivider*.
- Another control besides a tool button.

Allowing toggled tool buttons

Use *AllowAllUp* to create a grouped tool button that acts as a toggle: click it once, it is down; click it again, it pops up. To make a grouped tool button a toggle, set its *AllowAllUp* property to *True*.

As with speed buttons, setting *AllowAllUp* to *True* for any tool button in a group automatically sets the same property value for all buttons in the group.

Adding a cool bar component

Note The *TCoolBar* component requires version 4.70 or later of COMCTL32.DLL and is not available in CLX.

The cool bar component (*TCoolBar*)—also called a *rebar*—displays windowed controls on independently movable, resizable bands. The user can position the bands by dragging the resizing grips on the left side of each band.

To add a cool bar to a form in a Windows application,

1. Add a cool bar component to the form (from the Win32 page of the component palette). The cool bar automatically aligns to the top of the form.
2. Add windowed controls from the component palette to the bar.

Only VCL components that descend from *TWinControl* are windowed controls. You can add graphic controls—such as labels or speed buttons—to a cool bar, but they will not appear on separate bands.

Setting the appearance of the cool bar

The cool bar component offers several useful configuration options. Table 6.8 lists some actions you can set to change a tool button's appearance:

Table 6.8 Setting a cool button's appearance

To make the cool bar:	Set the toolbar's:
Resize automatically to accommodate the bands it contains	*AutoSize* property to *True.*
Bands maintain a uniform height	*FixedSize* property to *True*.
Reorient to vertical rather than horizontal	*Vertical* property to *True*. This changes the effect of the *FixedSize* property.
Prevent the *Text* properties of the bands from displaying at runtime	*ShowText* property to *False*. Each band in a cool bar has its own *Text* property.
Remove the border around the bar	*BandBorderStyle* to *bsNone.*
Keep users from changing the bands' order at runtime. (The user can still move and resize the bands.)	*FixedOrder* to *True.*
Create a background image for the cool bar	*Bitmap* property to *TBitmap* object.
Choose a list of images to appear on the left of any band	*Images* property to *TImageList* object.

To assign images to individual bands, select the cool bar and double-click on the *Bands* property in the Object Inspector. Then select a band and assign a value to its *ImageIndex* property.

Responding to clicks

When the user clicks a control, such as a button on a toolbar, the application generates an *OnClick* event which you can respond to with an event handler. Since *OnClick* is the default event for buttons, you can generate a skeleton handler for the event by double-clicking the button at design time. For more information, see “Working with events and event handlers” on page 3-25 and “Generating a handler for a component’s default event” on page 3-26.

Assigning a menu to a tool button

If you are using a toolbar (*TToolBar*) with tool buttons (*TToolButton*), you can associate menu with a specific button:

1 Select the tool button.

2 In the Object Inspector, assign a pop-up menu (*TPopupMenu*) to the tool button’s *DropDownMenu* property.

If the menu’s *AutoPopup* property is set to *True*, it will appear automatically when the button is pressed.

Adding hidden toolbars

Toolbars do not have to be visible all the time. In fact, it is often convenient to have a number of toolbars available, but show them only when the user wants to use them. Often you create a form that has several toolbars, but hide some or all of them.

To create a hidden toolbar,

1 Add a toolbar, cool bar, or panel component to the form.
2 Set the component’s *Visible* property to *False*.

Although the toolbar remains visible at design time so you can modify it, it remains hidden at runtime until the application specifically makes it visible.

Hiding and showing toolbars

Often, you want an application to have multiple toolbars, but you do not want to clutter the form with them all at once. Or you may want to let users decide whether to display toolbars. As with all components, toolbars can be shown or hidden at runtime as needed.

To hide or show a toolbar at runtime, set its *Visible* property to *False* or *True*, respectively. Usually you do this in response to particular user events or changes in the operating mode of the application. To do this, you typically have a close button on each toolbar. When the user clicks that button, the application hides the corresponding toolbar.

You can also provide a means of toggling the toolbar. In the following example, a toolbar of pens is toggled from a button on the main toolbar. Since each click presses or releases the button, an *OnClick* event handler can show or hide the Pen toolbar depending on whether the button is up or down.

```
procedure TForm1.PenButtonClick(Sender: TObject);
begin
  PenBar.Visible := PenButton.Down;
end;
```

Demo programs

For examples of Windows applications that use actions and action lists, refer to Demos\RichEdit. In addition, the Application wizard (File|New Project page), MDI Application, SDI Application, and Winx Logo Applications can use the action and action list objects. For examples of cross-platform applications, refer to Demos\CLX.

Chapter

7

Working with controls

Controls are visual components that the user can interact with at runtime. This chapter describes a variety of features common to many controls.

Implementing drag-and-drop in controls

Drag-and-drop is often a convenient way for users to manipulate objects. You can let users drag an entire control, or let them drag items from one control—such as a list box or tree view—into another.

- Starting a drag operation
- Accepting dragged items
- Dropping items
- Ending a drag operation
- Customizing drag and drop with a drag object
- Changing the drag mouse pointer

Starting a drag operation

Every control has a property called *DragMode* that determines how drag operations are initiated. If *DragMode* is *dmAutomatic*, dragging begins automatically when the user presses a mouse button with the cursor on the control. Because *dmAutomatic* can interfere with normal mouse activity, you may want to set *DragMode* to *dmManual* (the default) and start the dragging by handling mouse-down events.

To start dragging a control manually, call the control's *BeginDrag* method. *BeginDrag* takes a Boolean parameter called *Immediate* and, optionally, an integer parameter called *Threshold*. If you pass *True* for *Immediate*, dragging begins immediately. If you pass *False*, dragging does not begin until the user moves the mouse the number of pixels specified by *Threshold*. Calling

```
BeginDrag False)
```

allows the control to accept mouse clicks without beginning a drag operation.

You can place other conditions on whether to begin dragging, such as checking which mouse button the user pressed, by testing the parameters of the mouse-down event before calling *BeginDrag*. The following code, for example, handles a mouse-down event in a file list box by initiating a drag operation only if the left mouse button was pressed.

```
procedure TFMForm.FileListBox1MouseDown(Sender: TObject;
  Button: TMouseButton; Shift: TShiftState; X, Y: Integer);
begin
  if Button = mbLeft then  { drag only if left button pressed }
    with Sender as TFileListBox do  { treat Sender as TFileListBox }
      begin
        if ItemAtPos(Point(X, Y), True) >= 0 then  { is there an item here? }
          BeginDrag(False);  { if so, drag it }
    end;
end;
```

Accepting dragged items

When the user drags something over a control, that control receives an *OnDragOver* event, at which time it must indicate whether it can accept the item if the user drops it there. The drag cursor changes to indicate whether the control can accept the dragged item. To accept items dragged over a control, attach an event handler to the control's *OnDragOver* event.

The drag-over event has a parameter called *Accept* that the event handler can set to *True* if it will accept the item. If *Accept* is *True*, the application sends a drag-and-drop event to the control.

The drag-over event has other parameters, including the source of the dragging and the current location of the mouse cursor, that the event handler can use to determine whether to accept the drop. In the following example, a directory tree view accepts dragged items only if they come from a file list box.

```
procedure TFMForm.DirectoryOutline1DragOver(Sender, Source: TObject; X,
  Y: Integer; State: TDragState; var Accept: Boolean);
begin
  if Source is TFileListBox then
    Accept := True
  else
    Accept := False;
end;
```

Dropping items

If a control indicates that it can accept a dragged item, it needs to handle the item should it be dropped. To handle dropped items, attach an event handler to the *OnDragDrop* event of the control accepting the drop. Like the drag-over event, the drag-and-drop event indicates the source of the dragged item and the coordinates of the mouse cursor over the accepting control. The latter parameter allows you to monitor the path an item takes while being dragged; you might, for example, want to use this information to change the color of components as they are passed over.

In the following example, a directory tree view, accepting items dragged from a file list box, responds by moving files to the directory on which they are dropped.

```
procedure TFMForm.DirectoryOutline1DragDrop(Sender, Source: TObject; X,
  Y: Integer);
begin
  if Source is TFileListBox then
    with DirectoryOutline1 do
      ConfirmChange('Move', FileListBox1.FileName, Items[GetItem(X, Y)].FullPath);
end;
```

Ending a drag operation

A drag operation ends when the item is either successfully dropped or released over a control that cannot accept it. At this point an end-drag event is sent to the control from which the item was dragged. To enable a control to respond when items have been dragged from it, attach an event handler to the control's *OnEndDrag* event.

The most important parameter in an *OnEndDrag* event is called *Target*, which indicates which control, if any, accepts the drop. If *Target* is **nil**, it means no control accepts the dragged item. The *OnEndDrag* event also includes the coordinates on the receiving control.

In this example, a file list box handles an end-drag event by refreshing its file list.

```
procedure TFMForm.FileListBox1EndDrag(Sender, Target: TObject; X, Y: Integer);
begin
  if Target <> nil then FileListBox1.Update;
end;
```

Customizing drag and drop with a drag object

You can use a *TDragObject* descendant to customize an object's drag-and-drop behavior. The standard drag-over and drag-and-drop events indicate the source of the dragged item and the coordinates of the mouse cursor over the accepting control. To get additional state information, derive a custom drag object from *TDragObject* or *TDragObjectEx* and override its virtual methods. Create the custom drag object in the *OnStartDrag* event.

Normally, the source parameter of the drag-over and drag-and-drop events is the control that starts the drag operation. If different kinds of control can start an operation involving the same kind of data, the source needs to support each kind of control. When you use a descendant of *TDragObject*, however, the source is the drag object itself; if each control creates the same kind of drag object in its *OnStartDrag* event, the target needs to handle only one kind of object. The drag-over and drag-and-drop events can tell if the source is a drag object, as opposed to the control, by calling the *IsDragObject* function.

TDragObjectEx descendants are freed automatically whereas descendants of *TDragObject* are not. If you have *TDragObject* descendants that you are not explicitly freeing, you can change them so they descend from *TDragObjectEx* instead to prevent memory loss.

Drag objects let you drag items between a form implemented in the application's main executable file and a form implemented using a DLL, or between forms that are implemented using different DLLs.

Changing the drag mouse pointer

You can customize the appearance of the mouse pointer during drag operations by setting the source component's *DragCursor* property (VCL only).

Implementing drag-and-dock in controls

Note Drag and dock properties are available in the VCL but not CLX.

Descendants of *TWinControl* can act as docking sites and descendants of *TControl* can act as child windows that are docked into docking sites. For example, to provide a docking site at the left edge of a form window, align a panel to the left edge of the form and make the panel a docking site. When dockable controls are dragged to the panel and released, they become child controls of the panel.

- Making a windowed control a docking site
- Making a control a dockable child
- Controlling how child controls are docked
- Controlling how child controls are undocked
- Controlling how child controls respond to drag-and-dock operations

Making a windowed control a docking site

Note Drag and dock properties are available in the VCL but not CLX.

To make a windowed control a docking site,

1. Set the *DockSite* property to *True*.
2. If the dock site object should not appear except when it contains a docked client, set its *AutoSize* property to *True*. When *AutoSize* is *True*, the dock site is sized to 0 until it accepts a child control for docking. Then it resizes to fit around the child control.

Making a control a dockable child

Note Drag and dock properties are available in the VCL but not CLX.

To make a control a dockable child,

1. Set its *DragKind* property to *dkDock*. When *DragKind* is *dkDock*, dragging the control moves the control to a new docking site or undocks the control so that it becomes a floating window. When *DragKind* is *dkDrag* (the default), dragging the control starts a drag-and-drop operation which must be implemented using the *OnDragOver*, *OnEndDrag*, and *OnDragDrop* events.

2 Set its *DragMode* to *dmAutomatic*. When *DragMode* is *dmAutomatic*, dragging (for drag-and-drop or docking, depending on *DragKind*) is initiated automatically when the user starts dragging the control with the mouse. When *DragMode* is *dmManual*, you can still begin a drag-and-dock (or drag-and-drop) operation by calling the *BeginDrag* method.

3 Set its *FloatingDockSiteClass* property to indicate the *TWinControl* descendant that should host the control when it is undocked and left as a floating window. When the control is released and not over a docking site, a windowed control of this class is created dynamically, and becomes the parent of the dockable child. If the dockable child control is a descendant of *TWinControl*, it is not necessary to create a separate floating dock site to host the control, although you may want to specify a form in order to get a border and title bar. To omit a dynamic container window, set *FloatingDockSiteClass* to the same class as the control, and it will become a floating window with no parent.

Controlling how child controls are docked

Note Drag and dock properties are available in the VCL but not CLX.

A docking site automatically accepts child controls when they are released over the docking site. For most controls, the first child is docked to fill the client area, the second splits that into separate regions, and so on. Page controls dock children into new tab sheets (or merge in the tab sheets if the child is another page control).

Three events allow docking sites to further constrain how child controls are docked:

```
property OnGetSiteInfo: TGetSiteInfoEvent;
TGetSiteInfoEvent = procedure(Sender: TObject; DockClient: TControl; var   InfluenceRect:
TRect; var CanDock: Boolean) of object;
```

OnGetSiteInfo occurs on the docking site when the user drags a dockable child over the control. It allows the site to indicate whether it will accept the control specified by the *DockClient* parameter as a child, and if so, where the child must be to be considered for docking. When *OnGetSiteInfo* occurs, *InfluenceRect* is initialized to the screen coordinates of the docking site, and *CanDock* is initialized to *True*. A more limited docking region can be created by changing *InfluenceRect* and the child can be rejected by setting *CanDock* to *False*.

```
property OnDockOver: TDockOverEvent;
TDockOverEvent = procedure(Sender: TObject; Source: TDragDockObject; X, Y:  Integer; State:
TDragState; var Accept: Boolean) of object;
```

OnDockOver occurs on the docking site when the user drags a dockable child over the control. It is analogous to the *OnDragOver* event in a drag-and-drop operation. Use it to signal that the child can be released for docking, by setting the *Accept* parameter. If the dockable control is rejected by the *OnGetSiteInfo* event handler (perhaps because it is the wrong type of control), *OnDockOver* does not occur.

```
property OnDockDrop: TDockDropEvent;
TDockDropEvent = procedure(Sender: TObject; Source: TDragDockObject; X, Y:  Integer) of
object;
```

OnDockDrop occurs on the docking site when the user releases the dockable child over the control. It is analogous to the *OnDragDrop* event in a normal drag-and-drop operation. Use this event to perform any necessary accommodations to accepting the control as a child control. Access to the child control can be obtained using the *Control* property of the *TDockObject* specified by the *Source* parameter.

Controlling how child controls are undocked

Note Drag and dock properties are available in the VCL but not CLX.

A docking site automatically allows child controls to be undocked when they are dragged and have a *DragMode* property of *dmAutomatic*. Docking sites can respond when child controls are dragged off, and even prevent the undocking, in an *OnUnDock* event handler:

```
property OnUnDock: TUnDockEvent;
TUnDockEvent = procedure(Sender: TObject; Client: TControl; var Allow: Boolean)   of
object;
```

The *Client* parameter indicates the child control that is trying to undock, and the *Allow* parameter lets the docking site (*Sender*) reject the undocking. When implementing an *OnUnDock* event handler, it can be useful to know what other children (if any) are currently docked. This information is available in the read-only *DockClients* property, which is an indexed array of *TControl*. The number of dock clients is given by the read-only *DockClientCount* property.

Controlling how child controls respond to drag-and-dock operations

Note Drag and dock properties are available in the VCL but not CLX.

Dockable child controls have two events that occur during drag-and-dock operations: *OnStartDock*, analogous to the *OnStartDrag* event of a drag-and-drop operation, allows the dockable child control to create a custom drag object. *OnEndDock*, like *OnEndDrag*, occurs when the dragging terminates.

Working with text in controls

The following sections explain how to use various features of rich edit and memo controls. Some of these features work with edit controls as well.

- Setting text alignment
- Adding scrollbars at runtime
- Adding the clipboard object
- Selecting text
- Selecting all text
- Cutting, copying, and pasting text
- Deleting selected text
- Disabling menu items
- Providing a pop-up menu
- Handling the OnPopup event

Setting text alignment

In a rich edit or memo component, text can be left- or right-aligned or centered. To change text alignment, set the edit component's *Alignment* property. Alignment takes effect only if the *WordWrap* property is *True*; if word wrapping is turned off, there is no margin to align to.

For example, the following code attaches an OnClick event handler to the Character | Left menu item, then attaches the same event handler to both the Right and Center menu items on the Character menu.

```
procedure TEditForm.AlignClick(Sender: TObject);
begin
  Left1.Checked := False;  { clear all three checks }
  Right1.Checked := False;
  Center1.Checked := False;
  with Sender as TMenuItem do Checked := True;  { check the item clicked }
  with Editor do  { then set Alignment to match }
    if Left1.Checked then
      Alignment := taLeftJustify
    else if Right1.Checked then
      Alignment := taRightJustify
    else if Center1.Checked then
      Alignment := taCenter;
end;
```

Adding scroll bars at runtime

Rich edit and memo components can contain horizontal or vertical scroll bars, or both, as needed. When word-wrapping is enabled, the component needs only a vertical scroll bar. If the user turns off word-wrapping, the component might also need a horizontal scroll bar, since text is not limited by the right side of the editor.

To add scroll bars at runtime,

1. Determine whether the text might exceed the right margin. In most cases, this means checking whether word wrapping is enabled. You might also check whether any text lines actually exceed the width of the control.
2. Set the rich edit or memo component's *ScrollBars* property to include or exclude scroll bars.

The following example attaches an *OnClick* event handler to a Character | WordWrap menu item.

```
procedure TEditForm.WordWrap1Click(Sender: TObject);
begin
  with Editor do
  begin
    WordWrap := not WordWrap;  { toggle word-wrapping }
    if WordWrap then
      ScrollBars := ssVertical  { wrapped requires only vertical }
    else
```

```
      ScrollBars := ssBoth;  { unwrapped might need both }
      WordWrap1.Checked := WordWrap;  { check menu item to match property }
    end;
  end;
```

The rich edit and memo components handle their scroll bars in a slightly different way. The rich edit component can hide its scroll bars if the text fits inside the bounds of the component. The memo always shows scroll bars if they are enabled.

Adding the clipboard object

Most text-handling applications provide users with a way to move selected text between documents, including documents in different applications. The *Clipboard* object in Delphi encapsulates a clipboard (such as the Windows Clipboard) and includes methods for cutting, copying, and pasting text (and other formats, including graphics). The *Clipboard* object is declared in the *Clipbrd* unit.

To add the *Clipboard* object to an application,

1. Select the unit that will use the clipboard.
2. Search for the `implementation` reserved word.
3. Add *Clipbrd* to the `uses` clause below `implementation`.
   - If there is already a `uses` clause in the `implementation` part, add *Clipbrd* to the end of it.
   - If there is not already a `uses` clause, add one that says

```
uses Clipbrd;
```

For example, in an application with a child window, the uses clause in the unit's implementation part might look like this:

```
uses
  MDIFrame, Clipbrd;
```

Selecting text

Before you can send any text to the clipboard, that text must be selected. Highlighting of selected text is built into the edit components. When the user selects text, it appears highlighted.

Table 7.1 lists properties commonly used to handle selected text.

Table 7.1 Properties of selected text

Property	Description
SelText	Contains a string representing the selected text in the component.
SelLength	Contains the length of a selected string.
SelStart	Contains the starting position of a string.

Selecting all text

The *SelectAll* method selects the entire contents of the rich edit or memo component. This is especially useful when the component's contents exceed the visible area of the component. In most other cases, users select text with either keystrokes or mouse dragging.

To select the entire contents of a rich edit or memo control, call the *RichEdit1* control's *SelectAll* method.

For example,

```
procedure TMainForm.SelectAll(Sender: TObject);
begin
  RichEdit1.SelectAll;  { select all text in RichEdit }
end;
```

Cutting, copying, and pasting text

Applications that use the *Clipbrd* unit can cut, copy, and paste text, graphics, and objects through the clipboard. The edit components that encapsulate the standard text-handling controls all have methods built into them for interacting with the clipboard. (See "Using the clipboard with graphics" on page 8-21 for information on using the clipboard with graphics.)

To cut, copy, or paste text with the clipboard, call the edit component's *CutToClipboard*, *CopyToClipboard*, and *PasteFromClipboard* methods, respectively.

For example, the following code attaches event handlers to the *OnClick* events of the Edit|Cut, Edit|Copy, and Edit|Paste commands, respectively:

```
procedure TEditForm.CutToClipboard(Sender: TObject);
begin
  Editor.CutToClipboard;
end;
procedure TEditForm.CopyToClipboard(Sender: TObject);
begin
  Editor.CopyToClipboard;
end;
procedure TEditForm.PasteFromClipboard(Sender: TObject);
begin
  Editor.PasteFromClipboard;
end;
```

Deleting selected text

You can delete the selected text in an edit component without cutting it to the clipboard. To do so, call the *ClearSelection* method. For example, if you have a Delete item on the Edit menu, your code could look like this:

```
procedure TEditForm.Delete(Sender: TObject);
begin
  RichEdit1.ClearSelection;
end;
```

Disabling menu items

It is often useful to disable menu commands without removing them from the menu. For example, in a text editor, if there is no text currently selected, the Cut, Copy, and Delete commands are inapplicable. An appropriate time to enable or disable menu items is when the user selects the menu. To disable a menu item, set its *Enabled* property to *False*.

In the following example, an event handler is attached to the *OnClick* event for the Edit item on a child form's menu bar. It sets *Enabled* for the Cut, Copy, and Delete menu items on the Edit menu based on whether *RichEdit1* has selected text. The Paste command is enabled or disabled based on whether any text exists on the clipboard.

```
procedure TEditForm.Edit1Click(Sender: TObject);
var
  HasSelection: Boolean;  { declare a temporary variable }
begin
  Paste1.Enabled := Clipboard.HasFormat(CF_TEXT);  {enable or disable the Paste
                                                    menu item}
  HasSelection := Editor.SelLength > 0;  { True if text is selected }
  Cut1.Enabled := HasSelection;  { enable menu items if HasSelection is True }
  Copy1.Enabled := HasSelection;
  Delete1.Enabled := HasSelection;
end;
```

The *HasFormat* method of the clipboard returns a Boolean value based on whether the clipboard contains objects, text, or images of a particular format. By calling *HasFormat* with the parameter *CF_TEXT*, you can determine whether the clipboard contains any text, and enable or disable the Paste item as appropriate.

Chapter 8, "Working with graphics and multimedia" provides more information about using the clipboard with graphics.

Providing a pop-up menu

Pop-up, or local, menus are a common ease-of-use feature for any application. They enable users to minimize mouse movement by clicking the right mouse button in the application workspace to access a list of frequently used commands.

In a text editor application, for example, you can add a pop-up menu that repeats the Cut, Copy, and Paste editing commands. These pop-up menu items can use the same event handlers as the corresponding items on the Edit menu. You don't need to create accelerator or shortcut keys for pop-up menus because the corresponding regular menu items generally already have shortcuts.

A form's *PopupMenu* property specifies what pop-up menu to display when a user right-clicks any item on the form. Individual controls also have *PopupMenu* properties that can override the form's property, allowing customized menus for particular controls.

To add a pop-up menu to a form,

1 Place a pop-up menu component on the form.

2 Use the Menu Designer to define the items for the pop-up menu.

3 Set the *PopupMenu* property of the form or control that displays the menu to the name of the pop-up menu component.

4 Attach handlers to the *OnClick* events of the pop-up menu items.

Handling the OnPopup event

You may want to adjust pop-up menu items before displaying the menu, just as you may want to enable or disable items on a regular menu. With a regular menu, you can handle the *OnClick* event for the item at the top of the menu, as described in "Disabling menu items" on page 7-10.

With a pop-up menu, however, there is no top-level menu bar, so to prepare the pop-up menu commands, you handle the event in the menu component itself. The pop-up menu component provides an event just for this purpose, called *OnPopup*.

To adjust menu items on a pop-up menu before displaying them,

1 Select the pop-up menu component.
2 Attach an event handler to its *OnPopup* event.
3 Write code in the event handler to enable, disable, hide, or show menu items.

In the following code, the *Edit1Click* event handler described previously in "Disabling menu items" on page 7-10 is attached to the pop-up menu component's *OnPopup* event. A line of code is added to *Edit1Click* for each item in the pop-up menu.

```
procedure TEditForm.Edit1Click(Sender: TObject);
var
  HasSelection: Boolean;
begin
  Paste1.Enabled := Clipboard.HasFormat(CF_TEXT);
  Paste2.Enabled := Paste1.Enabled;{Add this line}
  HasSelection := Editor.SelLength <> 0;
  Cut1.Enabled := HasSelection;
  Cut2.Enabled := HasSelection;{Add this line}
  Copy1.Enabled := HasSelection;
  Copy2.Enabled := HasSelection;{Add this line}
  Delete1.Enabled := HasSelection;
end;
```

Adding graphics to controls

Several controls let you customize the way the control is rendered. These include list boxes, combo boxes, menus, headers, tab controls, list views, status bars, tree views, and tool bars. Instead of using the standard method of drawing a control or its items, the control's owner (generally, the form) draws them at runtime. The most common use for owner-draw controls is to provide graphics instead of, or in addition to, text for items. For information on using owner-draw to add images to menus, see "Adding images to menu items" on page 6-35.

All owner-draw controls contain lists of items. Usually, those lists are lists of strings that are displayed as text, or lists of objects that contain strings that are displayed as text. You can associate an object with each item in a list to make it easy to use that object when drawing items.

In general, creating an owner-draw control in Delphi involves these steps:

1. Indicating that a control is owner-drawn
2. Adding graphical objects to a string list
3. Drawing owner-drawn items

Indicating that a control is owner-drawn

To customize the drawing of a control, you must supply event handlers that render the control's image when it needs to be painted. Some controls receive these events automatically. For example, list views, tree views, and tool bars all receive events at various stages in the drawing process without your having to set any properties. These events have names such as "OnCustomDraw" or "OnAdvancedCustomDraw".

Other controls, however, require you to set a property before they receive owner-draw events. List boxes, combo boxes, header controls, and status bars have a property called *Style*. *Style* determines whether the control uses the default drawing (called the "standard" style) or owner drawing. Grids use a property called *DefaultDrawing* to enable or disable the default drawing. List views and tab controls have a property called *OwnerDraw* that enables or disabled the default drawing.

List boxes and combo boxes have additional owner-draw styles, called *fixed* and *variable*, as Table 7.2 describes. Other controls are always fixed, although the size of the item that contains the text may vary, the size of each item is determined before drawing the control.

Table 7.2 Fixed vs. variable owner-draw styles

Owner-draw style	Meaning	Examples
Fixed	Each item is the same height, with that height determined by the *ItemHeight* property.	*lbOwnerDrawFixed*, *csOwnerDrawFixed*
Variable	Each item might have a different height, determined by the data at runtime.	*lbOwnerDrawVariable*, *csOwnerDrawVariable*

Adding graphical objects to a string list

Every string list has the ability to hold a list of objects in addition to its list of strings.

For example, in a file manager application, you may want to add bitmaps indicating the type of drive along with the letter of the drive. To do that, you need to add the bitmap images to the application, then copy those images into the proper places in the string list as described in the following sections.

Adding images to an application

An image control is a nonvisual control that contains a graphical image, such as a bitmap. You use image controls to display graphical images on a form. You can also use them to hold hidden images that you'll use in your application. For example, you can store bitmaps for owner-draw controls in hidden image controls, like this:

1 Add image controls to the main form.
2 Set their *Name* properties.
3 Set the *Visible* property for each image control to *False*.
4 Set the *Picture* property of each image to the desired bitmap using the Picture editor from the Object Inspector.

The image controls are invisible when you run the application.

Adding images to a string list

Once you have graphical images in an application, you can associate them with the strings in a string list. You can either add the objects at the same time as the strings, or associate objects with existing strings. The preferred method is to add objects and strings at the same time, if all the needed data is available.

The following example shows how you might want to add images to a string list. This is part of a file manager application where, along with a letter for each valid drive, it adds a bitmap indicating each drive's type. The *OnCreate* event handler looks like this:

```
procedure TFMForm.FormCreate(Sender: TObject);
var
  Drive: Char;
  AddedIndex: Integer;
begin
  for Drive := 'A' to 'Z' do  { iterate through all possible drives }
  begin
    case GetDriveType(Drive + ':/') of  { positive values mean valid drives }
     DRIVE_REMOVABLE:  { add a tab }
       AddedIndex := DriveTabSet.Tabs.AddObject(Drive, Floppy.Picture.Graphic);
     DRIVE_FIXED:  { add a tab }
       AddedIndex := DriveTabSet.Tabs.AddObject(Drive, Fixed.Picture.Graphic);
     DRIVE_REMOTE:  { add a tab }
       AddedIndex := DriveTabSet.Tabs.AddObject(Drive, Network.Picture.Graphic);
    end;
    if UpCase(Drive) = UpCase(DirectoryOutline.Drive) then  { current drive? }
     DriveTabSet.TabIndex := AddedIndex;  { then make that current tab }
  end;
end;
```

Drawing owner-drawn items

When you indicate that a control is owner-drawn, either by setting a property or supplying a custom draw event handler, the control is no longer drawn on the screen. Instead, the operating system generates events for each visible item in the control. Your application handles the events to draw the items.

To draw the items in an owner-draw control, do the following for each visible item in the control. Use a single event handler for all items.

1 Size the item, if needed.

  Items of the same size (for example, with a list box style of *lsOwnerDrawFixed*), do not require sizing.

2 Draw the item.

Sizing owner-draw items

Before giving your application the chance to draw each item in a variable owner-draw control, the operating system generates a measure-item event. The measure-item event tells the application where the item appears on the control.

Delphi determines the size of the item (generally, it is just large enough to display the item's text in the current font). Your application can handle the event and change the rectangle chosen. For example, if you plan to substitute a bitmap for the item's text, change the rectangle to be the size of the bitmap. If you want a bitmap and text, adjust the rectangle to be big enough for both.

To change the size of an owner-draw item, attach an event handler to the measure-item event in the owner-draw control. Depending on the control, the name of the event can vary. List boxes and combo boxes use *OnMeasureItem*. Grids have no measure-item event.

The sizing event has two important parameters: the index number of the item and the size of that item. The size is variable: the application can make it either smaller or larger. The positions of subsequent items depend on the size of preceding items.

For example, in a variable owner-draw list box, if the application sets the height of the first item to five pixels, the second item starts at the sixth pixel down from the top, and so on. In list boxes and combo boxes, the only aspect of the item the application can alter is the height of the item. The width of the item is always the width of the control.

Owner-draw grids cannot change the sizes of their cells as they draw. The size of each row and column is set before drawing by the *ColWidths* and *RowHeights* properties.

The following code, attached to the *OnMeasureItem* event of an owner-draw list box, increases the height of each list item to accommodate its associated bitmap.

```
procedure TFMForm.DriveTabSetMeasureTab(Sender: TObject; Index: Integer;
  var TabWidth: Integer);  { note that TabWidth is a var parameter}
var
  BitmapWidth: Integer;
begin
  BitmapWidth := TBitmap(DriveTabSet.Tabs.Objects[Index]).Width;
  { increase tab width by the width of the associated bitmap plus two }
  Inc(TabWidth, 2 + BitmapWidth);
end;
```

Note You must typecast the items from the *Objects* property in the string list. *Objects* is a property of type *TObject* so that it can hold any kind of object. When you retrieve objects from the array, you need to typecast them back to the actual type of the items.

Drawing owner-draw items

When an application needs to draw or redraw an owner-draw control, the operating system generates draw-item events for each visible item in the control. Depending on the control, the item may also receive draw events for the item as a whole or subitems.

To draw each item in an owner-draw control, attach an event handler to the draw-item event for that control.

The names of events for owner drawing typically start with one of the following:

- *OnDraw*, such as *OnDrawItem* or *OnDrawCell*
- *OnCustomDraw*, such as *OnCustomDrawItem*
- *OnAdvancedCustomDraw*, such as *OnAdvancedCustomDrawItem*

The draw-item event contains parameters identifying the item to draw, the rectangle in which to draw, and usually some information about the state of the item (such as whether the item has focus). The application handles each event by rendering the appropriate item in the given rectangle.

For example, the following code shows how to draw items in a list box that has bitmaps associated with each string. It attaches this handler to the *OnDrawItem* event for the list box:

```
procedure TFMForm.DriveTabSetDrawTab(Sender: TObject; TabCanvas: TCanvas;
  R: TRect; Index: Integer; Selected: Boolean);
var
  Bitmap: TBitmap;
begin
  Bitmap := TBitmap(DriveTabSet.Tabs.Objects[Index]);
  with TabCanvas do
  begin
  Draw(R.Left, R.Top + 4, Bitmap);  { draw bitmap }
  TextOut(R.Left + 2 + Bitmap.Width,  { position text }
    R.Top + 2, DriveTabSet.Tabs[Index]);  { and draw it to the right of the
                                          bitmap }
  end;
end;
```

Chapter

8

Working with graphics and multimedia

Graphics and multimedia elements can add polish to your applications. Delphi offers a variety of ways to introduce these features into your application. To add graphical elements, you can insert pre-drawn pictures at design time, create them using graphical controls at design time, or draw them dynamically at runtime. To add multimedia capabilities, Delphi includes special components that can play audio and video clips. Note that multimedia components are not available for cross-platform programming.

Overview of graphics programming

The VCL graphics components defined in the Graphics unit encapsulate the Windows Graphics Device Interface (GDI), making it easy to add graphics to your Windows applications. CLX graphics components defined in the QGraphics unit encapsulate the Qt graphics widgets for adding graphics to cross-platform applications.

To draw graphics in a Delphi application, you draw on an object's *canvas*, rather than directly on the object. The canvas is a property of the object, and is itself an object. A main advantage of the canvas object is that it handles resources effectively and it takes care of device context, so your programs can use the same methods regardless of whether you are drawing on the screen, to a printer, or on bitmaps or metafiles (drawings in CLX). Canvases are available only at runtime, so you do all your work with canvases by writing code.

VCL Note Since *TCanvas* is a wrapper resource manager around the Windows device context, you can also use all Windows GDI functions on the canvas. The *Handle* property of the canvas *is* the device context Handle.

CLX Note *TCanvas* is a wrapper resource manager around a Qt painter. The *Handle* property of the canvas *is* typed pointer to an instance of a Qt painter object. Having this instance pointer exposed allows you to use low-level Qt graphics library functions that require an instance pointer to a painter object.

How graphic images appear in your application depends on the type of object whose canvas you draw on. If you are drawing directly onto the canvas of a control, the picture is displayed immediately. However, if you draw on an offscreen image such as a *TBitmap* canvas, the image is not displayed until a control copies from the bitmap onto the control's canvas. That is, when drawing bitmaps and assigning them to an image control, the image appears only when the control has an opportunity to process its *OnPaint* message (VCL) or event (CLX).

When working with graphics, you often encounter the terms *drawing* and *painting*:

- Drawing is the creation of a single, specific graphic element, such as a line or a shape, with code. In your code, you tell an object to draw a specific graphic in a specific place on its canvas by calling a drawing method of the canvas.
- Painting is the creation of the entire appearance of an object. Painting usually involves drawing. That is, in response to *OnPaint* events, an object generally draws some graphics. An edit box, for example, paints itself by drawing a rectangle and then drawing some text inside. A shape control, on the other hand, paints itself by drawing a single graphic.

The examples in the beginning of this chapter demonstrate how to draw various graphics, but they do so in response to *OnPaint* events. Later sections show how to do the same kind of drawing in response to other events.

Refreshing the screen

At certain times, the operating system determines that objects onscreen need to refresh their appearance, so it generates WM_PAINT messages on Windows, which the VCL routes to *OnPaint* events. (If you are using CLX for cross-platform development, a paint event is generated, which CLX routes to *OnPaint* events.) If you have written an *OnPaint* event handler for that object, it is called when you use the *Refresh* method. The default name generated for the *OnPaint* event handler in a form is *FormPaint*. You may want to use the *Refresh* method at times to refresh a component or form. For example, you might call *Refresh* in the form's *OnResize* event handler to redisplay any graphics or if using the VCL, you want to paint a background on a form.

While some operating systems automatically handle the redrawing of the client area of a window that has been invalidated, Windows does not. In the Windows operating system anything drawn on the screen is permanent. When a form or control is temporarily obscured, for example during window dragging, the form or control must repaint the obscured area when it is re-exposed. For more information about the WM_PAINT message, see the Windows online Help.

If you use the *TImage* control to display a graphical image on a form, the painting and refreshing of the graphic contained in the *TImage* is handled automatically. The *Picture* property specifies the actual bitmap, drawing, or other graphic object that

TImage displays. You can also set the *Proportional* property to ensure that the image can be fully displayed in the image control without any distortion. Drawing on a *TImage* creates a persistent image. Consequently, you do not need to do anything to redraw the contained image. In contrast, *TPaintBox*'s canvas maps directly onto the screen device (VCL) or the painter (CLX), so that anything drawn to the *PaintBox*'s canvas is transitory. This is true of nearly all controls, including the form itself. Therefore, if you draw or paint on a *TPaintBox* in its constructor, you will need to add that code to your *OnPaint* event handler in order for the image to be repainted each time the client area is invalidated.

Types of graphic objects

The VCL/CLX provides the graphic objects shown in Table 8.1. These objects have methods to draw on the canvas, which are described in "Using Canvas methods to draw graphic objects" on page 8-9 and to load and save to graphics files, as described in "Loading and saving graphics files" on page 8-18.

Table 8.1 Graphic object types

Object	Description
Picture	Used to hold any graphic image. To add additional graphic file formats, use the Picture *Register* method. Use this to handle arbitrary files such as displaying images in an image control.
Bitmap	A powerful graphics object used to create, manipulate (scale, scroll, rotate, and paint), and store images as files on a disk. Creating copies of a bitmap is fast since the *handle* is copied, not the image.
Clipboard	Represents the container for any text or graphics that are cut, copied, or pasted from or to an application. With the clipboard, you can get and retrieve data according to the appropriate format; handle reference counting, and opening and closing the clipboard; manage and manipulate formats for objects in the clipboard.
Icon	Represents the value loaded from an icon file (::ICO file).
Metafile (VCL only) Drawing (CLX only)	Contains a file that records the operations required to construct an image, rather than contain the actual bitmap pixels of the image. Metafiles or drawings are extremely scalable without the loss of image detail and often require much less memory than bitmaps, particularly for high-resolution devices, such as printers. However, metafiles and drawings do not display as fast as bitmaps. Use a metafile or drawing when versatility or precision is more important than performance.

Common properties and methods of Canvas

Table 8.2 lists the commonly used properties of the Canvas object. For a complete list of properties and methods, see the *TCanvas* component in online Help.

Table 8.2 Common properties of the Canvas object

Properties	Descriptions
Font	Specifies the font to use when writing text on the image. Set the properties of the TFont object to specify the font face, color, size, and style of the font.
Brush	Determines the color and pattern the canvas uses for filling graphical shapes and backgrounds. Set the properties of the TBrush object to specify the color and pattern or bitmap to use when filling in spaces on the canvas.
Pen	Specifies the kind of pen the canvas uses for drawing lines and outlining shapes. Set the properties of the TPen object to specify the color, style, width, and mode of the pen.
PenPos	Specifies the current drawing position of the pen.
Pixels	Specifies the color of the area of pixels within the current ClipRect.

These properties are described in more detail in “Using the properties of the Canvas object” on page 8-5.

Table 8.3 is a list of several methods you can use:

Table 8.3 Common methods of the Canvas object

Method	Descriptions
Arc	Draws an arc on the image along the perimeter of the ellipse bounded by the specified rectangle.
Chord	Draws a closed figure represented by the intersection of a line and an ellipse.
CopyRect	Copies part of an image from another canvas into the canvas.
Draw	Renders the graphic object specified by the Graphic parameter on the canvas at the location given by the coordinates (X, Y).
Ellipse	Draws the ellipse defined by a bounding rectangle on the canvas.
FillRect	Fills the specified rectangle on the canvas using the current brush.
FloodFill (VCL only)	Fills an area of the canvas using the current brush.
FrameRect	Draws a rectangle using the Brush of the canvas to draw the border.
LineTo	Draws a line on the canvas from PenPos to the point specified by X and Y, and sets the pen position to (X, Y).
MoveTo	Changes the current drawing position to the point (X,Y).
Pie	Draws a pie-shaped the section of the ellipse bounded by the rectangle (X1, Y1) and (X2, Y2) on the canvas.

Table 8.3 Common methods of the Canvas object (continued)

Method	Descriptions
Polygon	Draws a series of lines on the canvas connecting the points passed in and closing the shape by drawing a line from the last point to the first point.
Polyline	Draws a series of lines on the canvas with the current pen, connecting each of the points passed to it in Points.
Rectangle	Draws a rectangle on the canvas with its upper left corner at the point (X1, Y1) and its lower right corner at the point (X2, Y2). Use *Rectangle* to draw a box using Pen and fill it using Brush.
RoundRect	Draws a rectangle with rounded corners on the canvas.
StretchDraw	Draws a graphic on the canvas so that the image fits in the specified rectangle. The graphic image may need to change its magnitude or aspect ratio to fit.
TextHeight, TextWidth	Returns the height and width, respectively, of a string in the current font. Height includes leading between lines.
TextOut	Writes a string on the canvas, starting at the point (X,Y), and then updates the PenPos to the end of the string.
TextRect	Writes a string inside a region; any portions of the string that fall outside the region do not appear.

These methods are described in more detail in “Using Canvas methods to draw graphic objects” on page 8-9.

Using the properties of the Canvas object

With the Canvas object, you can set the properties of a pen for drawing lines, a brush for filling shapes, a font for writing text, and an array of pixels to represent the image.

This section describes

- Using pens
- Using brushes
- Reading and setting pixels

Using pens

The *Pen* property of a canvas controls the way lines appear, including lines drawn as the outlines of shapes. Drawing a straight line is really just changing a group of pixels that lie between two points.

The pen itself has four properties you can change: *Color*, *Width*, *Style*, and *Mode*.

- Color property: Changes the pen color
- Width property: Changes the pen width
- Style property: Changes the pen style
- Mode property: Changes the pen mode

The values of these properties determine how the pen changes the pixels in the line. By default, every pen starts out black, with a width of 1 pixel, a solid style, and a mode called copy that overwrites anything already on the canvas.

You can use *TPenRecall* for quick saving off and restoring the properties of pens.

Changing the pen color

You can set the color of a pen as you would any other *Color* property at runtime. A pen's color determines the color of the lines the pen draws, including lines drawn as the boundaries of shapes, as well as other lines and polylines. To change the pen color, assign a value to the *Color* property of the pen.

To let the user choose a new color for the pen, put a color grid on the pen's toolbar. A color grid can set both foreground and background colors. For a non-grid pen style, you must consider the background color, which is drawn in the gaps between line segments. Background color comes from the Brush color property.

Since the user chooses a new color by clicking the grid, this code changes the pen's color in response to the *OnClick* event:

```
procedure TForm1.PenColorClick(Sender: TObject);
begin
  Canvas.Pen.Color := PenColor.ForegroundColor;
end;
```

Changing the pen width

A pen's width determines the thickness, in pixels, of the lines it draws.

Note When the thickness is greater than 1, Windows 95/98 always draw solid lines, regardless of the value of the pen's *Style* property.

To change the pen width, assign a numeric value to the pen's *Width* property.

Suppose you have a scroll bar on the pen's toolbar to set width values for the pen. And suppose you want to update the label next to the scroll bar to provide feedback to the user. Using the scroll bar's position to determine the pen width, you update the pen width every time the position changes.

This is how to handle the scroll bar's *OnChange* event:

```
procedure TForm1.PenWidthChange(Sender: TObject);
begin
  Canvas.Pen.Width := PenWidth.Position;{ set the pen width directly }
 PenSize.Caption := IntToStr(PenWidth.Position);{ convert to string for caption }
end;
```

Changing the pen style

A pen's *Style* property allows you to set solid lines, dashed lines, dotted lines, and so on.

VCL Note If developing a cross-platform application for deployment under Windows, Windows 95/98 does not support dashed or dotted line styles for pens wider than one pixel and makes all larger pens solid, no matter what style you specify.

The task of setting the properties of pen is an ideal case for having different controls share same event handler to handle events. To determine which control actually got the event, you check the *Sender* parameter.

To create one click-event handler for six pen-style buttons on a pen's toolbar, do the following:

1 Select all six pen-style buttons and select the Object Inspector | Events | *OnClick* event and in the Handler column, type `SetPenStyle`.

  Delphi generates an empty click-event handler called *SetPenStyle* and attaches it to the *OnClick* events of all six buttons.

2 Fill in the click-event handler by setting the pen's style depending on the value of *Sender*, which is the control that sent the click event:

```
procedure TForm1.SetPenStyle(Sender: TObject);
begin
  with Canvas.Pen do
  begin
    if Sender = SolidPen then Style := psSolid
   else if Sender = DashPen then Style := psDash
   else if Sender = DotPen then Style := psDot
   else if Sender = DashDotPen then Style := psDashDot
   else if Sender = DashDotDotPen then Style := psDashDotDot
   else if Sender = ClearPen then Style := psClear;
  end;
end;
```

Changing the pen mode

A pen's *Mode* property lets you specify various ways to combine the pen's color with the color on the canvas. For example, the pen could always be black, be an inverse of the canvas background color, inverse of the pen color, and so on. See *TPen* in online Help for details.

Getting the pen position

The current drawing position—the position from which the pen begins drawing its next line—is called the pen position. The canvas stores its pen position in its *PenPos* property. Pen position affects the drawing of lines only; for shapes and text, you specify all the coordinates you need.

To set the pen position, call the *MoveTo* method of the canvas. For example, the following code moves the pen position to the upper left corner of the canvas:

```
Canvas.MoveTo(0, 0);
```

Note Drawing a line with the *LineTo* method also moves the current position to the endpoint of the line.

Using brushes

The *Brush* property of a canvas controls the way you fill areas, including the interior of shapes. Filling an area with a brush is a way of changing a large number of adjacent pixels in a specified way.

The brush has three properties you can manipulate:

- Color property: Changes the fill color
- Style property: Changes the brush style
- Bitmap property: Uses a bitmap as a brush pattern

The values of these properties determine the way the canvas fills shapes or other areas. By default, every brush starts out white, with a solid style and no pattern bitmap.

You can use *TBrushRecall* for quick saving off and restoring the properties of brushes.

Changing the brush color

A brush's color determines what color the canvas uses to fill shapes. To change the fill color, assign a value to the brush's *Color* property. Brush is used for background color in text and line drawing so you typically set the background color property.

You can set the brush color just as you do the pen color, in response to a click on a color grid on the brush's toolbar (see "Changing the pen color" on page 8-6):

```
procedure TForm1.BrushColorClick(Sender: TObject);
begin
  Canvas.Brush.Color := BrushColor.ForegroundColor;
end;
```

Changing the brush style

A brush style determines what pattern the canvas uses to fill shapes. It lets you specify various ways to combine the brush's color with any colors already on the canvas. The predefined styles include solid color, no color, and various line and hatch patterns.

To change the style of a brush, set its *Style* property to one of the predefined values: *bsSolid*, *bsClear*, *bsHorizontal*, *bsVertical*, *bsFDiagonal*, *bsBDiagonal*, *bsCross*, or *bsDiagCross*.

This example sets brush styles by sharing a click-event handler for a set of eight brush-style buttons. All eight buttons are selected, the Object Inspector|Events|*OnClick* is set, and the *OnClick* handler is named *SetBrushStyle*. Here is the handler code:

```
procedure TForm1.SetBrushStyle(Sender: TObject);
begin
  with Canvas.Brush do
  begin
    if Sender = SolidBrush then Style := bsSolid
   else if Sender = ClearBrush then Style := bsClear
```

```
     else if Sender = HorizontalBrush then Style := bsHorizontal
     else if Sender = VerticalBrush then Style := bsVertical
     else if Sender = FDiagonalBrush then Style := bsFDiagonal
     else if Sender = BDiagonalBrush then Style := bsBDiagonal
     else if Sender = CrossBrush then Style := bsCross
     else if Sender = DiagCrossBrush then Style := bsDiagCross;
    end;
  end;
```

Setting the Brush Bitmap property

A brush's *Bitmap* property lets you specify a bitmap image for the brush to use as a pattern for filling shapes and other areas.

The following example loads a bitmap from a file and assigns it to the Brush of the Canvas of Form1:

```
var
  Bitmap: TBitmap;
begin
  Bitmap := TBitmap.Create;
  try
    Bitmap.LoadFromFile('MyBitmap.bmp');
    Form1.Canvas.Brush.Bitmap := Bitmap;
    Form1.Canvas.FillRect(Rect(0,0,100,100));
  finally
    Form1.Canvas.Brush.Bitmap := nil;
    Bitmap.Free;
  end;
end;
```

Note The brush does not assume ownership of a bitmap object assigned to its *Bitmap* property. You must ensure that the Bitmap object remains valid for the lifetime of the Brush, and you must free the Bitmap object yourself afterwards.

Reading and setting pixels

You will notice that every canvas has an indexed *Pixels* property that represents the individual colored points that make up the image on the canvas. You rarely need to access *Pixels* directly, it is available only for convenience to perform small actions such as finding or setting a pixel's color.

Note Setting and getting individual pixels is thousands of times slower than performing graphics operations on regions. Do not use the Pixel array property to access the image pixels of a general array. For high-performance access to image pixels, see the *TBitmap.ScanLine* property.

Using Canvas methods to draw graphic objects

This section shows how to use some common methods to draw graphic objects. It covers:

- Drawing lines and polylines

- Drawing shapes
- Drawing rounded rectangles
- Drawing polygons

Drawing lines and polylines

A canvas can draw straight lines and polylines. A straight line is just a line of pixels connecting two points. A polyline is a series of straight lines, connected end-to-end. The canvas draws all lines using its pen.

Drawing lines

To draw a straight line on a canvas, use the *LineTo* method of the canvas.

LineTo draws a line from the current pen position to the point you specify and makes the endpoint of the line the current position. The canvas draws the line using its pen.

For example, the following method draws crossed diagonal lines across a form whenever the form is painted:

```
procedure TForm1.FormPaint(Sender: TObject);
begin
 with Canvas do
 begin
   MoveTo(0, 0);
   LineTo(ClientWidth, ClientHeight);
   MoveTo(0, ClientHeight);
   LineTo(ClientWidth, 0);
 end;
end;
```

Drawing polylines

In addition to individual lines, the canvas can also draw polylines, which are groups of any number of connected line segments.

To draw a polyline on a canvas, call the *Polyline* method of the canvas.

The parameter passed to the *Polyline* method is an array of points. You can think of a polyline as performing a *MoveTo* on the first point and *LineTo* on each successive point. For drawing multiple lines, *Polyline* is faster than using the *MoveTo* method and the *LineTo* method because it eliminates a lot of call overhead.

The following method, for example, draws a rhombus in a form:

```
procedure TForm1.FormPaint(Sender: TObject);
begin
 with Canvas do
   Polyline([Point(0, 0), Point(50, 0), Point(75, 50), Point(25, 50), Point(0, 0)]);
end;
```

This example takes advantage of Delphi's ability to create an open-array parameter on-the-fly. You can pass any array of points, but an easy way to construct an array quickly is to put its elements in brackets and pass the whole thing as a parameter. For more information, see online Help.

Drawing shapes

Canvases have methods for drawing different kinds of shapes. The canvas draws the outline of a shape with its pen, then fills the interior with its brush. The line that forms the border for the shape is controlled by the current *Pen* object.

This section covers:

- Drawing rectangles and ellipses
- Drawing rounded rectangles
- Drawing polygons

Drawing rectangles and ellipses

To draw a rectangle or ellipse on a canvas, call the canvas's *Rectangle* method or *Ellipse* method, passing the coordinates of a bounding rectangle.

The *Rectangle* method draws the bounding rectangle; *Ellipse* draws an ellipse that touches all sides of the rectangle.

The following method draws a rectangle filling a form's upper left quadrant, then draws an ellipse in the same area:

```
procedure TForm1.FormPaint(Sender: TObject);
begin
 Canvas.Rectangle(0, 0, ClientWidth div 2, ClientHeight div 2);
 Canvas.Ellipse(0, 0, ClientWidth div 2, ClientHeight div 2);
end;
```

Drawing rounded rectangles

To draw a rounded rectangle on a canvas, call the canvas's *RoundRect* method.

The first four parameters passed to *RoundRect* are a bounding rectangle, just as for the *Rectangle* method or the *Ellipse* method. *RoundRect* takes two more parameters that indicate how to draw the rounded corners.

The following method, for example, draws a rounded rectangle in a form's upper left quadrant, rounding the corners as sections of a circle with a diameter of 10 pixels:

```
procedure TForm1.FormPaint(Sender: TObject);
begin
 Canvas.RoundRect(0, 0, ClientWidth div 2, ClientHeight div 2, 10, 10);
end;
```

Drawing polygons

To draw a polygon with any number of sides on a canvas, call the *Polygon* method of the canvas.

Polygon takes an array of points as its only parameter and connects the points with the pen, then connects the last point to the first to close the polygon. After drawing the lines, *Polygon* uses the brush to fill the area inside the polygon.

For example, the following code draws a right triangle in the lower left half of a form:

```
procedure TForm1.FormPaint(Sender: TObject);
begin
 Canvas.Polygon([Point(0, 0), Point(0, ClientHeight),
   Point(ClientWidth, ClientHeight)]);
end;
```

Handling multiple drawing objects in your application

Various drawing methods (rectangle, shape, line, and so on) are typically available on the toolbar and button panel. Applications can respond to clicks on speed buttons to set the desired drawing objects. This section describes how to:

- Keep track of which drawing tool to use
- Changing the tool with speed buttons
- Using drawing tools

Keeping track of which drawing tool to use

A graphics program needs to keep track of what kind of drawing tool (such as a line, rectangle, ellipse, or rounded rectangle) a user might want to use at any given time. You could assign numbers to each kind of tool, but then you would have to remember what each number stands for. You can do that more easily by assigning mnemonic constant names to each number, but your code won't be able to distinguish which numbers are in the proper range and of the right type. Fortunately, Object Pascal provides a means to handle both of these shortcomings. You can declare an enumerated type.

An enumerated type is really just a shorthand way of assigning sequential values to constants. Since it's also a type declaration, you can use Object Pascal's type-checking to ensure that you assign only those specific values.

To declare an enumerated type, use the reserved work type, followed by an identifier for the type, then an equal sign, and the identifiers for the values in the type in parentheses, separated by commas.

For example, the following code declares an enumerated type for each drawing tool available in a graphics application:

```
type
  TDrawingTool = (dtLine, dtRectangle, dtEllipse, dtRoundRect);
```

By convention, type identifiers begin with the letter *T*, and groups of similar constants (such as those making up an enumerated type) begin with a 2-letter prefix (such as *dt* for “drawing tool”).

The declaration of the TDrawingTool type is equivalent to declaring a group of constants:

```
const
  dtLine = 0;
  dtRectangle = 1;
  dtEllipse = 2;
  dtRoundRect = 3;
```

The main difference is that by declaring the enumerated type, you give the constants not just a value, but also a type, which enables you to use Object Pascal's type-checking to prevent many errors. A variable of type TDrawingTool can be assigned only one of the constants dtLine..dtRoundRect. Attempting to assign some other number (even one in the range 0..3) generates a compile-time error.

In the following code, a field added to a form keeps track of the form's drawing tool:

```
type
  TDrawingTool = (dtLine, dtRectangle, dtEllipse, dtRoundRect);
 TForm1 = class(TForm)
    ...{ method declarations }
 public
    Drawing: Boolean;
   Origin, MovePt: TPoint;
   DrawingTool: TDrawingTool;{ field to hold current tool }
  end;
```

Changing the tool with speed buttons

Each drawing tool needs an associated *OnClick* event handler. Suppose your application had a toolbar button for each of four drawing tools: line, rectangle, ellipse, and rounded rectangle. You would attach the following event handlers to the *OnClick* events of the four drawing-tool buttons, setting *DrawingTool* to the appropriate value for each:

```
procedure TForm1.LineButtonClick(Sender: TObject);{ LineButton }
begin
  DrawingTool := dtLine;
end;

procedure TForm1.RectangleButtonClick(Sender: TObject);{ RectangleButton }
begin
  DrawingTool := dtRectangle;
end;

procedure TForm1.EllipseButtonClick(Sender: TObject);{ EllipseButton }
begin
  DrawingTool := dtEllipse;
end;

procedure TForm1.RoundedRectButtonClick(Sender: TObject);{ RoundRectButton }
begin
  DrawingTool := dtRoundRect;
end;
```

Using drawing tools

Now that you can tell what tool to use, you must indicate how to draw the different shapes. The only methods that perform any drawing are the mouse-move and mouse-up handlers, and the only drawing code draws lines, no matter what tool is selected.

To use different drawing tools, your code needs to specify how to draw, based on the selected tool. You add this instruction to each tool's event handler.

This section describes

- Drawing shapes
- Sharing code among event handlers

Drawing shapes

Drawing shapes is just as easy as drawing lines: Each one takes a single statement; you just need the coordinates.

Here’s a rewrite of the *OnMouseUp* event handler that draws shapes for all four tools:

```
procedure TForm1.FormMouseUp(Sender: TObject; Button TMouseButton; Shift: TShiftState;
                            X,Y: Integer);
begin
  case DrawingTool of
    dtLine:
      begin
        Canvas.MoveTo(Origin.X, Origin.Y);
       Canvas.LineTo(X, Y)
      end;
   dtRectangle: Canvas.Rectangle(Origin.X, Origin.Y, X, Y);
   dtEllipse: Canvas.Ellipse(Origin.X, Origin.Y, X, Y);
   dtRoundRect: Canvas.RoundRect(Origin.X, Origin.Y, X, Y,
                   (Origin.X - X) div 2, (Origin.Y - Y) div 2);
  end;
 Drawing := False;
end;
```

Of course, you also need to update the *OnMouseMove* handler to draw shapes:

```
procedure TForm1.FormMouseMove(Sender: TObject; Shift: TShiftState; X, Y: Integer);
begin
  if Drawing then
  begin
    Canvas.Pen.Mode := pmNotXor;
   case DrawingTool of
      dtLine: begin
                Canvas.MoveTo(Origin.X, Origin.Y);
               Canvas.LineTo(MovePt.X, MovePt.Y);
               Canvas.MoveTo(Origin.X, Origin.Y);
               Canvas.LineTo(X, Y);
              end;
     dtRectangle: begin
                      Canvas.Rectangle(Origin.X, Origin.Y, MovePt.X, MovePt.Y);
                     Canvas.Rectangle(Origin.X, Origin.Y, X, Y);
                   end;
     dtEllipse: begin
                    Canvas.Ellipse(Origin.X, Origin.Y, X, Y);
                   Canvas.Ellipse(Origin.X, Origin.Y, X, Y);
                  end;
     dtRoundRect: begin
                     Canvas.RoundRect(Origin.X, Origin.Y, X, Y,
                       (Origin.X - X) div 2, (Origin.Y - Y) div 2);
                    Canvas.RoundRect(Origin.X, Origin.Y, X, Y,
                       (Origin.X - X) div 2, (Origin.Y - Y) div 2);
                  end;
      end;
     MovePt := Point(X, Y);
    end;
   Canvas.Pen.Mode := pmCopy;
  end;
```

Typically, all the repetitious code that is in the above example would be in a separate routine. The next section shows all the shape-drawing code in a single routine that all mouse-event handlers can call.

Sharing code among event handlers

Any time you find that many your event handlers use the same code, you can make your application more efficient by moving the repeated code into a routine that all event handlers can share.

To add a method to a form,

1 Add the method declaration to the form object.

You can add the declaration in either the **public** or **private** parts at the end of the form object's declaration. If the code is just sharing the details of handling some events, it's probably safest to make the shared method **private**.

2 Write the method implementation in the implementation part of the form unit.

The header for the method implementation must match the declaration exactly, with the same parameters in the same order.

The following code adds a method to the form called *DrawShape* and calls it from each of the handlers. First, the declaration of *DrawShape* is added to the form object's declaration:

```
type
  TForm1 = class(TForm)
    ...{ fields and methods declared here}
 public
    { Public declarations }
   procedure DrawShape(TopLeft, BottomRight: TPoint; AMode: TPenMode);
  end;
```

Then, the implementation of *DrawShape* is written in the implementation part of the unit:

```
implementation
{$R *.FRM}
...{ other method implementations omitted for brevity }
procedure TForm1.DrawShape(TopLeft, BottomRight: TPoint; AMode: TPenMode);
begin
  with Canvas do
  begin
    Pen.Mode := AMode;
   case DrawingTool of
      dtLine:
        begin
          MoveTo(TopLeft.X, TopLeft.Y);
          LineTo(BottomRight.X, BottomRight.Y);
         end;
      dtRectangle: Rectangle(TopLeft.X, TopLeft.Y, BottomRight.X, BottomRight.Y);
      dtEllipse: Ellipse(TopLeft.X, TopLeft.Y, BottomRight.X, BottomRight.Y);
      dtRoundRect: RoundRect(TopLeft.X, TopLeft.Y, BottomRight.X, BottomRight.Y,
         (TopLeft.X - BottomRight.X) div 2, (TopLeft.Y - BottomRight.Y) div 2);
    end;
  end;
end;
```

The other event handlers are modified to call *DrawShape*.

```
procedure TForm1.FormMouseUp(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  DrawShape(Origin, Point(X, Y), pmCopy);{ draw the final shape }
 Drawing := False;
end;
procedure TForm1.FormMouseMove(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  if Drawing then
  begin
    DrawShape(Origin, MovePt, pmNotXor);{ erase the previous shape }
   MovePt := Point(X, Y);{ record the current point }
   DrawShape(Origin, MovePt, pmNotXor);{ draw the current shape }
  end;
end;
```

Drawing on a graphic

You don’t need any components to manipulate your application’s graphic objects. You can construct, draw on, save, and destroy graphic objects without ever drawing anything on screen. In fact, your applications rarely draw directly on a form. More often, an application operates on graphics and then uses an image control component to display the graphic on a form.

Once you move the application’s drawing to the graphic in the image control, it is easy to add printing, clipboard, and loading and saving operations for any graphic objects. graphic objects can be bitmap files, drawings, icons or whatever other graphics classes that have been installed such as jpeg graphics.

Note Because you are drawing on an offscreen image such as a *TBitmap* canvas, the image is not displayed until a control copies from a bitmap onto the control’s canvas. That is, when drawing bitmaps and assigning them to an image control, the image appears only when the control has an opportunity to process its paint message. But if you are drawing directly onto the canvas property of a control, the picture object is displayed immediately.

Making scrollable graphics

The graphic need not be the same size as the form: it can be either smaller or larger. By adding a scroll box control to the form and placing the graphic image inside it, you can display graphics that are much larger than the form or even larger than the screen. To add a scrollable graphic first you add a *TScrollBox* component and then you add the image control.

Adding an image control

An image control is a container component that allows you to display your bitmap objects. You use an image control to hold a bitmap that is not necessarily displayed all the time, or which an application needs to use to generate other pictures.

Note "Adding graphics to controls" on page 7-11 shows how to use graphics in controls.

Placing the control

You can place an image control anywhere on a form. If you take advantage of the image control's ability to size itself to its picture, you need to set the top left corner only. If the image control is a nonvisible holder for a bitmap, you can place it anywhere, just as you would a nonvisual component.

If you drop the image control on a scroll box already aligned to the form's client area, this assures that the scroll box adds any scroll bars necessary to access offscreen portions of the image's picture. Then set the image control's properties.

Setting the initial bitmap size

When you place an image control, it is simply a container. However, you can set the image control's *Picture* property at design time to contain a static graphic. The control can also load its picture from a file at runtime, as described in "Loading and saving graphics files" on page 8-18.

To create a blank bitmap when the application starts,

1 Attach a handler to the *OnCreate* event for the form that contains the image.

2 Create a bitmap object, and assign it to the image control's *Picture.Graphic* property.

In this example, the image is in the application's main form, *Form1*, so the code attaches a handler to *Form1*'s *OnCreate* event:

```
procedure TForm1.FormCreate(Sender: TObject);
var
  Bitmap: TBitmap;{ temporary variable to hold the bitmap }
begin
  Bitmap := TBitmap.Create;{ construct the bitmap object }
 Bitmap.Width := 200;{ assign the initial width... }
 Bitmap.Height := 200;{ ...and the initial height }
 Image.Picture.Graphic := Bitmap;{ assign the bitmap to the image control }
 Bitmap.Free; {We are done with the bitmap, so free it }
end;
```

Assigning the bitmap to the picture's *Graphic* property copies the bitmap to the picture object. However, the picture object does not take ownership of the bitmap, so after making the assignment, you must free it.

If you run the application now, you see that client area of the form has a white region, representing the bitmap. If you size the window so that the client area cannot display the entire image, you'll see that the scroll box automatically shows scroll bars to allow display of the rest of the image. But if you try to draw on the image, you don't get any graphics, because the application is still drawing on the form, which is now behind the image and the scroll box.

Drawing on the bitmap

To draw on a bitmap, use the image control's canvas and attach the mouse-event handlers to the appropriate events in the image control. Typically, you would use region operations (fills, rectangles, polylines, and so on). These are fast and efficient methods of drawing.

An efficient way to draw images when you need to access individual pixels is to use the bitmap *ScanLine* property. For general-purpose usage, you can set up the bitmap pixel format to 24 bits and then treat the pointer returned from *ScanLine* as an array of RGB. Otherwise, you will need to know the native format of the *ScanLine* property. This example shows how to use *ScanLine* to get pixels one line at a time.

```
procedure TForm1.Button1Click(Sender: TObject);
// This example shows drawing directly to the Bitmap
var
  x,y : integer;
  Bitmap : TBitmap;
  P : PByteArray;
begin
  Bitmap := TBitmap.create;
  try
    Bitmap.LoadFromFile('C:\Program Files\Borland\Delphi 4\Images\Splash\256color\
factory.bmp');
    for y := 0 to Bitmap.height -1 do
    begin
      P := Bitmap.ScanLine[y];
      for x := 0 to Bitmap.width -1 do
        P[x] := y;
    end;
  canvas.draw(0,0,Bitmap);
  finally
    Bitmap.free;
  end;
end;
```

Loading and saving graphics files

Graphic images that exist only for the duration of one running of an application are of very limited value. Often, you either want to use the same picture every time, or you want to save a created picture for later use. The image component makes it easy to load pictures from a file and save them again.

The components you use to load, save, and replace graphic images support many graphic formats including bitmap files, metafiles, glyphs, and so on. They also support installable graphic classes.

The way to load and save graphics files is the similar to any other files and is described in the following sections:

- Loading a picture from a file
- Saving a picture to a file
- Replacing the picture

Loading a picture from a file

Your application should provide the ability to load a picture from a file if your application needs to modify the picture or if you want to store the picture outside the application so a person or another application can modify the picture.

To load a graphics file into an image control, call the *LoadFromFile* method of the image control's *Picture* object.

The following code gets a file name from an open picture file dialog box, and then loads that file into an image control named *Image*:

```
procedure TForm1.Open1Click(Sender: TObject);
begin
  if OpenPictureDialog1.Execute then
  begin
    CurrentFile := OpenPictureDialog1.FileName;
   Image.Picture.LoadFromFile(CurrentFile);
  end;
end;
```

Saving a picture to a file

The picture object can load and save graphics in several formats, and you can create and register your own graphic-file formats so that picture objects can load and store them as well.

To save the contents of an image control in a file, call the *SaveToFile* method of the image control's *Picture* object.

The *SaveToFile* method requires the name of a file in which to save. If the picture is newly created, it might not have a file name, or a user might want to save an existing picture in a different file. In either case, the application needs to get a file name from the user before saving, as shown in the next section.

The following pair of event handlers, attached to the File|Save and File|Save As menu items, respectively, handle the resaving of named files, saving of unnamed files, and saving existing files under new names.

```
procedure TForm1.Save1Click(Sender: TObject);
begin
  if CurrentFile <> '' then
    Image.Picture.SaveToFile(CurrentFile){ save if already named }
 else SaveAs1Click(Sender);{ otherwise get a name }
end;
procedure TForm1.Saveas1Click(Sender: TObject);
begin
  if SaveDialog1.Execute then{ get a file name }
  begin
```

```
    CurrentFile := SaveDialog1.FileName;{ save the user-specified name }
   Save1Click(Sender);{ then save normally }
  end;
end;
```

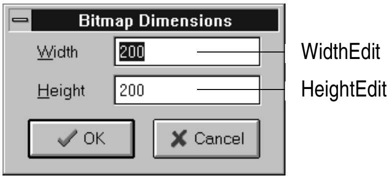
Replacing the picture

You can replace the picture in an image control at any time. If you assign a new graphic to a picture that already has a graphic, the new graphic replaces the existing one.

To replace the picture in an image control, assign a new graphic to the image control's *Picture* object.

Creating the new graphic is the same process you used to create the initial graphic (see "Setting the initial bitmap size" on page 8-17), but you should also provide a way for the user to choose a size other than the default size used for the initial graphic. An easy way to provide that option is to present a dialog box, such as the one in Figure 8.1.

Figure 8.1 Bitmap-dimension dialog box from the BMPDlg unit.



Width 200

Height 200

This particular dialog box is created in the *BMPDlg* unit included with the *GraphEx* project (in the EXAMPLES\DOC\GRAPHEX directory).

With such a dialog box in your project, add it to the uses clause in the unit for your main form. You can then attach an event handler to the File | New menu item's *OnClick* event. Here's an example:

```
procedure TForm1.New1Click(Sender: TObject);
var
  Bitmap: TBitmap;{ temporary variable for the new bitmap }
begin
  with NewBMPForm do
  begin
    ActiveControl := WidthEdit;{ make sure focus is on width field }
   WidthEdit.Text := IntToStr(Image.Picture.Graphic.Width);{ use current dimensions... }
   HeightEdit.Text := IntToStr(Image.Picture.Graphic.Height);{ ...as default }
   if ShowModal <> idCancel then{ continue if user doesn't cancel dialog box }
    begin
      Bitmap := TBitmap.Create;{ create fresh bitmap object }
     Bitmap.Width := StrToInt(WidthEdit.Text);{ use specified width }
     Bitmap.Height := StrToInt(HeightEdit.Text);{ use specified height }
     Image.Picture.Graphic := Bitmap;{ replace graphic with new bitmap }
     CurrentFile := '';{ indicate unnamed file }
     Bitmap.Free;
    end;
  end;
end;
```

Note Assigning a new bitmap to the picture object's *Graphic* property causes the picture object to copy the new graphic, but it does not take ownership of it. The picture object maintains its own internal graphic object. Because of this, the previous code frees the bitmap object after making the assignment.

Using the clipboard with graphics

You can use the Windows clipboard to copy and paste graphics within your applications or to exchange graphics with other applications. The VCL's clipboard object makes it easy to handle different kinds of information, including graphics.

Before you can use the clipboard object in your application, you must add the Clipbrd (QClipbrd in CLX) unit to the **uses** clause of any unit that needs to access clipboard data.

For cross-platform applications, data that is stored on the clipboard when using CLX is stored as a mime type with an associated *TStream* object. CLX provides the following predefined mime source and mime type string constants for the following CLX objects:

- TBitmap = 'image/delphi.bitmap'
- TComponent = 'application/delphi.component'
- TPicture = 'image/delphi.picture'
- TDrawing = 'image/delphi.drawing'

Copying graphics to the clipboard

You can copy any picture, including the contents of image controls, to the clipboard. Once on the clipboard, the picture is available to all applications.

To copy a picture to the clipboard, assign the picture to the clipboard object using the *Assign* method.

This code shows how to copy the picture from an image control named *Image* to the clipboard in response to a click on an Edit|Copy menu item:

```
procedure TForm1.Copy1Click(Sender: TObject);
begin
  Clipboard.Assign(Image.Picture)
end.
```

Cutting graphics to the clipboard

Cutting a graphic to the clipboard is exactly like copying it, but you also erase the graphic from the source.

To cut a graphic from a picture to the clipboard, first copy it to the clipboard, then erase the original.

In most cases, the only issue with cutting is how to show that the original image is erased. Setting the area to white is a common solution, as shown in the following code that attaches an event handler to the *OnClick* event of the Edit|Cut menu item:

```
procedure TForm1.Cut1Click(Sender: TObject);
var
  ARect: TRect;
begin
  Copy1Click(Sender);{ copy picture to clipboard }
 with Image.Canvas do
  begin
    CopyMode := cmWhiteness;{ copy everything as white }
   ARect := Rect(0, 0, Image.Width, Image.Height);{ get bitmap rectangle }
   CopyRect(ARect, Image.Canvas, ARect);{ copy bitmap over itself }
   CopyMode := cmSrcCopy;{ restore normal mode }
  end;
end;
```

Pasting graphics from the clipboard

If the clipboard contains a bitmapped graphic, you can paste it into any image object, including image controls and the surface of a form.

To paste a graphic from the clipboard,

1 Call the clipboard's *HasFormat* method (if using the VCL) or *Provides* method (if using CLX) to see whether the clipboard contains a graphic.

HasFormat (or *Provides* in CLX) is a Boolean function. It returns *True* if the clipboard contains an item of the type specified in the parameter. To test for graphics on the Windows platform, you pass *CF_BITMAP*. In cross-platform applications, you pass *SDelphiBitmap*.

2 Assign the clipboard to the destination.

This code shows how to paste a picture from the clipboard into an image control in response to a click on an Edit|Paste menu item:

```
procedure TForm1.PasteButtonClick(Sender: TObject);
var
  Bitmap: TBitmap;
begin
 if Clipboard.HasFormat(CF_BITMAP) then { is there a bitmap on the Windows clipboard? )
 begin
   Image1.Picture.Bitmap.Assign(Clipboard);
 end;
end;
```

The same example in CLX for cross-platform development would look as follows:

```
procedure TForm1.PasteButtonClick(Sender: TObject);
var
  Bitmap: TBitmap;
begin
 if Clipboard.Provides(SDelphiBitmap) then { is there a bitmap on the clipboard? )
```

```
    begin
      Image1.Picture.Bitmap.Assign(Clipboard);
    end;
  end;
```

The graphic on the clipboard could come from this application, or it could have been copied from another application, such as Microsoft Paint. You do not need to check the clipboard format in this case because the paste menu should be disabled when the clipboard does not contain a supported format.

Rubber banding example

This example describes the details of implementing the "rubber banding" effect in an graphics application that tracks mouse movements as the user draws a graphic at runtime. The example code in this section is taken from a sample application located in the Demos\DOC\Graphexdirectory. The application draws lines and shapes on a window's canvas in response to clicks and drags: pressing a mouse button starts drawing, and releasing the button ends the drawing.

To start with, the example code shows how to draw on the surface of the main form. Later examples demonstrate drawing on a bitmap.

The following topics describe the example:

- Responding to the mouse
- Adding a field to a form object to track mouse actions
- Refining line drawing

Responding to the mouse

Your application can respond to the mouse actions: mouse-button down, mouse moved, and mouse-button up. It can also respond to a click (a complete press-and-release, all in one place) that can be generated by some kinds of keystrokes (such as pressing *Enter* in a modal dialog box).

This section covers:

- What's in a mouse event
- Responding to a mouse-down action
- Responding to a mouse-up action
- Responding to a mouse move

What's in a mouse event?

The VCL has three mouse events: *OnMouseDown* event, *OnMouseMove* event, and *OnMouseUp* event.

When an application detects a mouse action, it calls whatever event handler you've defined for the corresponding event, passing five parameters. Use the information in those parameters to customize your responses to the events. The five parameters are as follows:

Table 8.4 Mouse-event parameters

Parameter	Meaning
Sender	The object that detected the mouse action
Button	Indicates which mouse button was involved: *mbLeft*, *mbMiddle*, or *mbRight*
Shift	Indicates the state of the *Alt*, *Ctrl*, and *Shift* keys at the time of the mouse action
X, *Y*	The coordinates where the event occurred

Most of the time, you need the coordinates returned in a mouse-event handler, but sometimes you also need to check *Button* to determine which mouse button caused the event.

Note Delphi uses the same criteria as Microsoft Windows in determining which mouse button has been pressed. Thus, if you have switched the default "primary" and "secondary" mouse buttons (so that the right mouse button is now the primary button), clicking the primary (right) button will record *mbLeft* as the value of the *Button* parameter.

Responding to a mouse-down action

Whenever the user presses a button on the mouse, an *OnMouseDown* event goes to the object the pointer is over. The object can then respond to the event.

To respond to a mouse-down action, attach an event handler to the *OnMouseDown* event.

The VCL generates an empty handler for a mouse-down event on the form:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
 Shift: TShiftState; X, Y: Integer);
begin
end;
```

Responding to a mouse-down action

The following code displays the string 'Here!' at the location on a form clicked with the mouse:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
 Shift: TShiftState; X, Y: Integer);
begin
 Canvas.TextOut(X, Y, 'Here!');{ write text at (X, Y) }
end;
```

When the application runs, you can press the mouse button down with the mouse cursor on the form and have the string, "Here!" appear at the point clicked. This code sets the current drawing position to the coordinates where the user presses the button:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
 Shift: TShiftState; X, Y: Integer);
begin
 Canvas.MoveTo(X, Y);{ set pen position }
end;
```

Pressing the mouse button now sets the pen position, setting the line's starting point. To draw a line to the point where the user releases the button, you need to respond to a mouse-up event.

Responding to a mouse-up action

An *OnMouseUp* event occurs whenever the user releases a mouse button. The event usually goes to the object the mouse cursor is over when the user presses the button, which is not necessarily the same object the cursor is over when the button is released. This enables you, for example, to draw a line as if it extended beyond the border of the form.

To respond to mouse-up actions, define a handler for the *OnMouseUp* event.

Here's a simple *OnMouseUp* event handler that draws a line to the point of the mouse-button release:

```
procedure TForm1.FormMouseUp(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  Canvas.LineTo(X, Y);{ draw line from PenPos to (X, Y) }
end;
```

This code lets a user draw lines by clicking, dragging, and releasing. In this case, the user cannot see the line until the mouse button is released.

Responding to a mouse move

An *OnMouseMove* event occurs periodically when the user moves the mouse. The event goes to the object that was under the mouse pointer when the user pressed the button. This allows you to give the user some intermediate feedback by drawing temporary lines while the mouse moves.

To respond to mouse movements, define an event handler for the *OnMouseMove* event. This example uses mouse-move events to draw intermediate shapes on a form while the user holds down the mouse button, thus providing some feedback to the user. The *OnMouseMove* event handler draws a line on a form to the location of the *OnMouseMove* event:

```
procedure TForm1.FormMouseMove(Sender: TObject;Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  Canvas.LineTo(X, Y);{ draw line to current position }
end;
```

With this code, moving the mouse over the form causes drawing to follow the mouse, even before the mouse button is pressed.

Mouse-move events occur even when you haven't pressed the mouse button.

If you want to track whether there is a mouse button pressed, you need to add an object field to the form object.

Adding a field to a form object to track mouse actions

To track whether a mouse button was pressed, you must add an object field to the form object. When you add a component to a form, Delphi adds a field that represents that component to the form object, so that you can refer to the component by the name of its field. You can also add your own fields to forms by editing the type declaration in the form unit's header file.

In the following example, the form needs to track whether the user has pressed a mouse button. To do that, it adds a Boolean field and sets its value when the user presses the mouse button.

To add a field to an object, edit the object's type definition, specifying the field identifier and type after the **public** directive at the bottom of the declaration.

Delphi "owns" any declarations before the **public** directive: that's where it puts the fields that represent controls and the methods that respond to events.

The following code gives a form a field called *Drawing* of type Boolean, in the form object's declaration. It also adds two fields to store points *Origin* and *MovePt* of typeTPoint.

```
type
  TForm1 = class(TForm)
   procedure FormMouseDown(Sender: TObject; Button: TMouseButton;
      Shift: TShiftState; X, Y: Integer);
   procedure FormMouseUp(Sender: TObject; Button: TMouseButton;
      Shift: TShiftState; X, Y: Integer);
   procedure FormMouseMove(Sender: TObject; Button: TMouseButton;
      Shift: TShiftState; X, Y: Integer);
 public
    Drawing: Boolean;{ field to track whether button was pressed }
    Origin, MovePt: TPoint;{ fields to store points }
  end;
```

When you have a *Drawing* field to track whether to draw, set it to *True* when the user presses the mouse button, and *False* when the user releases it:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  Drawing := True;{ set the Drawing flag }
 Canvas.MoveTo(X, Y);
end;
procedure TForm1.FormMouseUp(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  Canvas.LineTo(X, Y);
 Drawing := False;{ clear the Drawing flag }
end;
```

Then you can modify the *OnMouseMove* event handler to draw only when *Drawing* is *True*:

```
procedure TForm1.FormMouseMove(Sender: TObject;Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
```

```
begin
  if Drawing then{ only draw if Drawing flag is set }
   Canvas.LineTo(X, Y);
end;
```

This results in drawing only between the mouse-down and mouse-up events, but you still get a scribbled line that tracks the mouse movements instead of a straight line.

The problem is that each time you move the mouse, the mouse-move event handler calls *LineTo*, which moves the pen position, so by the time you release the button, you've lost the point where the straight line was supposed to start.

Refining line drawing

With fields in place to track various points, you can refine an application's line drawing.

Tracking the origin point

When drawing lines, track the point where the line starts with the *Origin* field.

Origin must be set to the point where the mouse-down event occurs, so the mouse-up event handler can use *Origin* to place the beginning of the line, as in this code:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  Drawing := True;
 Canvas.MoveTo(X, Y);
 Origin := Point(X, Y);{ record where the line starts }
end;
procedure TForm1.FormMouseUp(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  Canvas.MoveTo(Origin.X, Origin.Y);{ move pen to starting point }
 Canvas.LineTo(X, Y);
 Drawing := False;
end;
```

Those changes get the application to draw the final line again, but they do not draw any intermediate actions--the application does not yet support "rubber banding."

Tracking movement

The problem with this example as the *OnMouseMove* event handler is currently written is that it draws the line to the current mouse position from the last *mouse position,* not from the original position. You can correct this by moving the drawing position to the origin point, then drawing to the current point:

```
procedure TForm1.FormMouseMove(Sender: TObject;Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  if Drawing then
  begin
    Canvas.MoveTo(Origin.X, Origin.Y);{ move pen to starting point }
```

```
      Canvas.LineTo(X, Y);
    end;
  end;
```

The above tracks the current mouse position, but the intermediate lines do not go away, so you can hardly see the final line. The example needs to erase each line before drawing the next one, by keeping track of where the previous one was. The *MovePt* field allows you to do this.

MovePt must be set to the endpoint of each intermediate line, so you can use *MovePt* and *Origin* to erase that line the next time a line is drawn:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  Drawing := True;
 Canvas.MoveTo(X, Y);
 Origin := Point(X, Y);
 MovePt := Point(X, Y);{ keep track of where this move was }
end;
procedure TForm1.FormMouseMove(Sender: TObject;Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  if Drawing then
  begin
    Canvas.Pen.Mode := pmNotXor;{ use XOR mode to draw/erase }
   Canvas.MoveTo(Origin.X, Origin.Y);{ move pen back to origin }
   Canvas.LineTo(MovePt.X, MovePt.Y);{ erase the old line }
   Canvas.MoveTo(Origin.X, Origin.Y);{ start at origin again }
   Canvas.LineTo(X, Y);{ draw the new line }
  end;
 MovePt := Point(X, Y);{ record point for next move }
 Canvas.Pen.Mode := pmCopy;
end;
```

Now you get a "rubber band" effect when you draw the line. By changing the pen's mode to *pmNotXor*, you have it combine your line with the background pixels. When you go to erase the line, you're actually setting the pixels back to the way they were. By changing the pen mode back to *pmCopy* (its default value) after drawing the lines, you ensure that the pen is ready to do its final drawing when you release the mouse button.

Working with multimedia

Delphi allows you to add multimedia components to your applications. To do this, you can use either the *TAnimate* component on the Win32 page or the *TMediaPlayer* component on the System page of the Component palette. Use the animate component when you want to add silent video clips to your application. Use the media player component when you want to add audio and/or video clips to an application.

For more information on the *TAnimate* and *TMediaPlayer* components, see the VCL on-line help.

The following topics are discussed in this section:

- Adding silent video clips to an application
- Adding audio and/or video clips to an application

Adding silent video clips to an application

The animation control in Delphi allows you to add silent video clips to your application.

To add a silent video clip to an application:

1. Double-click the animate icon on the Win32 page of the Component palette. This automatically puts an animation control on the form window in which you want to display the video clip.
2. Using the Object Inspector, select the *Name* property and enter a new *nam*e for your animation control. You will use this name when you call the animation control. (Follow the standard rules for naming Delphi identifiers).

   Always work directly with the Object Inspector when setting design time properties and creating event handlers.
3. Do one of the following:
   - Select the *Common AVI* property and choose one of the AVIs available from the drop down list; or
   - Select the *FileName* property and click the ellipsis (…) button, choose an AVI file from any available local or network directories and click Open in the Open AVI dialog; or
   - Select the resource of an AVI using the *ResName* or *ResID* properties. Use *ResHandle* to indicate the module that contains the resource identified by *ResName* or *ResID*.

   This loads the AVI file into memory. If you want to display the first frame of the AVI clip on-screen until it is played using the *Active* property or the *Play* method, then set the *Open* property to *True*.
4. Set the *Repetitions* property to the number of times you want to the AVI clip to play. If this value is 0, then the sequence is repeated until the *Stop* method is called.
5. Make any other changes to the animation control settings. For example, if you want to change the first frame displayed when animation control opens, then set the *StartFrame* property to the desired frame value.
6. Set the *Active* property to *True* using the drop down list or write an event handler to run the AVI clip when a specific event takes place at runtime. For example, to activate the AVI clip when a button object is clicked, write the button's *OnClick* event specifying that. You may also call the *Play* method to specify when to play the AVI.

Note If you make any changes to the form or any of the components on the form after setting *Active* to *True*, the *Active* property becomes *False* and you have to reset it to *True*. Do this either just before runtime or at runtime.

Example of adding silent video clips

Suppose you want to display an animated logo as the first screen that appears when your application starts. After the logo finishes playing the screen disappears.

To run this example, create a new project and save the Unit1.pas file as Frmlogo.pas and save the Project1.dpr file as Logo.dpr. Then:

1. Double-click the animate icon from the Win32 page of the Component palette.
2. Using the Object Inspector, set its Name property to *Logo1*.
3. Select its FileName property, click the ellipsis (…) button, choose the cool.avi file from your ..\Demos\Coolstuf directory. Then click Open in the Open AVI dialog.

   This loads the cool.avi file into memory.
4. Position the animation control box on the form by clicking and dragging it to the top right hand side of the form.
5. Set its Repetitions property to 5.
6. Click the form to bring focus to it and set its Name property to *LogoForm1* and its Caption property to *Logo Window*. Now decrease the height of the form to right-center the animation control on it.
7. Double-click the form's *OnActivate* event and write the following code to run the AVI clip when the form is in focus at runtime:

   ```
   Logo1.Active := True;
   ```
8. Double-click the Label icon on the Standard page of the Component palette. Select its Caption property and enter *Welcome to Cool Images 4.0*. Now select its Font property, click the ellipsis (…) button and choose Font Style: Bold, Size: 18, Color: Navy from the Font dialog and click OK. Click and drag the label control to center it on the form.
9. Click the animation control to bring focus back to it. Double-click its *OnStop* event and write the following code to close the form when the AVI file stops:

   ```
   LogoForm1.Close;
   ```
10. Select Run|Run to execute the animated logo window.

Adding audio and/or video clips to an application

The media player component in Delphi allows you to add audio and/or video clips to your application. It opens a media device and plays, stops, pauses, records, etc., the audio and/or video clips used by the media device. The media device may be hardware or software.

Note Audio and video clip support is not provided for cross-platform programming.

To add an audio and/or video clip to an application:

1 Double-click the media player icon on the System page of the Component palette. This automatically put a media player control on the form window in which you want the media feature.

2 Using the Object Inspector, select the *Name* property and enter a new name for your media player control. You will use this when you call the media player control. (Follow the standard rules for naming Delphi identifiers.)

   Always work directly with the Object Inspector when setting design time properties and creating event handlers.

3 Select the *DeviceType* property and choose the appropriate device type to open using the *AutoOpen* property or the *Open* method. (If *DeviceType* is dtAutoSelect the device type is selected based on the file extension of the media file specified by the *FileName* property.) For more information on device types and their functions, see Table 8.5.

4 If the device stores its media in a file, specify the name of the media file using the *FileName* property. Select the *FileName* property, click the ellipsis (…) button, and choose a media file from any available local or network directories and click Open in the Open dialog. Otherwise, insert the hardware the media is stored in (disk, cassette, and so on) for the selected media device, at runtime.

5 Set the *AutoOpen* property to *True*. This way the media player automatically opens the specified device when the form containing the media player control is created at runtime. If *AutoOpen* is *False*, the device must be opened with a call to the *Open* method.

6 Set the *AutoEnable* property to *True* to automatically enable or disable the media player buttons as required at runtime; or, double-click the *EnabledButtons* property to set each button to *True* or *False* depending on which ones you want to enable or disable.

   The multimedia device is played, paused, stopped, and so on when the user clicks the corresponding button on the media player component. The device can also be controlled by the methods that correspond to the buttons (Play, Pause, Stop, Next, Previous, and so on).

7 Position the media player control bar on the form by either clicking and dragging it to the appropriate place on the form or by selecting the *Align* property and choosing the appropriate align position from the drop down list.

   If you want the media player to be invisible at runtime, set the *Visible* property to *False* and control the device by calling the appropriate methods (*Play*, *Pause*, *Stop*, *Next*, *Previous*, *Step*, *Back*, *Start Recording*, *Eject*).

8 Make any other changes to the media player control settings. For example, if the media requires a display window, set the *Display* property to the control that

displays the media. If the device uses multiple tracks, set the *Tracks* property to the desired track.

Table 8.5 Multimedia device types and their functions

Device Type	Software/Hardware used	Plays	Uses Tracks	Uses a Display Window
dtAVIVideo	AVI Video Player for Windows	AVI Video files	No	Yes
dtCDAudio	CD Audio Player for Windows or a CD Audio Player	CD Audio Disks	Yes	No
dtDAT	Digital Audio Tape Player	Digital Audio Tapes	Yes	No
dtDigitalVideo	Digital Video Player for Windows	AVI, MPG, MOV files	No	Yes
dtMMMovie	MM Movie Player	MM film	No	Yes
dtOverlay	Overlay device	Analog Video	No	Yes
dtScanner	Image Scanner	N/A for Play (scans images on Record)	No	No
dtSequencer	MIDI Sequencer for Windows	MIDI files	Yes	No
dtVCR	Video Cassette Recorder	Video Cassettes	No	Yes
dtWaveAudio	Wave Audio Player for Windows	WAV files	No	No

Example of adding audio and/or video clips (VCL only)

This example runs an AVI video clip of a multimedia advertisement for Delphi. To run this example, create a new project and save the Unit1.pas file to FrmAd.pas and save the Project1.dpr file to DelphiAd.dpr. Then:

1. Double-click the media player icon on the System page of the Component palette.
2. Using the Object Inspector, set the Name property of the media player to *VideoPlayer1*.
3. Select its DeviceType property and choose dtAVIVideo from the drop down list.
4. Select its FileName property, click the ellipsis (…) button, choose the speedis.avi file from your ..\Demos\Coolstuf directory. Click Open in the Open dialog.
5. Set its AutoOpen property to *True* and its Visible property to *False*.
6. Double-click the Animate icon from the Win32 page of the Component palette. Set its AutoSize property to *False*, its Height property to *175* and Width property to *200*. Click and drag the animation control to the top left corner of the form.
7. Click the media player to bring back focus to it. Select its Display property and choose Animate1 from the drop down list.

8 Click the form to bring focus to it and select its Name property and enter *Delphi_Ad*. Now resize the form to the size of the animation control.

9 Double-click the form's *OnActivate* event and write the following code to run the AVI video when the form is in focus:

```
VideoPlayer1.Play;
```

10 Choose Run | Run to execute the AVI video.

Chapter

9

Writing multi-threaded applications

Delphi provides several objects that make writing multi-threaded applications easier. Multi-threaded applications are applications that include several simultaneous paths of execution. While using multiple threads requires careful thought, it can enhance your programs by

- **Avoiding bottlenecks.** With only one thread, a program must stop all execution when waiting for slow processes such as accessing files on disk, communicating with other machines, or displaying multimedia content. The CPU sits idle until the process completes. With multiple threads, your application can continue execution in separate threads while one thread waits for the results of a slow process.
- **Organizing program behavior.** Often, a program's behavior can be organized into several parallel processes that function independently. Use threads to launch a single section of code simultaneously for each of these parallel cases. Use threads to assign priorities to various program tasks so that you can give more CPU time to more critical tasks.
- **Multiprocessing.** If the system running your program has multiple processors, you can improve performance by dividing the work into several threads and letting them run simultaneously on separate processors.

Note Not all operating systems implement true multi-processing, even when it is supported by the underlying hardware. For example, Windows 9x only simulates multiprocessing, even if the underlying hardware supports it.

Defining thread objects

For most applications, you can use a thread object to represent an execution thread in your application. Thread objects simplify writing multi-threaded applications by encapsulating the most commonly needed uses of threads.

Note Thread objects do not allow you to control the security attributes or stack size of your threads. If you need to control these, you must use the *BeginThread* function. Even when using *BeginThread*, you can still benefit from some of the thread synchronization objects and methods described in "Coordinating threads" on page 9-7. For more information on using *BeginThread*, see the online help.

To use a thread object in your application, you must create a new descendant of *TThread*. To create a descendant of *TThread*, choose File | New from the main menu. In the new objects dialog box, select Thread Object. You are prompted to provide a class name for your new thread object. After you provide the name, Delphi creates a new unit file to implement the thread.

Note Unlike most dialog boxes in the IDE that require a class name, the New Thread Object dialog does not automatically prepend a 'T' to the front of the class name you provide.

The automatically generated unit file contains the skeleton code for your new thread object. If you named your thread *TMyThread*, it would look like the following:

```
unit Unit2;
interface
uses
  Classes;
type
  TMyThread = class(TThread)
  private
    { Private declarations }
  protected
    procedure Execute; override;
  end;
implementation
{ TMyThread }
procedure TMyThread.Execute;
begin
  { Place thread code here }
end;
end.
```

You must fill in the code for the *Execute* method. These steps are described in the following sections.

Initializing the thread

If you want to write initialization code for your new thread class, you must override the Create method. Add a new constructor to the declaration of your thread class and write the initialization code as its implementation. This is where you can assign a default priority for your thread and indicate whether it should be freed automatically when it finishes executing.

Assigning a default priority

Priority indicates how much preference the thread gets when the operating system schedules CPU time among all the threads in your application. Use a high priority thread to handle time critical tasks, and a low priority thread to perform other tasks. To indicate the priority of your thread object, set the *Priority* property.

If writing a Windows application, *Priority* values fall along a seven-point scale, as described in Table 9.1:

Table 9.1 Thread priorities

Value	Priority
tpIdle	The thread executes only when the system is idle. Windows won't interrupt other threads to execute a thread with *tpIdle* priority.
tpLowest	The thread's priority is two points below normal.
tpLower	The thread's priority is one point below normal.
tpNormal	The thread has normal priority.
tpHigher	The thread's priority is one point above normal.
tpHighest	The thread's priority is two points above normal.
tpTimeCritical	The thread gets highest priority.

Note If writing a cross-platform application, you must use separate code for assigning priorities on Windows and Linux. On Linux, *Priority* is a numeric value that depends on the threading policy which can only be changed by root. See the CLX version of *TThread* and *Priority* online Help for details.

Warning Boosting the thread priority of a CPU intensive operation may “starve” other threads in the application. Only apply priority boosts to threads that spend most of their time waiting for external events.

The following code shows the constructor of a low-priority thread that performs background tasks which should not interfere with the rest of the application’s performance:

```
constructor TMyThread.Create(CreateSuspended: Boolean);
begin
  inherited Create(CreateSuspended);
  Priority := tpIdle;
end;
```

Indicating when threads are freed

Usually, when threads finish their operation, they can simply be freed. In this case, it is easiest to let the thread object free itself. To do this, set the *FreeOnTerminate* property to *True*.

There are times, however, when the termination of a thread must be coordinated with other threads. For example, you may be waiting for one thread to return a value before performing an action in another thread. To do this, you do not want to free the first thread until the second has received the return value. You can handle this situation by setting *FreeOnTerminate* to *False* and then explicitly freeing the first thread from the second.

Writing the thread function

The *Execute* method is your thread function. You can think of it as a program that is launched by your application, except that it shares the same process space. Writing the thread function is a little trickier than writing a separate program because you must make sure that you don't overwrite memory that is used by other threads in your application. On the other hand, because the thread shares the same process space with other threads, you can use the shared memory to communicate between threads.

Using the main VCL/CLX thread

When you use objects from the VCL or CLX object hierarchies, their properties and methods are not guaranteed to be thread-safe. That is, accessing properties or executing methods may perform some actions that use memory which is not protected from the actions of other threads. Because of this, a main thread is set aside for access of VCL and CLX objects. This is the thread that handles all Windows messages received by components in your application.

If all objects access their properties and execute their methods within this single thread, you need not worry about your objects interfering with each other. To use the main thread, create a separate routine that performs the required actions. Call this separate routine from within your thread's *Synchronize* method. For example:

```
procedure TMyThread.PushTheButton;
begin
  Button1.Click;
end;
⋮
procedure TMyThread.Execute;
begin
  ⋮
  Synchronize(PushTheButton);
  ⋮
end;
```

Synchronize waits for the main thread to enter the message loop and then executes the passed method.

Note Because *Synchronize* uses the message loop, it does not work in console applications. You must use other mechanisms, such as critical sections, to protect access to VCL or CLX objects in console applications.

You do not always need to use the main thread. Some objects are thread-aware. Omitting the use of the *Synchronize* method when you know an object's methods are thread-safe will improve performance because you don't need to wait for the VCL or CLX thread to enter its message loop. You do not need to use the *Synchronize* method in the following situations:

- Data access components are thread-safe as follows: For BDE-enabled datasets, each thread must have its own database session component. The one exception to this is when you are using Access drivers, which are built using a Microsoft library that is not thread-safe. For dbDirect, as long as the vendor client library is thread-safe, the dbDirect components will be thread-safe. ADO and InterbaseExpress components are thread-safe.

When using data access components, you must still wrap all calls that involve data-aware controls in the *Synchronize* method. Thus, for example, you need to synchronize calls that link a data control to a dataset by setting the *DataSet* property of the data source object, but you don't need to synchronize to access the data in a field of the dataset.

For more information about using database sessions with threads in BDE-enabled applications, see "Managing multiple sessions" on page 20-28.

- VisualCLX objects are not thread-safe.
- DataCLX objects are thread-safe.
- Graphics objects are thread-safe. You do not need to use the main VCL or CLX thread to access *TFont*, *TPen*, *TBrush, TBitmap, TMetafile* (VCL only), *TDrawing* (CLX only), or *TIcon*. Canvas objects can be used outside the *Synchronize* method by locking them (see "Locking objects" on page 9-7).
- While list objects are not thread-safe, you can use a thread-safe version, *TThreadList*, instead of *TList*.

Call the *CheckSynchronize* routine periodically within the main thread of your application so that background threads can synchronize their execution with the main thread. The best place to call *CheckSynchronize* is when the application is idle (for example, from an *OnIdle* event handler). This ensures that it is safe to make method calls in the background thread.

Using thread-local variables

Your *Execute* method and any of the routines it calls have their own local variables, just like any other Object Pascal routines. These routines also can access any global variables. In fact, global variables provide a powerful mechanism for communicating between threads.

Sometimes, however, you may want to use variables that are global to all the routines running in your thread, but not shared with other instances of the same thread class. You can do this by declaring thread-local variables. Make a variable thread-local by declaring it in a **threadvar** section. For example,

```
threadvar
   x : integer;
```

declares an integer type variable that is private to each thread in the application, but global within each thread.

The threadvar section can only be used for global variables. Pointer and Function variables can't be thread variables. Types that use copy-on-write semantics, such as long strings don't work as thread variables either.

Checking for termination by other threads

Your thread begins running when the *Execute* method is called (see "Executing thread objects" on page 9-10) and continues until *Execute* finishes. This reflects the model that the thread performs a specific task, and then stops when it is finished. Sometimes, however, an application needs a thread to execute until some external criterion is satisfied.

You can allow other threads to signal that it is time for your thread to finish executing by checking the *Terminated* property. When another thread tries to terminate your thread, it calls the *Terminate* method. *Terminate* sets your thread's *Terminated* property to *True*. It is up to your *Execute* method to implement the *Terminate* method by checking and responding to the *Terminated* property. The following example shows one way to do this:

```
procedure TMyThread.Execute;
begin
  while not Terminated do
    PerformSomeTask;
end;
```

Handling exceptions in the thread function

The *Execute* method must catch all exceptions that occur in the thread. If you fail to catch an exception in your thread function, your application can cause access violations. This may not be obvious when you are developing your application, because the IDE catches the exception, but when you run your application outside of the debugger, the exception will cause a runtime error and the application will stop running.

To catch the exceptions that occur inside your thread function, add a **try**...**except** block to the implementation of the *Execute* method:

```
procedure TMyThread.Execute;
begin
  try
    while not Terminated do
      PerformSomeTask;
  except
    { do something with exceptions }
  end;
end;
```

Writing clean-up code

You can centralize the code that cleans up when your thread finishes executing. Just before a thread shuts down, an *OnTerminate* event occurs. Put any clean-up code in the *OnTerminate* event handler to ensure that it is always executed, no matter what execution path the *Execute* method follows.

The *OnTerminate* event handler is not run as part of your thread. Instead, it is run in the context of the main VCL or CLX thread of your application. This has two implications:

- You can't use any thread-local variables in an *OnTerminate* event handler (unless you want the main VCL or CLX thread values).

- You can safely access any components and VCL or CLX objects from the *OnTerminate* event handler without worrying about clashing with other threads.

For more information about the main VCL or CLX thread, see "Using the main VCL/ CLX thread" on page 9-4.

Coordinating threads

When writing the code that runs when your thread is executed, you must consider the behavior of other threads that may be executing simultaneously. In particular, care must be taken to avoid two threads trying to use the same global object or variable at the same time. In addition, the code in one thread can depend on the results of tasks performed by other threads.

Avoiding simultaneous access

To avoid clashing with other threads when accessing global objects or variables, you may need to block the execution of other threads until your thread code has finished an operation. Be careful not to block other execution threads unnecessarily. Doing so can cause performance to degrade seriously and negate most of the advantages of using multiple threads.

Locking objects

Some objects have built-in locking that prevents the execution of other threads from using that object instance.

For example, canvas objects (*TCanvas* and descendants) have a *Lock* method that prevents other threads from accessing the canvas until the *Unlock* method is called.

The VCL and CLX also both include a thread-safe list object, *TThreadList*. Calling *TThreadList.LockList* returns the list object while also blocking other execution threads from using the list until the *UnlockList* method is called. Calls to *TCanvas.Lock* or *TThreadList.LockList* can be safely nested. The lock is not released until the last locking call is matched with a corresponding unlock call in the same thread.

Using critical sections

If objects do not provide built-in locking, you can use a critical section. Critical sections work like gates that allow only a single thread to enter at a time. To use a critical section, create a global instance of *TCriticalSection. TCriticalSection* has two methods, *Acquire* (which blocks other threads from executing the section) and *Release* (which removes the block).

Each critical section is associated with the global memory you want to protect. Every thread that accesses that global memory should first use the *Acquire* method to ensure that no other thread is using it. When finished, threads call the *Release* method so that other threads can access the global memory by calling *Acquire*.

Warning Critical sections only work if every thread uses them to access the associated global memory. Threads that ignore the critical section and access the global memory without calling *Acquire* can introduce problems of simultaneous access.

For example, consider an application that has a global critical section variable, *LockXY*, that blocks access to global variables X and Y. Any thread that uses X or Y must surround that use with calls to the critical section such as the following:

```
LockXY.Acquire; { lock out other threads }
try
  Y := sin(X);
finally
  LockXY.Release;
end;
```

Using the multi-read exclusive-write synchronizer

When you use critical sections to protect global memory, only one thread can use the memory at a time. This can be more protection than you need, especially if you have an object or variable that must be read often but to which you very seldom write. There is no danger in multiple threads reading the same memory simultaneously, as long as no thread is writing to it.

When you have some global memory that is read often, but to which threads occasionally write, you can protect it using *TMultiReadExclusiveWriteSynchronizer*. This object acts like a critical section, but allows multiple threads to read the memory it protects as long as no thread is writing to it. Threads must have exclusive access to write to memory protected by *TMultiReadExclusiveWriteSynchronizer*.

To use a multi-read exclusive-write synchronizer, create a global instance of *TMultiReadExclusiveWriteSynchronizer* that is associated with the global memory you want to protect. Every thread that reads from this memory must first call the *BeginRead* method. *BeginRead* ensures that no other thread is currently writing to the memory. When a thread finishes reading the protected memory, it calls the *EndRead* method. Any thread that writes to the protected memory must call *BeginWrite* first. *BeginWrite* ensures that no other thread is currently reading or writing to the memory. When a thread finishes writing to the protected memory, it calls the *EndWrite* method, so that threads waiting to read the memory can begin.

Warning Like critical sections, the multi-read exclusive-write synchronizer only works if every thread uses it to access the associated global memory. Threads that ignore the synchronizer and access the global memory without calling *BeginRead* or *BeginWrite* introduce problems of simultaneous access.

Other techniques for sharing memory

When using objects in the VCL or CLX, use the main thread to execute your code. Using the main thread ensures that the object does not indirectly access any memory that is also used by VCL or CLX objects in other threads. See “Using the main VCL/CLX thread” on page 9-4 for more information on the main thread.

If the global memory does not need to be shared by multiple threads, consider using thread-local variables instead of global variables. By using thread-local variables, your thread does not need to wait for or lock out any other threads. See “Using thread-local variables” on page 9-5 for more information about thread-local variables.

Waiting for other threads

If your thread must wait for another thread to finish some task, you can tell your thread to temporarily suspend execution. You can either wait for another thread to completely finish executing, or you can wait for another thread to signal that it has completed a task.

Waiting for a thread to finish executing

To wait for another thread to finish executing, use the *WaitFor* method of that other thread. *WaitFor* doesn't return until the other thread terminates, either by finishing its own *Execute* method or by terminating due to an exception. For example, the following code waits until another thread fills a thread list object before accessing the objects in the list:

```
if ListFillingThread.WaitFor then
begin
  with ThreadList1.LockList do
  begin
    for I := 0 to Count - 1 do
      ProcessItem(Items[I]);
  end;
  ThreadList1.UnlockList;
end;
```

In the previous example, the list items were only accessed when the *WaitFor* method indicated that the list was successfully filled. This return value must be assigned by the *Execute* method of the thread that was waited for. However, because threads that call *WaitFor* want to know the result of thread execution, not code that calls *Execute*, the *Execute* method does not return any value. Instead, the *Execute* method sets the *ReturnValue* property. *ReturnValue* is then returned by the *WaitFor* method when it is called by other threads. Return values are integers. Your application determines their meaning.

Waiting for a task to be completed

Sometimes, you need to wait for a thread to finish some operation rather than waiting for a particular thread to complete execution. To do this, use an event object. Event objects (*TEvent*) should be created with global scope so that they can act like signals that are visible to all threads.

When a thread completes an operation that other threads depend on, it calls *TEvent.SetEvent*. *SetEvent* turns on the signal, so any other thread that checks will know that the operation has completed. To turn off the signal, use the *ResetEvent* method.

For example, consider a situation where you must wait for several threads to complete their execution rather than a single thread. Because you don't know which thread will finish last, you can't simply use the *WaitFor* method of one of the threads. Instead, you can have each thread increment a counter when it is finished, and have the last thread signal that they are all done by setting an event.

The following code shows the end of the *OnTerminate* event handler for all of the threads that must complete. *CounterGuard* is a global critical section object that prevents multiple threads from using the counter at the same time. *Counter* is a global variable that counts the number of threads that have completed.

```
procedure TDataModule.TaskThreadTerminate(Sender: TObject);
begin
  ⋮
  CounterGuard.Acquire; { obtain a lock on the counter }
  Dec(Counter);   { decrement the global counter variable }
  if Counter = 0 then
    Event1.SetEvent; { signal if this is the last thread }
  CounterGuard.Release; { release the lock on the counter }
  ⋮
end;
```

The main thread initializes the Counter variable, launches the task threads, and waits for the signal that they are all done by calling the *WaitFor* method. *WaitFor* waits for a specified time period for the signal to be set, and returns one of the values from Table 9.2.

Table 9.2 WaitFor return values

Value	Meaning
wrSignaled	The signal of the event was set.
wrTimeout	The specified time elapsed without the signal being set.
wrAbandoned	The event object was destroyed before the timeout period elapsed.
wrError	An error occurred while waiting.

The following shows how the main thread launches the task threads and then resumes when they have all completed:

```
Event1.ResetEvent; { clear the event before launching the threads }
for i := 1 to Counter do
  TaskThread.Create(False); { create and launch task threads }
if Event1.WaitFor(20000) <> wrSignaled then
  raise Exception;
{ now continue with the main thread. All task threads have finished }
```

Note If you do not want to stop waiting for an event after a specified time period, pass the *WaitFor* method a parameter value of INFINITE. Be careful when using INFINITE, because your thread will hang if the anticipated signal is never received.

Executing thread objects

Once you have implemented a thread class by giving it an *Execute* method, you can use it in your application to launch the code in the *Execute* method. To use a thread, first create an instance of the thread class. You can create a thread instance that starts running immediately, or you can create your thread in a suspended state so that it only begins when you call the *Resume* method. To create a thread so that it starts up immediately, set the constructor's *CreateSuspended* parameter to *False***.** For example, the following line creates a thread and starts its execution:

```
SecondProcess := TMyThread.Create(false); {create and run the thread }
```

Warning Do not create too many threads in your application. The overhead in managing multiple threads can impact performance. The recommended limit is 16 threads per process on single processor systems. This limit assumes that most of those threads are waiting for external events. If all threads are active, you will want to use fewer.

You can create multiple instances of the same thread type to execute parallel code. For example, you can launch a new instance of a thread in response to some user action, allowing each thread to perform the expected response.

Overriding the default priority

When the amount of CPU time the thread should receive is implicit in the thread's task, its priority is set in the constructor. This is described in "Initializing the thread" on page 9-2. However, if the thread priority varies depending on when the thread is executed, create the thread in a suspended state, set the priority, and then start the thread running:

```
SecondProcess :=  TMyThread.Create(True); { create but don't run }
SecondProcess.Priority := tpLower; { set the priority lower than normal }
SecondProcess.Resume; { now run the thread }
```

Note If writing a cross-platform application, you must use separate code for assigning priorities on Windows and Linux. On Linux, *Priority* is a numeric value that depends on the threading policy which can only be changed by root. See the CLX version of *TThread* and *Priority* online Help for details.

Starting and stopping threads

A thread can be started and stopped any number of times before it finishes executing. To stop a thread temporarily, call its *Suspend* method. When it is safe for the thread to resume, call its *Resume* method. *Suspend* increases an internal counter, so you can nest calls to *Suspend* and *Resume*. The thread does not resume execution until all suspensions have been matched by a call to *Resume*.

You can request that a thread end execution prematurely by calling the *Terminate* method. *Terminate* sets the thread's *Terminated* property to *True*. If you have implemented the *Execute* method properly, it checks the *Terminated* property periodically, and stops execution when *Terminated* is *True*.

Debugging multi-threaded applications

When debugging multi-threaded applications, it can be confusing trying to keep track of the status of all the threads that are executing simultaneously, or even to determine which thread is executing when you stop at a breakpoint. You can use the Thread Status box to help you keep track of and manipulate all the threads in your application. To display the Thread status box, choose View | Threads from the main menu.

When a debug event occurs (breakpoint, exception, paused), the thread status view indicates the status of each thread. Right-click the Thread Status box to access commands that locate the corresponding source location or make a different thread current. When a thread is marked as current, the next step or run operation is relative to that thread.

The Thread Status box lists all your application's execution threads by their thread ID. If you are using thread objects, the thread ID is the value of the *ThreadID* property. If you are not using thread objects, the thread ID for each thread is returned by the call to *BeginThread*.

For additional details on the Thread Status box, see online Help.

Chapter

10

Using CLX for cross-platform development

You can use Delphi to develop cross-platform 32-bit applications that run on both the Windows and Linux operating systems. To do this, you can start with an existing Windows application and modify it, or you can create a new application by following the recommended practices for writing platform-independent code. Kylix is Borland's Delphi for Linux software that allows you to compile and develop applications on Linux. If you want to develop and deploy applications on Linux and Windows, you'll need to use Kylix as well as Delphi.

This chapter describes how to change Delphi applications so they will compile on Linux and includes information on the differences between developing applications on Windows and Linux. It also provides guidelines for writing code that is portable between the different environments.

Note Most applications developed using CLX (with no operating system specific API calls) will run on both Linux and Windows platforms. The application must be compiled on the platform on which you want it to run.

Creating cross-platform applications

You create cross-platform applications much as you create any Delphi application. You need to use CLX visual components, and you should not use operating system specific APIs if you want the application to be completely cross-platform. (See "Writing portable code" on page 10-17 for tips on writing cross-platform applications.)

To create a cross-platform application:

1 In the IDE, choose File | New | CLX application.
The Component palette shows components that can be used in CLX applications.

Note Some Windows only nonvisual components can be used in CLX applications. The Component palette includes ADO, BDE, System, DataSnap, InterBase, Site Express, FastNet, QReport, COM+, BizSnap, and Servers tabs which include functionality that will only work in Windows CLX applications. If you plan to compile your application on Linux as well, do not use the components on these tabs or use **$IFDEF**s to mark these sections of the code as Windows only.

2. Develop your application within the IDE. Remember to use only CLX components in your application.
3. Compile and test the application on each platform on which you want to run the application. Review any error messages to see where additional changes need to be made.

When moving an application to Kylix, you need to reset your project options. That's because the .dof file which stores the project options is recreated on Kylix and called .kof (with the default options set). You can also store many of the compiler options with the application by typing Ctrl+O+O. The options are placed at the beginning of the currently open file.

The form file in cross-platform applications will have an extension of xfm instead of dfm. This is to distinguish cross-platform forms that use CLX components from forms that use VCL components. An xfm form file will work on both Windows or Linux but a dfm form only works on Windows.

You could also begin development of a cross-platform application by starting on Kylix instead of Delphi:

1. Develop, compile and test the application on Linux using Kylix.
2. Move the application source files over to Windows.
3. Reset your project options.
4. Recompile the application on Windows using Delphi.

For information on writing platform-independent database or internet applications, see "Cross-platform database applications" on page 10-23 and "Cross-platform Internet applications" on page 10-29.

Porting VCL applications to CLX

If you have Delphi applications that were written for the Windows environment, you can make them cross platform. How easy it will be depends on the nature and complexity of the application and how many Windows dependencies there are.

The following sections describe some of the major differences between the Windows and Linux environments and provide guidelines on how to get started porting an application.

Porting techniques

The following are different approaches you can take to port an application from one platform to another:

Table 10.1 Porting techniques

Technique	Description
Platform-specific port	Targets an operating system and underlying APIs
Cross-platform port	Targets a cross-platform API
Windows emulation	Leave the code alone and port the API it uses

Platform-specific ports

Platform-specific ports tend to be time-consuming, expensive, and only produce a single targeted result. They create different code bases, which makes them particularly difficult to maintain. However, each port is designed for the specific operating system and can take advantage of platform-specific functionality. So, the application typically runs faster.

Cross-platform ports

Cross-platform ports generally provide the quickest technique and the ported applications target multiple platforms. In reality, the amount of work involved in developing cross-platform applications is highly dependent on the existing code. If code has been developed without regard for platform independence, you may run into scenarios where platform-independent “logic” and platform-dependent “implementation” are mixed together.

The cross-platform approach is the preferable approach because business logic is expressed in platform-independent terms. Some services are abstracted behind an internal interface that looks the same on all platforms, but has a specific implementation on each. Delphi’s runtime library is an example of this: The interface is very similar on both platforms, although the implementation may be vastly different. You should separate cross-platform parts, then implement specific services on top. In the end, this approach is the least expensive solution, because of reduced maintenance costs due to a largely shared source base and an improved application architecture.

Windows emulation ports

Windows emulation is the most complex method and it can be very costly, but the resulting Linux application will look most similar to an existing Windows application. This approach involves implementing Windows functionality on Linux. From an engineering point of view, this is solution is very hard to maintain.

Where you want to emulate Windows APIs, you can include two distinct sections using **$IFDEF**s to indicate sections of the code that apply specifically to Windows or Linux.

Porting your application

If you are porting an application that you want to run on both Windows and Linux, you need to modify your code or use **$IFDEF**s to indicate sections of the code that apply specifically to Windows or Linux.

Follow these general steps to port your VCL application to CLX:

1. Open the project containing the application you want to change in Delphi.
2. Copy .dfm files to .xfm files of the same name (for example, rename unit1.dfm to unit1.xfm). Rename (or **$IFDEF**) the reference to the .dfm file in the unit file(s) from `{$R *.dfm}` to `{$R *.xfm}`. (The .xfm file will work in both Kylix and Delphi.)

   For example, change the form reference in the **implementation** section from

   ```
   {$R *.dfm}
   ```

   to

   ```
   {$R *.xfm}
   ```

3. Change (or **$IFDEF**) all **uses** clauses so they refer to the correct units in CLX. (See "CLX and VCL unit comparison" on page 10-9 for information.)

   For example, change the following **uses** clause in a Windows application

   ```
   uses Windows, Messages, SysUtils, Variants, Classes, Graphics, Controls, Forms, Dialogs,
   StdCtrls;
   ```

   to the following for a CLX application:

   ```
   uses Windows, Messages, SysUtils, Variants, Classes, QForms, QControls, QStdCtrls;
   ```

4. Save the project and reopen it. Now the Component palette shows components that can be used in CLX applications.

Note Some Windows only nonvisual components can be used in CLX applications. The Component palette includes ADO, BDE, System, DataSnap, InterBase, Internet Express, Site Express, FastNet, QReport, COM+, Web Services, and Servers tabs which include functionality that will only work in Windows CLX applications. If you plan to compile your application on Linux as well, do not use the components on these tabs or use **$IFDEF**s to mark these sections of the code as Windows only.

5. Rewrite any code that does not require Windows dependencies making the code more platform-independent. Do this using the runtime library routines and constants. (See "Writing portable code" on page 10-17 for information.)
6. Find equivalent functionality for features that are different on Linux. Use **$IFDEF**s (sparingly) to delimit Windows-specific information. (See "Using conditional directives" on page 10-18 for information.)

   For example, you can **$IFDEF** platform-specific code in your source files:

   ```
   [$IFDEF MSWINDOWS]
   IniFile.LoadfromFile('c:\x.txt');
   [$ENDIF]

   [$IFDEF LINUX]
   IniFile.LoadfromFile('/home/name/x.txt');
   [$ENDIF]
   ```

7 Search for references to pathnames in all the project files.

- Pathnames in Linux use a forward slash / as a delimiter (for example, /usr/lib) and files may be located in different directories on the Linux system. Use the PathDelim constant (in SysUtils) to specify the path delimiter that is appropriate for the system. Determine the correct location for any files on Linux.
- Change references to drive letters (for example, C:\) and code that looks for drive letters by looking for a colon at position 2 in the string. Use the DriveDelim constant (in SysUtils) to specify the location in terms that are appropriate for the system.
- In places where you specify multiple paths, change the path separator from semicolon (;) to colon (:). Use the PathSep constant (in SysUtils) to specify the path separator that is appropriate for the system.
- Because file names are case-sensitive in Linux, make sure that your application doesn’t change the case of file names or assume a certain case.

8 Compile, text and debug your application.

To transfer the application to Linux:

1 Move your Delphi Windows application source files and other project-related files onto your Linux computer. (You can share source files between Linux and Windows if you want the program to run on both platforms. Or you can transfer the files using a tool such as ftp using the ASCII mode.)

   Source files should include your unit files (.pas files), project file (.dpr file), and any package files (.dpk files). Project-related files include form files (.xfm files), resource files (.res files), and project options files (.dof files–in Kylix these change to .kof files). If you want to compile your application from the command line only (rather than using the IDE), you’ll need the configuration file (.cfg file–in Kylix this changes to .conf).

2 Open the project in Kylix. You will receive warnings on Windows-specific features that are in use.

3 Compile the project using Kylix. Review any error messages to see where additional changes need to be made.

CLX versus VCL

Kylix uses the Borland Component Library for Cross Platform (CLX) in place of the Visual Component Library (VCL). Within the VCL, many controls provide an easy way to access Windows controls. Similarly, CLX provides access to Qt widgets (from window + gadget) in the Qt shared libraries. Delphi includes both CLX and the VCL.

CLX looks much like the VCL. Most of the component names are the same, many properties have the same names. In addition, CLX, as well as the VCL, will be available on Windows (check the latest release of Delphi to determine availability).

CLX components can be grouped into the following parts:

Table 10.2 CLX parts

Part	Description
VisualCLX	Native cross-platform GUI components and graphics. The components in this area may differ on Linux and Windows.
DataCLX	Client data-access components. The components in this area are a subset of the local, client/server, and n-tier based on client datasets. The code is the same on Linux and Windows.
NetCLX	Internet components including Apache DSO and CGI Web Broker. These are the same on Linux and Windows.
RTL	Runtime Library up to and including Classes.pas. The code is the same on Linux and Windows.

Widgets in VisualCLX replace Windows controls. In CLX, *TWidgetControl* replaces the VCL's *TWinControl*. Other components (such as *TScrollingWidget*) have corresponding names. However, you do not need to change occurrences of *TWinControl* to *TWidgetControl*. Type declarations, such as the following

```
TWinControl = TWidgetControl;
```

appear in the QControls.pas source file to simplify sharing of source code. *TWidgetControl* and its descendants all have a *Handle* property that is a reference to the Qt object; and a *Hooks* property, which is a reference to the hook objects that handle the event mechanism.

Unit names and locations of some classes are different for CLX. You will need to modify **uses** clauses to eliminate references to units that don't exist in CLX and to change the names to CLX units. (Most project files and the interface sections of most units contain a **uses** clause. The implementation section of a unit can also contain its own **uses** clause.)

What CLX does differently

Although much of CLX is implemented so that it is consistent with the VCL, some features are implemented differently. This section provides an overview of some of the differences between CLX and VCL implementations to be aware of when writing cross-platform applications.

Look and feel

The visual environment in Linux looks somewhat different than it does in Windows. The look of dialogs may differ depending on which window manager is in use (for example, if using KDE or Gnome).

Styles

Application-wide "styles" can be used in addition to the *OwnerDraw* properties. You can use the *TApplication.Style* property to specify the look and feel of an application's graphical elements. Using styles, a widget or an application can take on a whole new look. You can still use owner draw on Linux but using styles is recommended.

Variants

All of the variant/safe array code that was in System is in two new units:

- Variants.pas
- VarUtils.pas

The operating system dependent code is now isolated in VarUtils.pas, and it also contains generic versions of everything needed by Variants.pas. If you are converting a VCL application that included Windows calls to a CLX application, you need to replace these calls to calls into VarUtils.pas.

If you want to use variants, you must include the Variants unit to your **uses** clause.

VarIsEmpty does a simple test against *varEmpty* to see if a variant is clear, and on Linux you need to use the *VarIsClear* function to clear a variant.

Custom variant data handler

You can define custom data types for variants. This introduces operator overloading while the type is assigned to the variant. To create a new variant type, descend from the class, *TCustomVariantType*, and instantiate your new variant type.

For an example, see VarCmplx.pas. This unit implements complex mathematics support via custom variants. It supports the following variant operations: addition, subtraction, multiplication, division (not integer division), and negation. It also handles conversion to and from: SmallInt, Integer, Single, Double, Currency, Date, Boolean, Byte, OleStr, and String. Any of the float/ordinal conversion will lose any imaginary portion of the complex value.

Registry

Linux does not use a registry to store configuration information. Instead, you use text configuration files and environment variables instead of using the registry. System configuration files on Linux are often located in /etc, for example, /etc/hosts. Other user profiles are located in hidden files (preceded with a dot), such as .bashrc, which holds bash shell settings or .XDefaults, which is used to set defaults for X programs.

Registry-dependent code may be changed to using a local configuration text file instead stored, for example, in the same directory as the application. Writing a unit containing all the registry functions but diverting all output to a local configuration file is one way you could handle a former dependency on the registry.

To place information in a global location on Linux, you could store a global configuration file in the root directory. This makes it so all of your applications can access the same configuration file. However, you must be sure that the file permissions and access rights are set up correctly.

You can also use ini files in cross-platform applications. However, in CLX, you need to use *TMemIniFile* instead of *TRegIniFile.*

Other differences

CLX implementation also has some other differences that affect the way your application works. This section describes some of those differences.

ToggleButton doesn't get toggled by the Enter key. Pressing Enter doesn't simulate a click event on Kylix as it does in Delphi.

TColorDialog does not have a *TColorDialog.Options* property to set. Therefore, you cannot customize the appearance and functionality of the color selection dialog. Also, *TColorDialog* is not always modal. You can manipulate the title bar of an application with a modal dialog on Kylix (that is, you can select the parent form of the color dialog and do things like maximizing it while the color dialog is open).

At runtime, combo boxes work differently on Kylix than they do in Delphi. On Kylix (but not on Delphi), you can add a item to a drop down by entering text and pressing Enter in the edit field of a combo box. You can turn this feature off by setting *InsertMode* to ciNone. It is also possible to add empty (no string) items to the list in the combo box. Also, if you keep pressing the down arrow key, it does not stop at the last item of the combo box list. It cycles around to the top again.

TCustomEdit does not implement *Undo*, *ClearUndo*, or *CanUndo.* So there is no way to programmatically undo edits. But application users can undo their edits in an edit box (*TEdit*) at runtime by right-clicking on the edit box and choosing the Undo command.

The key value in a *OnKeyDown* event or *KeyUp* event for the Enter key on Windows is 13. On Linux, this value is 4100. If you check for a hardcoded numeric value for a key, such as checking for a value of 13 for the Enter key, you need to change this when porting a Delphi application to Kylix.

Additional differences exist. Refer to the CLX online documentation for details on all of the CLX objects or in versions of Delphi that include the source code you can refer to the code, it is located in ..\Delphi6\Source\VCL\CLX.

Missing in CLX

When using CLX instead of the VCL, many of the objects are the same. However, the objects may be missing some features (such as properties, methods, or events). The following general features are missing in CLX:

- Bi-directional properties (*BidiMode*) for right-to-left text output or input
- Generic bevel properties on common controls (note that some objects still have bevel properties)
- Docking properties and methods
- Backward compatibility features such components on the Win3.1 tab and *Ctl3D*
- *DragCursor* and *DragKind* (but drag and drop is included)

Features that will not port

Some Windows-specific features supported on Delphi will not transport directly to Linux environments. Features, such as COM, ActiveX, OLE, BDE, and ADO are dependent on Windows technology and are not available in Kylix. The following table lists features that are different on the two platforms and lists the equivalent Kylix feature, if one is available.

Table 10.3 Changed or different features

Delphi/Windows feature	Kylix/Linux feature
ADO components	Regular database components
Automation Servers	Not available
BDE	dbExpress and regular database components
COM+ components (including ActiveX)	Not available
DataSnap	Not yet available
FastNet	Not available
Internet Express	Not yet available
Legacy components (such as items on the Win 3.1 Component palette tab)	Not available
Messaging Application Programming Interface (MAPI) includes a standard library of Windows messaging functions.	SMTP/POP3 let you send, receive, and save email messages
Quick Reports	Not available
Web Services (SOAP)	Not yet available
WebSnap	Not yet available
Windows API calls	CLX methods, Qt calls, libc calls, or calls to other system libraries
Windows messaging	Qt events
Winsock	BSD sockets

The Linux equivalent of Windows DLLs are shared object libraries (.so files), which contain position-independent code (PIC). This has the following consequences:

- Variables referring to an absolute address in memory (using the **absolute** directive) are not allowed.
- Global memory references and calls to external functions are made relative to the EBX register, which must be preserved across calls.

You only need to worry about global memory references and calls to external functions if using assembler—Kylix or Delphi generates the correct code. (For information, see “Including inline assembler code” on page 10-20.)

Kylix library modules and packages are implemented using .so files.

CLX and VCL unit comparison

All of the objects in the VCL or CLX are defined in unit files (.pas source files). For example, you can find the implementation of *TObject* in the System unit, and the Classes unit defines the base *TComponent* class. When you drop an object onto a form or use an object within your application, the name of the unit is added to the **uses** clause which tells the compiler which units to link into the project.

This section provides tables that list the CLX units and the comparable VCL unit, list the units that are for CLX only, and list the units that are for VCL only.

The following table lists VCL units and the comparable CLX units:

Table 10.4 VCL and equivalent CLX units

VCL units	CLX units
ActnList	QActnList
Buttons	QButtons
CheckLst	QCheckLst
Classes	Classes
Clipbrd	QClipbrd
ComCtrls	QComCtrls
Consts	Consts, QConsts, and RTLConsts
Contnrs	Contnrs
Controls	QControls
DateUtils	DateUtils
DB	DB
DBActns	QDBActns
DBClient	DBClient
DBCommon	DBCommon
DBConnAdmin	DBConnAdmin
DBConsts	DBConsts
DBCtrls	QDBCtrls
DBGrids	QDBGrids
DBLocal	DBLocal
DBLocalS	DBLocalS
DBLogDlg	DBLogDlg
DBXpress	DBXpress
Dialogs	QDialogs
DSIntf	DSIntf
ExtCtrls	QExtCtrls
FMTBCD	FMTBCD
Forms	QForms
Graphics	QGraphics
Grids	QGrids
HelpIntfs	HelpIntfs
ImgList	QImgList
IniFiles	IniFiles
Mask	QMask
MaskUtils	MaskUtils

Table 10.4 VCL and equivalent CLX units (continued)

VCL units	CLX units
Masks	Masks
Math	Math
Menus	QMenus
Midas	Midas
MidConst	MidConst
Printers	QPrinters
Provider	Provider
Qt	Qt
Search	QSearch
Sockets	Sockets
StdActns	QStdActns
StdCtrls	QStdCtrls
SqlConst	SqlConst
SqlExpr	SqlExpr
SqlTimSt	SqlTimSt
SyncObjs	SyncObjs
SysConst	SysConst
SysInit	SysInit
System	System
SysUtils	SysUtils
Types	Types and QTypes
TypInfo	TypInfo
Variants	Variants
VarUtils	VarUtils

The following units are in CLX but not VCL:

Table 10.5 Units in CLX, not VCL

Unit	Description
DirSel	Directory selection
QStyle	GUI look and feel

The following Windows VCL units are not included in CLX mostly because they concern Windows-specific features that are not available on Linux such as ADO, COM, and the BDE. The reason for the unit's exclusion is listed.

Table 10.6 VCL-only units

Unit	Reason for exclusion
ADOConst	No ADO feature
ADODB	No ADO feature
AppEvnts	No TApplicationEvent object

Table 10.6 VCL-only units (continued)

Unit	Reason for exclusion
AxCtrls	No COM feature
BdeConst	No BDE feature
ComStrs	No COM feature
ConvUtils	New feature for Delphi 6
CorbaCon	No Corba feature
CorbaStd	No Corba feature
CorbaVCL	No Corba feature
CtlPanel	No Windows Control Panel support
DataBkr	May appear later in upsell
DBCGrids	No BDE feature
DBExcept	No BDE feature
DBInpReq	No BDE feature
DBLookup	Obsolete
DbOleCtl	No COM feature
DBPWDlg	No BDE feature
DBTables	No BDE feature
DdeMan	No DDE feature
DRTable	No BDE feature
ExtActns	New feature to Delphi 6
ExtDlgs	No picture dialogs
FileCtrl	Obsolete
ListActns	New feature to Delphi 6
MConnect	No COM feature
Messages	Windows-specific area
MidasCon	Obsolete
MPlayer	Windows-specific media player
Mtsobj	No COM feature
MtsRdm	No COM feature
Mtx	No COM feature
mxConsts	No COM feature
ObjBrkr	May appear later in upsell
OleConstMay	No COM feature
OleCtnrs	No COM feature
OleCtrls	No COM feature
OLEDB	No COM feature
OleServer	No COM feature
Outline	Obsolete
Registry	Windows-specific registry support
ScktCnst	Replaced by Sockets
ScktComp	Replaced by Sockets

Table 10.6 VCL-only units (continued)

Unit	Reason for exclusion
SConnect	Unsupported connection protocols
StdConvs	New feature to Delphi 6
SvcMgr	NT Services support
Tabnotbk	Obsolete
Tabs	Obsolete
ToolWin	No docking feature
VarCmplx	New feature to Delphi 6
VarConv	New feature to Delphi 6
VCLCom	No COM feature
WebConst	Windows-specific constants
Windows	Windows-specific (API)

Differences in CLX object constructors

When a CLX object is created, either implicitly in the Forms Designer by placing that object on the form or explicitly in code by using the *Create* method of the object, an instance of the underlying associated widget is created also. The instance of the widget is owned by this CLX object. When the CLX object is deleted by calling the *Free* method or automatically deleted by the CLX object's parent container, the underlying widget is also deleted. This is the same type of functionality that you see in the VCL in Windows applications.

When you explicitly create a CLX object in code, by calling into the Qt interface library such as QWidget_Create(), you are creating an instance of a Qt widget that is not owned by a CLX object. This passes the instance of an existing Qt widget to the CLX object to use during its construction. This CLX object does not own the Qt widget that is passed to it. Therefore, when you call the *Free* method after creating the object in this manner, only the CLX object is destroyed and not the underlying Qt widget instance. This is different from the VCL.

Some CLX objects let you assume ownership of the underlying widget using the *OwnHandle* method. After calling *OwnHandle*, if you delete the CLX object, the underlying widget is destroyed as well.

Sharing source files between Windows and Linux

If you want your application to run on both Windows and Linux, you can share the source files making them accessible to both operating systems. You can do this many ways such as placing the source files on a server that is accessible to both computers or by using Samba on the Linux machine to provide access to files through Microsoft network file sharing for both Linux and Windows. You can choose to keep the source on Linux and create a shared drive on Linux. Or you can keep the source on Windows and create a share on Windows for the Linux machine to access.

You can continue to develop and compile the file on Kylix using objects that are supported by both VCL and CLX. When you are finished, you can compile on both Linux and Windows.

Form files (.dfm files in Delphi) are called .xfm files in Kylix. If you create a new CLX application in Delphi or Kylix, an .xfm is created instead of a .dfm. If you plan to write cross-platform applications, the .xfm will work both on Delphi and Kylix.

Environmental differences between Windows and Linux

Currently, cross-platform means an application that can run virtually unchanged on both the Windows and Linux operating systems. The following table lists some of the differences between Linux and the Windows operating environments.

Table 10.7 Differences in the Linux and Windows operating environments

Difference	Description
File name case sensitivity	In Linux, a capital letter is *not* the same as a lowercase letter. The file Test.txt is *not* the same file as test.txt. You need to pay close attention to capitalization of file names on Linux.
Line ending characters	On Windows, lines of text are terminated by CR/LF (that is, ASCII 13 + ASCII 10), but on Linux it is LF. While the code editor in Kylix can handle the difference, you should be aware of this when importing code from Windows.
End of file character	In DOS and Windows, the character value #26 (Ctrl-Z) is treated as the end of the text file, even if there is data in the file after that character. Linux has no special end of file character; the text data ends at the end of the file.
Batch files/shell scripts	The Linux equivalent of .bat files are shell scripts. A script is a text file containing instructions, saved and made executable with the command, `chmod +x <scriptfile>`. To execute it, type its name. (The scripting language depends on the shell you are using on Linux. Bash is commonly used.)
Command confirmation	In DOS or Windows, if you try to delete a file or folder, it asks for confirmation ("Are you sure you want to do that?"). Generally, Linux won't ask; it will just do it. This makes it easy to accidentally destroy a file or the entire file system. There is no way to undo a deletion on Linux unless a file is backed up on another media.
Command feedback	If a command succeeds on Linux, it redisplays the command prompt without a status message.
Command switches	Linux uses a dash (-) to indicate command switches or a double dash (--) for multiple character options where DOS uses a slash (/) or dash (-).

Table 10.7 Differences in the Linux and Windows operating environments (continued)

Difference	Description
Configuration files	On Windows, configuration is done in the registry or in files such as autoexec.bat. On Linux, configuration files are created as hidden files starting with a dot (.). Many are placed in the /etc directory and your home directory. Linux also uses environment variables such as LD_LIBRARY_PATH (search path for libraries). Other important environment variables: HOME Your home directory (/home/sam) TERM Terminal type (xterm, vt100, console) SHELL Path to your shell (/bin/bash) USER Your login name (sfuller) PATH List to search for programs They are specified in the shell or in rc files such as the .bashrc.
DLLs	On Linux, you use shared object files (.so). In Windows, these are dynamic link libraries (DLLs).
Drive letters	Linux doesn't have drive letters. An example Linux pathname is /lib/security. See DriveDelim in the runtime library.
Exceptions	Operating system exceptions are called signals on Linux.
Executable files	On Linux, executable files require no extension. On Windows, executable files have an exe extension.
File name extensions	Linux does not use file name extensions to identify file types or to associate files with applications.
File permissions	On Linux, files (and directories) are assigned read, write, and execute permissions for the file owner, group, and others. For example, `-rwxr-xr-x` means, from left to right: `-` is the file type (`-` = ordinary file, `d` = directory, `l` = link); `rwx` are the permissions for the file owner (read, write, execute); `r-x` are the permissions for the group of the file owner (read, execute); and `r-x` are the permissions for all other users (read, execute). The root user (superuser) can override these permissions. You need to make sure that your application runs under the correct user and has proper access to required files.
Make utility	Borland's make utility is not available on the Linux platform. Instead, you can use Linux's own GNU make utility.
Multitasking	Linux fully supports multitasking. You can run several programs (in Linux, called processes) at the same time. You can launch processes in the background (using & after the command) and continue working straight away. Linux also lets you have several sessions.
Pathnames	Linux uses a forward slash (/) wherever DOS uses a backslash (\). A PathDelim constant can be used to specify the appropriate character for the platform. See PathDelim in the runtime library.
Search path	When executing programs, Windows always checks the current directory first, then looks at the PATH environment variable. Linux never looks in the current directory but searches only the directories listed in PATH. To run a program in the current directory, you usually have to type ./ before it. You can also modify your PATH to include ./ as the first path to search.

Table 10.7 Differences in the Linux and Windows operating environments (continued)

Difference	Description
Search path separator	Windows uses the semicolon as a search path separator. Linux uses a colon. See PathDelim in the runtime library.
Symbolic links	On Linux, a symbolic link is a special file that points to another file on disk. Place symbolic links in the global bin directory that points to your application's main files and you don't have to modify the system search path. A symbolic link is created with the ln (link) command. Windows has shortcuts for the GUI desktop. To make a program available at the command line, Windows install programs typically modify the system search path.

Directory structure on Linux

Directories are different in Linux. Any file or device can be mounted anywhere on the file system.

Note Linux pathnames use forward slashes as opposed to Windows use of backslashes. The initial slash stands for the root directory.

Following are some commonly used directories in Linux.

Table 10.8 Common Linux directories

Directory	Contents
/	The root or top directory of the entire Linux file system
/root	The root file system; the Superuser's home directory
/bin	Commands, utilities
/sbin	System utilities
/dev	Devices shown as files
/lib	Libraries
/home/username	Files owned by the user where username is the user's login name.
/opt	Optional
/boot	Kernel that gets called when the system starts up
/etc	Configuration files
/usr	Applications, programs. Usually includes directories like /usr/spool, /usr/man, /usr/include, /usr/local
/mnt	Other media mounted on the system such as a CD or a floppy disk drive
/var	Logs, messages, spool files
/proc	Virtual file system and reporting system statistics
/tmp	Temporary files

Note Different distributions of Linux sometimes place files in different locations. A utility program may be placed in /bin in a Red Hat distribution but in /usr/local/bin in a Debian distribution.

Refer to www.pathname.com for additional details on the organization of the UNIX/Linux hierarchical file system and to read the *Filesystem Hierarchy Standard*.

Writing portable code

If you are writing cross-platform applications that are meant to run on Windows and Linux, you can write code that compiles under different conditions. Using conditional compilation, you can maintain your Windows coding, yet also make allowances for Linux operating system differences.

To create applications that are easily portable between Windows and Linux, remember to

- reduce or isolate calls to platform-specific (Win32 or Linux) APIs; use CLX methods instead.
- eliminate Windows messaging (PostMessage, SendMessage) constructs within an application.
- use *TMemIniFile* instead of *TRegIniFile*.
- observe and preserve case-sensitivity in file and directory names.
- port any external assembler TASM code. The GNU assembler, “as,” does not support the TASM syntax. (See “Including inline assembler code” on page 10-20.)

Try to write the code to use platform-independent runtime library routines and use constants found in System, SysUtils, and other runtime library units. For example, use the PathDelim constant to insulate your code from ‘/’ versus ‘\’ platform differences.

Another example involves the use of multibyte characters on both platforms. Windows code traditionally expects only 2 bytes per multibyte character. In Linux, multibyte character encoding can have many more bytes per char (up to 6 bytes for UTF-8). Both platforms can be accommodated using the StrNextChar function in SysUtils. Existing Windows code such as the following

```
while p^ <> #0 do
begin
   if p^ in LeadBytes then
      inc(p);
   inc(p);
end;
```

can be replaced with platform-independent code like this:

```
while p^ <> #0 do
begin
  if p^ in LeadBytes then
    p := StrNextChar(p)
  else
    inc(p);
end;
```

This example is platform portable and supports multibyte characters longer than 2 bytes, but still avoids the performance cost of a procedure call for non-multibyte locales.

If using runtime library functions is not a workable solution, try to isolate the platform-specific code in your routine into one chunk or into a subroutine. Try to limit the number of **$IFDEF** blocks to maintain source code readability and portability. The conditional symbol WIN32 is not defined on Linux. The conditional symbol LINUX is defined, indicating the source code is being compiled for the Linux platform.

Using conditional directives

Using **$IFDEF** compiler directives is a reasonable way to conditionalize your code for the Windows and Linux platforms. However, because **$IFDEF**s make source code harder to understand and maintain, you need to understand when it is reasonable to use **$IFDEF**s. When considering the use of **$IFDEF**s, the top questions should be "Why does this code require an **$IFDEF**?" and "Can this be written without an **$IFDEF**?"

Follow these guidelines for using **$IFDEF**s within cross-platform applications:

- Try not to use **$IFDEF**s unless absolutely necessary. **$IFDEF**s in a source file are only evaluated when source code is compiled. Unlike C/C++, Delphi does not require unit sources (header files) to compile a project. Full rebuilds of all source code is an uncommon event for most Delphi projects.
- Do not use **$IFDEF**s in package (.dpk) files. Limit their use to source files. Component writers need to create two design-time packages when doing cross-platform development, not one package using **$IFDEF**s.
- In general, use **$IFDEF** MSWINDOWS to test for any Windows platform including WIN32. Reserve the use of **$IFDEF** WIN32 for distinguishing between specific Windows platforms, such as 32-bit versus 64-bit Windows. Don't limit your code to WIN32 unless you know for sure that it will not work in WIN64.
- Avoid negative tests like **$IFNDEF** unless absolutely required. **$IFNDEF** LINUX is *not* equivalent to **$IFDEF** MSWINDOWS.
- Avoid **$IFNDEF/$ELSE** combinations. Use a positive test instead (**$IFDEF**) for better readability.
- Avoid **$ELSE** clauses on platform-sensitive **$IFDEF**s. Use separate **$IFDEF** blocks for LINUX- and MSWINDOWS-specific code instead of **$IFDEF** LINUX/**$ELSE** or **$IFDEF** MSWINDOWS/**$ELSE**.

  For example, old code may contain

  ```
  {$IFDEF WIN32}
     (32-bit Windows code)
  {$ELSE}
     (16-bit Windows code)   //!! By mistake, Linux could fall into this code.
  {$ENDIF}
  ```

  For any non-portable code in **$IFDEF**s, it is better for the source code to fail to compile than to have the platform fall into an **$ELSE** clause and fail mysteriously at runtime. Compile failures are easier to find than runtime failures.

- Use the **$IF** syntax for complicated tests. Replace nested **$IFDEF**s with a boolean expression in an **$IF** directive. You should terminate the **$IF** directive using **$IFEND**, not **$ENDIF**. This allows you to place **$IF** expressions within **$IFDEF**s to hide the new **$IF** syntax from previous compilers.

All of the conditional directives are documented in the online Help. Also see, the topic "Conditional Compilation" in Help for more information.

Terminating conditional directives

Use the **$IFEND** directive to terminate **$IF** and **$ELSEIF** conditional directives. This allows **$IF/$IFEND** blocks to be hidden from older compilers inside of using **$IFDEF/ $ENDIF**. Older compilers won't recognize the **$IFEND** directive. **$IF** can only be terminated with **$IFEND**. You can only terminate old-style directives (**$IFDEF, $IFNDEF, $IFOPT**) with **$ENDIF**.

Note When nesting an **$IF** inside of **$IFDEF/$ENDIF**, do not use **$ELSE** with the **$IF**. Older compilers will see the **$ELSE** and think it is part of the **$IFDEF**, producing a compile error down the line. You can use {**$ELSEIF** True} as a substitute for {**$ELSE**} in this situation, since the **$ELSEIF** won't be taken if the **$IF** is taken first, and the older compilers won't know **$ELSEIF**. Hiding **$IF** for backwards compatibility is primarily an issue for third party vendors and application developers who want their code to run on several different versions.

$ELSEIF is a combination of **$ELSE** and **$IF**. The **$ELSEIF** directive allows you to write multi-part conditional blocks where only one of the conditional blocks will be taken. For example:

```
{$IFDEF doit}
   do_doit
{$ELSEIF  RTLVersion >= 14}
    goforit
{$ELSEIF  somestring = 'yes'}
    beep
{$ELSE}
    last chance
{$IFEND}
```

Of these four cases, only one is taken. If none of the first three conditions is true, the **$ELSE** clause is taken. **$ELSEIF** must be terminated by **$IFEND**. **$ELSEIF** cannot appear after **$ELSE**. Conditions are evaluated top to bottom like a normal **$IF...$ELSE** sequence. In the example, if doit is not defined, RTLVersion is 15, and somestring = 'yes', only the "goforit" block will be taken not the "beep" block, even though the conditions for both are true.

If you forget to use an **$ENDIF** to end one of your **$IFDEF**s, the compiler reports the following error message at the end of the source file:

```
Missing ENDIF
```

If you have more than a few **$IF/$IFDEF** directives in your source file, it can be difficult to determine which one is causing the problem. Kylix or Delphi reports the following error message on the source line of the last **$IF/$IFDEF** compiler directive with no matching **$ENDIF/$IFEND**:

```
Unterminated conditional directive
```

You can start looking for the problem at that location.

Emitting messages

The **$MESSAGE** compiler directive allows source code to emit hints, warnings, and errors just as the compiler does.

```
{$MESSAGE  HINT|WARN|ERROR|FATAL 'text string' }
```

The message type is optional. If no message type is indicated, the default is HINT. The text string is required and must be enclosed in single quotes.

Examples:

`{$MESSAGE 'Boo!'}` emits a hint.

`{$Message Hint 'Feed the cats'}` emits a hint.

`{$Message Warn 'Looks like rain.'}` emits a warning.

`{$Message Error 'Not implemented'}` emits an error, continues compiling.

`{$Message Fatal 'Bang. Yer dead.'}` emits an error, terminates the compiler.

Including inline assembler code

If you include inline assembler code in your Windows applications, you may not be able to use the same code on Linux because of position-independent code (PIC) requirements on Linux. Linux shared object libraries (DLL equivalents) require that all code be relocatable in memory without modification. This primarily affects inline assembler routines that use global variables or other absolute addresses, or that call external functions.

For units that contain only Object Pascal code, the compiler automatically generates PIC when required. PIC units have a .dpu extension (instead of .dcu). It's a good idea to compile every Pascal unit source file into both PIC and non-PIC formats; use the -p compiler switch to generate PIC. Precompiled units are available in both forms.

You may want to code assembler routines differently depending on whether you'll be compiling to an executable or a shared library; use {**$IFDEF** PIC} to branch the two versions of your assembler code. Or you can consider rewriting the routine in Object Pascal to avoid the issue.

Following are the PIC rules for inline assembler code:

- PIC requires all memory references be made relative to the EBX register, which contains the current module's base address pointer (in Linux called the Global Offset Table or GOT). So, instead of

  ```
  MOV EAX,GlobalVar
  ```

  use

  ```
  MOV EAX,[EBX].GlobalVar
  ```

- PIC requires that you preserve the EBX register across calls into your assembly code (same as on Win32), and also that you restore the EBX register *before* making calls to external functions (different from Win32).
- While PIC code will work in base executables, it may slow the performance and generate more code. You don't have any choice in shared objects, but in executables you probably still want to get the highest level of performance that you can.

Messages and system events

Message loops and events work differently on Linux and in CLX, but this primarily affects component writing. Most component and property editors port easily. *TObject.Dispatch* and message method syntax on classes work fine on Linux; under Linux, however, operating system notifications are handled using system events rather than messages.

To create an event handler in a cross-platform application, you can override one of the methods described in Table 10.9 to write your own custom message instead of responding to Windows messages. In the override, call the inherited method so any default processes still take place.

Table 10.9 TWidgetControl protected methods for responding to system events

Method	Description
ChangeBounds	Used when a *TWidgetControl* is resized. Roughly analogous to WM_SIZE or WM_MOVE in Windows. Qt sets the “geometry” of a widget based on the client area, VCL uses the entire control size, which includes what Qt refers to as the frame.
ChangeScale	Called automatically when resizing controls. Used to change the scale of a form and all its controls for a different screen resolution or font size. Because ChangeScale modifies the control’s Top, Left, Width, and Height properties, it changes the position of the control and its children as well as their size.
ColorChanged	Called when the color of the control has been changed.
CursorChanged	Called when the cursor changes shape. The mouse cursor assumes this shape when it's over this widget.
EnabledChanged	Called when an application changes the enabled state of a window or control.
FontChanged	Called when the collection of font resources changed. It sets the font for the widget and informs all children about the change. Roughly analogous to the WM_FONTCHANGE message.
PaletteChanged	Called when the system palette has been changed. .
ShowHintChanged	Called when Help hints are displayed or hidden on a control.
StyleChanged	Called when the window or control’s GUI styles have changed.
TabStopChanged	Called when the tab order on the form has been changed.
VisibleChanged	Called when a control is hidden or shown.
WidgetDestroyed	Called when a widget underlying a control is destroyed.

Qt is a C++ toolkit, so all of its widgets are C++ objects. CLX is written in Object Pascal, and Object Pascal does not interact directly with C++ objects. In addition, Qt uses multiple inheritance in a few places. So Delphi includes an interface layer that converts all of the Qt classes to a series of straight C functions. These are then wrapped in a shared object in Linux and a DLL in Windows.

Every *TWidgetControl* has *CreateWidget*, *InitWidget*, and *HookEvents* virtual methods that almost always have to be overridden. *CreateWidget* creates the Qt widget, and assigns the Handle to the FHandle private field variable. *InitWidget* gets called after the widget is constructed, and the Handle is valid.

Some property assignments in Delphi CLX have moved from the Create constructor to *InitWidget*. This will allow delayed construction of the Qt object until it's really needed. For example, say you have a property named *Color*. In SetColor, you can check with HandleAllocated to see if you have a Qt handle. If the Handle is allocated, you can make the proper call to Qt to set the color. If not, you can store the value in a private field variable, and, in *InitWidget*, you set the property.

Linux supports two types of events: Widget and System. *HookEvents* is a virtual method that hooks the CLX controls event methods to a special hook object that communicates with the Qt object. The hook object is really just a set of method pointers. System events on Kylix go through *EventHandler*, which is basically a replacement for *WndProc*.

Programming differences on Linux

The Linux wchar_t widechar is 32 bits per character. The 16-bit Unicode standard that Object Pascal widechars support is a subset of the 32-bit UCS standard supported by Linux and the GNU libraries. Pascal widechar data must be widened to 32 bits per character before it can be passed to an OS function as wchar_t.

In Linux, widestrings are reference counted like long strings (in Windows, they're not).

Multibyte handling differs in Linux. In Windows, multibyte characters (MBCS) are represented as 1- and 2-byte char codes. In Linux, they are represented in 1 to 6 bytes.

AnsiStrings can carry multibyte character sequences, dependent upon the user's locale settings. The Linux encoding for multibyte characters such as Japanese, Chinese, Hebrew, and Arabic may not be compatible with the Windows encoding for the same locale. Unicode is portable, whereas multibyte is not.

In Linux, you cannot use variables on absolute addresses. The syntax `var X: Integer absolute $1234;` is not supported in PIC and is not allowed in Delphi.

Cross-platform database applications

On Windows, Delphi provides several choices for how to access database information. These include using ADO, the Borland Database Engine (BDE), and InterBase Express. These three choices are not available on Kylix, however. Instead, you can use *dbExpress*, a new, cross-platform data access technology, which is also available on Windows, starting with Delphi version 6.

Before you port a database application to *dbExpress* so that it will run on Linux, you should understand the differences between using *dbExpress* and the data access mechanism you were using. These differences occur at different levels.

- At the lowest level, there is a layer that communicates between your application and the database server. This could be ADO, the BDE, or the InterBase client software. This layer is replaced by *dbExpress*, which is a set of lightweight drivers for dynamic SQL processing.
- The low-level data access is wrapped in a set of components that you add to data modules or forms. These components include database connection components, which represent the connection to a database server, and datasets, which represent the data fetched from the server. Although there are some very important differences, due to the unidirectional nature of *dbExpress* cursors, the differences are less pronounced at this level, because datasets all share a common ancestor, as do database connection components.
- At the user-interface level, there are the fewest differences. CLX data-aware controls are designed to be as similar as possible to the corresponding Windows controls. The major differences at the user interface level arise from changes needed to accommodate the use of cached updates.

For information on porting existing database applications to *dbExpress*, see “Porting database applications to Linux” on page 10-25. For information on designing new *dbExpress* applications, see Chapter 14, “Designing database applications.”

dbExpress differences

On Linux, *dbExpress* manages the communication with database servers. *dbExpress* consists of a set of lightweight drivers that implement a set of common interfaces. Each driver is a shared object (.so file) that must be linked to your application. Because *dbExpress* is designed to be cross-platform, it will also be available on Windows as a set of dynamic-link libraries (.dlls).

As with any data-access layer, *dbExpress* requires the client-side software provided by the database vendor. In addition, it uses a database-specific driver, plus two configuration files, dbxconnections and dbxdrivers. This is markedly less than you need for, say, the BDE, which requires the main Borland Database Engine library (Idapi32.dll) plus a database-specific driver and a number of other supporting libraries.

Here are some other differences between *dbExpress* and the other data-access layers from which you need to port your application:

- *dbExpress* allows for a simpler and faster path to remote databases. As a result, you can expect a noticeable performance increase for simple, straight-through data access.
- *dbExpress* can process queries and stored procedures, but does not support the concept of opening tables.
- *dbExpress* returns only unidirectional cursors.
- *dbExpress* has no built-in update support other than the ability to execute an INSERT, DELETE, or UPDATE query.
- *dbExpress* does no metadata caching, and the design time metadata access interface is implemented using the core data-access interface.
- *dbExpress* executes only queries requested by the user, thereby optimizing database access by not introducing any extra queries.
- *dbExpress* manages a record buffer or a block of record buffers internally. This differs from the BDE, where clients are required to allocate the memory used to buffer records.
- *dbExpress* does not support local tables that are not SQL-based (such as Paradox, dBase, or FoxPro).
- *dbExpress* drivers exist for InterBase, Oracle, DB2, and MySQL. If you are using a different database server, you must either port your data to one of these databases, write a *dbExpress* driver for the database server you are using, or obtain a third-party *dbExpress* driver for your database server.

Component-level differences

When you write a *dbExpress* application, it requires a different set of data-access components than those used in your existing database applications. The *dbExpress* components share the same base classes as other data-access components (*TDataSet* and *TCustomConnection*), which means that many of the properties, methods, and events are the same as the components used in your existing applications.

Table 10.10 lists some of the important database components used in InterBase Express, BDE, and ADO in the Windows environment and shows the comparable *dbExpress* components for use on Linux and in cross-platform applications.

Table 10.10 Comparable data-access components

InterBase Express components	BDE components	ADO components	dbExpress components
TIBDatabase	*TDatabase*	*TADOConnection*	*TSQLConnection*
TIBTable	*TTable*	*TADOTable*	*TSQLTable*
TIBQuery	*TQuery*	*TADOQuery*	*TSQLQuery*
TIBStoredProc	*TStoredProc*	*TADOStoredProc*	*TSQLStoredProc*
TIBDataSet		*TADODataSet*	*TSQLDataSet*

The *dbExpress* datasets (*TSQLTable*, *TSQLQuery*, *TSQLStoredProc*, and *TSQLDataSet*) are more limited than their counterparts, however, because they do not support editing and only allow forward navigation. For details on the differences between the *dbExpress* datasets and the other datasets that are available on Windows, see Chapter 22, "Using unidirectional datasets.".

Because of the lack of support for editing and navigation, most *dbExpress* applications do not work directly with the *dbExpress* datasets. Rather, they connect the *dbExpress* dataset to a client dataset, which buffers records in memory and provides support for editing and navigation. For more information about this architecture, see "Database architecture" on page 14-5.

Note For very simple applications, you can use *TSQLClientDataSet* instead of a *dbExpress* dataset connected to a client dataset. This has the benefit of simplicity, because there is a 1:1 correspondence between the dataset in the application you are porting and the dataset in the ported application, but is less flexible that explicitly connecting a *dbExpress* dataset to a client dataset. For most applications, it is recommended that you use a *dbExpress* dataset connected to a *TClientDataSet* component.

User interface-level differences

CLX data-aware controls are designed to be as similar as possible to the corresponding Windows controls. As a result, porting the user-interface portion of your database applications introduces few additional considerations beyond those involved in porting any Windows application to CLX.

The major differences at the user interface level arise from differences in the way *dbExpress* datasets or client datasets supply data.

If you are using only *dbExpress* datasets, then you must adjust your user interface to accommodate the fact that the datasets do not support editing and only support forward navigation. Thus, for example, you may need to remove controls that allow users to move to a previous record. Because *dbExpress* datasets do not buffer data, you can't display data in a data-aware grid: only one record can be displayed at a time.

If you have connected the *dbExpress* dataset to a client dataset, then the user interface elements associated with editing and navigation should still work. You need only reconnect them to the client dataset. The main consideration in this case is handling how updates are written to the database. By default, most datasets on Windows write updates to the database server automatically when they are posted (for example, when the user moves to a new record). Client datasets, on the other hand, always cache updates in memory. For information on how to accommodate this difference, see "Updating data in dbExpress applications" on page 10-27.

Porting database applications to Linux

Porting your database application to *dbExpress* allows you to create a cross-platform application that runs both on Windows and Linux. The porting process involves making changes to your application because the technology is different. How difficult it is to port depends on the type of application it is, how complex it is, and what it needs to accomplish. An application that heavily uses Windows-specific technologies such as ADO will be more difficult to port than one that uses Delphi database technology.

Follow these general steps to port your Windows/VCL database application to Kylix/CLX:

1. Consider where database data is stored. *dbExpress* provides drivers for Oracle, Interbase, DB2, and MySQL. The data needs to reside on one of these SQL servers.

   Some versions of Delphi include the Data Pump utility which you can use to move local database data from platforms such as Paradox, dBase, and FoxPro onto one of the supported platforms. (See the datapump.hlp file in Program Files\Common Files\Borland\Shared\BDE for information on using the utility.)

2. If you have not isolated your user interface forms from data modules containing the datasets and connection components, you may want to consider doing so before you start the port. That way, you isolate the portions of your application that require a completely new set of components into data modules. Forms that represent the user interface can then be ported like any other application. For details, see "Porting your application" on page 10-4.

   The remaining steps assume that your datasets and connection components are isolated in their own data modules.

3. Create a new data module to hold the CLX versions of your datasets and connection components.

4. For each dataset in the original application, add a *dbExpress* dataset, *TDataSetProvider* component, and *TClientDataSet* component. Use the correspondences in Table 10.10 to decide which *dbExpress* dataset to use. Give these components meaningful names.

   - Set the *ProviderName* property of the *TClientDataSet* component to the name of the *TDataSetProvider* component.
   - Set the *DataSet* property of the *TDataSetProvider* component to the *dbExpress* dataset.
   - Change the *DataSet* property of any data source components that referred to the original dataset so that it now refers to the client dataset.

5. Set properties on the new dataset to match the original dataset:

   - If the original dataset was a *TTable*, *TADOTable*, or *TIBTable* component, set the new *TSQLTable*'s *TableName* property to the original dataset's *TableName*. Also copy any properties used to set up master/detail relationships or specify indexes. Properties specifying ranges and filters should be set on the client dataset rather than the new *TSQLTable* component.
   - If the original dataset was a *TQuery*, *TADOQuery*, or *TIBQuery* component, set the new *TSQLQuery* component's *SQL* property to the original dataset's *SQL* property. Set the *Params* property of the new *TSQLQuery* to match the value of the original dataset's *Params* or *Parameters* property. If you have set the *DataSource* property to establish a master/detail relationship, copy this as well.

- If the original dataset was a *TStoredProc*, *TADOStoredProc*, or *TIBStoredProc* component, set the new *TSQLStoredProc* component's *StoredProcName* to the *StoredProcName* or *ProcedureName* property of the original dataset. Set the *Params* property of the new *TSQLStoredProc* to match the value of the original dataset's *Params* or *Parameters* property.

6. For any database connection components in the original application (*TDatabase*, *TIBDatabase*, or *TADOConnection*), add a *TSQLConnection* component to the new data module. You must also add a *TSQLConnection* component for every database server to which you connected without a connection component (for example, by using the *ConnectionString* property on an ADO dataset or by setting the *DatabaseName* property of a BDE dataset to a BDE alias).
7. For each *dbExpress* dataset placed in step 4, set its *SQLConnection* property to the *TSQLConnection* component that corresponds to the appropriate database connection.
8. On each *TSQLConnection* component, specify the information needed to establish a database connection. To do so, double-click the *TSQLConnection* component to display the Connection Editor and set parameter values to indicate the appropriate settings. If you had to transfer data to a new database server in step 1, then specify settings appropriate to the new server. If you are using the same server as before, you can look up some of this information on the original connection component:

   - If the original application used *TDatabase*, you must transfer the information that appears in the *Params* and *TransIsolation* properties.
   - If the original application used *TADOConnection*, you must transfer the information that appears in the *ConnectionString* and *IsolationLevel* properties.
   - If the original application used *TIBDatabase*, you must transfer the information that appears in the *DatabaseName* and *Params* properties.
   - If there was no original connection component, you must transfer the information associated with the BDE alias or that appeared in the dataset's *ConnectionString* property.

   You may want to save this set of parameters under a new connection name. For more details on this process, see "Controlling connections" on page 17-2.

Updating data in dbExpress applications

dbExpress applications use client datasets to support editing. When you post edits to a client dataset, the changes are written to the client dataset's in-memory snapshot of the data, but are not automatically written to the database server. If your original application used a client dataset for caching updates, then you do not need to change anything to support editing on Linux. However, if you relied on the default behavior of most datasets on Windows, which is to write edits to the database server when you post records, you must make changes to accommodate the use of a client dataset.

There are two ways to convert an application that did not previously cache updates:

- You can mimic the behavior of the dataset on Windows by writing code to apply each updated record to the database server as soon as it is posted. To do this, supply the client dataset with an *AfterPost* event handler that applies update to the database server:

```
procedure TForm1.ClientDataSet1AfterPost(DataSet: TDataSet);
begin
  with DataSet as TClientDataSet do
    ApplyUpdates(1);
end;
```

- You can adjust your user interface to deal with cached updates. This approach has certain advantages, such as reducing the amount of network traffic and minimizing transaction times. However, if you switch to using cached updates, you must decide when to apply those updates back to the database server, and probably make user interface changes to let users initiate the application of updates or inform provide them with feedback about whether their edits have been written to the database. Further, because update errors are not detected when the user posts a record, you will need to change the way you report such errors to the user, so that they can see which update caused a problem as well as what type of problem occurred.

If your original application used the support provided by the BDE or ADO for caching updates, you will need to make some adjustments in your code to switch to using a client dataset. The following table lists the properties, events, and methods that support cached updates on BDE and ADO datasets, and the corresponding properties, methods and events on *TClientDataSet*:

Table 10.11 Properties, methods, and events for cached updates

On BDE datasets (or TDatabase)	On ADO datasets	On TClientDataSet	Purpose
CachedUpdates	*LockType*	Not needed, client datasets always cache updates.	Determines whether cached updates are in effect.
Not supported.	*CursorType*	Not supported.	Specifies how isolated the dataset is from changes on the server.
UpdatesPending	Not supported.	*ChangeCount*	Indicates whether the local cache contains updated records that need to be applied to the database.
UpdateRecordTypes	*FilterGroup*	*StatusFilter*	Indicates the kind of updated records to make visible when applying cached updates.
UpdateStatus	*RecordStatus*	*UpdateStatus*	Indicates if a record is unchanged, modified, inserted, or deleted.
OnUpdateError	Not supported.	*OnReconcileError*	An event for handling update errors on a record-by-record basis.
ApplyUpdates (on dataset or database)	UpdateBatch	*ApplyUpdates*	Applies records in the local cache to the database.

Table 10.11 Properties, methods, and events for cached updates (continued)

On BDE datasets (or TDatabase)	On ADO datasets	On TClientDataSet	Purpose
CancelUpdates	CancelUpdates or CancelBatch	*CancelUpdates*	Removes pending updates from the local cache without applying them.
CommitUpdates	Handled automatically	*Reconcile*	Clears the update cache following successful application of updates.
FetchAll	Not supported	*GetNextPacket* (and *PacketRecords*)	Copies database records to the local cache for editing and updating.
RevertRecord	CancelBatch	*RevertRecord*	Undoes updates to the current record if updates are not yet applied.

Cross-platform Internet applications

An Internet application is a client/server application that uses standard Internet protocols for connecting the client to the server. Because your applications use standard Internet protocols for client/server communications, you can make your applications cross-platform. For example, a server-side program for an Internet application communicates with the client through the Web server software for the machine. The server application is typically written for Linux or Windows, but can also be cross-platform. The clients can be on either platform.

You can use Delphi or Kylix to create Web server applications as CGI or Apache applications for deployment on Linux. On Windows, you can create other types of Web servers such as Microsoft Server DLLs (ISAPI), Netscape Server DLLs (NSAPI), and Windows CGI applications. Only straight CGI applications and some applications that use Web Broker will run on both Windows and Linux.

Porting Internet applications to Linux

If you have existing Internet applications that you want to make cross-platform, you should consider whether you want to port your Web server application or if you want to create a new application on Linux. See Chapter 27, “Creating Internet applications” for information on writing Web servers. If your application uses Web Broker and writes to the Web Broker interface and does not use native API calls, it will not be as difficult to port it to Linux.

If your application writes to ISAPI, NSAPI, Windows CGI, or other Web APIs, it will be more difficult to port. You will need to search through your source files and translate these API calls into Apache (see httpd.pas in the Internet directory for function prototypes for Apache APIs) or CGI calls. You also need to make all other suggested changes described in “Porting VCL applications to CLX” on page 10-2.

Chapter

11

Working with packages and components

A *package* is a special dynamic-link library used by Delphi applications, the IDE, or both. *Runtime packages* provide functionality when a user runs an application. *Design-time packages* are used to install components in the IDE and to create special property editors for custom components. A single package can function at both design time and runtime, and design-time packages frequently work by calling runtime packages. To distinguish them from other DLLs, package libraries are stored in files that end with the .bpl (Borland package library) extension.

Like other runtime libraries, packages contain code that can be shared among applications. For example, the most frequently used Delphi components reside in a package called vcl. Each time you create an application, it automatically uses vcl. When you compile an application created this way, the application's executable image contains only the code and data unique to it; the common code is in the runtime package called vcl60.bpl. A computer with several package-enabled applications installed on it needs only a single copy of vcl60.bpl, which is shared by all the applications and the Delphi IDE itself.

Delphi ships with several precompiled runtime packages that encapsulate VCL and CLX components. Delphi also uses design-time packages to manipulate components in the IDE.

You can build applications with or without packages. However, if you want to add custom components to the IDE, you must install them as design-time packages.

You can create your own runtime packages to share among applications. If you write Delphi components, you can compile your components into design-time packages before installing them.

Why use packages?

Design-time packages simplify the tasks of distributing and installing custom components. Runtime packages, which are optional, offer several advantages over conventional programming. By compiling reused code into a runtime library, you can share it among applications. For example, all of your applications—including Delphi itself—can access standard components through packages. Since the applications don't have separate copies of the component library bound into their executables, the executables are much smaller—saving both system resources and hard disk storage. Moreover, packages allow faster compilation because only code unique to the application is compiled with each build.

Packages and standard DLLs

Create a package when you want to make a custom component that's available through the IDE. Create a standard DLL when you want to build a library that can be called from any application, regardless of the development tool used to build the application.

The following table lists the file types associated with packages:

Table 11.1 Compiled package files

File extension	Contents
dpk	The source file listing the units contained in the package.
dcp	A binary image containing a package header and the concatenation of all dcu files in the package, including all symbol information required by the compiler. A single dcp file is created for each package. The base name for the dcp is the base name of the dpk source file. You must have a .dcp file to build an application with packages.
dcu	A binary image for a unit file contained in a package. One dcu is created, when necessary, for each unit file.
bpl	The runtime package. This file is a Windows DLL with special Delphi-specific features. The base name for the bpl is the base name of the dpk source file.

You can include VCL or CLX or both types of components in a package. Packages meant to be cross-platform should include CLX components only.

Note Packages share their global data with other modules in an application.

For more information about DLLs and packages, see the *Object Pascal Language Guide*.

Runtime packages

Runtime packages are deployed with Delphi applications. They provide functionality when a user runs the application.

To run an application that uses packages, a computer must have both the application's executable file and all the packages (.bpl files) that the application uses.

The .bpl files must be on the system path for an application to use them. When you deploy an application, you must make sure that users have correct versions of any required .bpls.

Using packages in an application

To use packages in an application,

1. Load or create a project in the IDE.
2. Choose Project|Options.
3. Choose the Packages tab.
4. Select the "Build with Runtime Packages" check box, and enter one or more package names in the edit box underneath. (Runtime packages associated with installed design-time packages are already listed in the edit box.)
5. To add a package to an existing list, click the Add button and enter the name of the new package in the Add Runtime Package dialog. To browse from a list of available packages, click the Add button, then click the Browse button next to the Package Name edit box in the Add Runtime Package dialog.

   If you edit the Search Path edit box in the Add Runtime Package dialog, you will be changing Delphi's global Library Path.

   You do not need to include file extensions with package names (or the number representing the Delphi release); that is, vcl60.bpl is written as vcl. If you type directly into the Runtime Packages edit box, be sure to separate multiple names with semicolons. For example:

   ```
   rtl;vcl;vcldb;vclado;vclx;Vclbde;
   ```

Packages listed in the Runtime Packages edit box are automatically linked to your application when you compile. Duplicate package names are ignored, and if the edit box is empty the application is compiled without packages.

Runtime packages are selected for the current project only. To make the current choices into automatic defaults for new projects, select the "Defaults" check box at the bottom of the dialog.

Note When you create an application with packages, you still need to include the names of the original Delphi units in the **uses** clause of your source files. For example, the source file for your main form might begin like this:

```
unit MainForm;

interface

uses
Windows, Messages, SysUtils, Variants, Classes, Graphics, Controls, Forms,
  Dialogs;
```

The units referenced in this example are contained in the vcl and rtl packages. Nonetheless, you must keep these references in the **uses** clause, even if you use vcl and rtl in your application, or you will get compiler errors. In generated source files, Delphi adds these units to the **uses** clause automatically.

Dynamically loading packages

To load a package at runtime, call the *LoadPackage* function. *LoadPackage* loads the package, checks for duplicate units, and calls the initialization blocks of all units contained in the package. For example, the following code could be executed when a file is chosen in a file-selection dialog.

```
with OpenDialog1 do
  if Execute then
    with PackageList.Items do
      AddObject(FileName, Pointer(LoadPackage(FileName)));
```

To unload a package dynamically, call *UnloadPackage*. Be careful to destroy any instances of classes defined in the package and to unregister classes that were registered by it.

Deciding which runtime packages to use

Delphi ships with several precompiled runtime packages, including rtl and vcl, which supply basic language and component support.

The vcl package contains the most commonly used components; the rtl package includes all the non-component system functions and Windows interface elements. It does not include database or other special components, which are available in separate packages.

To create a client/server database application that uses packages, you need at least three runtime packages: vcl and vcldb. If you want to use Outline components in your application, you also need vclx. To use these packages, choose Project|Options, select the Packages tab, and enter the following list in the Runtime Packages edit box.

```
rtl;vcl;Vcldb;vclx;
```

Actually, you don't have to include vcl and rtl, because they are referenced in the Requires clause of vcldb. (See "Requires clause" on page 11-8.) Your application will compile just the same whether or not vcl and rtl are included in the Runtime Packages edit box.

Custom packages

A custom package is either a bpl you code and compile yourself or a precompiled package from a third-party vendor. To use a custom runtime package with an application, choose Project|Options and add the name of the package to the Runtime Packages edit box on the Packages page. For example, suppose you have a statistical package called stats.bpl. To use it in an application, the line you enter in the Runtime Packages edit box might look like this:

```
rtl;vcl;vcldb;stats
```

If you create your own packages, you can add them to the list as needed.

Design-time packages

Design-time packages are used to install components on the IDE's Component palette and to create special property editors for custom components.

Delphi ships with many design-time component packages preinstalled in the IDE. Which ones are installed depends on which version of Delphi you are using and whether or not you have customized it. You can view a list of what packages are installed on your system by choosing Component | Install Packages.

The design-time packages work by calling runtime packages, which they reference in their Requires clauses. (See "Requires clause" on page 11-8.) For example, dclstd references vcl. Dclstd itself contains additional functionality that makes most of the standard components available on the Component palette.

In addition to preinstalled packages, you can install your own component packages, or component packages from third-party developers, in the IDE. The dclusr design-time package is provided as a default container for new components.

Installing component packages

All components are installed in the IDE as packages. If you've written your own components, create and compile a package that contains them. (See "Creating and editing packages" on page 11-6.) Your component source code must follow the model described in Part V, "Creating custom components".

To install or uninstall your own components, or components from a third-party vendor, follow these steps:

1. If you are installing a new package, copy or move the package files to a local directory. If the package is shipped with .bpl, .dcp, and .dcu files, be sure to copy all of them. (For information about these files, see , "Package files created by a successful compilation.")

   The directory where you store the .dcp file—and the .dcu files, if they are included with the distribution—must be in the Delphi Library Path.

   If the package is shipped as a .dpc (package collection) file, only the one file needs to be copied; the .dpc file contains the other files. (For more information about package collection files, see "Package collection files" on page 11-13.)

2. Choose Component | Install Packages from the IDE menu, or choose Project | Options and click the Packages tab.

3. A list of available packages appears under "Design packages."

   - To install a package in the IDE, select the check box next to it.
   - To uninstall a package, deselect its check box.
   - To see a list of components included in an installed package, select the package and click Components.

- To add a package to the list, click Add and browse in the Open Package dialog box for the directory where the .bpl or .dpc file resides (see step 1). Select the .bpl or .dpc file and click Open. If you select a .dpc file, a new dialog box appears to handle the extraction of the .bpl and other files from the package collection.
- To remove a package from the list, select the package and click Remove.

4 Click OK.

The components in the package are installed on the Component palette pages specified in the components' *RegisterComponents* procedure, with the names they were assigned in the same procedure.

New projects are created with all available packages installed, unless you change the default settings. To make the current installation choices into the automatic default for new projects, check the Default check box at the bottom of the Packages tab of the Project Options dialog box.

To remove components from the Component palette without uninstalling a package, select Component | Configure Palette, or select Tools | Environment Options and click the Palette tab. The Palette options tab lists each installed component along with the name of the Component palette page where it appears. Selecting any component and clicking Hide removes the component from the palette.

Creating and editing packages

Creating a package involves specifying

- A *name* for the package.
- A list of other packages to be *required* by, or linked to, the new package.
- A list of unit files to be *contained* by, or bound into, the package when it is compiled. The package is essentially a wrapper for these source-code units, which contain the functionality of the compiled .bpl. The Contains clause is where you put the source-code units for custom components that you want to compile into a package.

Package source files, which end with the .dpk extension, are generated by the Package editor.

Creating a package

To create a package, follow the procedure below. Refer to "Understanding the structure of a package" on page 11-8 for more information about the steps outlined here.

Note Do not use IFDEFs in a package file (.dpk) such as when doing cross-platform development. You can use them in the source code, however.

1 Choose File | New, select the Package icon, and click OK.

2. The generated package is displayed in the Package editor.
3. The Package editor shows a *Requires* node and a *Contains* node for the new package.
4. To add a unit to the **contains** clause, click the Add to package speed button. In the Add unit page, type a .pas file name in the Unit file name edit box, or click Browse to browse for the file, and then click OK. The unit you've selected appears under the Contains node in the Package editor. You can add additional units by repeating this step.
5. To add a package to the **requires** clause, click the Add to package speed button. In the Requires page, type a .dcp file name in the Package name edit box, or click Browse to browse for the file, and then click OK. The package you've selected appears under the Requires node in the Package editor. You can add additional packages by repeating this step.
6. Click the Options speed button, and decide what kind of package you want to build.
   - To create a design-time only package (a package that cannot be used at runtime), select the Designtime only radio button. (Or add the {$DESIGNONLY} compiler directive to the dpk file.)
   - To create a runtime-only package (a package that cannot be installed), select the Runtime only radio button. (Or add the {$RUNONLY} compiler directive to the dpk file.)
   - To create a package that is available at both design time and runtime, select the Designtime and runtime radio button.
7. In the Package editor, click the Compile package speed button to compile your package.

Editing an existing package

You can open an existing package for editing in several ways:

- Choose File | Open (or File | Reopen) and select a dpk file.
- Choose Component | Install Packages, select a package from the Design Packages list, and click the Edit button.
- When the Package editor is open, select one of the packages in the Requires node, right-click, and choose Open.

To edit a package's description or set usage options, click the Options speed button in the Package editor and select the Description tab.

The Project Options dialog has a Default check box in the lower left corner. If you click OK when this box is checked, the options you've chosen are saved as default settings for new projects. To restore the original defaults, delete or rename the defproj.dof file.

Editing package source files manually

Package source files, like project files, are generated by Delphi from information you supply. Like project files, they can also be edited manually. A package source file should be saved with the .dpk (Delphi package) extension to avoid confusion with other files containing Object Pascal source code.

To open a package source file in the Code editor,

1. Open the package in the Package editor.
2. Right-click in the Package editor and select View Source.
   - The **package** heading specifies the name for the package.
   - The **requires** clause lists other, external packages used by the current package. If a package does not contain any units that use units in another package, then it doesn't need a **requires** clause.
   - The **contains** clause identifies the unit files to be compiled and bound into the package. All units used by contained units which do not exist in required packages will also be bound into the package, although they won't be listed in the contains clause (the compiler will give a warning).

   For example, the following code declares the vcldb package (in the source file vcldb60.bpl):

```
package vcldb;
   requires vcldb;
   contains rtl, vcl, Db, DBActns, DBOleCtl, Dbcgrids, dbCommon, dbConsts, Dbctrls,
Dbgrids, Dblogdlg, SQLTimSt, FmtBcd;
end.
```

Understanding the structure of a package

Packages include the following parts:

- Package name
- Requires clause
- Contains clause

Naming packages

Package names must be unique within a project. If you name a package STATS, the Package editor generates a source file for it called STATS.dpk; the compiler generates an executable and a binary image called STATS.bpl and STATS.dcp, respectively. Use STATS to refer to the package in the **requires** clause of another package, or when using the package in an application.

Requires clause

The **requires** clause specifies other, external packages that are used by the current package. An external package included in the **requires** clause is automatically linked at compile time into any application that uses both the current package and one of the units contained in the external package.

If the unit files contained in your package make references to other packaged units, the other packages should appear in your package's **requires** clause or you should add them. If the other packages are omitted from the **requires** clause, the compiler will import them into your package 'implicitly contained units'.

Note Most packages that you create will require rtl. If using VCL components, you'll also need to include the vcl package. If using CLX components for cross-platform programming, you need to include VisualCLX.

Avoiding circular package references

Packages cannot contain circular references in their **requires** clause. This means that

- A package cannot reference itself in its own **requires** clause.
- A chain of references must terminate without rereferencing any package in the chain. If package A requires package B, then package B cannot require package A; if package A requires package B and package B requires package C, then package C cannot require package A.

Handling duplicate package references

Duplicate references in a package's **requires** clause—or in the Runtime Packages edit box—are ignored by the compiler. For programming clarity and readability, however, you should catch and remove duplicate package references.

Contains clause

The **contains** clause identifies the unit files to be bound into the package. If you are writing your own package, put your source code in pas files and include them in the **contains** clause.

Avoiding redundant source code uses

A package cannot appear in the **contains** clause of another package.

All units included directly in a package's **contains** clause, or included indirectly in any of those units, are bound into the package at compile time.

A unit cannot be contained (directly or indirectly) in more than one package used by the same application, *including the Delphi IDE*. This means that if you create a package that contains one of the units in vcl you won't be able to install your package in the IDE. To use an already-packaged unit file in another package, put the first package in the second package's **requires** clause.

Compiling packages

You can compile a package from the IDE or from the command line. To recompile a package by itself from the IDE,

1. Choose File | Open.
2. Select Delphi package (*.dpk) from the Files of Type drop-down list.
3. Select a .dpk file in the dialog.
4. When the Package editor opens, click the Compile speed button.

You can insert compiler directives into your package source code. For more information, see "Package-specific compiler directives", below.

If you compile from the command line, several package-specific switches are available. For more information, see "Using the command-line compiler and linker" on page 11-12.

Package-specific compiler directives

The following table lists package-specific compiler directives that you can insert into your source code.

Table 11.2 Package-specific compiler directives

Directive	Purpose
{$IMPLICITBUILD OFF}	Prevents a package from being implicitly recompiled later. Use in .dpk files when compiling packages that provide low-level functionality, that change infrequently between builds, or whose source code will not be distributed.
{$G-} or {IMPORTEDDATA OFF}	Disables creation of imported data references. This directive increases memory-access efficiency, but prevents the unit where it occurs from referencing variables in other packages.
{$WEAKPACKAGEUNIT ON}	Packages unit "weakly." See "Weak packaging" on page 11-11 below.
{$DENYPACKAGEUNIT ON}	Prevents unit from being placed in a package.
{$DESIGNONLY ON}	Compiles the package for installation in the IDE. (Put in .dpk file.)
{$RUNONLY ON}	Compiles the package as runtime only. (Put in .dpk file.)

Note Including **{$DENYPACKAGEUNIT ON}** in your source code prevents the unit file from being packaged. Including **{$G-}** or **{$IMPORTEDDATA OFF}** may prevent a package from being used in the same application with other packages. Packages compiled with the **{$DESIGNONLY ON}** directive should not ordinarily be used in applications, since they contain extra code required by the IDE. Other compiler directives may be included, if appropriate, in package source code. See Compiler directives in the online help for information on compiler directives not discussed here.

Refer to "Creating packages and DLLs" on page 5-9 for additional directives that can be used in all libraries.

Weak packaging

The **$WEAKPACKAGEUNIT** directive affects the way a .dcu file is stored in a package's .dcp and .bpl files. (For information about files generated by the compiler, see "Package files created by a successful compilation" on page 11-12.) If **{$WEAKPACKAGEUNIT ON}** appears in a unit file, the compiler omits the unit from bpls when possible, and creates a non-packaged local copy of the unit when it is required by another application or package. A unit compiled with this directive is said to be "weakly packaged."

For example, suppose you've created a package called PACK that contains only one unit, UNIT1. Suppose UNIT1 does not use any further units, but it makes calls to RARE.dll. If you put **{$WEAKPACKAGEUNIT ON}** in UNIT1.pas when you compile your package, UNIT1 will not be included in PACK.bpl; you will not have to distribute copies of RARE.dll with PACK. However, UNIT1 will still be included in PACK.dcp. If UNIT1 is referenced by another package or application that uses PACK, it will be copied from PACK.dcp and compiled directly into the project.

Now suppose you add a second unit, UNIT2, to PACK. Suppose that UNIT2 uses UNIT1. This time, even if you compile PACK with **{$WEAKPACKAGEUNIT ON}** in UNIT1.pas, the compiler will include UNIT1 in PACK.bpl. But other packages or applications that reference UNIT1 will use the (non-packaged) copy taken from PACK.dcp.

Note Unit files containing the **{$WEAKPACKAGEUNIT ON}** directive must not have global variables, initialization sections, or finalization sections.

The **$WEAKPACKAGEUNIT** directive is an advanced feature intended for developers who distribute their packages to other Delphi programmers. It can help you to avoid distribution of infrequently used DLLs, and to eliminate conflicts among packages that may depend on the same external library.

For example, Delphi's PenWin unit references PenWin.dll. Most projects don't use PenWin, and most computers don't have PenWin.dll installed on them. For this reason, the PenWin unit is weakly packaged in vcl. When you compile a project that uses PenWin and the vcl package, PenWin is copied from VCL60.dcp and bound directly into your project; the resulting executable is statically linked to PenWin.dll.

If PenWin were not weakly packaged, two problems would arise. First, vcl itself would be statically linked to PenWin.dll, and so you could not load it on any computer which didn't have PenWin.dll installed. Second, if you tried to create a package that contained PenWin, a compiler error would result because the PenWin unit would be contained in both vcl and your package. Thus, without weak packaging, PenWin could not be included in standard distributions of vcl.

Using the command-line compiler and linker

When you compile from the command line, you can use the package-specific switches listed in the following table.

Table 11.3 Package-specific command-line compiler switches

Switch	Purpose
-$G-	Disables creation of imported data references. Using this switch increases memory-access efficiency, but prevents packages compiled with it from referencing variables in other packages.
-LE*path*	Specifies the directory where the package bpl file will be placed.
-LN*path*	Specifies the directory where the package dcp file will be placed.
-LU*package*	Use packages.
-Z	Prevents a package from being implicitly recompiled later. Use when compiling packages that provide low-level functionality, that change infrequently between builds, or whose source code will not be distributed.

Note Using the **-$G-** switch may prevent a package from being used in the same application with other packages. Other command-line options may be used, if appropriate, when compiling packages. See “The Command-line compiler” in the online help for information on command-line options not discussed here.

Package files created by a successful compilation

To create a package, you compile a source file that has a .dpk extension. The base name of the .dpk file becomes the base name of the files generated by the compiler. For example, if you compile a package source file called traypak.dpk, the compiler creates a package called traypak.bpl.

The following table lists the files produced by the successful compilation of a package.

Table 11.4 Compiled package files

File extension	Contents
dcp	A binary image containing a package header and the concatenation of all dcu files in the package. A single dcp file is created for each package. The base name for the dcp is the base name of the dpk source file.
dcu	A binary image for a unit file contained in a package. One dcu is created, when necessary, for each unit file.
bpl	The runtime package. This file is a Windows DLL with special Delphi-specific features. The base name for the bpl is the base name of the dpk source file.

When compiled, the bpi, bpl, and lib files are generated by default in the directories specified in Library page of the Tools | Environment Options dialog. You can override the default settings by clicking the Options speed button in the Package editor to display the Project Options dialog; make any changes on the Directories/ Conditionals page.

Deploying packages

You deploy packages much like you deploy other applications. For general deployment information, refer to Chapter 13, “Deploying applications”.

Deploying applications that use packages

When distributing an application that uses runtime packages, make sure that your users have the application’s .exe file as well as all the library (.bpl or .dll) files that the application calls. If the library files are in a different directory from the .exe file, they must be accessible through the user’s Path. You may want to follow the convention of putting library files in the Windows\System directory. If you use InstallShield Express, your installation script can check the user’s system for any packages it requires before blindly reinstalling them.

Distributing packages to other developers

If you distribute runtime or design-time packages to other Delphi developers, be sure to supply both .dcp and .bpl files. You will probably want to include .dcu files as well.

Package collection files

Package collections (.dpc files) offer a convenient way to distribute packages to other developers. Each package collection contains one or more packages, including bpls and any additional files you want to distribute with them. When a package collection is selected for IDE installation, its constituent files are automatically extracted from their .pce container; the Installation dialog box offers a choice of installing all packages in the collection or installing packages selectively.

To create a package collection,

1. Choose Tools | Package Collection Editor to open the Package Collection editor.
2. Click the Add a Package speed button, then select a bpl in the Select Package dialog and click Open. To add more bpls to the collection, click the Add a Package speed button again. A tree diagram on the left side of the Package editor displays the bpls as you add them. To remove a package, select it and click the Remove Package speed button.
3. Select the Collection node at the top of the tree diagram. On the right side of the Package Collection editor, two fields will appear:
    - In the Author/Vendor Name edit box, you can enter optional information about your package collection that will appear in the Installation dialog when users install packages.

- Under Directory List, list the default directories where you want the files in your package collection to be installed. Use the Add, Edit, and Delete buttons to edit this list. For example, suppose you want all source code files to be copied to the same directory. In this case, you might enter `Source` as a Directory Name with `C:\MyPackage\Source` as the Suggested Path. The Installation dialog box will display `C:\MyPackage\Source` as the suggested path for the directory.

4 In addition to bpls, your package collection can contain .dcp, .dcu, and .pas (unit) files, documentation, and any other files you want to include with the distribution. Ancillary files are placed in file groups associated with specific packages (bpls); the files in a group are installed only when their associated bpl is installed. To place ancillary files in your package collection, select a bpl in the tree diagram and click the Add File Group speed button; type a name for the file group. Add more file groups, if desired, in the same way. When you select a file group, new fields will appear on the right in the Package Collection editor,

- In the Install Directory list box, select the directory where you want files in this group to be installed. The drop-down list includes the directories you entered under Directory List in step 3, above.
- Check the Optional Group check box if you want installation of the files in this group to be optional.
- Under Include Files, list the files you want to include in this group. Use the Add, Delete, and Auto buttons to edit the list. The Auto button allows you to select all files with specified extensions that are listed in the **contains** clause of the package; the Package Collection editor uses Delphi's global Library Path to search for these files.

5 You can select installation directories for the packages listed in the **requires** clause of any package in your collection. When you select a bpl in the tree diagram, four new fields appear on the right side of the Package Collection editor:

- In the Required Executables list box, select the directory where you want the .bpl files for packages listed in the **requires** clause to be installed. (The drop-down list includes the directories you entered under Directory List in step 3, above.) The Package Collection Editor searches for these files using Delphi's global Library Path and lists them under Required Executable Files.
- In the Required Libraries list box, select the directory where you want the .dcp files for packages listed in the **requires** clause to be installed. (The drop-down list includes the directories you entered under Directory List in step 3, above.) The Package Collection Editor searches for these files using Delphi's global Library Path and lists them under Required Library Files.

6 To save your package collection source file, choose File | Save. Package collection source files should be saved with the .pce extension.

7 To build your package collection, click the Compile speed button. The Package Collection editor generates a .dpc file with the same name as your source (.pce) file. If you have not yet saved the source file, the editor queries you for a file name before compiling.

To edit or recompile an existing .pce file, select File | Open in the Package Collection editor and locate the file you want to work with.

Chapter

12

Creating international applications

This chapter discusses guidelines for writing applications that you plan to distribute to an international market. By planning ahead, you can reduce the amount of time and code necessary to make your application function in its foreign market as well as in its domestic market.

Internationalization and localization

To create an application that you can distribute to foreign markets, there are two major steps that need to be performed:

- Internationalization
- Localization

If your version of Delphi includes the Translation Tools, you can use the them to manage localization. For more information, see the online Help for the Translation Tools (ETM.hlp).

Internationalization

Internationalization is the process of enabling your program to work in multiple locales. A locale is the user's environment, which includes the cultural conventions of the target country as well as the language. Windows supports a large set of locales, each of which is described by a language and country pair.

Localization

Localization is the process of translating an application so that it functions in a specific locale. In addition to translating the user interface, localization may include functionality customization. For example, a financial application may be modified to be aware of the different tax laws in different countries.

Internationalizing applications

You need to complete the following steps to create internationalized applications:

- You must enable your code to handle strings from international character sets.
- You need to design your user interface so that it can accommodate the changes that result from localization.
- You need to isolate all resources that need to be localized.

Enabling application code

You must make sure that the code in your application can handle the strings it will encounter in the various target locales.

Character sets

The United States edition of Windows uses the ANSI Latin-1 (1252) character set. However, other editions of Windows use different character sets. For example, the Japanese version of Windows uses the Shift-JIS character set (code page 932), which represents Japanese characters as multibyte character codes.

There are generally three types of characters sets:

- Single-byte
- Multibyte
- Fixed-width multibyte

Windows and Linux both support single-byte and multibyte character sets as well as Unicode. With a single-byte character set, each byte in a string represents one character. The ANSI character set used by many Western operating systems is a single-byte character set.

In a multibyte character set, some characters are represented by one byte and others by more than one byte. The first byte of a multibyte character is called the lead byte. In general, the lower 128 characters of a multibyte character set map to the 7-bit ASCII characters, and any byte whose ordinal value is greater than 127 is the lead byte of a multibyte character. Only single-byte characters can contain the null value (#0). Multibyte character sets—especially double-byte character sets (DBCS)—are widely used for Asian languages, while the UTF-8 character set used by Linux is a multibyte encoding of Unicode.

OEM and ANSI character sets

It is sometimes necessary to convert between the Windows character set (ANSI) and the character set specified by the code page of the user's machine (called the OEM character set).

Multibyte character sets

The ideographic character sets used in Asia cannot use the simple 1:1 mapping between characters in the language and the one byte (8-bit) *char* type. These languages have too many characters to be represented using the 1-byte *char*. Instead, a multibyte string can contain one or more bytes per character. AnsiStrings can contain a mix of single-byte and multibyte characters.

The lead byte of every multibyte character code is taken from a reserved range that depends on the specific character set. The second and subsequent bytes can sometimes be the same as the character code for a separate 1-byte character, or it can fall in the range reserved for the first byte of multibyte characters. Thus, the only way to tell whether a particular byte in a string represents a single character or is part of a multibyte character is to read the string, starting at the beginning, parsing it into 2 or more byte characters when a lead byte from the reserved range is encountered.

When writing code for Asian locales, you must be sure to handle all string manipulation using functions that are enabled to parse strings into multibyte characters. Delphi provides you with many runtime library functions that allow you to do this, many of which are listed here:

AdjustLineBreaks
AnsiCompareFileName
AnsiExtractQuotedStr
AnsiLastChar
AnsiLowerCase
AnsiLowerCaseFileName
AnsiPos
AnsiQuotedStr
AnsiStrComp
AnsiStrIComp
AnsiStrLastChar
AnsiStrLComp
AnsiStrLIComp
AnsiStrLower
AnsiStrPos
AnsiStrRScan
AnsiStrScan
AnsiStrUpper
AnsiUpperCase
AnsiUpperCaseFileName
ByteToCharIndex
ByteToCharLen
ByteType
ChangeFileExt
CharToByteIndex
CharToByteLen
ExtractFileDir
ExtractFileExt
ExtractFileName
ExtractFilePath
ExtractRelativePath
FileSearch
IsDelimiter
IsPathDelimiter
LastDelimiter
StrByteType
StringReplace
WrapText

Remember that the length of the strings in bytes does not necessarily correspond to the length of the string in characters. Be careful not to truncate strings by cutting a multibyte character in half. Do not pass characters as a parameter to a function or procedure, since the size of a character can't be known up front. Instead, always pass a pointer to a character or a string.

Wide characters

Another approach to working with ideographic character sets is to convert all characters to a wide character encoding scheme such as Unicode. Unicode characters and strings are also called wide characters and wide character strings. In the Unicode character set, each character is represented by two bytes. Thus a Unicode string is a sequence not of individual bytes but of two-byte words.

The first 256 Unicode characters map to the ANSI character set. The Windows operating system supports Unicode (UCS-2). The Linux operating system supports UCS-4, a superset of UCS-2. Delphi/Kylix supports UCS-2 on both platforms. Because wide characters are two bytes instead of one, the character set can represent many more different characters.

Using a wide character encoding scheme has the advantage that you can make many of the usual assumptions about strings that do not work for MBCS systems. There is a direct relationship between the number of bytes in the string and the number of characters in the string. You do not need to worry about cutting characters in half or mistaking the second half of a character for the start of a different character.

The biggest disadvantage of working with wide characters is that Windows 9x only supports a few wide character API function calls. Because of this, the VCL components represent all string values as single byte or MBCS strings. Translating between the wide character system and the MBCS system every time you set a string property or read its value would require additional code and slow your application down. However, you may want to translate into wide characters for some special string processing algorithms that need to take advantage of the 1:1 mapping between characters and *WideChars*.

Including bi-directional functionality in applications

Some languages do not follow the left to right reading order commonly found in western languages, but rather read words right to left and numbers left to right. These languages are termed bi-directional (BiDi) because of this separation. The most common bi-directional languages are Arabic and Hebrew, although other Middle East languages are also bi-directional.

TApplication has two properties, *BiDiKeyboard* and *NonBiDiKeyboard*, that allow you to specify the keyboard layout. In addition, the VCL supports bi-directional localization through the *BiDiMode* and *ParentBiDiMode* properties. The following table lists VCL objects that have these properties:

Table 12.1 VCL objects that support BiDi

Component palette page	VCL object
Standard	TButton
	TCheckBox
	TComboBox
	TEdit
	TGroupBox
	TLabel

Table 12.1 VCL objects that support BiDi (continued)

Component palette page	VCL object
	TListBox
	TMainMenu
	TMemo
	TPanel
	TPopupMenu
	TRadioButton
	TRadioGroup
	TScrollBar
Additional	TActionMainMenuBar
	TActionToolBar
	TBitBtn
	TCheckListBox
	TColorBox
	TDrawGrid
	TLabeledEdit
	TMaskEdit
	TScrollBox
	TSpeedButton
	TStaticLabel
	TStaticText
	TStringGrid
	TValueListEditor
Win32	TComboBoxEx
	TDateTimePicker
	THeaderControl
	THotKey
	TListView
	TMonthCalendar
	TPageControl
	TRichEdit
	TStatusBar
	TTreeView
Data Controls	TDBCheckBox
	TDBComboBox
	TDBEdit
	TDBGrid
	TDBListBox
	TDBLookupComboBox
	TDBLookupListBox
	TDBMemo

Table 12.1 VCL objects that support BiDi (continued)

Component palette page	VCL object
	TDBRadioGroup
	TDBRichEdit
	TDBText
QReport	TQRDBText
	TQRExpr
	TQRLabel
	TQRMemo
	TQRPreview
	TQRSysData
Other classes	TApplication (has no *ParentBiDiMode*)
	TBoundLabel
	TControl (has no *ParentBiDiMode*)
	TCustomHeaderControl (has no *ParentBiDiMode*)
	TForm
	TFrame
	THeaderSection
	THintWindow (has no *ParentBiDiMode*)
	TMenu
	TStatusPanel
	TTabControl
	TValueListEditor

Notes *THintWindow* picks up the *BiDiMode* of the control that activated the hint.

Bi-directional properties

The objects listed in Table 12.1, "VCL objects that support BiDi," on page 12-4 have the properties *BiDiMode* and *ParentBiDiMode*. These properties, along with *TApplication*'s *BiDiKeyboard* and *NonBiDiKeyboard*, support bi-directional localization.

Note Bi-directional properties are not available in CLX for cross-platform programming.

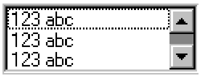
BiDiMode property

The property *BiDiMode* is a new enumerated type, *TBiDiMode*, with four states: *bdLeftToRight*, *bdRightToLeft*, *bdRightToLeftNoAlign*, and *bdRightToLeftReadingOnly.*

bdLeftToRight

bdLeftToRight draws text using left to right reading order, and the alignment and scroll bars are not changed. For instance, when entering right to left text, such as Arabic or Hebrew, the cursor goes into push mode and the text is entered right to left. Latin text, such as English or French, is entered left to right. *bdLeftToRight* is the default value.

Figure 12.1 TListBox set to bdLeftToRight

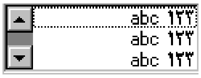


123 abc
123 abc
123 abc

bdRightToLeft

bdRightToLeft draws text using right to let reading order, the alignment is changed and the scroll bar is moved. Text is entered as normal for right-to-left languages such as Arabic or Hebrew. When the keyboard is changed to a Latin language, the cursor goes into push mode and the text is entered left-to-right.

Figure 12.2 TListBox set to bdRightToLeft

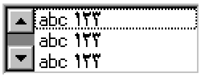


abc ١٢٣
abc ١٢٣
abc ١٢٣

bdRightToLeftNoAlign

bdRightToLeftNoAlign draws text using right to left reading order, the alignment is not changed, and the scroll bar is moved.

Figure 12.3 TListBox set to bdRightToLeftNoAlign

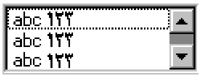


abc ١٢٣
abc ١٢٣
abc ١٢٣

bdRightToLeftReadingOnly

bdRightToLeftReadingOnly draws text using right to left reading order, and the alignment and scroll bars are not changed.

Figure 12.4 TListBox set to bdRightToLeftReadingOnly



abc ١٢٣
abc ١٢٣
abc ١٢٣

ParentBiDiMode property

ParentBiDiMode is a Boolean property. When *True* (the default) the control looks to its parent to determine what *BiDiMode* to use. If the control is a *TForm* object, the form uses the *BiDiMode* setting from *Application*. If all the *ParentBiDiMode* properties are *True*, when you change *Application's BiDiMode* property, all forms and controls in the project are updated with the new setting.

FlipChildren method

The *FlipChildren* method allows you to flip the position of a container control's children. Container controls are controls that can accept other controls, such as *TForm*, *TPanel*, and *TGroupBox*. *FlipChildren* has a single boolean parameter, *AllLevels*. When *False*, only the immediate children of the container control are flipped. When *True*, all the levels of children in the container control are flipped.

Delphi flips the controls by changing the Left property and the alignment of the control. If a control's left side is five pixels from the left edge of its parent control, after it is flipped the edit control's right side is five pixels from the right edge of the parent control. If the edit control is left aligned, calling *FlipChildren* will make the control right aligned.

To flip a control at design-time select Edit|Flip Children and select either All or Selected, depending on whether you want to flip all the controls, or just the children of the selected control. You can also flip a control by selecting the control on the form, right-clicking, and selecting Flip Children from the context menu.

Note Selecting an edit control and issuing a Flip Children|Selected command does nothing. This is because edit controls are not containers.

Additional methods

There are several other methods useful for developing applications for bi-directional users.

Method	Description
OkToChangeFieldAlignment	Used with database controls. Checks to see if the alignment of a control can be changed.
DBUseRightToLeftAlignment	A wrapper for database controls for checking alignment.
ChangeBiDiModeAlignment	Changes the alignment parameter passed to it. No check is done for *BiDiMode* setting, it just converts left alignment into right alignment and vice versa, leaving center-aligned controls alone.
IsRightToLeft	Returns *True* if any of the right to left options are selected. If it returns *False* the control is in left to right mode.
UseRightToLeftReading	Returns *True* if the control is using right to left reading.
UseRightToLeftAlignment	Returns *True* if the control is using right to left alignment. It can be overridden for customization.
UseRightToLeftScrollBar	Returns *True* if the control is using a left scroll bar.
DrawTextBiDiModeFlags	Returns the correct draw text flags for the BiDiMode of the control.
DrawTextBiDiModeFlagsReadingOnly	Returns the correct draw text flags for the *BiDiMode* of the control, limiting the flag to its reading order.
AddBiDiModeExStyle	Adds the appropriate *ExStyle* flags to the control that is being created.

Locale-specific features

You can add extra features to your application for specific locales. In particular, for Asian language environments, you may want your application to control the input method editor (IME) that is used to convert the keystrokes typed by the user into character strings.

VCL components offer support in programming the IME. Most windowed controls that work directly with text input have an *ImeName* property that allows you to specify a particular IME that should be used when the control has input focus. They also provide an *ImeMode* property that specifies how the IME should convert keyboard input. *TWinControl* introduces several protected methods that you can use to control the IME from classes you define. In addition, the global *Screen* variable provides information about the IMEs available on the user's system.

The global *Screen* variable (available in VCL and CLX) also provides information about the keyboard mapping installed on the user's system. You can use this to obtain locale-specific information about the environment in which your application is running.

Designing the user interface

When creating an application for several foreign markets, it is important to design your user interface so that it can accommodate the changes that occur during translation.

Text

All text that appears in the user interface must be translated. English text is almost always shorter than its translations. Design the elements of your user interface that display text so that there is room for the text strings to grow. Create dialogs, menus, status bars, and other user interface elements that display text so that they can easily display longer strings. Avoid abbreviations—they do not exist in languages that use ideographic characters.

Short strings tend to grow in translation more than long phrases. Table 12.2 provides a rough estimate of how much expansion you should plan for given the length of your English strings:

Table 12.2 Estimating string lengths

Length of English string (in characters)	Expected increase
1-5	100%
6-12	80%
13-20	60%
21-30	40%
31-50	20%
over 50	10%

Graphic images

Ideally, you will want to use images that do not require translation. Most obviously, this means that graphic images should not include text, which will always require translation. If you must include text in your images, it is a good idea to use a label object with a transparent background over an image rather than including the text as part of the image.

There are other considerations when creating graphic images. Try to avoid images that are specific to a particular culture. For example, mailboxes in different countries look very different from each other. Religious symbols are not appropriate if your application is intended for countries that have different dominant religions. Even color can have different symbolic connotations in different cultures.

Formats and sort order

The date, time, number, and currency formats used in your application should be localized for the target locale. If you use only the Windows formats, there is no need to translate formats, as these are taken from the user's Windows Registry. However, if you specify any of your own format strings, be sure to declare them as resourced constants so that they can be localized.

The order in which strings are sorted also varies from country to country. Many European languages include diacritical marks that are sorted differently, depending on the locale. In addition, in some countries, 2-character combinations are treated as a single character in the sort order. For example, in Spanish, the combination *ch* is sorted like a single unique letter between *c* and *d*. Sometimes a single character is sorted as if it were two separate characters, such as the German *eszett*.

Keyboard mappings

Be careful with key-combinations shortcut assignments. Not all the characters available on the US keyboard are easily reproduced on all international keyboards. Where possible, use number keys and function keys for shortcuts, as these are available on virtually all keyboards.

Isolating resources

The most obvious task in localizing an application is translating the strings that appear in the user interface. To create an application that can be translated without altering code everywhere, the strings in the user interface should be isolated into a single module. Delphi automatically creates a .dfm (.xfm in CLX applications) file that contains the resources for your menus, dialogs, and bitmaps.

In addition to these obvious user interface elements, you will need to isolate any strings, such as error messages, that you present to the user. String resources are not included in the form file. You can isolate them by declaring constants for them using the **resourcestring** keyword. For more information about resource string constants, see the Object Pascal Language Guide. It is best to include all resource strings in a single, separate unit.

Creating resource DLLs

Isolating resources simplifies the translation process. The next level of resource separation is the creation of a resource DLL. A resource DLL contains all the resources and only the resources for a program. Resource DLLs allow you to create a program that supports many translations simply by swapping the resource DLL.

Use the Resource DLL wizard to create a resource DLL for your program. The Resource DLL wizard requires an open, saved, compiled project. It will create an RC file that contains the string tables from used RC files and **resourcestring** strings of the project, and generate a project for a resource only DLL that contains the relevant forms and the created RES file. The RES file is compiled from the new RC file.

You should create a resource DLL for each translation you want to support. Each resource DLL should have a file name extension specific to the target locale. The first two characters indicate the target language, and the third character indicates the country of the locale. If you use the Resource DLL wizard, this is handled for you. Otherwise, use the following code to obtain the locale code for the target translation:

```
unit locales;

interface

uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
  StdCtrls;

type
  TForm1 = class(TForm)
    Button1: TButton;
    LocaleList: TListBox;
    procedure Button1Click(Sender: TObject);
  private
    { Private declarations }
  public
    { Public declarations }
  end;

var
  Form1: TForm1;

implementation

{$R *.DFM}

function GetLocaleData(ID: LCID; Flag: DWORD): string;
var
  BufSize: Integer;
begin
  BufSize := GetLocaleInfo(ID, Flag, nil, 0);
  SetLength(Result, BufSize);
  GetLocaleinfo(ID, Flag, PChar(Result), BufSize);
  SetLength(Result, BufSize - 1);
end;

{ Called for each supported locale. }
function LocalesCallback(Name: PChar): Bool; stdcall;
var
  LCID: Integer;
begin
  LCID := StrToInt('$' + Copy(Name, 5, 4));
  Form1.LocaleList.Items.Add(GetLocaleData(LCID, LOCALE_SLANGUAGE));
  Result := Bool(1);
end;

procedure TForm1.Button1Click(Sender: TObject);
var
  I: Integer;
begin
```

```
    with Languages do
    begin
      for I := 0 to Count - 1 do
      begin
        ListBox1.Items.Add(Name[I]);
      end;
    end;
  end;
```

Using resource DLLs

The executable, DLLs, and packages that make up your application contain all the necessary resources. However, to replace those resources by localized versions, you need only ship your application with localized resource DLLs that have the same name as your EXE, DLL, or BPL files.

When your application starts up, it checks the locale of the local system. If it finds any resource DLLs with the same name as the EXE, DLL, or BPL files it is using, it checks the extension on those DLLs. If the extension of the resource module matches the language and country of the system locale, your application will use the resources in that resource module instead of the resources in the executable, DLL, or package. If there is not a resource module that matches both the language and the country, your application will try to locate a resource module that matches just the language. If there is no resource module that matches the language, your application will use the resources compiled with the executable, DLL, or package.

If you want your application to use a different resource module than the one that matches the locale of the local system, you can set a locale override entry in the Windows registry. Under the HKEY_CURRENT_USER\Software\Borland\Locales key, add your application's path and file name as a string value and set the data value to the extension of your resource DLLs. At startup, the application will look for resource DLLs with this extension before trying the system locale. Setting this registry entry allows you to test localized versions of your application without changing the locale on your system.

For example, the following procedure can be used in an install or setup program to set the registry key value that indicates the locale to use when loading Delphi applications:

```
procedure SetLocalOverrides(FileName: string, LocaleOverride: string);
var
  Reg: TRegistry;
begin
  Reg := TRegistry.Create;
  try
    if Reg.OpenKey('Software\Borland\Locales', True) then
      Reg.WriteString(LocalOverride, FileName);
  finally
    Reg.Free;
end;
```

Within your application, use the global *FindResourceHInstance* function to obtain the handle of the current resource module. For example:

```
LoadStr(FindResourceHInstance(HInstance), IDS_AmountDueName, szQuery, SizeOf(szQuery));
```

You can ship a single application that adapts itself automatically to the locale of the system it is running on, simply by providing the appropriate resource DLLs.

Dynamic switching of resource DLLs

In addition to locating a resource DLL at application startup, it is possible to switch resource DLLs dynamically at runtime. To add this functionality to your own applications, you need to include the ReInit unit in your **uses** statement. (ReInit is located in the Richedit sample in the Demos directory.) To switch languages, you should call *LoadResourceModule*, passing the LCID for the new language, and then call *ReinitializeForms*.

For example, the following code switches the interface language to French:

```
const
  FRENCH = (SUBLANG_FRENCH shl 10) or LANG_FRENCH;
if LoadNewResourceModule(FRENCH) <> 0 then
  ReinitializeForms;
```

The advantage of this technique is that the current instance of the application and all of its forms are used. It is not necessary to update the registry settings and restart the application or reacquire resources required by the application, such as logging in to database servers.

When you switch resource DLLs the properties specified in the new DLL overwrite the properties in the running instances of the forms.

Note Any changes made to the form properties at runtime will be lost. Once the new DLL is loaded, default values are not reset. Avoid code that assumes that the form objects are reinitialized to the their startup state, apart from differences due to localization.

Localizing applications

Once your application is internationalized, you can create localized versions for the different foreign markets in which you want to distribute it.

Localizing resources

Ideally, your resources have been isolated into a resource DLL that contains form files (.dfm or .xfm) and a resource file. You can open your forms in the IDE and translate the relevant properties.

Note In a resource DLL project, you cannot add or delete components. It is possible, however, to change properties in ways that could cause runtime errors, so be careful to modify only those properties that require translation. To avoid mistakes, you can configure the Object Inspector to display only localizable properties; to do so, right-click in the Object Inspector and use the View menu to filter out unwanted property categories.

You can open the RC file and translate relevant strings. Use the StringTable editor by opening the RC file from the Project Manager.

Chapter

13

Deploying applications

Once your Delphi application is up and running, you can deploy it. That is, you can make it available for others to run. A number of steps must be taken to deploy an application to another computer so that the application is completely functional. What is required by a given application varies, depending on the type of application. The following sections describe considerations when deploying different types of applications:

- Deploying general applications
- Deploying CLX applications
- Deploying database applications
- Deploying Web applications
- Programming for varying host environments
- Software license requirements

Note Information included in these sections is for deploying applications on Windows. If writing cross-platform applications for deployment on Linux, you need to refer to deployment information provided in your Kylix documentation.

Deploying general applications

Beyond the executable file, an application may require a number of supporting files, such as DLLs, package files, and helper applications. In addition, the Windows registry may need to contain entries for an application, from specifying the location of supporting files to simple program settings. The process of copying an application's files to a computer and making any needed registry settings can be automated by an installation program, such as InstallShield Express. These are the main deployment concerns common to nearly all types of applications:

- Using installation programs
- Identifying application files

Delphi applications that access databases and those that run across the Web require additional installation steps beyond those that apply to general applications. For additional information on installing database applications, see “Deploying database applications” on page 13-6. For more information on installing Web applications, see “Deploying Web applications” on page 13-9. For more information on installing ActiveX controls, see “Deploying an ActiveX control on the Web” on page 38-15.

Using installation programs

Simple Delphi applications that consist of only an executable file are easy to install on a target computer. Just copy the executable file onto the computer. However, more complex applications that comprise multiple files require more extensive installation procedures. These applications require dedicated installation programs.

Setup toolkits automate the process of creating installation programs, often without needing to write any code. Installation programs created with Setup toolkits perform various tasks inherent to installing Delphi applications, including: copying the executable and supporting files to the host computer, making Windows registry entries, and installing the Borland Database Engine for BDE database applications.

InstallShield Express is a setup toolkit that is bundled with Delphi. InstallShield Express is certified for use with Delphi and the Borland Database Engine. It is based on Windows Installer (MSI) technology.

InstallShield Express is not automatically installed when Delphi is installed, so it must be manually installed if you want to use it to create installation programs. Run the installation program from the Delphi CD to install InstallShield Express. For more information on using InstallShield Express to create installation programs, see the InstallShield Express online help.

Other setup toolkits are available. However, if deploying BDE database applications, you should only use toolkits based on MSI technology and those which are certified to deploy the Borland Database Engine.

Identifying application files

Besides the executable file, a number of other files may need to be distributed with an application.

- Application files
- Package files
- Merge modules
- ActiveX controls

Application files

The following types of files may need to be distributed with an application.

Table 13.1 Application files

Type	File name extension
Program files	.exe and .dll
Package files	.bpl and .dcp
Help files	.hlp, .cnt, and .toc (if used) or any other help files your application supports
ActiveX files	.ocx (sometimes supported by a DLL)
Local table files	.dbf, .mdx, .dbt, .ndx, .db, .px, .y*, .x*, .mb, .val, .qbe, .gd*

Package files

If the application uses runtime packages, those package files need to be distributed with the application. InstallShield Express handles the installation of package files the same as DLLs, copying the files and making necessary entries in the Windows registry. You can also use merge modules for deploying runtime packages with MSI-based setup tools including InstallShield Express. See the next section for details.

Borland recommends installing the runtime package files supplied by Borland in the Windows\System directory. This serves as a common location so that multiple applications would have access to a single instance of the files. For packages you created, it is recommended that you install them in the same directory as the application. Only the .BPL files need to be distributed.

Note If deploying packages with CLX applications, you need to include clx60.bpl rather than vcl60.bpl.

If you are distributing packages to other developers, supply both the .BPL and the .DCP files.

Merge modules

InstallShield Express 3.0 is based on Windows Installer (MSI) technology. That is why Delphi includes merge modules. Merge modules provide a standard method that you can use to deliver shared code, files, resources, Registry entries, and setup logic to applications as a single compound file. You can use merge modules for deploying runtime packages with MSI-based setup tools including InstallShield Express.

The runtime libraries have some interdependencies because of the way they are grouped together. The result of this is that when one package is added to an install project, the install tool will automatically add or report a dependency on one or more other packages.For example, if you add the VCLInternet merge module to an install project, the install tool should also automatically add or report a dependency on the VCLDatabase and StandardVCL modules.

The dependencies for each merge module are listed in the table below. The various install tools may react to these dependencies differently. The InstallShield for Windows Installer automatically adds the required modules if it can find them.

Other tools may simply report a dependency or may generate a build failure if all required modules are not included in the project.

Table 13.2 Merge modules and their dependencies

Merge module	BPLs included	Dependencies
ADORTL	adortl60.bpl	DatabaseRTL, BaseRTL
BaseClientDataSet	cds60.bpl	DatabaseRTL, BaseRTL, DataSnap, dbExpress
BaseRTL	rtl60.bpl	No dependencies
BaseVCL	vcl60.bpl, vclx60.bpl	BaseRTL
BDEClientDataSet	bdecds60.bpl	BaseClientDataSet, DataBaseRTL, BaseRTL, DataSnap, dbExpress, BDERTL
BDEInternet	inetdbbde60.bpl	Internet, DatabaseRTL, BaseRTL, BDERTL
BDERTL	bdertl60.bpl	DatabaseRTL, BaseRTL
DatabaseRTL	dbrtl60.bpl	BaseRTL
DatabaseVCL	vcldb60.bpl	BaseVCL, DatabaseRTL, BaseRTL
DataSnap	dsnap60.bpl	DatabaseRTL, BaseRTL
DataSnapConnection	dsnapcon60.bpl	DataSnap, DatabaseRTL, BaseRTL
DataSnapCorba	dsnapcrba60.bpl	DataSnapConnection, DataSnap, DatabaseRTL, BaseRTL, BaseVCL
DataSnapEntera	dsnapent60.bpl	DataSnap, DatabaseRTL, BaseRTL, BaseVCL
DBCompatVCL	vcldbx60.bpl	DatabaseVCL, BaseVCL, BaseRTL
dbExpress	dbexpress60.bpl	DatabaseRTL, BaseRTL
dbExpressClientDataSet	dbxcds60.bpl	BaseClientDataSet, DataBaseRTL, BaseRTL, DataSnap, dbExpress
DBXInternet	inetdbxpress60.bpl	Internet, DatabaseRTL, BaseRTL, dbExpress, DatabaseVCL, BaseVCL
DecisionCube	dss60.bpl	TeeChart, BaseVCL, BaseRTL, DatabaseVCL, DatabaseRTL, BDERTL
FastNet	nmfast60.bpl	BaseVCL, BaseRTL
InterbaseVCL	vclib60.bpl	BaseClientDataSet, DatabaseRTL, BaseRTL, DataSnap, dbExpress, BaseVCL
Internet	inet60.bpl, inetdb60.bpl	DatabaseRTL, BaseRTL
InternetDirect	indy60.bpl	BaseVCL, BaseRTL
Office2000Components	dcloffice2k60.bpl	DatabaseVCL, BaseVCL, DatabaseRTL, BaseRTL
QuickReport	qrpt60.bpl	BaseVCL, BaseRTL, BDERTL, DatabaseRTL
SampleVCL	vclsmp60.bpl	BaseVCL, BaseRTL
TeeChart	tee60.bpl, teedb60.bpl, teeqr60.bpl, teeui60.bpl	BaseVCL, BaseRTL
VCLIE	vclie60.bpl	BaseVCL, BaseRTL
VisualCLX	visualclx60.bpl	BaseRTL
WebDataSnap	webdsnap60.bpl	XMLRTL, Internet, DataSnapConnection, DataSnap, DatabaseRTL, BaseRTL

Table 13.2 Merge modules and their dependencies (continued)

Merge module	BPLs included	Dependencies
WebSnap	websnap60.bpl, vcljpg60.bpl	WebDataSnap, XMLRTL, Internet, DataSnapConnection, DataSnap, DatabaseRTL, BaseRTL, BaseVCL
XMLRTL	xmlrtl60.bpl	Internet, DatabaseRTL, BaseRTL

ActiveX controls

Certain components bundled with Delphi are ActiveX controls. The component wrapper is linked into the application's executable file (or a runtime package), but the .OCX file for the component also needs to be deployed with the application. These components include

- Chart FX, copyright SoftwareFX Inc.
- VisualSpeller Control, copyright Visual Components, Inc.
- Formula One (spreadsheet), copyright Visual Components, Inc.
- First Impression (VtChart), copyright Visual Components, Inc.
- Graph Custom Control, copyright Bits Per Second Ltd.

ActiveX controls of your own creation need to be registered on the deployment computer before use. Installation programs such as InstallShield Express automate this registration process. To manually register an ActiveX control, use the TRegSvr demo application or the Microsoft utility REGSRV32.EXE (not included with all Windows versions).

DLLs that support an ActiveX control also need to be distributed with an application.

Helper applications

Helper applications are separate programs without which your Delphi application would be partially or completely unable to function. Helper applications may be those supplied with the operating system, by Borland, or they might be third-party products. An example of a helper application is the InterBase utility program Server Manager, which administers InterBase databases, users, and security.

If an application depends on a helper program, be sure to deploy it with your application, where possible. Distribution of helper programs may be governed by redistribution license agreements. Consult the documentation for the helper for specific information.

DLL locations

You can install .dll files used only by a single application in the same directory as the application. DLLs that will be used by a number of applications should be installed in a location accessible to all of those applications. A common convention for locating such community DLLs is to place them either in the Windows or the Windows\ System directory. A better way is to create a dedicated directory for the common .dll files, similar to the way the Borland Database Engine is installed.

Deploying CLX applications

If you are writing cross-platform applications that will be deployed on both Windows and Linux, you need to compile and deploy the applications on both platforms. The steps for deploying CLX applications are the same as those for general applications. For information on deploying general applications, see “Deploying general applications” on page 13-1. For information on installing database CLX applications, see “Deploying database applications” on page 13-6.

Note When deploying CLX applications on Windows, you need to include qtintf.dll with the application to include the CLX runtime. If deploying packages with CLX applications, you need to include clx60.bpl rather than vcl60.bpl.

See Chapter 10, “Using CLX for cross-platform development” for information on writing CLX applications.

Deploying database applications

Applications that access databases involve special installation considerations beyond copying the application’s executable file onto the host computer. Database access is most often handled by a separate database engine, the files of which cannot be linked into the application’s executable file. The data files, when not created beforehand, must be made available to the application. Multi-tier database applications require even more specialized handling on installation, because the files that make up the application are typically located on multiple computers.

Since several different database technologies (ADO, BDE, dbExpress, and InterBase Express) are supported, deployment requirements differ for each. Regardless of which you are using, you need to make sure that the client side software is installed on the system where you plan to run the database application. BDE, ADO, and dbExpress also require drivers to interact with the client-side software of the database. InterBase does not require drivers because the IBX components communicate directly with the database.

Specific information on how to deploy dbExpress, BDE, and multi-tiered database applications is described in the following sections:

- Deploying dbExpress database applications
- Deploying BDE applications
- Deploying multi-tiered database applications (DataSnap)

Database applications that use client datasets such as *TClientDataSet* or *TSQLClientDataSet* or dataset providers require you to include libmidas.dcu and crtl.dcu (for static linking when providing a standalone executable); if you are packaging your application (with the executable and any needed DLLs), you need to include Midas.dll.

If deploying database applications that use ADO, you need to be sure that MDAC version 2.1 or later is installed on the system where you plan to run the application. MDAC is automatically installed with software such as Windows 2000 and Internet Explorer version 5 or later. You also need to be sure the drivers for the database server you want to connect to are installed on the client. No other deployment steps are required.

If deploying database applications that use InterBase Express, you need to be sure that the InterBase client is installed on the system where you plan to run the application. InterBase requires gd32.dll and interbase.msg to be located in an accessible directory. No other deployment steps are required. InterBase Express components communicate directly with the database and do not require additional drivers. For more information, refer to the Embedded Installation Guide posted on the Borland Web site.

In addition to the technologies described here, you can also use third-party database engines to provide database access for Delphi applications. Consult the documentation or vendor for the database engine regarding redistribution rights, installation, and configuration.

Deploying dbExpress database applications

dbExpress is a set of drivers that provide fast access to database information. dbExpress components support cross-platform development because they are also available on Linux. Refer to Chapter 22, “Using unidirectional datasets” for more information about using the dbExpress components.

You can deploy dbExpress applications either as a stand-alone executable file or as an executable file that includes associated dbExpress driver DLLs.

To deploy dbExpress applications as standalone executable files, the dbExpress object files must be statically linked into your executable. You do this by including the following DCUs, located in the lib directory:

Table 13.3 dbExpress deployment as standalone executable

Database unit	When to include
dbExpInt	Applications connecting to InterBase databases
dbExpOra	Applications connecting to Oracle databases
dbExpDb2	Applications connecting to DB2 databases
dbExpMy	Applications connecting to MySQL databases
Crtl, MidasLib	Required by dbExpress executables that use client datasets such as *TSQLClientDataSet*

If you are not deploying a standalone executable, you can deploy associated dbExpress drivers and DataSnap DLLs with your executable. The following table lists the appropriate DLLs and when to include them:

Table 13.4 dbExpress deployment with driver DLLs

Database DLL	When to deploy
dbexpint.dll	Applications connecting to InterBase databases
dbexpora.dll	Applications connecting to Oracle databases
dbexpdb2.dll.	Applications connecting to DB2 databases
dbexpmy.dll	Applications connecting to MySQL databases
Midas.dll	Required by database applications that use client datasets

Deploying BDE applications

The Borland Database Engine (BDE) defines a large API for interacting with databases. Of all the data access mechanisms, the BDE supports the broadest range of functions and comes with the most supporting utilities. It is the best way to work with data in Paradox or dBASE tables.

Database access for an application is provided by various database engines. An application can use the BDE or a third-party database engine. SQL Links is provided (not available in all versions) to enable native access to SQL database systems. The following sections describe installation of the database access elements of an application:

- Borland Database Engine
- SQL Links

Borland Database Engine

For standard Delphi data components to have database access, the Borland Database Engine (BDE) must be present and accessible. See the BDEDEPLOY document for specific rights and limitations on redistributing the BDE.

Borland recommends use of InstallShield Express (or other certified installation program) for installing the BDE. InstallShield Express will create the necessary registry entries and define any aliases the application may require. Using a certified installation program to deploy the BDE files and subsets is important because:

- Improper installation of the BDE or BDE subsets can cause other applications using the BDE to fail. Such applications include not only Borland products, but many third-party programs that use the BDE.
- Under Windows 9x and Windows NT, BDE configuration information is stored in the Windows registry instead of .INI files, as was the case under 16-bit Windows. Making the correct entries and deletions for install and uninstall is a complex task.

It is possible to install only as much of the BDE as an application actually needs. For instance, if an application only uses Paradox tables, it is only necessary to install that portion of the BDE required to access Paradox tables. This reduces the disk space needed for an application. Certified installation programs, like InstallShield Express, are capable of performing partial BDE installations. Be sure to leave BDE system files that are not used by the deployed application, but that are needed by other programs.

SQL Links

SQL Links provides the drivers that connect an application (through the Borland Database Engine) with the client software for an SQL database. See the DEPLOY document for specific rights and limitations on redistributing SQL Links. As is the case with the Borland Database Engine (BDE), SQL Links must be deployed using InstallShield Express (or other certified installation program).

Note SQL Links only connects the BDE to the client software, not to the SQL database itself. It is still necessary to install the client software for the SQL database system used. See the documentation for the SQL database system or consult the vendor that supplies it for more information on installing and configuring client software.

Table 13.5 shows the names of the driver and configuration files SQL Links uses to connect to the different SQL database systems. These files come with SQL Links and are redistributable in accordance with the Delphi license agreement.

Table 13.5 SQL database client software files

Vendor	Redistributable files
Oracle 7	SQLORA32.DLL and SQL_ORA.CNF
Oracle8	SQLORA8.DLL and SQL_ORA8.CNF
Sybase Db-Lib	SQLSYB32.DLL and SQL_SYB.CNF
Sybase Ct-Lib	SQLSSC32.DLL and SQL_SSC.CNF
Microsoft SQL Server	SQLMSS32.DLL and SQL_MSS.CNF
Informix 7	SQLINF32.DLL and SQL_INF.CNF
Informix 9	SQLINF9.DLL and SQL_INF9.CNF
DB/2	SQLDB232.DLL and SQL_DB2.CNF
InterBase	SQLINT32.DLL and SQL_INT.CNF

Install SQL Links using InstallShield Express or other certified installation program. For specific information concerning the installation and configuration of SQL Links, see the help file SQLLNK32.HLP, by default installed into the main BDE directory.

Deploying multi-tiered database applications (DataSnap)

DataSnap provides multi-tier database capability to Delphi applications by allowing client applications to connect to providers in an application server.

Install DataSnap along with a multi-tier application using InstallShield Express (or other Borland-certified installation scripting utility). See the DEPLOY document (found in the main Delphi directory) for details on the files that need to be redistributed with an application. Also see the REMOTE document for related information on what DataSnap files can be redistributed and how.

Deploying Web applications

Some Delphi applications are designed to be run over the World Wide Web, such as those in the form of Server-side Extension DLLs (ISAPI and Apache), CGI applications, and ActiveForms.

The steps for deploying Web applications are the same as those for general applications, except the application's files are deployed on the Web server. For information on installing general applications, see "Deploying general applications" on page 13-1. For information on deploying database Web applications, see "Deploying database applications" on page 13-6.

Here are some special considerations for deploying Web applications:

- For BDE database applications, the Borland Database Engine (or alternate database engine) is installed with the application files on the Web server.
- For dbExpress applications, the dbExpress DLLs must be included in the path. If included, the dbExpress driver is installed with the application files on the Web server.
- Security for the directories should be set so that the application can access all needed database files.
- The directory containing an application must have read and execute attributes.
- The application should not use hard-coded paths for accessing database or other files.
- The location of an ActiveX control is indicated by the CODEBASE parameter of the <OBJECT> HTML tag.

Deployment on Apache is described in the next section.

Deployment on Apache

WebBroker supports Apache version 1.3.9 and later for DLLs and CGI applications. Apache is configured by files in the conf directory.

If creating Apache DLLs, you need to be sure to set appropriate directives in the Apache server configuration file, called httpd.conf. The DLL should be physically located in the Modules subdirectory of the Apache software.

If creating CGI applications, the physical directory (specified in the Directory directive of the httpd.conf file) must have the ExecCGI option set to allow execution of programs so the CGI script can be executed. To ensure that permissions are set up properly, you need to either use the ScriptAlias directive or set Options ExecCGI to on.

The ScriptAlias directive creates a virtual directory on your server and marks the target directory as containing CGI scripts. For example, you could add the following line to your httpd.conf file:

```
ScriptAlias /cgi-bin "c:\inetpub\cgi-bin"
```

This would cause requests such as /cgi-bin/mycgi to be satisfied by running the script c:\inetpub\cgi-bin\mycgi.

You can also set Options to All or to ExecCGI using the Directory directive in httpd.conf. The Options directive controls which server features are available in a particular directory. Directory directives are used to enclose a set of directives that apply to the named directory and its subdirectories. An example of the Directory directive is shown below:

```
<Directory <apache-root-dir>\cgi-bin>
    AllowOverride None
    Options ExecCGI
    Order allow,deny
    Allow from all
</Directory>
```

In this example, Options is set to ExecCGI permitting execution of CGI scripts in the directory cgi-bin.

Note Apache executes locally on the server within the account specified in the User directive in the httpd.conf file. Make sure that the user has the appropriate rights to access the resources needed by the application.

Information concerning the deployment of Apache software can be found in the Apache LICENSE file, which is included in the Apache distribution. You can also find configuration information on the Apache Web site at www.apache.org.

Programming for varying host environments

Due to the nature of various operating system environments, there are a number of factors that vary with user preference or configuration. The following factors can affect an application deployed to another computer:

- Screen resolutions and color depths
- Fonts
- Operating systems versions
- Helper applications
- DLL locations

Screen resolutions and color depths

The size of the desktop and number of available colors on a computer is configurable and dependent on the hardware installed. These attributes are also likely to differ on the deployment computer compared to those on the development computer.

An application's appearance (window, object, and font sizes) on computers configured for different screen resolutions can be handled in various ways:

- Design the application for the lowest resolution users will have (typically, 640x480). Take no special actions to dynamically resize objects to make them proportional to the host computer's screen display. Visually, objects will appear smaller the higher the resolution is set.
- Design using any screen resolution on the development computer and, at runtime, dynamically resize all forms and objects proportional to the difference between the screen resolutions for the development and deployment computers (a screen resolution difference ratio).
- Design using any screen resolution on the development computer and, at runtime, dynamically resize only the application's forms. Depending on the location of visual controls on the forms, this may require the forms be scrollable for the user to be able to access all controls on the forms.

Considerations when not dynamically resizing

If the forms and visual controls that make up an application are not dynamically resized at runtime, design the application's elements for the lowest resolution.

Otherwise, the forms of an application run on a computer configured for a lower screen resolution than the development computer may overlap the boundaries of the screen.

For example, if the development computer is set up for a screen resolution of 1024x768 and a form is designed with a width of 700 pixels, not all of that form will be visible within the desktop on a computer configured for a 640x480 screen resolution.

Considerations when dynamically resizing forms and controls

If the forms and visual controls for an application are dynamically resized, accommodate all aspects of the resizing process to ensure optimal appearance of the application under all possible screen resolutions. Here are some factors to consider when dynamically resizing the visual elements of an application:

- The resizing of forms and visual controls is done at a ratio calculated by comparing the screen resolution of the development computer to that of the computer onto which the application installed. Use a constant to represent one dimension of the screen resolution on the development computer: either the height or the width, in pixels. Retrieve the same dimension for the user's computer at runtime using the *TScreen.Height* or the *TScreen.Width* property. Divide the value for the development computer by the value for the user's computer to derive the difference ratio between the two computers' screen resolutions.
- Resize the visual elements of the application (forms and controls) by reducing or increasing the size of the elements and their positions on forms. This resizing is proportional to the difference between the screen resolutions on the development and user computers. Resize and reposition visual controls on forms automatically by setting the *CustomForm.Scaled* property to *True* and calling the *TWinControl.ScaleBy* method (*TWidgetControl.ScaleBy* for cross-platform applications). The *ScaleBy* method does not change the form's height and width, though. Do this manually by multiplying the current values for the *Height* and *Width* properties by the screen resolution difference ratio.
- The controls on a form can be resized manually, instead of automatically with the *TWinControl.ScaleBy* method (*TWidgetControl.ScaleBy* for cross-platform applications), by referencing each visual control in a loop and setting its dimensions and position. The *Height* and *Width* property values for visual controls are multiplied by the screen resolution difference ratio. Reposition visual controls proportional to screen resolution differences by multiplying the *Top* and *Left* property values by the same ratio.
- If an application is designed on a computer configured for a higher screen resolution than that on the user's computer, font sizes will be reduced in the process of proportionally resizing visual controls. If the size of the font at design time is too small, the font as resized at runtime may be unreadable. For example, the default font size for a form is 8. If the development computer has a screen resolution of 1024x768 and the user's computer 640x480, visual control dimensions will be reduced by a factor of 0.625 (640 / 1024 = 0.625). The original font size of 8 is reduced to 5 (8 * 0.625 = 5). Text in the application appears jagged and unreadable as it is displayed in the reduced font size.

- Some visual controls, such as *TLabel* and *TEdit*, dynamically resize when the size of the font for the control changes. This can affect deployed applications when forms and controls are dynamically resized. The resizing of the control due to font size changes are in addition to size changes due to proportional resizing for screen resolutions. This effect is offset by setting the *AutoSize* property of these controls to *False*.
- Avoid making use of explicit pixel coordinates, such as when drawing directly to a canvas. Instead, modify the coordinates by a ratio proportionate to the screen resolution difference ratio between the development and user computers. For example, if the application draws a rectangle to a canvas ten pixels high by twenty wide, instead multiply the ten and twenty by the screen resolution difference ratio. This ensures that the rectangle visually appears the same size under different screen resolutions.

Accommodating varying color depths

To account for all deployment computers not being configured with the same color availability, the safest way is to use graphics with the least possible number of colors. This is especially true for control glyphs, which should typically use 16-color graphics. For displaying pictures, either provide multiple copies of the images in different resolutions and color depths or explain in the application the minimum resolution and color requirements for the application.

Fonts

The Windows and Linux operating systems come with a standard sets of fonts. When designing an application to be deployed on other computers, realize that not all computers will have fonts outside the standard sets.

Text components used in the application should all use fonts that are likely to be available on all deployment computers.

When use of a nonstandard font is absolutely necessary in an application, you need to distribute that font with the application. Either the installation program or the application itself must install the font on the deployment computer. Distribution of third-party fonts may be subject to limitations imposed by the font creator.

Windows has a safety measure to account for attempts to use a font that does not exist on the computer. It substitutes another, existing font that it considers the closest match. While this may circumvent errors concerning missing fonts, the end result may be a degradation of the visual appearance of the application. It is better to prepare for this eventuality at design time.

To make a nonstandard font available to a Windows application, use the Windows API functions *AddFontResource* and *DeleteFontResource*. Deploy the .fot file for the nonstandard font with the application.

Operating systems versions

When using operating system APIs or accessing areas of the operating system from an application, there is the possibility that the function, operation, or area may not be available on computers with different operating system versions.

To account for this possibility, you have a few options:

- Specify in the application's system requirements the versions of the operating system on which the application can run. It is the user's responsibility to install and use the application only under compatible operating system versions.
- Check the version of the operating system as the application is installed. If an incompatible version of the operating system is present, either halt the installation process or at least warn the installer of the problem.
- Check the operating system version at runtime, just prior to executing an operation not applicable to all versions. If an incompatible version of the operating system is present, abort the process and alert the user. Alternately, provide different code to run dependent on different operating system versions. For example, some operations are performed differently on Windows 95/98 than on Windows NT/2000. Use the Windows API function *GetVersionEx* to determine the Windows version.

Software license requirements

The distribution of some files associated with Delphi applications is subject to limitations or cannot be redistributed at all. The following documents describe the legal stipulations regarding the distribution of these files:

- DEPLOY
- README
- No-nonsense license agreement
- Third-party product documentation

DEPLOY

DEPLOY covers the some of the legal aspects of distributing of various components and utilities, and other product areas that can be part of or associated with a Delphi application. DEPLOY is a document installed in the main Delphi directory. The topics covered include

- .exe, .dll, and .bpl files
- Components and design-time packages
- Borland Database Engine (BDE)
- ActiveX controls
- Sample Images
- SQL Links

README

README contains last minute information about Delphi, possibly including information that could affect the redistribution rights for components, or utilities, or other product areas. README is a document installed into the main Delphi directory.

No-nonsense license agreement

The Delphi no-nonsense license agreement, a printed document, covers other legal rights and obligations concerning Delphi.

Third-party product documentation

Redistribution rights for third-party components, utilities, helper applications, database engines, and other products are governed by the vendor supplying the product. Consult the documentation for the product or the vendor for information regarding the redistribution of the product with Delphi applications prior to distribution.

Part

II

Developing database applications

The chapters in “Developing Database Applications” present concepts and skills necessary for creating Delphi database applications.

Note You need the Professional or Enterprise edition of Delphi to develop database applications. To implement more advanced Client/Server databases, you need the Delphi features available in the Enterprise edition.

Chapter

14

Designing database applications

Database applications let users interact with information that is stored in databases. Databases provide structure for the information, and allow it to be shared among different applications.

Delphi provides support for relational database applications. Relational databases organize information into tables, which contain rows (records) and columns (fields). These tables can be manipulated by simple operations known as the relational calculus.

When designing a database application, you must understand how the data is structured. Based on that structure, you can then design a user interface to display data to the user and allow the user to enter new information or modify existing data.

This chapter introduces some common considerations for designing a database application and the decisions involved in designing a user interface.

Using databases

Delphi includes many components for accessing databases and representing the information they contain. They are grouped according to the data access mechanism:

- The BDE page of the component palette contains components that use the Borland Database Engine (BDE). The BDE defines a large API for interacting with databases. Of all the data access mechanisms, the BDE supports the broadest range of functions and comes with the most supporting utilities. It is the best way to work with data in Paradox or dBASE tables. However, it is also the most complicated mechanism to deploy. For more information about using the BDE components, see Chapter 20, “Using the Borland Database Engine.”
- The ADO page of the component palette contains components that use ActiveX Data Objects (ADO) to access database information through OLEDB. ADO is a Microsoft Standard. There is a broad range of ADO drivers available for connecting to different database servers. Using ADO-based components lets you

integrate your application into an ADO-based environment (for example, making use of ADO-based application servers). For more information about using the ADO components, see Chapter 21, “Working with ADO components”.

- The dbExpress page of the component palette contains components that use dbExpress to access database information. dbExpress is a lightweight set of drivers that provide the fastest access to database information. In addition, dbExpress components support cross-platform development because they are also available on Linux. However, dbExpress database components also support the narrowest range of data manipulation functions. For more information about using the dbExpress components, see Chapter 22, “Using unidirectional datasets”.
- The InterBase page of the Component palette contains components that access InterBase databases directly, without going through a separate engine layer.
- The Data Access page of the component palette contains components that can be used with any data access mechanism. This page includes *TClientDataset*, which can work with data stored on disk or, using the *TDataSetProvider* component also on this page, with components from one of the other groups. For more information about using client datasets, see Chapter 23, “Using client datasets”. For more information about *TDataSetProvider*, see Chapter 24, “Using provider components”.

Note Different versions of Delphi include different drivers for accessing database servers using the BDE, ADO, or dbExpress.

When designing a database application, you must decide which set of components to use. Each data access mechanism differs in its range of functional support, the ease of deployment, and the availability of drivers to support different database servers.

In addition to choosing a data access mechanism, you must choose a database server. There are different types of databases and you will want to consider the advantages and disadvantages of each type before settling on a particular database server.

All types of databases contain tables which store information. In addition, most (but not all) servers support additional features such as

- Database security
- Transactions
- Referential integrity, stored procedures, and triggers

Types of databases

Relational database servers vary in the way they store information and in the way they allow multiple users to access that information simultaneously. Delphi provides support for two types of relational database server:

- **Remote database servers** reside on a separate machine. Sometimes, the data from a remote database server does not even reside on a single machine, but is distributed over several servers. Although remote database servers vary in the way they store information, they provide a common logical interface to clients. This common interface is Structured Query Language (SQL). Because you access them using SQL, they are sometimes called SQL servers. (Another name is Remote

Database Management system, or RDBMS.) In addition to the common commands that make up SQL, most remote database servers support a unique “dialect” of SQL. Examples of SQL servers include InterBase, Oracle, Sybase, Informix, Microsoft SQL server, and DB2.

- **Local databases** reside on your local drive or on a local area network. They often have proprietary APIs for accessing the data. When they are shared by several users, they use file-based locking mechanisms. Because of this, they are sometimes called file-based databases. Examples of local databases include Paradox, dBASE, FoxPro, and Access.

Applications that use local databases are called **single-tiered applications** because the application and the database share a single file system. Applications that use remote database servers are called **two-tiered applications** or **multi-tiered applications** because the application and the database operate on independent systems (or tiers).

Choosing the type of database to use depends on several factors. For example, your data may already be stored in an existing database. If you are creating the database tables your application uses, you may want to consider the following questions:

- How many users will be sharing these tables? Remote database servers are designed for access by several users at the same time. They provide support for multiple users through a mechanism called transactions. Some local databases (such as Local InterBase) also provide transaction support, but many only provide file-based locking mechanisms, and some (such as client dataset files) provide no multi-user support at all.
- How much data will the tables hold? Remote database servers can hold more data than local databases. Some remote database servers are designed for warehousing large quantities of data while others are optimized for other criteria (such as fast updates).
- What type of performance (speed) do you require from the database? Local databases are usually faster than remote database servers because they reside on the same system as the database application. Different remote database servers are optimized to support different types of operations, so you may want to consider performance when choosing a remote database server.
- What type of support will be available for database administration? Local databases require less support than remote database servers. Typically, they are less expensive to operate because they do not require separately installed servers or expensive site licenses.

Database security

Databases often contain sensitive information. Different databases provide security schemes for protecting that information. Some databases, such as Paradox and dBASE, only provide security at the table or field level. When users try to access protected tables, they are required to provide a password. Once users have been authenticated, they can see only those fields (columns) for which they have permission.

Most SQL servers require a password and user name to use the database server at all. Once the user has logged in to the database, that username and password determine which tables can be used. For information on providing passwords to SQL servers, see “Controlling server login” on page 17-4.

When designing database applications, you must consider what type of authentication is required by your database server. Often, applications are designed to hide the explicit database login from users, who need only log in to the application itself. If you do not want to require your users to provide a database password, you must either use a database that does not require one or you must provide the password and username to the server programmatically. When providing the password programmatically, care must be taken that security can’t be breached by reading the password from the application.

If you require your user to supply a password, you must consider when the password is required. If you are using a local database but intend to scale up to a larger SQL server later, you may want to prompt for the password at the point when you will eventually log in to the SQL database, rather than when opening individual tables.

If your application requires multiple passwords because you must log in to several protected systems or databases, you can have your users provide a single master password that is used to access a table of passwords required by the protected systems. The application then supplies passwords programmatically, without requiring the user to provide multiple passwords.

In multi-tiered applications, you may want to use a different security model altogether. You can use HTTPs, CORBA, or COM+ to control access to middle tiers, and let the middle tiers handle all details of logging into database servers.

Transactions

A transaction is a group of actions that must all be carried out successfully on one or more tables in a database before they are committed (made permanent). If any of the actions in the group fails, then all actions are rolled back (undone).

Transactions ensure that

- All updates in a single transaction are either committed or aborted and rolled back to their previous state. This is referred to as **atomicity**.
- A transaction is a correct transformation of the system state, preserving the state invariants. This is referred to as **consistency**.
- Concurrent transactions do not see each other's partial or uncommitted results, which might create inconsistencies in the application state. This is referred to as **isolation**.
- Committed updates to records survive failures, including communication failures, process failures, and server system failures. This is referred to as **durability**.

Thus, transactions protect against hardware failures that occur in the middle of a database command or set of commands. Transactional logging allows you to recover the durable state after disk media failures. Transactions also form the basis of multi-user concurrency control on SQL servers. When each user interacts with the database only through transactions, one user’s commands can’t disrupt the unity of another user’s transaction. Instead, the SQL server schedules incoming transactions, which either succeed as a whole or fail as a whole.

Transaction support is not part of most local databases, although it is provided by local InterBase. In addition, the BDE drivers provide limited transaction support for some local databases. Database transaction support is provided by the component that represents the database connection. For details on managing transactions using a database connection component, see “Managing transactions” on page 17-5.

In multi-tiered applications, you can create transactions that include actions other than database operations or that span multiple databases. For details on using transactions in multi-tiered applications, see “Managing transactions in multi-tiered applications” on page 25-18.

Referential integrity, stored procedures, and triggers

All relational databases have certain features in common that allow applications to store and manipulate data. In addition, databases often provide other, database-specific, features that can prove useful for ensuring consistent relationships between the tables in a database. These include

- **Referential integrity.** Referential integrity provides a mechanism to prevent master/detail relationships between tables from being broken. When the user attempts to delete a field in a master table which would result in orphaned detail records, referential integrity rules prevent the deletion or automatically delete the orphaned detail records.
- **Stored procedures.** Stored procedures are sets of SQL statements that are named and stored on an SQL server. Stored procedures usually perform common database-related tasks on the server, and sometimes return sets of records (datasets).
- **Triggers.** Triggers are sets of SQL statements that are automatically executed in response to a particular command.

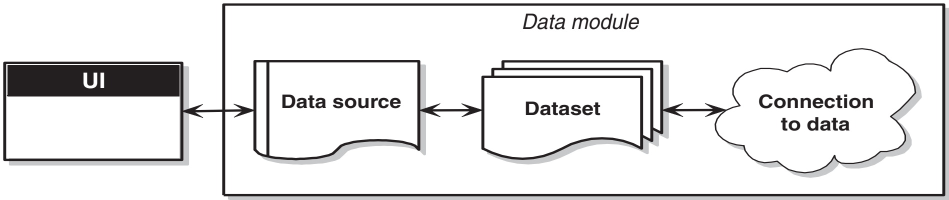
Database architecture

Database applications are built from user interface elements, components that represent database information (datasets), and components that connect these to each other and to the source of the database information. How you organize these pieces is the architecture of your database application.

General structure

While there are many distinct ways to organize the components in a database application, most follow the general scheme illustrated in Figure 14.1:

Figure 14.1 Generic Database Architecture



The user interface form

It is a good idea to isolate the user interface on a form that is completely separate from the rest of the application. This has several advantages. By isolating the user interface from the components that represent the database information itself, you introduce a greater flexibility into your design: Changes to the way you manage the database information do not require you to rewrite your user interface, and changes to the user interface do not require you to change the portion of your application that works with the database. In addition, this type of isolation lets you develop common forms that you can share between multiple applications, thereby providing a consistent user interface. By storing links to well-designed forms in the Object Repository, you and other developers can build on existing foundations rather than starting over from scratch for each new project. Sharing forms also makes it possible for you to develop corporate standards for application interfaces. For more information about creating the user interface for a database application, see “Designing the user interface” on page 14-15.

The data module

If you have isolated your user interface into its own form, you can use a data module to house the components that represent database information (datasets), and the components that connect these datasets to the other parts of your application. Like the user interface forms, you can share data modules in the Object Repository so that they can be reused or shared between applications.

The data source

The first item in the data module is a data source. The data source acts as a conduit between the user interface and a dataset that represents information from a database. Several data-aware controls on a form can share a single data source, in which case the display in each control is synchronized so that as the user scrolls through records, the corresponding value in the fields for the current record is displayed in each control.

The dataset

The heart of your database application is the dataset. This component represents a set of records from the underlying database. These records can be the data from a single database table, a subset of the fields or records in a table, or information from more than one table joined into a single view. By using datasets, your application logic is buffered from restructuring of the physical tables in your databases. When the underlying database changes, you might need to alter the way the dataset component specifies the data it contains, but the rest of your application can continue to work without alteration. For more information on the common properties and methods of datasets, see Chapter 18, “Understanding datasets”.

The data connection

Different types of datasets use different mechanisms for connecting to the underlying database information. These different mechanisms, in turn, make up the major differences in the architecture of the database applications you can build. There are four basic mechanisms for connecting to the data:

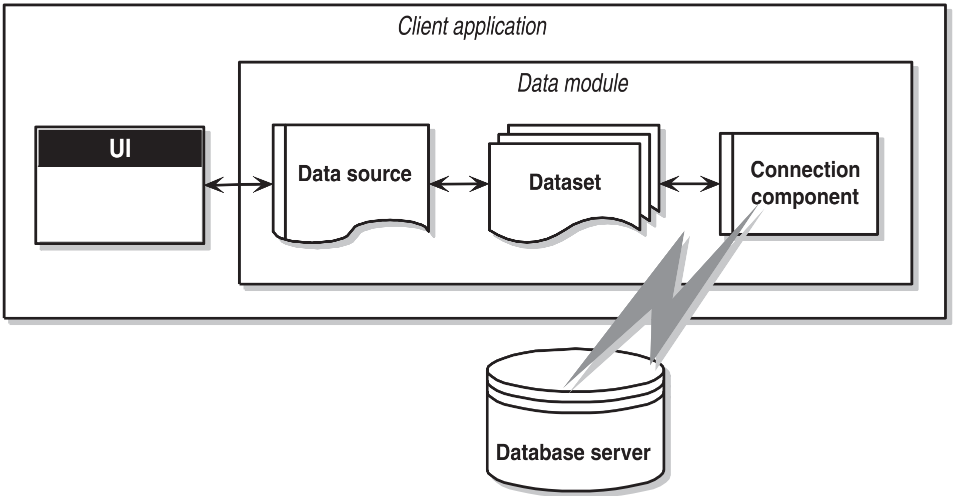
- Connecting directly to a database server. Most datasets use a descendant of *TCustomConnection* to represent the connection to a database server.
- Using a dedicated file on disk. Client datasets support the ability to work with a dedicated file on disk. No separate connection component is needed when working with a dedicated file because the client dataset itself knows how to read from and write to the file.
- Connecting to another dataset. Client datasets can work with data provided by another dataset. A *TDataSetProvider* component serves as an intermediary between the client dataset and its source dataset. This dataset provider can reside in the same data module as the client dataset, or it can be part of an application server running on another machine. If the provider is part of an application server, you also need a special descendant of *TCustomConnection* to represent the connection to the application server.
- Obtaining data from an RDS DataSpace object. ADO datasets can use a *TRDSConnection* component to marshal data in multi-tier database applications that are built using ADO-based application servers.

Sometimes, these mechanisms can be combined in a single application.

Connecting directly to a database server

The most common database architecture is the one where the dataset uses a connection component to establish a connection to a database server. The dataset then fetches data directly from the server and posts edits directly to the server. This is illustrated in Figure 14.2.

Figure 14.2 Connecting directly to the database server



Each type of dataset uses its own type of connection component, which represents a single data access mechanism:

- If the dataset is a BDE dataset such as *TTable*, *TQuery*, or *TStoredProc*, the connection component is a *TDataBase* object. You connect the dataset to the database component by setting its *Database* property. You do not need to explicitly add a database component when using BDE dataset. If you set the dataset's *DatabaseName* property, a database component is created for you automatically at runtime.
- If the dataset is an ADO dataset such as *TADODataSet*, *TADOTable*, *TADOQuery*, or *TADOStoredProc*, the connection component is a *TADOConnection* object. You connect the dataset to the ADO connection component by setting its *ADOConnection* property. As with BDE datasets, you do not need to explicitly add the connection component: instead you can set the dataset's *ConnectionString* property.
- If the dataset is a dbExpress dataset such as *TSQLDataSet*, *TSQLTable*, *TSQLQuery*, or *TSQLStoredProc*, the connection component is a *TSQLConnection* object. You connect the dataset to the SQL connection component by setting its *SQLConnection* property. When using dbExpress datasets, you must explicitly add the connection component. Another difference between dbExpress datasets and the other datasets is that dbExpress datasets are always read-only and unidirectional: This means you can only navigate by iterating through the records in order, and you can't use the dataset methods that support editing.
- If the dataset is an InterBase Express dataset such as *TIBDataSet*, *TIBTable*, *TIBQuery*, or *TIBStoredProc*, the connection component is a *TIBDatabase* object. You connect the dataset to the IB database component by setting its *Database* property. As with dbExpress datasets, you must explicitly add the connection component.

In addition to the components listed above, you can use a specialized client dataset such as *TBDEClientDataSet*, *TSQLClientDataSet*, or *TIBClientDataSet* with a database connection component. When using one of these client datasets, specify the appropriate type of connection component as the value of the *DBConnection* property.

Although each type of dataset uses a different connection component, they all perform many of the same tasks and surface many of the same properties, methods, and events. For more information on the commonalities among the various database connection components, see Chapter 17, “Connecting to databases”.

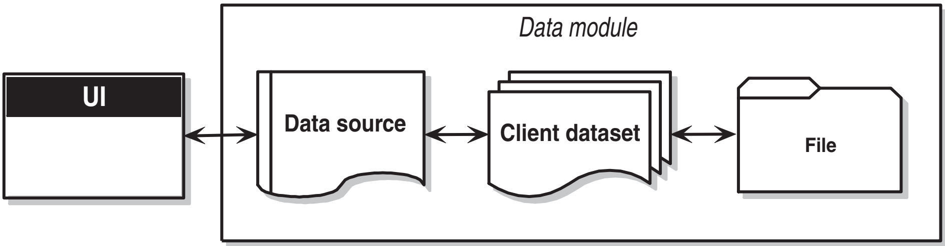
This architecture represents either a single-tiered or two-tiered application, depending on whether the database server is a local database such or a remote database server. The logic that manipulates database information is in the same application that implements the user interface, although isolated into a data module.

Note The connection components or drivers needed to create two-tiered applications are not available in all version of Delphi.

Using a dedicated file on disk

The simplest form of database application you can write does not use a database server at all. Instead, it uses MyBase, the ability of client datasets to save themselves to a file and to load the data from a file. This architecture is illustrated in Figure 14.3:

Figure 14.3 A file-based database application



When using this file-based approach, your application writes changes to disk using the client dataset’s *SaveToFile* method. *SaveToFile* takes one parameter, the name of the file which is created (or overwritten) containing the table. When you want to read a table previously written using the *SaveToFile* method, use the *LoadFromFile* method. *LoadFromFile* also takes one parameter, the name of the file containing the table.

If you always load to and save from the same file, you can use the *FileName* property instead of the *SaveToFile* and *LoadFromFile* methods. When *FileName* is set to a valid file name, the data is automatically loaded from the file when the client dataset is opened and saved to the file when the client dataset is closed.

This simple file-based architecture is a single-tiered application. The logic that manipulates database information is in the same application that implements the user interface, although isolated into a data module.

The file-based approach has the benefit of simplicity. There is no database server to install, configure, or deploy (If you do not statically link in midaslib.dcu, the client dataset does require midas.dll). There is no need for site licenses or database administration.

In addition, some versions of Delphi let you convert between arbitrary XML documents and the data packets that are used by a client dataset. Thus, the file-based approach can be used to work with XML documents as well as dedicated datasets. For information about converting between XML documents and client dataset data packets, see Chapter 26, “Using XML in database applications”.

The file-based approach offers no support for multiple users. The dataset should be dedicated entirely to the application. Data is saved to files on disk, and loaded at a later time, but there is no built-in protection to prevent multiple users from overwriting each other’s data files.

For more information about using a client dataset with data stored on disk, see “Using a client dataset with file-based data” on page 23-31.

Connecting to another dataset

There are specialized client datasets that use the BDE or *dbExpress* to connect to a database server. These specialized client datasets are, in fact, composite components that include another dataset internally to access the data and an internal provider component to package the data from the source dataset and to apply updates back to the database server. These composite components require some additional overhead, but provide certain benefits:

- Client datasets provide the most robust way to work with cached updates. By default, other types of datasets post edits directly to the database server. You can reduce network traffic by using a dataset that caches updates locally and applies them all later in a single transaction. For information on the advantages of using client datasets to cache updates, see “Using a client dataset to cache updates” on page 23-15.
- Client datasets can apply edits directly to a database server when the dataset is read-only. When using *dbExpress*, this is the only way to edit the data in the dataset (it is also the only way to navigate freely in the data when using *dbExpress*). Even when not using *dbExpress*, the results of some queries and all stored procedures are read-only. Using a client dataset provides a standard way to make such data editable.
- Because client datasets can work directly with dedicated files on disk, using a client dataset can be combined with a file-based model to allow for a flexible “briefcase” application. For information on the briefcase model, see “Combining approaches” on page 14-14.

In addition to these specialized client datasets, there is a generic client dataset (*TClientDataSet*), which does not include an internal dataset and dataset provider. Although *TClientDataSet* has no built-in database access mechanism, you can connect it to another, external, dataset from which it fetches data and to which it sends updates. Although this approach is a bit more complicated, there are times when it is preferable:

- Because the source dataset and dataset provider are external, you have more control over how they fetch data and apply updates. For example, the provider component surfaces a number of events that are not available when using a specialized client dataset to access data.
- When the source dataset is external, you can link it in a master/detail relationship with another dataset. An external provider automatically converts this arrangement into a single dataset with nested details. When the source dataset is internal, you can't create nested detail sets this way.
- Connecting a client dataset to an external dataset is an architecture that easily scales up to multiple tiers. Because the development process can get more involved and expensive as the number of tiers increases, you may want to start developing your application as a single-tiered or two-tiered application. As the amount of data, the number of users, and the number of different applications accessing the data grows, you may later need to scale up to a multi-tiered architecture. If you think you may eventually use a multi-tiered architecture, it can be worthwhile to start by using a client dataset with an external source dataset. This way, when you move the data access and manipulation logic to a middle tier, you protect your development investment because the code can be reused as your application grows.
- *TClientDataSet* can link to any source dataset. This means you can use custom datasets (third-party components) for which there is no corresponding specialized client dataset. Some versions of Delphi even include special provider components that connect a client dataset to an XML document rather than another dataset. (This works the same way as connecting a client dataset to another (source) dataset, except that the XML provider uses an XML document rather than a dataset. For information about these XML providers, see "Using an XML document as the source for a provider" on page 26-8.)

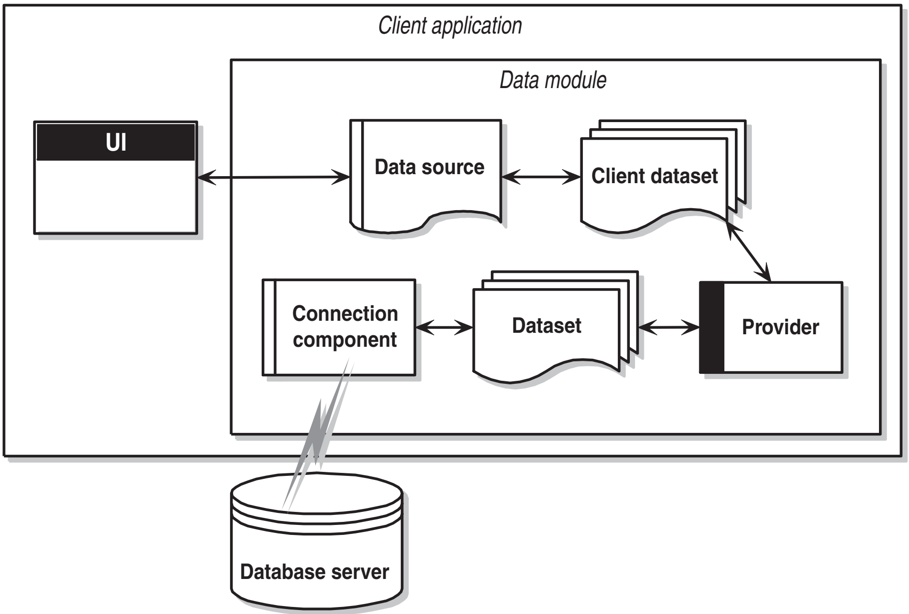
There are two versions of the architecture that connects a client dataset to an external dataset:

- Connecting a client dataset to another dataset in the same application.
- Using a multi-tiered architecture.

Connecting a client dataset to another dataset in the same application

By using a provider component, you can connect *TClientDataSet* to another (source) dataset. The provider packages database information into transportable data packets (which can be used by client datasets) and applies updates received in delta packets (which client datasets create) back to a database server. The architecture for this is illustrated in Figure 14.4:

Figure 14.4 Architecture combining a client dataset and another dataset



This architecture represents either a single-tiered or two-tiered application, depending on whether the database server is a local database or a remote database server. The logic that manipulates database information is in the same application that implements the user interface, although isolated into a data module.

To link the client dataset to the provider, set its *ProviderName* property to the name of the provider component. The provider must be in the same data module as the client dataset. To link the provider to the source dataset, set its *DataSet* property.

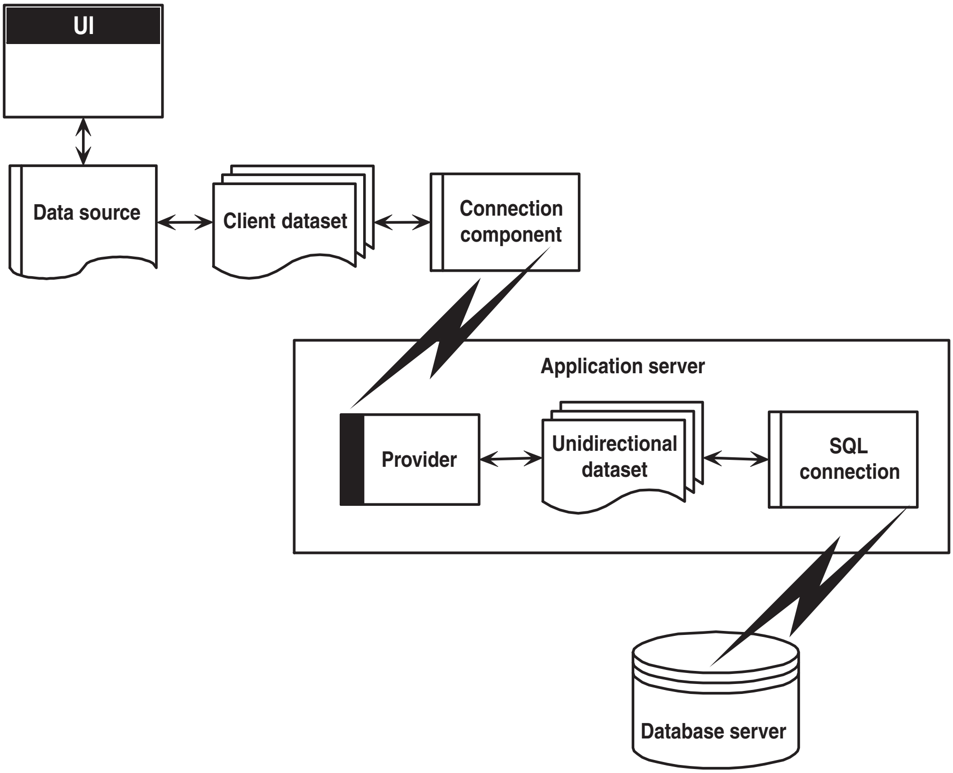
Once the client dataset is linked to the provider and the provider is linked to the source dataset, these components automatically handle all the details necessary for fetching, displaying, and navigating through the database records (assuming the source dataset is connected to a database). To apply user edits back to the database, you need only call the client dataset's *ApplyUpdates* method.

For more information on using a client dataset with a provider, see "Using a client dataset with a provider" on page 23-23.

Using a multi-tiered architecture

When the database information includes complicated relationships between several tables, or when the number of clients grows, you may want to use a multi-tiered application. Multi-tiered applications have middle tiers between the client application and database server. The architecture for this is illustrated in Figure 14.5:

Figure 14.5 Multi-tiered database architecture



The preceding figure represents three-tiered application. The logic that manipulates database information is on a separate system, or tier. This middle tier centralizes the logic that governs your database interactions so there is centralized control over data relationships. This allows different client applications to use the same data, while ensuring consistent data logic. It also allows for smaller client applications because much of the processing is off-loaded onto the middle tier. These smaller client applications are easier to install, configure, and maintain. Multi-tiered applications can also improve performance by spreading data-processing over several systems.

The multi-tiered architecture is very similar to the previous model. It differs mainly in that source dataset that connects to the database server and the provider that acts as an intermediary between that source dataset and the client dataset have both moved to a separate application. That separate application is called the application server (or sometimes the "remote data broker").

Because the provider has moved to a separate application, the client dataset can no longer connect to the source dataset by simply setting its *ProviderName* property. In addition, it must use some type of connection component to locate and connect to the application server.

There are several types of connection components that can connect a client dataset to an application server. They are all descendants of *TCustomRemoteServer*, and differ primarily in the communication protocol they use (TCP/IP, HTTP, DCOM, SOAP, or CORBA). Link the client dataset to its connection component by setting the *RemoteServer* property.

The connection component establishes a connection to the application server and returns an interface that the client dataset uses to call the provider specified by its *ProviderName* property. Each time the client dataset calls the application server, it passes the value of *ProviderName*, and the application server forwards the call to the provider.

For more information about connecting a client dataset to an application server, see Chapter 25, "Creating multi-tiered applications".

Combining approaches

The previous sections describe several architectures you can use when writing database applications. There is no reason, however, why you can't combine two or more of the available architectures in a single application. In fact, some combinations can be extremely powerful.

For example, you can combine the disk-based architecture described in "Using a dedicated file on disk" on page 14-9 with another approach such as those described in "Connecting a client dataset to another dataset in the same application" on page 14-11 or "Using a multi-tiered architecture" on page 14-12. These combinations are easy because all models use a client dataset to represent the data that appears in the user interface. The result is called the briefcase model (or sometimes the disconnected model, or mobile computing).

The briefcase model is useful in a situation such as the following: An onsite company database contains customer contact data that sales representatives can use and update in the field. While onsite, sales representatives download information from the database. Later, they work with it on their laptops as they fly across the country, and even update records at existing or new customer sites. When the sales reps return onsite, they upload their data changes to the company database for everyone to use.

When operating on site, the client dataset in a briefcase model application fetches its data from a provider. The client dataset is therefore connected to the database server and can, through the provider, fetch server data and send updates back to the server. Before disconnecting from the provider, the client dataset saves its snapshot of the information to a file on disk. While offsite, the client dataset loads its data from the file, and saves any changes back to that file. Finally, back onsite, the client dataset reconnects to the provider so that it can apply its updates to the database server or refresh its snapshot of the data.

Designing the user interface

The Data Controls page of the Component palette provides a set of data-aware controls that represent data from fields in a database record, and can permit users to edit that data and post changes back to the database. Using data-aware controls, you can build your database application's user interface (UI) so that information is visible and accessible to users. For more information on data-aware controls see Chapter 15, "Using data controls."

In addition to the basic data controls, you may also want to introduce other elements into your user interface:

- You may want your application to analyze the data contained in a database. Applications that analyze data do more than just display the data in a database, they also summarize the information in useful formats to help users grasp the impact of that data.
- You may want to print reports that provide a hard copy of the information displayed in your user interface.
- You may want to create a user interface that can be viewed from Web browsers. The simplest Web-based database applications are described in "Using database information in responses" on page 28-17. In addition, you can combine the Web-based approach with the multi-tiered architecture, as described in "Writing Web-based client applications."

Analyzing data

Some database applications do not present database information directly to the user. Instead, they analyze and summarize information from databases so that users can draw conclusions from the data.

The *TDBChart* component on the Data Controls page of the Component palette lets you present database information in a graphical format that enables users to quickly grasp the import of database information.

In addition, some versions of Delphi include a Decision Cube page on the Component palette. It contains six components that let you perform data analysis and cross-tabulations on data when building decision support applications. For more information about using the Decision Cube components, see Chapter 16, "Using decision support components".

If you want to build your own components that display data summaries based on various grouping criteria, you can use maintained aggregates with a client dataset. For more information about using maintained aggregates, see "Using maintained aggregates" on page 23-11.

Writing reports

If you want to let your users print database information from the datasets in your application, you can use the report components on the QReport page of the Component palette. Using these components you can visually build banded reports to present and summarize the information in your database tables. You can add summaries to group headers or footers to analyze the data based on grouping criteria.

Start a report for your application by selecting the QuickReport icon from the New Items dialog. Select File|New from the main menu, and go to the page labeled Business. Double-click the QuickReport Wizard icon to launch the wizard.

Note See the QuickReport demo that ships with Delphi for an example of how to use the components on the QReport page.

Chapter

15

Using data controls

The Data Controls page of the Component palette provides a set of data-aware controls that represent data from fields in a database record, and, if the dataset allows it, enable users to edit that data and post changes back to the database. By placing data controls onto the forms in your database application, you can build your database application's user interface (UI) so that information is visible and accessible to users.

The data-aware controls you add to your user interface depend on several factors, including the following:

- The type of data you are displaying. You can choose between controls that are designed to display and edit plain text, controls that work with formatted text, controls for graphics, multimedia elements, and so on. Controls that display different types of information are described in "Displaying a single record" on page 15-7.
- How you want to organize the information. You may choose to display information from a single record on the screen, or list the information from multiple records using a grid. "Choosing how to organize the data" on page 15-7 describes some of the possibilities.
- The type of dataset that supplies data to the controls. You want to use controls that reflect the limitations of the underlying dataset. For example, you would not use a grid with a unidirectional dataset because unidirectional datasets can only supply a single record at a time.
- How (or if) you want to let users navigate through the records of datasets and add or edit data. You may want to add your own controls or mechanisms to navigate and edit, or you may want to use a built-in control such as a data navigator. For more information about using a data navigator, see "Navigating and manipulating records" on page 15-28.

Note More complex data-aware controls for decision support are discussed in Chapter 16, "Using decision support components."

Regardless of the data-aware controls you choose to add to your interface, certain common features apply. These are described below.

Using common data control features

The following tasks are common to most data controls:

- Associating a data control with a dataset
- Editing and updating data
- Disabling and enabling data display
- Refreshing data display
- Enabling mouse, keyboard, and timer events

Data controls let you display and edit fields of data associated with the current record in a dataset. Table 15.1 summarizes the data controls that appear on the Data Controls page of the Component palette.

Table 15.1 Data controls

Data control	Description
TDBGrid	Displays information from a data source in a tabular format. Columns in the grid correspond to columns in the underlying table or query's dataset. Rows in the grid correspond to records.
TDBNavigator	Navigates through data records in a dataset. updating records, posting records, deleting records, canceling edits to records, and refreshing data display.
TDBText	Displays data from a field as a label.
TDBEdit	Displays data from a field in an edit box.
TDBMemo	Displays data from a memo or BLOB field in a scrollable, multi-line edit box.
TDBImage	Displays graphics from a data field in a graphics box.
TDBListBox	Displays a list of items from which to update a field in the current data record.
TDBComboBox	Displays a list of items from which to update a field, and also permits direct text entry like a standard data-aware edit box.
TDBCheckBox	Displays a check box that indicates the value of a Boolean field.
TDBRadioGroup	Displays a set of mutually exclusive options for a field.
TDBLookupListBox	Displays a list of items looked up from another dataset based on the value of a field.
TDBLookupComboBox	Displays a list of items looked up from another dataset based on the value of a field, and also permits direct text entry like a standard data-aware edit box.
TDBCtrlGrid	Displays a configurable, repeating set of data-aware controls within a grid.
TDBRichEdit	Displays formatted data from a field in an edit box.

Data controls are data-aware at design time. When you associate the data control with an active dataset while building an application, you can immediately see live data in the control. You can use the Fields editor to scroll through a dataset at design time to verify that your application displays data correctly without having to compile and run the application. For more information about the Fields editor, see "Creating persistent fields" on page 19-4.

At runtime, data controls display data and, if your application, the control, and the dataset all permit it, a user can edit data through the control.

Associating a data control with a dataset

Data controls connect to datasets by using a data source. A data source component (*TDataSource*) acts as a conduit between the control and a dataset containing data. Each data-aware control must be associated with a data source component to have data to display and manipulate. Similarly, all datasets must be associated with a data source component in order for their data to be displayed and manipulated in data-aware controls on a form.

Note Data source components are also required for linking unnested datasets in master-detail relationships.

To associate a data control with a dataset,

1. Place a dataset in a data module (or on a form), and set its properties as appropriate.
2. Place a data source in the same data module (or form). Using the Object Inspector, set its *DataSet* property to the dataset you placed in step 1.
3. Place a data control from the Data Access page of the Component palette onto a form.
4. Using the Object Inspector, set the *DataSource* property of the control to the data source component you placed in step 2.
5. Set the *DataField* property of the control to the name of a field to display, or select a field name from the drop-down list for the property. This step does not apply to *TDBGrid, TDBCtrlGrid,* and *TDBNavigator* because they access all available fields in the dataset.
6. Set the *Active* property of the dataset to *True* to display data in the control.

Changing the associated dataset at runtime

In the preceding example, the datasource was associated with its dataset by setting the *DataSet* property at design time. At runtime, you can switch the dataset for a data source component as needed. For example, the following code swaps the dataset for the *CustSource* data source component between the dataset components named *Customers* and *Orders*:

```
with CustSource do begin
  if (DataSet = Customers) then
    DataSet := Orders
    else
      DataSet := Customers;
  end;
```

You can also set the *DataSet* property to a dataset on another form to synchronize the data controls on two forms. For example:

```
procedure TForm2.FormCreate (Sender : TObject);
begin
  DataSource1.Dataset := Form1.Table1;
end;
```

Enabling and disabling the data source

The data source has an *Enabled* property that determines if it is connected to its dataset. When *Enabled* is *True*, the data source is connected to a dataset.

You can temporarily disconnect a single data source from its dataset by setting *Enabled* to *False*. When *Enabled* is *False*, all data controls attached to the data source component go blank and become inactive until *Enabled* is set to *True*. It is recommended, however, to control access to a dataset through a dataset component's *DisableControls* and *EnableControls* methods because they affect all attached data sources.

Responding to changes mediated by the data source

Because the data source provides the link between the data control and its dataset, it mediates all of the communication that occurs between the two. Typically, the data-aware control automatically responds to changes in the dataset. However, if your user interface is using controls that are not data-aware, you can use the events of a data source component to manually provide the same sort of response.

The *OnDataChange* event occurs whenever the data in a record may have changed, including field edits or when the cursor moves to a new record. This event is useful for making sure the control reflects the current field values in the dataset, because it is triggered by all changes. Typically, an *OnDataChange* event handler refreshes the value of a non-data-aware control that displays field data.

The *OnUpdateData* event occurs when the data in the current record is about to be posted. For instance, an *OnUpdateData* event occurs after *Post* is called, but before the data is actually posted to the underlying database server or local cache.

The *OnStateChange* event occurs when the state of the dataset changes. When this event occurs, you can examine the dataset's *State* property to determine its current state.

For example, the following *OnStateChange* event handler enables or disables buttons or menu items based on the current state:

```
procedure Form1.DataSource1.StateChange(Sender: TObject);
begin
  CustTableEditBtn.Enabled := (CustTable.State = dsBrowse);
  CustTableCancelBtn.Enabled := CustTable.State in [dsInsert, dsEdit, dsSetKey];
  CustTableActivateBtn.Enabled := CustTable.State in [dsInactive];
  ⋮
end;
```

Note For more information about dataset states, see "Determining dataset states" on page 18-3.

Editing and updating data

All data controls except the navigator display data from a database field. In addition, you can use them to edit and update data as long as the underlying dataset allows it.

Note Unidirectional datasets never permit users to edit and update data.

Enabling editing in controls on user entry

A dataset must be in *dsEdit* state to permit editing to its data. If the data source's *AutoEdit* property is *True* (the default), the data control handles the task of putting the dataset into *dsEdit* mode as soon as the user tries to edit its data.

If *AutoEdit* is *False*, you must provide an alternate mechanism for putting the dataset into edit mode. One such mechanism is to use a *TDBNavigator* control with an *Edit* button, which lets users explicitly put the dataset into edit mode. For more information about *TDBNavigator*, see "Navigating and manipulating records" on page 15-28. Alternately, you can write code that calls the dataset's *Edit* method when you want to put the dataset into edit mode.

Editing data in a control

A data control can only post edits to its associated dataset if the dataset's *CanModify* property is *True*. *CanModify* is always *False* for unidirectional datasets. Some datasets have a *ReadOnly* property that lets you specify whether *CanModify* is *True*.

Note Whether a dataset can update data depends on whether the underlying database table permits updates.

Even if the dataset's *CanModify* property is *True*, the *Enabled* property of the data source that connects the dataset to the control must be *True* as well before the control can post updates back to the database table. The *Enabled* property of the data source determines whether the control can display field values from the dataset, and therefore also whether a user can edit and post values. If *Enabled* is ***True*** (the default), controls can display field values.

Finally, you can control whether the user can even enter edits to the data that is displayed in the control. The *ReadOnly* property of the data control determines if a user can edit the data displayed by the control. If *False* (the default), users can edit data. Clearly, you will want to ensure that the control's *ReadOnly* property is *True* when the dataset's *CanModify* property is *False*. Otherwise, you give users the false impression that they can affect the data in the underlying database table.

In all data controls except *TDBGrid*, when you modify a field, the modification is copied to the underlying dataset when you Tab from the control. If you press Esc before you Tab from a field, the data control abandons the modifications, and the value of the field reverts to the value it held before any modifications were made.

In *TDBGrid*, modifications are posted when you move to a different record; you can press *Esc* in any record of a field before moving to another record to cancel all changes to the record.

When a record is posted, Delphi checks all data-aware controls associated with the dataset for a change in status. If there is a problem updating any fields that contain modified data, Delphi raises an exception, and no modifications are made to the record.

Note If your application caches updates (for example, using a client dataset), all modifications are posted to an internal cache. These modifications are not applied to the underlaying database table until you call the dataset's *ApplyUpdates* method.

Disabling and enabling data display

When your application iterates through a dataset or performs a search, you should temporarily prevent refreshing of the values displayed in data-aware controls each time the current record changes. Preventing refreshing of values speeds the iteration or search and prevents annoying screen-flicker.

DisableControls is a dataset method that disables display for all data-aware controls linked to a dataset. As soon as the iteration or search is over, your application should immediately call the dataset's *EnableControls* method to re-enable display for the controls.

Usually you disable controls before entering an iterative process. The iterative process itself should take place inside a **try...finally** statement so that you can re-enable controls even if an exception occurs during processing. The **finally** clause should call *EnableControls*. The following code illustrates how you might use *DisableControls* and *EnableControls* in this manner:

```
CustTable.DisableControls;
try
  CustTable.First; { Go to first record, which sets EOF False }
  while not CustTable.EOF do { Cycle until EOF is True }
  begin
    { Process each record here }
    ⋮
    CustTable.Next; { EOF False on success; EOF True when Next fails on last record }
  end;
finally
  CustTable.EnableControls;
end;
```

Refreshing data display

The *Refresh* method for a dataset flushes local buffers and refetches data for an open dataset. You can use this method to update the display in data-aware controls if you think that the underlying data has changed because other applications have simultaneous access to the data used in your application. If you are using cached updates, before you refresh the dataset you must apply any updates the dataset has currently cached.

Refreshing can sometimes lead to unexpected results. For example, if a user is viewing a record deleted by another application, then the record disappears the moment your application calls *Refresh*. Data can also appear to change if another user changes a record after you originally fetched the data and before you call *Refresh*.

Enabling mouse, keyboard, and timer events

The *Enabled* property of a data control determines whether it responds to mouse, keyboard, or timer events, and passes information to its data source. The default setting for this property is *True*.

To prevent mouse, keyboard, or timer events from reaching a data control, set its *Enabled* property to *False*. When *Enabled* is *False*, the data source that connects the control to its dataset does not receive information from the data control. The data control continues to display data, but the text displayed in the control is dimmed.

Choosing how to organize the data

When you build the user interface for your database application, you have choices to make about how you want to organize the display of information and the controls that manipulate that information.

One of the first decisions to make is whether you want to display a single record at a time, or multiple records.

In addition, you will want to add controls to navigate and manipulate records. The *TDBNavigator* control provides built-in support for many of the functions you may want to perform.

Displaying a single record

In many applications, you may only want to provide information about a single record of data at a time. For example, an order-entry application may display the information about a single order without indicating what other orders are currently logged. This information probably comes from a single record in an orders dataset.

Applications that display a single record are usually easy to read and understand, because all database information is about the same thing (in the previous case, the same order). The data-aware controls in these user interfaces represent a single field from a database record. The Data Controls page of the Component palette provides a wide selection of controls to represent different kinds of fields. These controls are typically data-aware versions of other controls that are available on the component palette. For example, the *TDBEdit* control is a data-aware version of the standard *TEdit* control which enables users to see and edit a text string.

Which control you use depends on the type of data (text, formatted text, graphics, boolean information, and so on) contained in the field.

Displaying data as labels

TDBText is a read-only control similar to the *TLabel* component on the Standard page of the Component palette. A *TDBText* control is useful when you want to provide display-only data on a form that allows user input in other controls. For example, suppose a form is created around the fields in a customer list table, and that once the user enters a street address, city, and state or province information in the form, you use a dynamic lookup to automatically determine the zip code field from a separate table. A *TDBText* component tied to the zip code table could be used to display the zip code field that matches the address entered by the user.

TDBText gets the text it displays from a specified field in the current record of a dataset. Because *TDBText* gets its text from a dataset, the text it displays is dynamic—the text changes as the user navigates the database table. Therefore you cannot specify the display text of *TDBText* at design time as you can with *TLabel*.

Note When you place a *TDBText* component on a form, make sure its *AutoSize* property is *True* (the default) to ensure that the control resizes itself as necessary to display data of varying widths. If *AutoSize* is *False*, and the control is too small, data display is clipped.

Displaying and editing fields in an edit box

TDBEdit is a data-aware version of an edit box component. *TDBEdit* displays the current value of a data field to which it is linked and permits it to be edited using standard edit box techniques.

For example, suppose *CustomersSource* is a *TDataSource* component that is active and linked to an open *TClientDataSet* called *CustomersTable*. You can then place a *TDBEdit* component on a form and set its properties as follows:

- *DataSource*: CustomersSource
- *DataField*: CustNo

The data-aware edit box component immediately displays the value of the current row of the *CustNo* column of the *CustomersTable* dataset, both at design time and at runtime.

Displaying and editing text in a memo control

TDBMemo is a data-aware component—similar to the standard *TMemo* component—that can display lengthy text data. *TDBMemo* displays multi-line text, and permits a user to enter multi-line text as well. You can use *TDBMemo* controls to display large text fields or text data contained in binary large object (BLOB) fields.

By default, *TDBMemo* permits a user to edit memo text. To prevent editing, set the *ReadOnly* property of the memo control to *True*. To display tabs and permit users to enter them in a memo, set the *WantTabs* property to *True*. To limit the number of characters users can enter into the database memo, use the *MaxLength* property. The default value for *MaxLength* is 0, meaning that there is no character limit other than that imposed by the operating system.

Several properties affect how the database memo appears and how text is entered. You can supply scroll bars in the memo with the *ScrollBars* property. To prevent word wrap, set the *WordWrap* property to ***False***. The *Alignment* property determines how the text is aligned within the control. Possible choices are *taLeftJustify* (the default), *taCenter*, and *taRightJustify*. To change the font of the text, use the *Font* property.

At runtime, users can cut, copy, and paste text to and from a database memo control. You can accomplish the same task programmatically by using the *CutToClipboard*, *CopyToClipboard*, and *PasteFromClipboard* methods.

Because the *TDBMemo* can display large amounts of data, it can take time to populate the display at runtime. To reduce the time it takes to scroll through data records, *TDBMemo* has an *AutoDisplay* property that controls whether the accessed data should be displayed automatically. If you set *AutoDisplay* to ***False***, *TDBMemo* displays the field name rather than actual data. Double-click inside the control to view the actual data.

Displaying and editing text in a rich edit memo control

TDBRichEdit is a data-aware component—similar to the standard *TRichEdit* component—that can display formatted text stored in a binary large object (BLOB) field. *TDBRichEdit* displays formatted, multi-line text, and permits a user to enter formatted multi-line text as well.

Note While *TDBRichEdit* provides properties and methods to enter and work with rich text, it does not provide any user interface components to make these formatting options available to the user. Your application must implement the user interface to surface rich text capabilities.

By default, *TDBRichEdit* permits a user to edit memo text. To prevent editing, set the *ReadOnly* property of the rich edit control to *True*. To display tabs and permit users to enter them in a memo, set the *WantTabs* property to *True*. To limit the number of characters users can enter into the database memo, use the *MaxLength* property. The default value for MaxLength is 0, meaning that there is no character limit other than that imposed by the operating system.

Because the *TDBRichEdit* can display large amounts of data, it can take time to populate the display at runtime. To reduce the time it takes to scroll through data records, *TDBRichEdit* has an *AutoDisplay* property that controls whether the accessed data should be displayed automatically. If you set *AutoDisplay* to *False*, *TDBRichEdit* displays the field name rather than actual data. Double-click inside the control to view the actual data.

Displaying and editing graphics fields in an image control

TDBImage is a data-aware control that displays graphics contained in BLOB fields.

By default, *TDBImage* permits a user to edit a graphics image by cutting and pasting to and from the Clipboard using the *CutToClipboard*, *CopyToClipboard*, and *PasteFromClipboard* methods. You can, instead, supply your own editing methods attached to the event handlers for the control.

By default, an image control displays as much of a graphic as fits in the control, cropping the image if it is too big. You can set the *Stretch* property to *True* to resize the graphic to fit within an image control as it is resized.

Because the *TDBImage* can display large amounts of data, it can take time to populate the display at runtime. To reduce the time it takes scroll through data records, *TDBImage* has an *AutoDisplay* property that controls whether the accessed data should automatically displayed. If you set *AutoDisplay* to *False*, *TDBImage* displays the field name rather than actual data. Double-click inside the control to view the actual data.

Displaying and editing data in list and combo boxes

There are four data controls that provide the user with a set of default data values to choose from at runtime. These are data-aware versions of standard list and combo box controls:

- *TDBListBox*, which displays a scrollable list of items from which a user can choose to enter in a data field. A data-aware list box displays a default value for a field in the current record and highlights its corresponding entry in the list. If the current row's field value is not in the list, no value is highlighted in the list box. When a user selects a list item, the corresponding field value is changed in the underlying dataset.
- *TDBComboBox*, which combines the functionality of a data-aware edit control and a drop-down list. At runtime it can display a drop-down list from which a user can pick from a predefined set of values, and it can permit a user to enter an entirely different value.
- *TDBLookupListBox*, which behaves like *TDBListBox* except the list of display items is looked up in another dataset.
- *TDBLookupComboBox*, which behaves like *TDBComboBox* except the list of display items is looked up in another dataset.

Note At runtime, users can use an incremental search to find list box items. When the control has focus, for example, typing 'ROB' selects the first item in the list box beginning with the letters 'ROB'. Typing an additional 'E' selects the first item starting with 'ROBE', such as 'Robert Johnson'. The search is case-insensitive. *Backspace* and *Esc* cancel the current search string (but leave the selection intact), as does a two second pause between keystrokes.

Using TDBListBox and TDBComboBox

When using *TDBListBox* or *TDBComboBox*, you must use the String List editor at design time to create the list of items to display. To bring up the String List editor, click the ellipsis button for the *Items* property in the Object Inspector. Then type in the items that you want to have appear in the list. At runtime, use the methods of the *Items* property to manipulate its string list.

When a *TDBListBox* or *TDBComboBox* control is linked to a field through its *DataField* property, the field value appears selected in the list. If the current value is not in the list, no item appears selected. However, *TDBComboBox* displays the current value for the field in its edit box, regardless of whether it appears in the *Items* list.

For *TDBListBox*, the *Height* property determines how many items are visible in the list box at one time. The *IntegralHeight* property controls how the last item can appear. If *IntegralHeight* is ***False*** (the default), the bottom of the list box is determined by the *ItemHeight* property, and the bottom item may not be completely displayed. If *IntegralHeight* is *True*, the visible bottom item in the list box is fully displayed.

For *TDBComboBox*, the *Style* property determines user interaction with the control. By default, *Style* is *csDropDown*, meaning a user can enter values from the keyboard, or choose an item from the drop-down list. The following properties determine how the *Items* list is displayed at runtime:

- *Style* determines the display style of the component:
  - *csDropDown* (default): Displays a drop-down list with an edit box in which the user can enter text. All items are strings and have the same height.
  - *csSimple*: Combines an edit control with a fixed size list of items that is always displayed. When setting *Style* to *csSimple*, be sure to increase the *Height* property so that the list is displayed.
  - *csDropDownList*: Displays a drop-down list and edit box, but the user cannot enter or change values that are not in the drop-down list at runtime.
  - *csOwnerDrawFixed* and *csOwnerDrawVariable*: Allows the items list to display values other than strings (for example, bitmaps) or to use different fonts for individual items in the list.
- *DropDownCount*: the maximum number of items displayed in the list. If the number of *Items* is greater than *DropDownCount*, the user can scroll the list. If the number of *Items* is less than *DropDownCount*, the list will be just large enough to display all the Items.
- *ItemHeight*: The height of each item when style is *csOwnerDrawFixed*.
- *Sorted*: If *True*, then the *Items* list is displayed in alphabetical order.

Displaying and editing data in lookup list and combo boxes

Lookup list boxes and lookup combo boxes (*TDBLookupListBox* and *TDBLookupComboBox*) present the user with a restricted list of choices from which to set a valid field value. When a user selects a list item, the corresponding field value is changed in the underlying dataset.

For example, consider an order form whose fields are tied to the *OrdersTable*. *OrdersTable* contains a *CustNo* field corresponding to a customer ID, but *OrdersTable* does not have any other customer information. The *CustomersTable*, on the other hand, contains a *CustNo* field corresponding to a customer ID, and also contains additional information, such as the customer's company and mailing address. It would be convenient if the order form enabled a clerk to select a customer by company name instead of customer ID when creating an invoice. A *TDBLookupListBox* that displays all company names in *CustomersTable* enables a user to select the company name from the list, and set the *CustNo* on the order form appropriately.

These lookup controls derive the list of display items from one of two sources:

- **A lookup field defined for a dataset.**
  To specify list box items using a lookup field, the dataset to which you link the

control must already define a lookup field. (This process is described in “Defining a lookup field” on page 19-8). To specify the lookup field for the list box items,

1. Set the *DataSource* property of the list box to the data source for the dataset containing the lookup field to use.
2. Choose the lookup field to use from the drop-down list for the *DataField* property.

When you activate a table associated with a lookup control, the control recognizes that its data field is a lookup field, and displays the appropriate values from the lookup.

- **A secondary data source, data field, and key**.
If you have not defined a lookup field for a dataset, you can establish a similar relationship using a secondary data source, a field value to search on in the secondary data source, and a field value to return as a list item. To specify a secondary data source for list box items,

1. Set the *DataSource* property of the list box to the data source for the control.
2. Choose a field into which to insert looked-up values from the drop-down list for the *DataField* property. The field you choose cannot be a lookup field.
3. Set the *ListSource* property of the list box to the data source for the dataset that contain the field whose values you want to look up.
4. Choose a field to use as a lookup key from the drop-down list for the *KeyField* property. The drop-down list displays fields for the dataset associated with data source you specified in Step 3. The field you choose need not be part of an index, but if it is, lookup performance is even faster.
5. Choose a field whose values to return from the drop-down list for the *ListField* property. The drop-down list displays fields for the dataset associated with the data source you specified in Step 3.

When you activate a table associated with a lookup control, the control recognizes that its list items are derived from a secondary source, and displays the appropriate values from that source.

To specify the number of items that appear at one time in a *TDBLookupListBox* control, use the *RowCount* property. The height of the list box is adjusted to fit this row count exactly.

To specify the number of items that appear in the drop-down list of *TDBLookupComboBox*, use the *DropDownRows* property instead.

Note You can also set up a column in a data grid to act as a lookup combo box. For information on how to do this, see “Defining a lookup list column” on page 15-20.

Handling Boolean field values with check boxes

TDBCheckBox is a data-aware check box control. It can be used to set the values of Boolean fields in a dataset. For example, a customer invoice form might have a check box control that when checked indicates the customer is tax-exempt, and when unchecked indicates that the customer is not tax-exempt.

The data-aware check box control manages its checked or unchecked state by comparing the value of the current field to the contents of *ValueChecked* and *ValueUnchecked* properties. If the field value matches the *ValueChecked* property, the control is checked. Otherwise, if the field matches the *ValueUnchecked* property, the control is unchecked.

Note The values in *ValueChecked* and *ValueUnchecked* cannot be identical.

Set the *ValueChecked* property to a value the control should post to the database if the control is checked when the user moves to another record. By default, this value is set to “true,” but you can make it any alphanumeric value appropriate to your needs. You can also enter a semicolon-delimited list of items as the value of *ValueChecked*. If any of the items matches the contents of that field in the current record, the check box is checked. For example, you can specify a *ValueChecked* string like:

```
DBCheckBox1.ValueChecked := 'True;Yes;On';
```

If the field for the current record contains values of “true,” “Yes,” or “On,” then the check box is checked. Comparison of the field to *ValueChecked* strings is case-insensitive. If a user checks a box for which there are multiple *ValueChecked* strings, the first string is the value that is posted to the database.

Set the *ValueUnchecked* property to a value the control should post to the database if the control is not checked when the user moves to another record. By default, this value is set to “false,” but you can make it any alphanumeric value appropriate to your needs. You can also enter a semicolon-delimited list of items as the value of *ValueUnchecked*. If any of the items matches the contents of that field in the current record, the check box is unchecked.

A data-aware check box is disabled whenever the field for the current record does not contain one of the values listed in the *ValueChecked* or *ValueUnchecked* properties.

If the field with which a check box is associated is a logical field, the check box is always checked if the contents of the field is *True*, and it is unchecked if the contents of the field is *False*. In this case, strings entered in the *ValueChecked* and *ValueUnchecked* properties have no effect on logical fields.

Restricting field values with radio controls

TDBRadioGroup is a data-aware version of a radio group control. It enables you to set the value of a data field with a radio button control where there is a limited number of possible values for the field. The radio group includes one button for each value a field can accept. Users can set the value for a data field by selecting the desired radio button.

The *Items* property determines the radio buttons that appear in the group. *Items* is a string list. One radio button is displayed for each string in *Items*, and each string appears to the right of a radio button as the button’s label.

If the current value of a field associated with a radio group matches one of the strings in the *Items* property, that radio button is selected. For example, if three strings, “Red,” “Yellow,” and “Blue,” are listed for *Items*, and the field for the current record contains the value “Blue,” then the third button in the group appears selected.

Note If the field does not match any strings in *Items*, a radio button may still be selected if the field matches a string in the *Values* property. If the field for the current record does not match any strings in *Items* or *Values*, no radio button is selected.

The *Values* property can contain an optional list of strings that can be returned to the dataset when a user selects a radio button and posts a record. Strings are associated with buttons in numeric sequence. The first string is associated with the first button, the second string with the second button, and so on. For example, suppose *Items* contains "Red," "Yellow," and "Blue," and *Values* contains "Magenta," "Yellow," and "Cyan." If a user selects the button labeled "Red," "Magenta" is posted to the database.

If strings for *Values* are not provided, the *Item* string for a selected radio button is returned to the database when a record is posted.

Displaying multiple records

Sometimes you want to display many records in the same form. For example, an invoicing application might show all the orders made by a single customer on the same form.

To display multiple records, use a grid control. Grid controls provide a multi-field, multi-record view of data that can make your application's user interface more compelling and effective. They are discussed in "Viewing and editing data with TDBGrid" on page 15-15 and "Creating a grid that contains other data-aware controls" on page 15-26.

Note You can't display multiple records when using a unidirectional dataset.

You may want to design a user interface that displays both fields from a single record and grids that represent multiple records. There are two models that combine these two approaches:

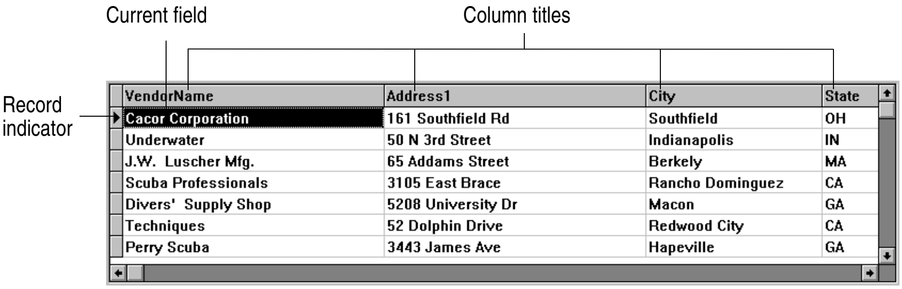
- **Master-detail forms:** You can represent information from both a master table and a detail table by including both controls that display a single field and grid controls. For example, you could display information about a single customer with a detail grid that displays the orders for that customer. For information about linking the underlying tables in a master-detail form, see "Creating master/detail relationships" on page 18-34 and "Establishing master/detail relationships using parameters" on page 18-46.
- **Drill-down forms**: In a form that displays multiple records, you can include single field controls that display detailed information from the current record only. This approach is particularly useful when the records include long memos or graphic information. As the user scrolls through the records of the grid, the memo or graphic updates to represent the value of the current record. Setting this up is very easy. The synchronization between the two displays is automatic if the grid and the memo or image control share a common data source.

Tip It is generally not a good idea to combine these two approaches on a single form. It is usually confusing for users to understand the data relationships in such forms.

Viewing and editing data with TDBGrid

A *TDBGrid* control lets you view and edit records in a dataset in a tabular grid format.

Figure 15.1 TDBGrid control



VendorName	Address1	City	State
Cacor Corporation	161 Southfield Rd	Southfield	OH
Underwater	50 N 3rd Street	Indianapolis	IN
J.W. Luscher Mfg.	65 Addams Street	Berkely	MA
Scuba Professionals	3105 East Brace	Rancho Dominguez	CA
Divers' Supply Shop	5208 University Dr	Macon	GA
Techniques	52 Dolphin Drive	Redwood City	CA
Perry Scuba	3443 James Ave	Hapeville	GA

Three factors affect the appearance of records displayed in a grid control:

- Existence of persistent column objects defined for the grid using the Columns editor. Persistent column objects provide great flexibility setting grid and data appearance. For information on using persistent columns, see "Creating a customized grid" on page 15-16.
- Creation of persistent field components for the dataset displayed in the grid. For more information about creating persistent field components using the Fields editor, see Chapter 19, "Working with field components."
- The dataset's *ObjectView* property setting for grids displaying ADT and array fields. See "Displaying ADT and array fields" on page 15-21.

A grid control has a *Columns* property that is itself a wrapper on a *TDBGridColumns* object. *TDBGridColumns* is a collection of *TColumn* objects representing all of the columns in a grid control. You can use the Columns editor to set up column attributes at design time, or use the *Columns* property of the grid to access the properties, events, and methods of *TDBGridColumns* at runtime.

Using a grid control in its default state

The *State* property of the grid's *Columns* property indicates whether persistent column objects exist for the grid. *Columns.State* is a runtime-only property that is automatically set for a grid. The default state is *csDefault*, meaning that persistent column objects do not exist for the grid. In that case, the display of data in the grid is determined primarily by the properties of the fields in the grid's dataset, or, if there are no persistent field components, by a default set of display characteristics.

When the grid's *Columns.State* property is *csDefault*, grid columns are dynamically generated from the visible fields of the dataset and the order of columns in the grid matches the order of fields in the dataset. Every column in the grid is associated with a field component. Property changes to field components immediately show up in the grid.

Using a grid control with dynamically-generated columns is useful for viewing and editing the contents of arbitrary tables selected at runtime. Because the grid's structure is not set, it can change dynamically to accommodate different datasets. A single grid with dynamically-generated columns can display a Paradox table at one moment, then switch to display the results of an SQL query when the grid's *DataSource* property changes or when the *DataSet* property of the data source itself is changed.

You can change the appearance of a dynamic column at design time or runtime, but what you are actually modifying are the corresponding properties of the field component displayed in the column. Properties of dynamic columns exist only so long as a column is associated with a particular field in a single dataset. For example, changing the *Width* property of a column changes the *DisplayWidth* property of the field associated with that column. Changes made to column properties that are not based on field properties, such as *Font*, exist only for the lifetime of the column.

If a grid's dataset consists of dynamic field components, the fields are destroyed each time the dataset is closed. When the field components are destroyed, all dynamic columns associated with them are destroyed as well. If a grid's dataset consists of persistent field components, the field components exist even when the dataset is closed, so the columns associated with those fields also retain their properties when the dataset is closed.

Note Changing a grid's *Columns.State* property to *csDefault* at runtime deletes all column objects in the grid (even persistent columns), and rebuilds dynamic columns based on the visible fields of the grid's dataset.

Creating a customized grid

A customized grid is one for which you define persistent column objects that describe how a column appears and how the data in the column is displayed. A customized grid lets you configure multiple grids to present different views of the same dataset (different column orders, different field choices, and different column colors and fonts, for example). A customized grid also enables you to let users modify the appearance of the grid at runtime without affecting the fields used by the grid or the field order of the dataset.

Customized grids are best used with datasets whose structure is known at design time. Because they expect field names established at design time to exist in the dataset, customized grids are not well suited to browsing arbitrary tables selected at runtime.

Understanding persistent columns

When you create persistent column objects for a grid, they are only loosely associated with underlying fields in a grid's dataset. Default property values for persistent columns are dynamically fetched from a default source (the associated field or the grid itself) until a value is assigned to the column property. Until you assign a column property a value, its value changes as its default source changes. Once you assign a value to a column property, it no longer changes when its default source changes.

For example, the default source for a column title caption is an associated field's *DisplayLabel* property. If you modify the *DisplayLabel* property, the column title reflects that change immediately. If you then assign a string to the column title's caption, the tile caption becomes independent of the associated field's *DisplayLabel* property. Subsequent changes to the field's *DisplayLabel* property no longer affect the column's title.

Persistent columns exist independently from field components with which they are associated. In fact, persistent columns do not have to be associated with field objects at all. If a persistent column's *FieldName* property is blank, or if the field name does not match the name of any field in the grid's current dataset, the column's *Field* property is NULL and the column is drawn with blank cells. If you override the cell's default drawing method, you can display your own custom information in the blank cells. For example, you can use a blank column to display aggregated values on the last record of a group of records that the aggregate summarizes. Another possibility is to display a bitmap or bar chart that graphically depicts some aspect of the record's data.

Two or more persistent columns can be associated with the same field in a dataset. For example, you might display a part number field at the left and right extremes of a wide grid to make it easier to find the part number without having to scroll the grid.

Note Because persistent columns do not have to be associated with a field in a dataset, and because multiple columns can reference the same field, a customized grid's *FieldCount* property can be less than or equal to the grid's column count. Also note that if the currently selected column in a customized grid is not associated with a field, the grid's *SelectedField* property is NULL and the *SelectedIndex* property is –1.

Persistent columns can be configured to display grid cells as a combo box drop-down list of lookup values from another dataset or from a static pick list, or as an ellipsis button (…) in a cell that can be clicked upon to launch special data viewers or dialogs related to the current cell.

Creating persistent columns

To customize the appearance of grid at design time, you invoke the Columns editor to create a set of persistent column objects for the grid. At runtime, the *State* property for a grid with persistent column objects is automatically set to *csCustomized*.

To create persistent columns for a grid control,

1. Select the grid component in the form.
2. Invoke the Columns editor by double clicking on the grid's *Columns* property in the Object Inspector.

The Columns list box displays the persistent columns that have been defined for the selected grid. When you first bring up the Columns editor, this list is empty because the grid is in its default state, containing only dynamic columns.

You can create persistent columns for all fields in a dataset at once, or you can create persistent columns on an individual basis. To create persistent columns for all fields:

1. Right-click the grid to invoke the context menu and choose Add All Fields. Note that if the grid is not already associated with a data source, Add All Fields is disabled. Associate the grid with a data source that has an active dataset before choosing Add All Fields.
2. If the grid already contains persistent columns, a dialog box asks if you want to delete the existing columns, or append to the column set. If you choose Yes, any existing persistent column information is removed, and all fields in the current dataset are inserted by field name according to their order in the dataset. If you choose No, any existing persistent column information is retained, and new column information, based on any additional fields in the dataset, are appended to the dataset.
3. Click Close to apply the persistent columns to the grid and close the dialog box.

To create persistent columns individually:

1. Choose the Add button in the Columns editor. The new column will be selected in the list box. The new column is given a sequential number and default name (for example, 0 - TColumn).
2. To associate a field with this new column, set the *FieldName* property in the Object Inspector.
3. To set the title for the new column, expand the *Title* property in the Object Inspector and set its *Caption* property.
4. Close the Columns editor to apply the persistent columns to the grid and close the dialog box.

At runtime, you can switch to persistent columns by assigning *csCustomized* to the *Columns.State* property. Any existing columns in the grid are destroyed and new persistent columns are built for each field in the grid's dataset. You can then add a persistent column at runtime by calling the *Add* method for the column list:

```
DBGrid1.Columns.Add;
```

Deleting persistent columns

Deleting a persistent column from a grid is useful for eliminating fields that you do not want to display. To remove a persistent column from a grid,

1. Double-click the grid to display the Columns editor.
2. Select the field to remove in the Columns list box.
3. Click Delete (you can also use the context menu or *Del* key, to remove a column).

Note If you delete all the columns from a grid, the *Columns.State* property reverts to its *csDefault* state and automatically build dynamic columns for each field in the dataset.

You can delete a persistent column at runtime by simply freeing the column object:

```
DBGrid1.Columns[5].Free;
```

Arranging the order of persistent columns

The order in which columns appear in the Columns editor is the same as the order the columns appear in the grid. You can change the column order by dragging and dropping columns within the Columns list box.

To change the order of a column,

1. Select the column in the Columns list box.
2. Drag it to a new location in the list box.

You can also change the column order by clicking on the column title of the actual grid and dragging the column to a new position, just as you can at runtime.

Note Reordering persistent fields in the Fields editor also reorders columns in a default grid, but not a custom grid.

Important You cannot reorder columns in grids containing both dynamic columns and dynamic fields at design time, since there is nothing persistent to record the altered field or column order.

At runtime, a user can use the mouse to drag a column to a new location in the grid if its *DragMode* property is set to *dmManual*. Reordering the columns of a grid with a *State* property of *csDefault* state also reorders field components in the dataset underlying the grid. The order of fields in the physical table is not affected. To prevent a user from rearranging columns at runtime, set the grid's *DragMode* property to *dmAutomatic*.

At runtime, the grid's *OnColumnMoved* event fires after a column has been moved.

Setting column properties at design time

Column properties determine how data is displayed in the cells of that column. Most column properties obtain their default values from properties associated with another component (called the *default source*) such as a grid or an associated field component.

To set a column's properties, select the column in The Columns editor and set its properties in the Object Inspector. The following table summarizes key column properties you can set.

Table 15.2 Column properties

Property	Purpose
Alignment	Left justifies, right justifies, or centers the field data in the column. Default source: *TField.Alignment*.
ButtonStyle	*cbsAuto*: (default) Displays a drop-down list if the associated field is a lookup field, or if the column's *PickList* property contains data. *cbsEllipsis*: Displays an ellipsis (...) button to the right of the cell. Clicking on the button fires the grid's *OnEditButtonClick* event. *cbsNone*: The column uses only the normal edit control to edit data in the column.
Color	Specifies the background color of the cells of the column. Default source: *TDBGrid.Color*. (For text foreground color, see the Font property.)

Table 15.2 Column properties (continued)

Property	Purpose
DropDownRows	The number of lines of text displayed by the drop-down list. Default: 7.
Expanded	Specifies whether the column is expanded. Only applies to columns representing ADT or array fields.
FieldName	Specifies the field name associated with this column. This can be blank.
ReadOnly	*True*: The data in the column cannot be edited by the user. *False*: (default) The data in the column can be edited.
Width	Specifies the width of the column in screen pixels. Default source: *TField.DisplayWidth*.
Font	Specifies the font type, size, and color used to draw text in the column. Default source: *TDBGrid.Font*.
PickList	Contains a list of values to display in a drop-down list in the column.
Title	Sets properties for the title of the selected column.

The following table summarizes the options you can specify for the *Title* property.

Table 15.3 Expanded TColumn Title properties

Property	Purpose
Alignment	Left justifies (default), right justifies, or centers the caption text in the column title.
Caption	Specifies the text to display in the column title. Default source: *TField.DisplayLabel*.
Color	Specifies the background color used to draw the column title cell. Default source: *TDBGrid.FixedColor*.
Font	Specifies the font type, size, and color used to draw text in the column title. Default source: *TDBGrid.TitleFont*.

Defining a lookup list column

You can create a column that displays a drop-down list of values, similar to a lookup combo box control. To specify that the column acts like a combo box, set the column's *ButtonStyle* property to *cbsAuto*. Once you populate the list with values, the grid automatically displays a combo box-like drop-down button when a cell of that column is in edit mode.

There are two ways to populate that list with the values for users to select:

- You can fetch the values from a lookup table. To make a column display a drop-down list of values drawn from a separate lookup table, you must define a lookup field in the dataset. For information about creating lookup fields, see "Defining a lookup field" on page 19-8. Once the lookup field is defined, set the column's *FieldName* to the lookup field name. The drop-down list is automatically populated with lookup values defined by the lookup field.
- You can specify a list of values explicitly at design time. To enter the list values at design time, double-click the *PickList* property for the column in the Object Inspector. This brings up the String List editor, where you can enter the values that populate the pick list for the column.

By default, the drop-down list displays 7 values. You can change the length of this list by setting the *DropDownRows* property.

Note To restore a column with an explicit pick list to its normal behavior, delete all the text from the pick list using the String List editor.

Putting a button in a column

A column can display an ellipsis button (…) to the right of the normal cell editor. *Ctrl+Enter* or a mouse click fires the grid's *OnEditButtonClick* event. You can use the ellipsis button to bring up forms containing more detailed views of the data in the column. For example, in a table that displays summaries of invoices, you could set up an ellipsis button in the invoice total column to bring up a form that displays the items in that invoice, or the tax calculation method, and so on. For graphic fields, you could use the ellipsis button to bring up a form that displays an image.

To create an ellipsis button in a column:

1 Select the column in the *Columns* list box.

2 Set *ButtonStyle* to *cbsEllipsis*.

3 Write an *OnEditButtonClick* event handler.

Restoring default values to a column

At runtime you can test a column's *AssignedValues* property to determine whether a column property has been explicitly assigned. Values that are not explicitly defined are dynamically based on the associated field or the grid's defaults.

You can undo property changes made to one or more columns. In the Columns editor, select the column or columns to restore, and then select Restore Defaults from the context menu. Restore defaults discards assigned property settings and restores a column's properties to those derived from its underlying field component

At runtime, you can reset all default properties for a single column by calling the column's *RestoreDefaults* method. You can also reset default properties for all columns in a grid by calling the column list's *RestoreDefaults* method:

```
DBGrid1.Columns.RestoreDefaults;
```

Displaying ADT and array fields

Sometimes the fields of the grid's dataset do not represent simple values such as text, graphics, numerical values, and so on. Some database servers allow fields that are a composite of simpler data types, such as ADT fields or array fields.

There are two ways a grid can display composite fields:

- It can "flatten out" the field so that each of the simpler types that make up the field appears as a separate field in the dataset. When a composite field is flattened out, its constituents appear as separate fields that reflect their common source only in that each field name is preceded by the name of the common parent field in the underlying database table.

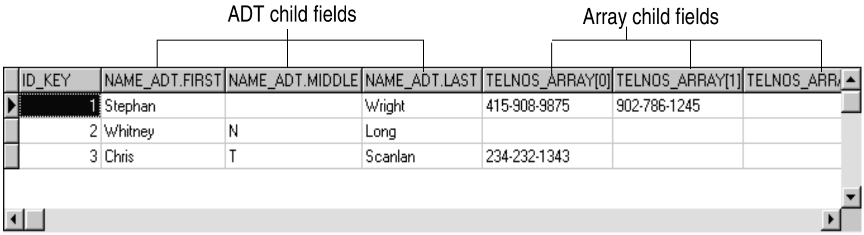
To display composite fields as if they were flattened out, set the dataset's *ObjectView* property to *False*. The dataset stores composite fields as a set of separate fields, and the grid reflects this by assigning each constituent part a separate column.

- It can display composite fields in a single column, reflecting the fact that they are a single field. When displaying composite fields in a single column, the column can be expanded and collapsed by clicking on the arrow in the title bar of the field, or by setting the *Expanded* property of the column:
    - When a column is expanded, each child field appears in its own sub-column with a title bar that appears below the title bar of the parent field. That is, the title bar for the grid increases in height, with the first row giving the name of the composite field, and the second row subdividing that for the individual parts. Fields that are not composites appear with title bars that are extra high. This expansion continues for constituents that are in turn composite fields (for example, a detail table nested in a detail table), with the title bar growing in height accordingly.
    - When the field is collapsed, only one column appears with an uneditable comma delimited string containing the child fields.

  To display a composite field in an expanding and collapsing column, set the dataset's *ObjectView* property to *True*. The dataset stores the composite field as a single field component that contains a set of nested sub-fields. The grid reflects this in a column that can expand or collapse

Figure 15.2 shows a grid with an ADT field and an array field. The dataset's *ObjectView* property is set to *False* so that each child field has a column.

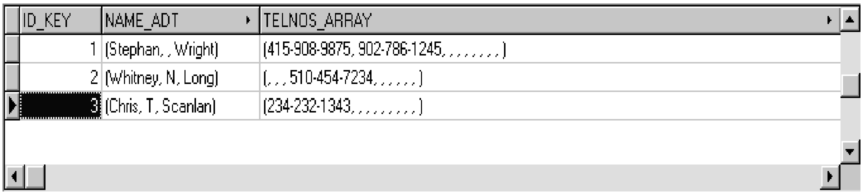
Figure 15.2 TDBGrid control with ObjectView set to False



ID_KEY	NAME_ADT.FIRST	NAME_ADT.MIDDLE	NAME_ADT.LAST	TELNOS_ARRAY[0]	TELNOS_ARRAY[1]	TELNOS_ARR
1	Stephan		Wright	415-908-9875	902-786-1245	
2	Whitney	N	Long			
3	Chris	T	Scanlan	234-232-1343		

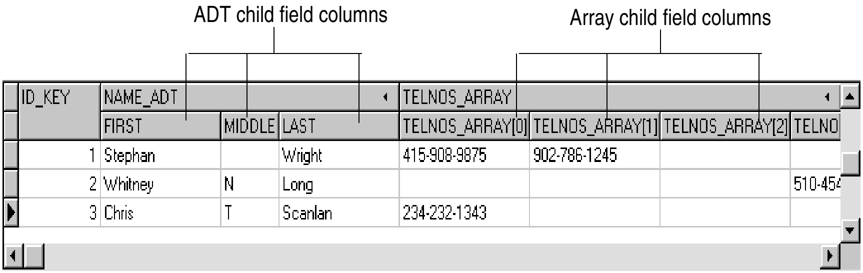
Figure 15.3 and 15.4 show the grid with an ADT field and an array field. Figure 15.3 shows the fields collapsed. In this state they cannot be edited. Figure 15.4 shows the fields expanded. The fields are expanded and collapsed by clicking on the arrow in the fields title bar.

Figure 15.3 TDBGrid control with Expanded set to False



ID_KEY	NAME_ADT	TELNOS_ARRAY
1	(Stephan, , Wright)	(415-908-9875, 902-786-1245, , , , , , , ,)
2	(Whitney, N, Long)	(, , , 510-454-7234, , , , , ,)
3	(Chris, T, Scanlan)	(234-232-1343, , , , , , , , ,)

Figure 15.4 TDBGrid control with Expanded set to True



ID_KEY	NAME_ADT			TELNOS_ARRAY			
	FIRST	MIDDLE	LAST	TELNOS_ARRAY[0]	TELNOS_ARRAY[1]	TELNOS_ARRAY[2]	TELNO
1	Stephan		Wright	415-908-9875	902-786-1245		
2	Whitney	N	Long				510-454
3	Chris	T	Scanlan	234-232-1343			

The following table lists the properties that affect the way ADT and array fields appear in a *TDBGrid*:

Table 15.4 Properties that affect the way composite fields appear

Property	Object	Purpose
Expandable	TColumn	Indicates whether the column can be expanded to show child fields in separate, editable columns. (read-only)
Expanded	TColumn	Specifies whether the column is expanded.
MaxTitleRows	TDBGrid	Specifies the maximum number of title rows that can appear in the grid
ObjectView	TDataSet	Specifies whether fields are displayed flattened out, or in object mode, where each object field can be expanded and collapsed.
ParentColumn	TColumn	Refers to the TColumn object that owns the child field's column.

Note In addition to ADT and array fields, some datasets include fields that refer to another dataset (dataset fields) or a record in another dataset (reference) fields. Data-aware grids display such fields as “(DataSet)” or “(Reference)”, respectively. At runtime an ellipsis button appears to the right. Clicking on the ellipsis brings up a new form with a grid displaying the contents of the field. For dataset fields, this grid displays the dataset that is the field’s value. For reference fields, this grid contains a single row that displays the record from another dataset.

Setting grid options

You can use the grid *Options* property at design time to control basic grid behavior and appearance at runtime. When a grid component is first placed on a form at design time, the *Options* property in the Object Inspector is displayed with a + (plus) sign to indicate that the *Options* property can be expanded to display a series of

Boolean properties that you can set individually. To view and set these properties, click on the + sign. The list of options in the Object Inspector below the *Options* property. The + sign changes to a – (minus) sign, that collapses the list back when you click it.

The following table lists the *Options* properties that can be set, and describes how they affect the grid at runtime.

Table 15.5 Expanded TDBGrid Options properties

Option	Purpose
dgEditing	*True*: (Default). Enables editing, inserting, and deleting records in the grid. *False*: Disables editing, inserting, and deleting records in the grid.
dgAlwaysShowEditor	*True*: When a field is selected, it is in Edit state. *False*: (Default). A field is not automatically in Edit state when selected.
dgTitles	*True*: (Default). Displays field names across the top of the grid. *False*: Field name display is turned off.
dgIndicator	*True*: (Default). The indicator column is displayed at the left of the grid, and the current record indicator (an arrow at the left of the grid) is activated to show the current record. On insert, the arrow becomes an asterisk. On edit, the arrow becomes an I-beam. *False*: The indicator column is turned off.
dgColumnResize	*True*: (Default). Columns can be resized by dragging the column rulers in the title area. Resizing changes the corresponding width of the underlying *TField* component. *False*: Columns cannot be resized in the grid.
dgColLines	*True*: (Default). Displays vertical dividing lines between columns. *False*: Does not display dividing lines between columns.
dgRowLines	*True*: (Default). Displays horizontal dividing lines between records. *False*: Does not display dividing lines between records.
dgTabs	*True*: (Default). Enables tabbing between fields in records. *False*: Tabbing exits the grid control.
dgRowSelect	*True*: The selection bar spans the entire width of the grid. *False*: (Default). Selecting a field in a record selects only that field.
dgAlwaysShowSelection	*True*: (Default). The selection bar in the grid is always visible, even if another control has focus. *False*: The selection bar in the grid is only visible when the grid has focus.
dgConfirmDelete	*True*: (Default). Prompt for confirmation to delete records (*Ctrl+Del*). *False*: Delete records without confirmation.
dgCancelOnExit	*True*: (Default). Cancels a pending insert when focus leaves the grid. This option prevents inadvertent posting of partial or blank records. *False*: Permits pending inserts.
dgMultiSelect	*True*: Allows user to select noncontiguous rows in the grid using *Ctrl+Shift* or *Shift+ arrow* keys. *False*: (Default). Does not allow user to multi-select rows.

Editing in the grid

At runtime, you can use a grid to modify existing data and enter new records, if the following default conditions are met:

- The *CanModify* property of the *Dataset* is *True*.
- The *ReadOnly* property of grid is *False*.

When a user edits a record in the grid, changes to each field are posted to an internal record buffer, but are not posted until the user moves to a different record in the grid. Even if focus is changed to another control on a form, the grid does not post changes until another the cursor for the dataset is moved to another record. When a record is posted, the dataset checks all associated data-aware components for a change in status. If there is a problem updating any fields that contain modified data, the grid raises an exception, and does not modify the record.

Note If your application caches updates, posting record changes only adds them to an internal cache. They are not posted back to the underlying database table until your application applies the updates.

You can cancel all edits for a record by pressing *Esc* in any field before moving to another record.

Controlling grid drawing

Your first level of control over how a grid control draws itself is setting column properties. The grid automatically uses the font, color, and alignment properties of a column to draw the cells of that column. The text of data fields is drawn using the *DisplayFormat* or *EditFormat* properties of the field component associated with the column.

You can augment the default grid display logic with code in a grid's *OnDrawColumnCell* event. If the grid's *DefaultDrawing* property is *True*, all the normal drawing is performed before your *OnDrawColumnCell* event handler is called. Your code can then draw on top of the default display. This is primarily useful when you have defined a blank persistent column and want to draw special graphics in that column's cells.

If you want to replace the drawing logic of the grid entirely, set *DefaultDrawing* to *False* and place your drawing code in the grid's *OnDrawColumnCell* event. If you want to replace the drawing logic only in certain columns or for certain field data types, you can call the *DefaultDrawColumnCell* inside your *OnDrawColumnCell* event handler to have the grid use its normal drawing code for selected columns. This reduces the amount of work you have to do if you only want to change the way Boolean field types are drawn, for example.

Responding to user actions at runtime

You can modify grid behavior by writing event handlers to respond to specific actions within the grid at runtime. Because a grid typically displays many fields and records at once, you may have very specific needs to respond to changes to individual columns. For example, you might want to activate and deactivate a button elsewhere on the form every time a user enters and exits a specific column.

The following table lists the grid events available in the Object Inspector.

Table 15.6 Grid control events

Event	Purpose
OnCellClick	Occurs when a user clicks on a cell in the grid.
OnColEnter	Occurs when a user moves into a column on the grid.
OnColExit	Occurs when a user leaves a column on the grid.
OnColumnMoved	Occurs when the user moves a column to a new location.
OnDblClick	Occurs when a user double clicks in the grid.
OnDragDrop	Occurs when a user drags and drops in the grid.
OnDragOver	Occurs when a user drags over the grid.
OnDrawColumnCell	Occurs when application needs to draw individual cells.
OnDrawDataCell	(obsolete) Occurs when application needs to draw individual cells if *State* is *csDefault*.
OnEditButtonClick	Occurs when the user clicks on an ellipsis button in a column.
OnEndDrag	Occurs when a user stops dragging on the grid.
OnEnter	Occurs when the grid gets focus.
OnExit	Occurs when the grid loses focus.
OnKeyDown	Occurs when a user presses any key or key combination on the keyboard when in the grid.
OnKeyPress	Occurs when a user presses a single alphanumeric key on the keyboard when in the grid.
OnKeyUp	Occurs when a user releases a key when in the grid.
OnStartDrag	Occurs when a user starts dragging on the grid.
OnTitleClick	Occurs when a user clicks the title for a column.

There are many uses for these events. For example, you might write a handler for the *OnDblClick* event that pops up a list from which a user can choose a value to enter in a column. Such a handler would use the *SelectedField* property to determine to current row and column.

Creating a grid that contains other data-aware controls

A *TDBCtrlGrid* control displays multiple fields in multiple records in a tabular grid format. Each cell in a grid displays multiple fields from a single row. To use a database control grid:

1. Place a database control grid on a form.
2. Set the grid's *DataSource* property to the name of a data source.

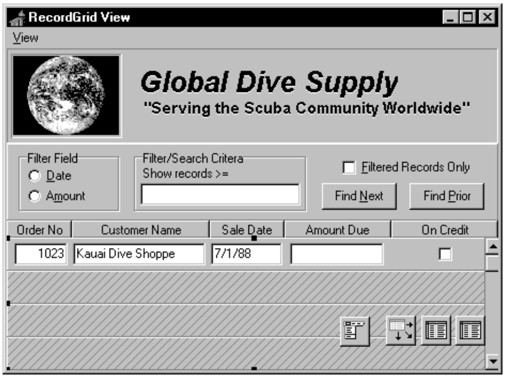
3 Place individual data controls within the design cell for the grid. The design cell for the grid is the top or leftmost cell in the grid, and is the only cell into which you can place other controls.

4 Set the *DataField* property for each data control to the name of a field. The data source for these data controls is already set to the data source of the database control grid.

5 Arrange the controls within the cell as desired.

When you compile and run an application containing a database control grid, the arrangement of data controls you set in the design cell at runtime is replicated in each cell of the grid. Each cell displays a different record in a dataset.

Figure 15.5 TDBCtrlGrid at design time



The following table summarizes some of the unique properties for database control grids that you can set at design time:

Table 15.7 Selected database control grid properties

Property	Purpose
AllowDelete	*True* (default): Permits record deletion. *False*: Prevents record deletion.
AllowInsert	*True* (default): Permits record insertion. *False*: Prevents record insertion.
ColCount	Sets the number of columns in the grid. Default = 1.
Orientation	*goVertical* (default): Display records from top to bottom. *goHorizontal*: Displays records from left to right.
PanelHeight	Sets the height for an individual panel. Default = 72.
PanelWidth	Sets the width for an individual panel. Default = 200.
RowCount	Sets the number of panels to display. Default = 3.
ShowFocus	*True* (default): Displays a focus rectangle around the current record's panel at runtime. *False*: Does not display a focus rectangle.

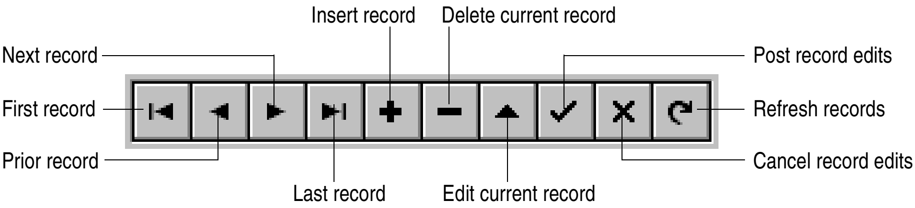
For more information about database control grid properties and methods, see the online *VCL Reference*.

Navigating and manipulating records

TDBNavigator provides users a simple control for navigating through records in a dataset, and for manipulating records. The navigator consists of a series of buttons that enable a user to scroll forward or backward through records one at a time, go to the first record, go to the last record, insert a new record, update an existing record, post data changes, cancel data changes, delete a record, and refresh record display.

Figure 15.6 shows the navigator that appears by default when you place it on a form at design time. The navigator consists of a series of buttons that let a user navigate from one record to another in a dataset, and edit, delete, insert, and post records. The *VisibleButtons* property of the navigator enables you to hide or show a subset of these buttons dynamically.

Figure 15.6 Buttons on the TDBNavigator control



The following table describes the buttons on the navigator.

Table 15.8 TDBNavigator buttons

Button	Purpose
First	Calls the dataset's *First* method to set the current record to the first record.
Prior	Calls the dataset's *Prior* method to set the current record to the previous record.
Next	Calls the dataset's *Next* method to set the current record to the next record.
Last	Calls the dataset's *Last* method to set the current record to the last record.
Insert	Calls the dataset's *Insert* method to insert a new record before the current record, and set the dataset in Insert state.
Delete	Deletes the current record. If the *ConfirmDelete* property is *True* it prompts for confirmation before deleting.
Edit	Puts the dataset in Edit state so that the current record can be modified.
Post	Writes changes in the current record to the database.
Cancel	Cancels edits to the current record, and returns the dataset to Browse state.
Refresh	Clears data control display buffers, then refreshes its buffers from the physical table or query. Useful if the underlying data may have been changed by another application.

Choosing navigator buttons to display

When you first place a *TDBNavigator* on a form at design time, all its buttons are visible. You can use the *VisibleButtons* property to turn off buttons you do not want to use on a form. For example, when working with a unidirectional dataset, only the

First, *Next*, and *Refresh* buttons are meaningful. On a form that is intended for browsing rather than editing, you might want to disable the *Edit*, *Insert*, *Delete*, *Post*, and *Cancel* buttons.

Hiding and showing navigator buttons at design time

The *VisibleButtons* property in the Object Inspector is displayed with a + sign to indicate that it can be expanded to display a Boolean value for each button on the navigator. To view and set these values, click on the + sign. The list of buttons that can be turned on or off appears in the Object Inspector below the *VisibleButtons* property. The + sign changes to a – (minus) sign, which you can click to collapse the list of properties.

Button visibility is indicated by the *Boolean* state of the button value. If a value is set to *True*, the button appears in the *TDBNavigator*. If ***False***, the button is removed from the navigator at design time and runtime.

Note As button values are set to *False*, they are removed from the *TDBNavigator* on the form, and the remaining buttons are expanded in width to fill the control. You can drag the control's handles to resize the buttons.

Hiding and showing navigator buttons at runtime

At runtime you can hide or show navigator buttons in response to user actions or application states. For example, suppose you provide a single navigator for navigating through two different datasets, one of which permits users to edit records, and the other of which is read-only. When you switch between datasets, you want to hide the navigator's *Insert, Delete, Edit, Post, Cancel*, and *Refresh* buttons for the read-only dataset, and show them for the other dataset.

For example, suppose you want to prevent edits to the *OrdersTable* by hiding the *Insert, Delete, Edit, Post, Cancel,* and *Refresh* buttons on the navigator, but that you also want to allow editing for the *CustomersTable*. The *VisibleButtons* property controls which buttons are displayed in the navigator. Here's one way you might code the *OnEnter* event handler:

```
procedure TForm1.CustomerCompanyEnter(Sender :TObject);
begin
  if Sender = CustomerCompany then
  begin
    DBNavigatorAll.DataSource := CustomerCompany.DataSource;
    DBNavigatorAll.VisibleButtons := [nbFirst,nbPrior,nbNext,nbLast];
  end
  else
  begin
    DBNavigatorAll.DataSource := OrderNum.DataSource;
    DBNavigatorAll.VisibleButtons := DBNavigatorAll.VisibleButtons + [nbInsert,
      nbDelete,nbEdit,nbPost,nbCancel,nbRefresh];
  end;
end;
```

Displaying fly-over help

To display fly-over help for each navigator button at runtime, set the navigator *ShowHint* property to *True*. When *ShowHint* is *True*, the navigator displays fly-by Help Hints whenever you pass the mouse cursor over the navigator buttons. *ShowHint* is *False* by default.

The *Hints* property controls the fly-over help text for each button. By default *Hints* is an empty string list. When *Hints* is empty, each navigator button displays default help text. To provide customized fly-over help for the navigator buttons, use the String list editor to enter a separate line of hint text for each button in the *Hints* property. When present, the strings you provide override the default hints provided by the navigator control.

Using a single navigator for multiple datasets

As with other data-aware controls, a navigator's *DataSource* property specifies the data source that links the control to a dataset. By changing a navigator's *DataSource* property at runtime, a single navigator can provide record navigation and manipulation for multiple datasets.

Suppose a form contains two edit controls linked to the *CustomersTable* and *OrdersTable* datasets through the *CustomersSource* and *OrdersSource* data sources respectively. When a user enters the edit control connected to *CustomersSource*, the navigator should also use *CustomersSource*, and when the user enters the edit control connected to *OrdersSource*, the navigator should switch to *OrdersSource* as well. You can code an *OnEnter* event handler for one of the edit controls, and then share that event with the other edit control. For example:

```
procedure TForm1.CustomerCompanyEnter(Sender :TObject);
begin
  if Sender = CustomerCompany then
    DBNavigatorAll.DataSource := CustomerCompany.DataSource
  else
    DBNavigatorAll.DataSource := OrderNum.DataSource;
end;
```

Chapter

16

Using decision support components

The decision support components help you create cross-tabulated—or, crosstab—tables and graphs. You can then use these tables and graphs to view and summarize data from different perspectives. For more information on cross-tabulated data, see "About crosstabs" on page 16-2.

Overview

The decision support components appear on the Decision Cube page of the component palette:

- The decision cube, *TDecisionCube*, is a multidimensional data store.
- The decision source, *TDecisionSource*, defines the current pivot state of a decision grid or a decision graph.
- The decision query, *TDecisionQuery*, is a specialized form of *TQuery* used to define the data in a decision cube.
- The decision pivot, *TDecisionPivot*, lets you open or close decision cube dimensions, or fields, by pressing buttons.
- The decision grid, *TDecisionGrid*, displays single- and multidimensional data in table form.
- The decision graph, *TDecisionGraph*, displays fields from a decision grid as a dynamic graph that changes when data dimensions are modified.

Figure 16.1 shows all the decision support components placed on a form at design time.

Figure 16.1 Decision support components at design time

		ShipVIA			
Terms	Country	DHL	Emery	FedEx	UPS
FOB	Algeria				$15,214.05
	America	$82,389.00	$20,321.75	$1,465.60	$66,475.85
	Canada	$10,152.00		$3,304.85	$48,988.40
	China	$67,448.65	$3,531.80	$787.80	$7,671.90
	France	$6,785.40		$20,108.00	$76,311.05

About crosstabs

Cross-tabulations, or crosstabs, are a way of presenting subsets of data so that relationships and trends are more visible. Table fields become the dimensions of the crosstab while field values define categories and summaries within a dimension.

You can use the decision support components to set up crosstabs in forms. *TDecisionGrid* shows data in a table, while *TDecisionGraph* charts it graphically. *TDecisionPivot* has buttons that make it easier to display and hide dimensions and move them between columns and rows.

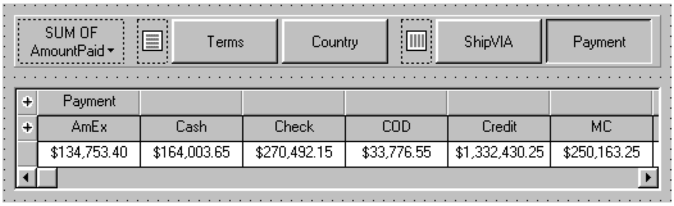
Crosstabs can be one-dimensional or multidimensional.

One-dimensional crosstabs

One-dimensional crosstabs show a summary row (or column) for the categories of a single dimension. For example, if Payment is the chosen column dimension and

Amount Paid is the summary category, the crosstab in Figure 16.2 shows the amount paid using each method.

Figure 16.2 One-dimensional crosstab



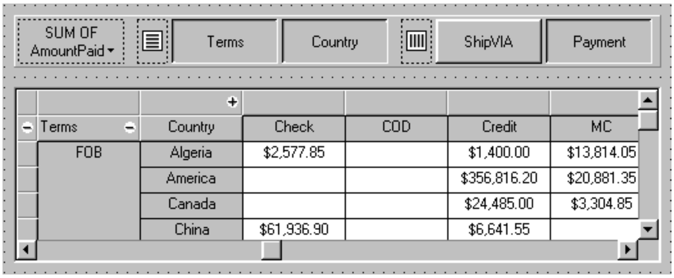
Payment					
AmEx	Cash	Check	COD	Credit	MC
$134,753.40	$164,003.65	$270,492.15	$33,776.55	$1,332,430.25	$250,163.25

Multidimensional crosstabs

Multidimensional crosstabs use additional dimensions for the rows and/or columns. For example, a two-dimensional crosstab could show amounts paid by payment method for each country.

A three-dimensional crosstab could show amounts paid by payment method and terms by country, as shown in Figure 16.3.

Figure 16.3 Three-dimensional crosstab



Terms	Country	Check	COD	Credit	MC
FOB	Algeria	$2,577.85		$1,400.00	$13,814.05
	America			$356,816.20	$20,881.35
	Canada			$24,485.00	$3,304.85
	China	$61,936.90		$6,641.55	

Guidelines for using decision support components

The decision support components listed on page 16-1 can be used together to present multidimensional data as tables and graphs. More than one grid or graph can be attached to each dataset. More than one instance of *TDecisionPivot* can be used to display the data from different perspectives at runtime.

To create a form with tables and graphs of multidimensional data, follow these steps:

1. Create a form.
2. Add these components to the form and use the Object Inspector to bind them as indicated:
   - A dataset, usually *TDecisionQuery* (for details, see “Creating decision datasets with the Decision Query editor” on page 16-6) or *TQuery*

- A decision cube, *TDecisionCube*, bound to the dataset by setting its *DataSet* property to the dataset's name
- A decision source, *TDecisionSource*, bound to the decision cube by setting its *DecisionCube* property to the decision cube's name

3 Add a decision pivot, *TDecisionPivot*, and bind it to the decision source with the Object Inspector by setting its *DecisionSource* property to the appropriate decision source name. The decision pivot is optional but useful; it lets the form developer and end users change the dimensions displayed in decision grids or decision graphs by pushing buttons.

In its default orientation, horizontal, buttons on the left side of the decision pivot apply to fields on the left side of the decision grid (rows); buttons on the right side apply to fields at the top of the decision grid (columns).

You can determine where the decision pivot's buttons appear by setting its *GroupLayout* property to *xtVertical*, *xtLeftTop*, or *xtHorizontal* (the default). For more information on decision pivot properties, see "Using decision pivots" on page 16-9.

4 Add one or more decision grids and graphs, bound to the decision source. For details, see "Creating and using decision grids" on page 16-10 and "Creating and using decision graphs" on page 16-13.

5 Use the Decision Query editor or *SQL* property of *TDecisionQuery* (or *TQuery*) to specify the tables, fields, and summaries to display in the grid or graph. The last field of the SQL SELECT should be the summary field. The other fields in the SELECT must be GROUP BY fields. For instructions, see "Creating decision datasets with the Decision Query editor" on page 16-6.

6 Set the *Active* property of the decision query (or alternate dataset component) to *True*.

7 Use the decision grid and graph to show and chart different data dimensions. See "Using decision grids" on page 16-11 and "Using decision graphs" on page 16-13 for instructions and suggestions.

For an illustration of all decision support components on a form, see Figure 16.1 on page 16-2.

Using datasets with decision support components

The only decision support component that binds directly to a dataset is the decision cube, *TDecisionCube. TDecisionCube* expects to receive data with groups and summaries defined by an SQL statement of an acceptable format. The GROUP BY phrase must contain the same non-summarized fields (and in the same order) as the SELECT phrase, and summary fields must be identified.

The decision query component, *TDecisionQuery*, is a specialized form of *TQuery*. You can use TDecisionQuery to more simply define the setup of dimensions (rows and columns) and summary values used to supply data to decision cubes (*TDecisionCube)*. You can also use an ordinary *TQuery* or other BDE-enabled dataset as a dataset for *TDecisionCube*, but the correct setup of the dataset and *TDecisionCube* are then the responsibility of the designer.

To work correctly with the decision cube, all projected fields in the dataset must either be dimensions or summaries. The summaries should be additive values (like sum or count), and should represent totals for each combination of dimension values. For maximum ease of setup, sums should be named “Sum...” in the dataset while counts should be named “Count...”.

The Decision Cube can pivot, subtotal, and drill-in correctly only for summaries whose cells are additive. (SUM and COUNT are additive, while AVERAGE, MAX, and MIN are not.) Build pivoting crosstab displays only for grids that contain only additive aggregators. If you are using non-additive aggregators, use a static decision grid that does not pivot, drill, or subtotal.

Since averages can be calculated using SUM divided by COUNT, a pivoting average is added automatically when SUM and COUNT dimensions for a field are included in the dataset. Use this type of average in preference to an average calculated using an AVERAGE statement.

Averages can also be calculated using COUNT(*). To use COUNT(*) to calculate averages, include a "COUNT(*) COUNTALL" selector in the query. If you use COUNT(*) to calculate averages, the single aggregator can be used for all fields. Use COUNT(*) only in cases where none of the fields being summarized include blank values, or where a COUNT aggregator is not available for every field.

Creating decision datasets with TQuery or TTable

If you use an ordinary *TQuery* component as a decision dataset, you must manually set up the SQL statement, taking care to supply a GROUP BY phrase which contains the same fields (and in the same order) as the SELECT phrase.

The SQL should look similar to this:

```
SELECT ORDERS."Terms", ORDERS."ShipVIA",
  ORDERS."PaymentMethod", SUM( ORDERS."AmountPaid" )
FROM "ORDERS.DB" ORDERS
GROUP BY ORDERS."Terms", ORDERS."ShipVIA", ORDERS."PaymentMethod"
```

The ordering of the SELECT fields should match the ordering of the GROUP BY fields.

With *TTable*, you must supply information to the decision cube about which of the fields in the query are grouping fields, and which are summaries. To do this, Fill in the Dimension Type for each field in the *DimensionMap* of the Decision Cube. You must indicate whether each field is a dimension or a summary, and if a summary, you must provide the summary type. Since pivoting averages depend on SUM/COUNT calculations, you must also provide the base field name to allow the decision cube to match pairs of SUM and COUNT aggregators.

Creating decision datasets with the Decision Query editor

All data used by the decision support components passes through the decision cube, which accepts a specially formatted dataset most easily produced by an SQL query. See “Using datasets with decision support components” on page 16-4 for more information.

While both *TTable* and *TQuery* can be used as decision datasets, it is easier to use *TDecisionQuery*; the Decision Query editor supplied with it can be used to specify tables, fields, and summaries to appear in the decision cube and will help you set up the SELECT and GROUP BY portions of the SQL correctly.

To use the Decision Query editor:

1. Select the decision query component on the form, then right-click and choose Decision Query editor. The Decision Query editor dialog box appears.
2. Choose the database to use.
3. For single-table queries, click the Select Table button.

   For more complex queries involving multi-table joins, click the Query Builder button to display the SQL Builder or type the SQL statement into the edit box on the SQL tab page.
4. Return to the Decision Query editor dialog box.
5. In the Decision Query editor dialog box, select fields in the Available Fields list box and assign them to be either Dimensions or Summaries by clicking the appropriate right arrow button. As you add fields to the Summaries list, select from the menu displayed the type of summary to use: sum, count, or average.
6. By default, all fields and summaries defined in the *SQL* property of the decision query appear in the Active Dimensions and Active Summaries list boxes. To remove a dimension or summary, select it in the list and click the left arrow beside the list, or double-click the item to remove. To add it back, select it in the Available Fields list box and click the appropriate right arrow.

Once you define the contents of the decision cube, you can further manipulate dimension display with its *DimensionMap* property and the buttons of *TDecisionPivot*. For more information, see the next section, “Using decision cubes,” “Using decision sources” on page 16-9, and “Using decision pivots” on page 16-9.

Note When you use the Decision Query editor, the query is initially handled in ANSI-92 SQL syntax, then translated (if necessary) into the dialect used by the server. The Decision Query editor reads and displays only ANSI standard SQL. The dialect translation is automatically assigned to the *TDecisionQuery*’s SQL property. To modify a query, edit the ANSI-92 version in the Decision Query rather then the SQL property.

Using decision cubes

The decision cube component, *TDecisionCube,* is a multidimensional data store that fetches its data from a dataset (typically a specially structured SQL statement entered through *TDecisionQuery* or *TQuery*). The data is stored in a form that makes its easy to pivot (that is, change the way in which the data is organized and summarized) without needing to run the query a second time.

Decision cube properties and events

The *DimensionMap* properties of *TDecisionCube* not only control which dimensions and summaries appear but also let you set date ranges and specify the maximum number of dimensions the decision cube may support. You can also indicate whether or not to display data during design. You can display names, (categories) values, subtotals, or data. Display of data at design time can be time consuming, depending on the data source.

When you click the ellipsis next to *DimensionMap* in the Object Inspector, the Decision Cube editor dialog box appears. You can use its pages and controls to set the *DimensionMap* properties.

The *OnRefresh* event fires whenever the decision cube cache is rebuilt. Developers can access the new dimension map and change it at that time to free up memory, change the maximum summaries or dimensions, and so on. *OnRefresh* is also useful if users access the Decision Cube editor; application code can respond to user changes at that time.

Using the Decision Cube editor

You can use the Decision Cube editor to set the *DimensionMap* properties of decision cubes. You can display the Decision Cube editor through the Object Inspector, as described in the previous section, or by right-clicking a decision cube on a form at design time and choosing Decision Cube editor.

The Decision Cube Editor dialog box has two tabs:

- Dimension Settings, used to activate or disable available dimensions, rename and reformat dimensions, put dimensions in a permanently drilled state, and set date ranges to display.
- Memory Control, used to set the maximum number of dimensions and summaries that can be active at one time, to display information about memory usage, and to determine the names and data that appear at design time.

Viewing and changing dimension settings

To view the dimension settings, display the Decision Cube editor and click the Dimension Settings tab. Then, select a dimension or summary in the Available Fields list. Its information appears in the boxes on the right side of the editor:

- To change the dimension or summary name that appears in the decision pivot, decision grid, or decision graph, enter a new name in the Display Name edit box.
- To determine whether the selected field is a dimension or summary, read the text in the Type edit box. If the dataset is a *TTable* component, you can use Type to specify whether the selected field is a dimension or summary.
- To disable or activate the selected dimension or summary, change the setting in the Active Type drop-down list box: Active, As Needed, or Inactive. Disabling a dimension or setting it to As Needed saves memory.
- To change the format of that dimension or summary, enter a format string in the Format edit box.
- To display that dimension or summary by Year, Quarter, or Month, change the setting in the Binning drop-down list box. Note that you can choose Set in the Binning list box to put the selected dimension or summary in a permanently "drilled down" state. This can be useful for saving memory when a dimension has many values. For more information, see "Decision support components and memory control" on page 16-19.
- To determine the starting value for ranges, or the drill-down value for a "Set" dimension, first choose the appropriate Grouping value in the Grouping drop-down, and then enter the starting range value or permanent drill-down value in the Initial Value drop-down list.

Setting the maximum available dimensions and summaries

To determine the maximum number of dimensions and summaries available for decision pivots, decision grids, and decision graphs bound to the selected decision cube, display the Decision Cube editor and click the Memory Control tab. Use the edit controls to adjust the current settings, if necessary. These settings help to control the amount of memory required by the decision cube. For more information, see "Decision support components and memory control" on page 16-19.

Viewing and changing design options

To determine how much information appears at design time, display the Decision Cube editor and click the Memory Control tab. Then, check the setting that indicates which names and data to display. Display of data or field names at design time can cause performance delays in some cases because of the time needed to fetch the data.

Using decision sources

The decision source component, *TDecisionSource,* defines the current pivot state of decision grids or decision graphs. Any two objects which use the same decision source also share pivot states.

Properties and events

The following are some special properties and events that control the appearance and behavior of decision sources:

- The *ControlType* property of *TDecisionSource* indicates whether the decision pivot buttons should act like check boxes (multiple selections) or radio buttons (mutually exclusive selections).
- The *SparseCols* and *SparseRows* properties of *TDecisionSource* indicate whether to display columns or rows with no values; if *True*, sparse columns or rows are displayed.
- *TDecisionSource* has the following events:
  - *OnLayoutChange* occurs when the user performs pivots or drill-downs that reorganize the data.
  - *OnNewDimensions* occurs when the data is completely altered, such as when the summary or dimension fields are altered.
  - *OnSummaryChange* occurs when the current summary is changed.
  - *OnStateChange* occurs when the Decision Cube activates or deactivates.
  - *OnBeforePivot* occurs when changes are committed but not yet reflected in the user interface. Developers have an opportunity to make changes, for example, in capacity or pivot state, before application users see the result of their previous action.
  - *OnAfterPivot* fires after a change in pivot state. Developers can capture information at that time.

Using decision pivots

The decision pivot component, *TDecisionPivot,* lets you open or close decision cube dimensions, or fields, by pressing buttons. When a row or column is opened by pressing a *TDecisionPivot* button, the corresponding dimension appears on the *TDecisionGrid* or *TDecisionGraph* component. When a dimension is closed, its detailed data doesn’t appear; it collapses into the totals of other dimensions. A dimension may also be in a “drilled” state, where only the summaries for a particular value of the dimension field appear.

You can also use the decision pivot to reorganize dimensions displayed in the decision grid and decision graph. Just drag a button to the row or column area or reorder buttons within the same area.

For illustrations of decision pivots at design time, see Figures 16.1, 16.2, and 16.3.

Decision pivot properties

The following are some special properties that control the appearance and behavior of decision pivots:

- The first properties listed for *TDecisionPivot* define its overall behavior and appearance. You might want to set *ButtonAutoSize* to *False* for *TDecisionPivot* to keep buttons from expanding and contracting as you adjust the size of the component.
- The *Groups* property of *TDecisionPivot* defines which dimension buttons appear. You can display the row, column, and summary selection button groups in any combination. Note that if you want more flexibility over the placement of these groups, you can place one *TDecisionPivot* on your form which contains only rows in one location, and a second which contains only columns in another location.
- Typically, *TDecisionPivot* is added above *TDecisionGrid*. In its default orientation, horizontal, buttons on the left side of *TDecisionPivot* apply to fields on the left side of *TDecisionGrid* (rows); buttons on the right side apply to fields at the top of *TDecisionGrid* (columns).
- You can determine where *TDecisionPivot*'s buttons appear by setting its *GroupLayout* property to *xtVertical*, *xtLeftTop*, or *xtHorizontal* (the default, described in the previous paragraph).

Creating and using decision grids

Decision grid components, *TDecisionGrid,* present cross-tabulated data in table form. These tables are also called crosstabs, described on page 16-2. Figure 16.1 on page 16-2 shows a decision grid on a form at design time.

Creating decision grids

To create a form with one or more tables of cross-tabulated data,

1. Follow steps 1–3 listed under “Guidelines for using decision support components” on page 16-3.
2. Add one or more decision grid components (*TDecisionGrid*) and bind them to the decision source, *TDecisionSource,* with the Object Inspector by setting their *DecisionSource* property to the appropriate decision source component.

3 Continue with steps 5–7 listed under “Guidelines for using decision support components.”

For a description of what appears in the decision grid and how to use it, see “Using decision grids” on page 16-11.

To add a graph to the form, follow the instructions in “Creating decision graphs” on page 16-13.

Using decision grids

The decision grid component, *TDecisionGrid*, displays data from decision cubes (*TDecisionCube*) bound to decision sources (*TDecisionSource*).

By default, the grid appears with dimension fields at its left side and/or top, depending on the grouping instructions defined in the dataset. Categories, one for each data value, appear under each field. You can

- Open and close dimensions
- Reorganize, or pivot, rows and columns
- Drill down for detail
- Limit dimension selection to a single dimension for each axis

For more information about special properties and events of the decision grid, see “Decision grid properties” on page 16-12.

Opening and closing decision grid fields

If a plus sign (+) appears in a dimension or summary field, one or more fields to its right are closed (hidden). You can open additional fields and categories by clicking the sign. A minus sign (-) indicates a fully opened (expanded) field. When you click the sign, the field closes. This outlining feature can be disabled; see “Decision grid properties” on page 16-12 for details.

Reorganizing rows and columns in decision grids

You can drag row and column headings to new locations within the same axis or to the other axis. In this way, you can reorganize the grid and see the data from new perspectives as the data groupings change. This pivoting feature can be disabled; see “Decision grid properties” on page 16-12 for details.

If you included a decision pivot, you can push and drag its buttons to reorganize the display. See “Using decision pivots” on page 16-9 for instructions.

Drilling down for detail in decision grids

You can drill down to see more detail in a dimension.

For example, if you right-click a category label (row heading) for a dimension with others collapsed beneath it, you can choose to drill down and only see data for that category. When a dimension is drilled, you do not see the category labels for that dimension displayed on the grid, since only the records for a single category value are being displayed. If you have a decision pivot on the form, it displays category values and lets you change to other values if you want.

To drill down into a dimension,

- Right-click a category label and choose Drill In To This Value, or
- Right-click a pivot button and choose Drilled In.

To make the complete dimension active again,

- Right-click the corresponding pivot button, or right-click the decision grid in the upper-left corner and select the dimension.

Limiting dimension selection in decision grids

You can change the *ControlType* property of the decision source to determine whether more than one dimension can be selected for each axis of the grid. For more information, see "Using decision sources" on page 16-9.

Decision grid properties

The decision grid component, *TDecisionGrid*, displays data from the *TDecisionCube* component bound to *TDecisionSource.* By default, data appears in a grid with category fields on the left side and top of the grid.

The following are some special properties that control the appearance and behavior of decision grids:

- *TDecisionGrid* has unique properties for each dimension. To set these, choose *Dimensions* in the Object Inspector, then select a dimension. Its properties then appear in the Object Inspector: *Alignment* defines the alignment of category labels for that dimension, *Caption* can be used to override the default dimension name, *Color* defines the color of category labels, *FieldName* displays the name of the active dimension, *Format* can hold any standard format for that data type, and *Subtotals* indicates whether to display subtotals for that dimension. With summary fields, these same properties are used to changed the appearance of the data that appears in the summary area of the grid. When you're through setting dimension properties, either click a component in the form or choose a component in the drop-down list box at the top of the Object Inspector.
- The *Options* property of *TDecisionGrid* lets you control display of grid lines (*cgGridLines = True*), enabling of outline features (collapse and expansion of dimensions with + and - indicators; *cgOutliner = True*), and enabling of drag-and-drop pivoting (*cgPivotable = True*).
- The *OnDecisionDrawCell* event of *TDecisionGrid* gives you a chance to change the appearance of each cell as it is drawn. The event passes the *String*, *Font*, and *Color* of the current cell as reference parameters. You are free to alter those parameters to achieve effects such as special colors for negative values. In addition to the *DrawState* which is passed by *TCustomGrid*, the event passes *TDecisionDrawState*, which can be used to determine what type of cell is being drawn. Further information about the cell can be fetched using the *Cells*, *CellValueArray*, or *CellDrawState* functions.

- The *OnDecisionExamineCell* event of *TDecisionGrid* lets you hook the right-click-on-event to data cells, and is intended to allow a program to display information (such as detail records) about that particular data cell. When the user right-clicks a data cell, the event is supplied with all the information which is was used to compose the data value, including the currently active summary value and a *ValueArray* of all the dimension values which were used to create the summary value.

Creating and using decision graphs

Decision graph components, *TDecisionGraph,* present cross-tabulated data in graphic form. Each decision graph shows the value of a single summary, such as Sum, Count, or Avg, charted for one or more dimensions. For more information on crosstabs, see page 16-2. For illustrations of decision graphs at design time, see Figure 16.1 on page 16-2 and Figure 16.4 on page 16-14.

Creating decision graphs

To create a form with one or more decision graphs,

1. Follow steps 1–3 listed under “Guidelines for using decision support components” on page 16-3.
2. Add one or more decision graph components (*TDecisionGraph*) and bind them to the decision source, *TDecisionSource,* with the Object Inspector by setting their *DecisionSource* property to the appropriate decision source component.
3. Continue with steps 5–7 listed under “Guidelines for using decision support components.”
4. Finally, right-click the graph and choose Edit Chart to modify the appearance of the graph series. You can set template properties for each graph dimension, then set individual series properties to override these defaults. For details, see “Customizing decision graphs” on page 16-15.

For a description of what appears in the decision graph and how to use it, see the next section, “Using decision graphs.”

To add a decision grid—or crosstab table—to the form, follow the instructions in “Creating and using decision grids” on page 16-10.

Using decision graphs

The decision graph component, *TDecisionGraph*, displays fields from the decision source (*TDecisionSource*) as a dynamic graph that changes when data dimensions are opened, closed, dragged and dropped, or rearranged with the decision pivot (*TDecisionPivot*).

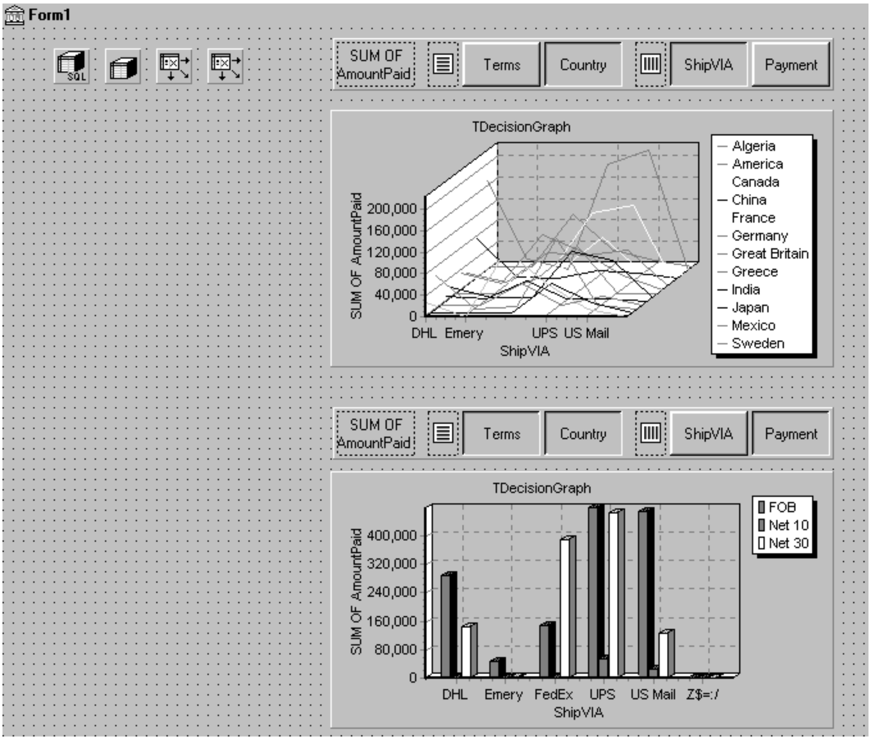
Graphed data comes from a specially formatted dataset such as *TDecisionQuery*. For an overview of how the decision support components handle and arrange this data, see page 16-1.

By default, the first row dimension appears as the x-axis and the first column dimension appears as the y-axis.

You can use decision graphs instead of or in addition to decision grids, which present cross-tabulated data in tabular form. Decision grids and decision graphs that are bound to the same decision source present the same data dimensions. To show different summary data for the same dimensions, you can bind more than one decision graph to the same decision source. To show different dimensions, bind decision graphs to different decision sources.

For example, in Figure 16.4 the first decision pivot and graph are bound to the first decision source and the second decision pivot and graph are bound to the second. So, each graph can show different dimensions.

Figure 16.4 Decision graphs bound to different decision sources



For more information about what appears in a decision graph, see the next section, “The decision graph display.”

To create a decision graph, see the previous section, “Creating decision graphs.”

For a discussion of decision graph properties and how to change the appearance and behavior of decision graphs, see “Customizing decision graphs” on page 16-15.

The decision graph display

By default, the decision graph plots summary values for categories in the first active row field (along the y-axis) against values in the first active column field (along the x-axis). Each graphed category appears as a separate series.

If only one dimension is selected—for example, by clicking only one *TDecisionPivot* button—only one series is graphed.

If you used a decision pivot, you can push its buttons to determine which decision cube fields (dimensions) are graphed. To exchange graph axes, drag the decision pivot dimension buttons from one side of the separator space to the other. If you have a one-dimensional graph with all buttons on one side of the separator space, you can use the Row or Column icon as a drop target for adding buttons to the other side of the separator and making the graph multidimensional.

If you only want one column and one row to be active at a time, you can set the *ControlType* property for *TDecisionSource* to *xtRadio*. Then, there can be only one active field at a time for each decision cube axis, and the decision pivot's functionality will correspond to the graph's behavior. *xtRadioEx* works the same as *xtRadio*, but does not allow the state where all row or all columns dimensions are closed.

When you have both a decision grid and graph connected to the same *TDecisionSource*, you'll probably want to set *ControlType* back to *xtCheck* to correspond to the more flexible behavior of *TDecisionGrid*.

Customizing decision graphs

The decision graph component, *TDecisionGraph,* displays fields from the decision source (*TDecisionSource*) as a dynamic graph that changes when data dimensions are opened, closed, dragged and dropped, or rearranged with the decision pivot (*TDecisionPivot*). You can change the type, colors, marker types for line graphs, and many other properties of decision graphs.

To customize a graph,

1. Right-click it and choose Edit Chart. The Chart Editing dialog box appears.
2. Use the Chart page of the Chart Editing dialog box to view a list of visible series, select the series definition to use when two or more are available for the same series, change graph types for a template or series, and set overall graph properties.

   The Series list on the Chart page shows all decision cube dimensions (preceded by Template:) and currently visible categories. Each category, or series, is a separate object. You can:

   - Add or delete series derived from existing decision-graph series. Derived series can provide annotations for existing series or represent values calculated from other series.
   - Change the default graph type, and change the title of templates and series.

For a description of the other Chart page tabs, search for the following topic in online Help: “Chart page (Chart Editing dialog box).”

3 Use the Series page to establish dimension templates, then customize properties for each individual graph series.

By default, all series are graphed as bar graphs and up to 16 default colors are assigned. You can edit the template type and properties to create a new default. Then, as you pivot the decision source to different states, the template is used to dynamically create the series for each new state. For template details, see “Setting decision graph template defaults” on page 16-16.

To customize individual series, follow the instructions in “Customizing decision graph series” on page 16-17.

For a description of each Series page tab, search for the following topic in online Help: “Series page (Chart Editing dialog box).”

Setting decision graph template defaults

Decision graphs display the values from two dimensions of the decision cube: one dimension is displayed as an axis of the graph, and the other is used to create a set of series. The template for that dimension provides default properties for those series (such as whether the series are bar, line, area, and so on). As users pivot from one state to another, any required series for the dimension are created using the series type and other defaults specified in the template.

A separate template is provided for cases where users pivot to a state where only one dimension is active. A one-dimensional state is often represented with a pie chart, so a separate template is provided for this case.

You can

- Change the default graph type.
- Change other graph template properties.
- View and set overall graph properties.

Changing the default decision graph type

To change the default graph type,

1 Select a template in the Series list on the Chart page of the Chart Editing dialog box.

2 Click the Change button.

3 Select a new type and close the Gallery dialog box.

Changing other decision graph template properties

To change color or other properties of a template,

1 Select the Series page at the top of the Chart Editing dialog box.

2 Choose a template in the drop-down list at the top of the page.

3 Choose the appropriate property tab and select settings.

Viewing overall decision graph properties

To view and set decision graph properties other than type and series,

1. Select the Chart page at the top of the Chart Editing dialog box.
2. Choose the appropriate property tab and select settings.

Customizing decision graph series

The templates supply many defaults for each decision cube dimension, such as graph type and how series are displayed. Other defaults, such as series color, are defined by *TDecisionGraph*. If you want you can override the defaults for each series.

The templates are intended for use when you want the program to create the series for categories as they are needed, and discard them when they are no longer needed. If you want, you can set up custom series for specific category values. To do this, pivot the graph so its current display has a series for the category you want to customize. When the series is displayed on the graph, you can use the Chart editor to

- Change the graph type.
- Change other series properties.
- Save specific graph series that you have customized.

To define series templates and set overall graph defaults, see “Setting decision graph template defaults” on page 16-16.

Changing the series graph type

By default, each series has the same graph type, defined by the template for its dimension. To change all series to the same graph type, you can change the template type. See “Changing the default decision graph type” on page 16-16 for instructions.

To change the graph type for a single series,

1. Select a series in the Series list on the Chart page of the Chart editor.
2. Click the Change button.
3. Select a new type and close the Gallery dialog box.
4. Check the Save Series check box.

Changing other decision graph series properties

To change color or other properties of a decision graph series,

1. Select the Series page at the top of the Chart Editing dialog box.
2. Choose a series in the drop-down list at the top of the page.
3. Choose the appropriate property tab and select settings.
4. Check the Save Series check box.

Saving decision graph series settings

By default, only settings for templates are saved at design time. Changes made to specific series are only saved if the Save box is checked for that series in the Chart Editing dialog box.

Saving series can be memory intensive, so if you don't need to save them you can uncheck the Save box.

Decision support components at runtime

At runtime, users can perform many operations by left-clicking, right-clicking, and dragging visible decision support components. These operations, discussed earlier in this chapter, are summarized below.

Decision pivots at runtime

Users can:

- Left-click the summary button at the left end of the decision pivot to display a list of available summaries. They can use this list to change the summary data displayed in decision grids and decision graphs.
- Right-click a dimension button and choose to:
  - Move it from the row area to the column area or the reverse.
  - Drill In to display detail data.
- Left-click a dimension button following the Drill In command and choose:
  - Open Dimension to move back to the top level of that dimension.
  - All Values to toggle between displaying just summaries and summaries plus all other values in decision grids.
  - From a list of available categories for that dimension, a category to drill into for detail values.
- Left-click a dimension button to open or close that dimension.
- Drag and drop dimension buttons from the row area to the column area and the reverse; they can drop them next to existing buttons in that area or onto the row or column icon.

Decision grids at runtime

Users can:

- Right-click within the decision grid and choose to:
  - Toggle subtotals on and off for individual data groups, for all values of a dimension, or for the whole grid.
  - Display the Decision Cube editor, described on page 16-7.
  - Toggle dimensions and summaries open and closed.

- Click + and – within the row and column headings to open and close dimensions.
- Drag and drop dimensions from rows to columns and the reverse.

Decision graphs at runtime

Users can drag from side to side or up and down in the graph grid area to scroll through off-screen categories and values.

Decision support components and memory control

When a dimension or summary is loaded into the decision cube, it takes up memory. Adding a new summary increases memory consumption linearly: that is, a decision cube with two summaries uses twice as much memory as the same cube with only one summary, a decision cube with three summaries uses three times as much memory as the same cube with one summary, and so on. Memory consumption for dimensions increases more quickly. Adding a dimension with 10 values increases memory consumption by a factor of 10. Adding a dimension with 100 values increases memory consumption 100 times. Thus adding dimensions to a decision cube can have a dramatic effect on memory use, and can quickly lead to performance problems. This effect is especially pronounced when adding dimensions that have many values.

The decision support components have a number of settings to help you control how and when memory is used. For more information on the properties and techniques mentioned here, look up *TDecisionCube* in the online Help.

Setting maximum dimensions, summaries, and cells

The decision cube's *MaxDimensions* and *MaxSummaries* properties can be used with the *CubeDim.ActiveFlag* property to control how many dimensions and summaries can be loaded at a time. You can set the maximum values on the Cube Capacity page of the Decision Cube editor to place some overall control on how many dimensions or summaries can be brought into memory at the same time.

Limiting the number of dimensions or summaries provides a rough limit on the amount of memory used by the decision cube. However, it does not distinguish between dimensions with many values and those with only a few. For greater control of the absolute memory demands of the decision cube, you can also limit the number of cells in the cube. Set the maximum number of cells on the Cube Capacity page of the Decision Cube editor.

Setting dimension state

The *ActiveFlag* property controls which dimensions get loaded. You can set this property on the Dimension Settings tab of the Decision Cube editor using the Activity Type control. When this control is set to *Active*, the dimension is loaded unconditionally, and will always take up space. Note that the number of dimensions in this state must always be less than *MaxDimensions*, and the number of summaries set to *Active* must be less than *MaxSummaries*. You should set a dimension or summary to *Active* only when it is critical that it be available at all times. An *Active* setting decreases the ability of the cube to manage the available memory.

When *ActiveFlag* is set to *AsNeeded*, a dimension or summary is loaded only if it can be loaded without exceeding the *MaxDimensions*, *MaxSummaries,* or *MaxCells* limit. The decision cube will swap dimensions and summaries that are marked *AsNeeded* in and out of memory to keep within the limits imposed by *MaxCells*, *MaxDimensions*, and *MaxSummaries*. Thus, a dimension or summary may not be loaded in memory if it is not currently being used. Setting dimensions that are not used frequently to *AsNeeded* results in better loading and pivoting performance, although there will be a time delay to access dimensions which are not currently loaded.

Using paged dimensions

When Binning is set to Set on the Dimension Settings tab of the Decision cube editor and Start Value is not NULL, the dimension is said to be “paged,” or “permanently drilled down.” You can access data for just a single value of that dimension at a time, although you can programmatically access a series of values sequentially. Such a dimension may not be pivoted or opened.

It is extremely memory intensive to include dimensional data for dimensions that have very large numbers of values. By making such dimensions paged, you can display summary information for one value at a time. Information is usually easier to read when displayed this way, and memory consumption is much easier to manage.

Chapter

17

Connecting to databases

Most dataset components can connect directly to a database server. Once connected, the dataset communicates with the server automatically. When you open the dataset, it populates itself with data from the server, and when you post records, they are sent back the server and applied. A single connection component can be shared by multiple datasets, or each dataset can use its own connection.

Each type of dataset connects to the database server using its own type of connection component, which is designed to work with a single data access mechanism. The following table lists these data access mechanisms and the associated connection components:

Table 17.1 Database connection components

Data access mechanism	Connection component
The Borland Database Engine (BDE).	TDatabase
ActiveX Data Objects (ADO).	TADOConnection
dbExpress.	TSQLConnection
InterBase Express.	TIBDatabase

Note For a discussion of some pros and cons of each of these mechanisms, see "Using databases" on page 14-1.

The connection component provides all the information necessary to establish a database connection. This information is different for each type of connection component:

- For information about describing a BDE-based connection, see "Identifying the database" on page 20-13.
- For information about describing an ADO-based connection, see "Connecting to a data store using TADOConnection" on page 21-3
- For information about describing a dbExpress connection, see "Setting up TSQLConnection" on page 22-3

- For information about describing an InterBase Express connection, see the online help for *TIBDatabase*.

Although each type of dataset uses a different connection component, they are all descendants of *TCustomConnection*. They all perform many of the same tasks and surface many of the same properties, methods, and events. This chapter discusses many of these common tasks.

Using implicit connections

No matter what data access mechanism you are using, you can always create the connection component explicitly and use it to manage the connection to and communication with a database server. For BDE-enabled and ADO-based datasets, you also have the option of describing the database connection through properties of the dataset and letting the dataset generate an implicit connection. For BDE-enabled datasets, you specify an implicit connection using the *DatabaseName* property. For ADO-based datasets, you use the *ConnectionString* property.

When using an implicit connection, you do not need to explicitly create a connection component. This can simplify your application development, and the default connection you specify can cover a wide variety of situations. For complex, mission-critical client/server applications with many users and different requirements for database connections, however, you should create your own connection components to tune each database connection to your application's needs. Explicit connection components give you greater control. For example, you need to access the connection component to perform the following tasks:

- Customize database server login support. (Implicit connections display a default login dialog to prompt the user for a user name and password.)
- Control transactions and specify transaction isolation levels.
- Execute SQL commands on the server without using a dataset.
- Perform actions on all open datasets that are connected to the same database.

In addition, if you have multiple datasets that all use the same server, it can be easier to use an connection component, so that you only have to specify the server to use in one place. That way, if you later change the server, you do not need to update several dataset components: only the connection component.

Controlling connections

Before you can establish a connection to a database server, your application must provide certain key pieces of information that describe the desired server. Each type of connection component surfaces a different set of properties to let you identify the server. In general, however, they all provide a way for you to name the server you want and supply a set of connection parameters that control how the connection is formed. Connection parameters vary from server to server. They can include information such as user name and password, the maximum size of BLOB fields, SQL roles, and so on.

Once you have identified the desired server and any connection parameters, you can use the connection component to explicitly open or close a connection. The connection component generates events when it opens or closes a connection that you can use to customize the response of your application to changes in the database connection.

Connecting to a database server

There are two ways to connect to a database server using a connection component:

- Call the *Open* method.
- Set the *Connected* property to *True*.

Calling the *Open* method sets *Connected* to *True*.

Note When a connection component is not connected to a server and an application attempts to open one of its associated datasets, the dataset automatically calls the connection component's *Open* method.

When you set *Connected* to *True*, the connection component first generates a *BeforeConnect* event, where you can perform any initialization. For example, you can use this event to alter connection parameters.

After the *BeforeConnect* event, the connection component may display a default login dialog, depending on how you choose to control server login. It then passes the user name and password to the driver, opening a connection.

Once the connection is open, the connection component generates an *AfterConnect* event, where you can perform any tasks that require an open connection.

Note Some connection components generate additional events as well when establishing a connection.

Once a connection is established, it is maintained as long as there is at least one active dataset using it. When there are no more active datasets, the connection component drops the connection. Some connection components surface a *KeepConnection* property that allows the connection to remain open even if all the datasets that use it are closed. If *KeepConnection* is *True*, the connection is maintained. For connections to remote database servers, or for applications that frequently open and close datasets, setting *KeepConnection* to *True* reduces network traffic and speeds up the application. If *KeepConnection* is *False,* the connection is dropped when there are no active datasets using the database. If a dataset that uses the database is later opened, the connection must be reestablished and initialized.

Disconnecting from a database server

There are two ways to disconnect a server using a connection component:

- Set the *Connected* property to *False*.
- Call the *Close* method.

Calling *Close* sets *Connected* to *False*.

When *Connected* is set to *False*, the connection component generates a *BeforeDisconnect* event, where you can perform any cleanup before the connection closes. For example, you can use this event to cache information about all open datasets before they are closed.

After the *BeforeConnect* event, the connection component closes all open datasets and disconnects from the server.

Finally, the connection component generates an *AfterDisconnect* event, where you can respond to the change in connection status, such as enabling a Connect button in your user interface.

Note Calling *Close* or setting *Connected* to *False* disconnects from a database server even if the connection component has a *KeepConnection* property that is *True*.

Controlling server login

Most remote database servers include security features to prohibit unauthorized access. Usually, the server requires a user name and password login before permitting database access.

At design time, if a server requires a login, a standard login dialog box prompts for a user name and password when you first attempt to connect to the database.

At runtime, there are three ways you can handle a server's request for a login:

- Let the default login dialog and processes handle the login. This is the default approach. Set the *LoginPrompt* property of the connection component to *True* (the default) and add DBLogDlg to the uses clause of the unit that declares the connection component. Your application displays the standard login dialog box when the server requests a user name and password.
- Supply the login information before the login attempt. Each type of connection component uses a different mechanism for specifying the user name and password:
  - For BDE, dbExpress, and InterBase express datasets, the user name and password connection parameters can be accessed through the *Params* property. (For BDE datasets, the parameter values can also be associated with a BDE alias, while for dbExpress datasets, they can also be associated with a connection name).
  - For ADO datasets, the user name and password can be included in the *ConnectionString* property (or provided as parameters to the *Open* method).

  If you specify the user name and password before the server requests them, be sure to set the *LoginPrompt* to *False*, so that the default login dialog does not appear. For example, the following code sets the user name and password on a SQL connection component in the *BeforeConnect* event handler, decrypting an encrypted password that is associated with the current connection name:

```
procedure TForm1.SQLConnectionBeforeConnect(Sender: TObject);
begin
  with Sender as TSQLConnection do
  begin
```

```
    if LoginPrompt = False then
    begin
      Params.Values['User_Name'] := 'SYSDBA';
      Params.Values['Password'] := Decrypt(Params.Values['Password']);
    end;
  end;
end;
```

Note that setting the user name and password at design-time or using hard-coded strings in code causes the values to be embedded in the application's executable file. This still leaves them easy to find, compromising server security.

- Provide your own custom handling for the login event. The connection component generates an event when it needs the user name and password.
  - For *TDatabase*, *TSQLConnection*, and *TIBDatabase*, this is an *OnLogin* event. The event handler has two parameters, the connection component, and a local copy of the user name and password parameters in a string list. (*TSQLConnection* includes the database parameter as well). You must set the *LoginPrompt* property to *True* for this event to occur. Having a *LoginPrompt* value of *False* and assigning a handler for the *OnLogin* event creates a situation where it is impossible to log in to the database because the default dialog does not appear and the *OnLogin* event handler never executes.
  - For *TADOConnection*, the event is an *OnWillConnect* event. The event handler has five parameters, the connection component and four parameters that return values to influence the connection (including two for user name and password). This event always occurs, regardless of the value of *LoginPrompt*.

  Write an event handler for the event in which you set the login parameters. Here is an example where the values for the USER NAME and PASSWORD parameters are provided from a global variable (*UserName*) and a method that returns a password given a user name (*PasswordSearch*)

```
procedure TForm1.Database1Login(Database: TDatabase; LoginParams: TStrings);
begin
  LoginParams.Values['USER NAME'] := UserName;
  LoginParams.Values['PASSWORD'] := PasswordSearch(UserName);
end;
```

  As with the other methods of providing login parameters, when writing an *OnLogin* or *OnWillConnect* event handler, avoid hard coding the password in your application code. It should appear only as an encrypted value, an entry in a secure database your application uses to look up the value, or be dynamically obtained from the user.

Managing transactions

A *transaction* is a group of actions that must all be carried out successfully on one or more tables in a database before they are *committed* (made permanent). If one of the actions in the group fails, then all actions are *rolled back* (undone). By using transactions, you ensure that the database is not left in an inconsistent state when a problem occurs completing one of the actions that make up the transaction.

For example, in a banking application, transferring funds from one account to another is an operation you would want to protect with a transaction. If, after decrementing the balance in one account, an error occurred incrementing the balance in the other, you want to roll back the transaction so that the database still reflects the correct total balance.

It is always possible to manage transactions by sending SQL commands directly to the database. Most databases provide their own transaction management model, although some have no transaction support at all. For servers that support it, you may want to code your own transaction management directly, taking advantage of advanced transaction management capabilities on a particular database server, such as schema caching.

If you do not need to use any advanced transaction management capabilities, connection components provide a set of methods and properties you can use to manage transactions without explicitly sending any SQL commands. Using these properties and methods has the advantage that you do not need to customize your application for each type of database server you use, as long as the server supports transactions. (The BDE also provides limited transaction support for local tables with no server transaction support. When not using the BDE, trying to start transactions on a database that does not support them causes connection components to raise an exception.)

Warning When a dataset provider component applies updates, it implicitly generates transactions for any updates. Be careful that any transactions you explicitly start do not conflict with those generated by the provider.

Starting a transaction

When you start a transaction, all subsequent statements that read from or write to the database occur in the context of that transaction, until the transaction is explicitly terminated or (in the case of overlapping transactions) until another transaction is started. Each statement is considered part of a group. Changes must be successfully committed to the database, or every change made in the group must be undone.

While the transaction is in process, your view of the data in database tables is determined by your transaction isolation level. For information about transaction isolation levels, see “Specifying the transaction isolation level” on page 17-9.

For *TADOConnection*, start a transaction by calling the *BeginTrans* method:

```
Level := ADOConnection1.BeginTrans;
```

BeginTrans returns the level of nesting for the transaction that started. A nested transaction is one that is nested within another, parent, transaction. After the server starts the transaction, the ADO connection receives an *OnBeginTransComplete* event.

For *TDatabase,* use the *StartTransaction*method instead. *TDataBase* does not support nested or overlapped transactions: If you call a *TDatabase* component’s *StartTransaction* method while another transaction is underway, it raises an exception. To avoid calling *StartTransaction*, you can check the *InTransaction* property:

```
if not Database1.InTransaction then
  Database1.StartTransaction;
```

TSQLConnection also uses the *StartTransaction*method, but it uses a version that gives you a lot more control. Specifically, *StartTransaction* takes a transaction descriptor, which lets you manage multiple simultaneous transactions and specify the transaction isolation level on a per-transaction basis. (For more information on transaction levels, see "Specifying the transaction isolation level" on page 17-9.) In order to manage multiple simultaneous transactions, set the *TransactionID* field of the transaction descriptor to a unique value. *TransactionID* can be any value you choose, as long as it is unique (does not conflict with any other transaction currently underway). Depending on the server, transactions started by *TSQLConnection* can be nested (as they can be when using ADO) or they can be overlapped.

```
var
  TD: TTransactionDesc;
begin
  TD.TransactionID := 1;
  TD.IsolationLevel := xilREADCOMMITTED;
  SQLConnection1.StartTransaction(TD);
```

By default, with overlapped transactions, the first transaction becomes inactive when the second transaction starts, although you can postpone committing or rolling back the first transaction until later. If you are using *TSQLConnection* with an InterBase database, you can identify each dataset in your application with a particular active transaction, by setting its *TransactionLevel* property. That is, after starting a second transaction, you can continue to work with both transactions simultaneously, simply by associating a dataset with the transaction you want.

Note Unlike *TADOConnection*, *TSQLConnection* and *TDatabase* do not receive any events when the transactions starts.

InterBase express offers you even more control than *TSQLConnection* by using a separate transaction component rather than starting transactions using the connection component. You can, however, use *TIBDatabase* to start a default transaction:

```
if not IBDatabase1.DefaultTransaction.InTransaction then
  IBDatabase1.DefaultTransaction.StartTransaction;
```

You can have overlapped transactions by using two separate transaction components. Each transaction component has a set of parameters that let you configure the transaction. These let you specify the transaction isolation level, as well as other properties of the transaction.

Ending a transaction

Ideally, a transaction should only last as long as necessary. The longer a transaction is active, the more simultaneous users that access the database, and the more concurrent, simultaneous transactions that start and end during the lifetime of your transaction, the greater the likelihood that your transaction will conflict with another when you attempt to commit any changes.

Ending a successful transaction

When the actions that make up the transaction have all succeeded, you can make the database changes permanent by committing the transaction. For *TDatabase*, you commit a transaction using the *Commit* method:

```
MyOracleConnection.Commit;
```

For *TSQLConnection*, you also use the *Commit* method, but you must specify which transaction you are committing by supplying the transaction descriptor you gave to the *StartTransaction* method:

```
MyOracleConnection.Commit(TD);
```

For *TIBDatabase*, you commit a transaction object using its *Commit* method:

```
IBDatabase1.DefaultTransaction.Commit;
```

For *TADOConnection*, you commit a transaction using the *CommitTrans* method:

```
ADOConnection1.CommitTrans;
```

Note It is possible for a nested transaction to be committed, only to have the changes rolled back later if the parent transaction is rolled back.

After the transaction is successfully committed, an ADO connection component receives an *OnCommitTransComplete* event. Other connection components do not receive any similar events.

A call to commit the current transaction is usually attempted in a **try...except** statement. That way, if the transaction cannot commit successfully, you can use the **except** block to handle the error and retry the operation or to roll back the transaction.

Ending an unsuccessful transaction

If an error occurs when making the changes that are part of the transaction or when trying to commit the transaction, you will want to discard all changes that make up the transaction. Discarding these changes is called rolling back the transaction.

For *TDatabase*, you roll back a transaction by calling the *Rollback* method:

```
MyOracleConnection.Rollback;
```

For *TSQLConnection*, you also use the *Rollback* method, but you must specify which transaction you are rolling back by supplying the transaction descriptor you gave to the *StartTransaction* method:

```
MyOracleConnection.Rollback(TD);
```

For *TIBDatabase*, you roll back a transaction object by calling its *Rollback* method:

```
IBDatabase1.DefaultTransaction.Rollback;
```

For *TADOConnection*, you roll back a transaction by calling the *RollbackTrans* method:

```
ADOConnection1.RollbackTrans;
```

After the transaction is successfully rolled back, an ADO connection component receives an *OnRollbackTransComplete* event. Other connection components do not receive any similar events.

A call to roll back the current transaction usually occurs in

- Exception handling code when you can't recover from a database error.
- Button or menu event code, such as when a user clicks a Cancel button.

Specifying the transaction isolation level

Transaction isolation level determines how a transaction interacts with other simultaneous transactions when they work with the same tables. In particular, it affects how much a transaction "sees" of other transactions' changes to a table.

Each server type supports a different set of possible transaction isolation levels. There are three possible transaction isolation levels:

- *DirtyRead*: When the isolation level is *DirtyRead*, your transaction sees all changes made by other transactions, even if they have not been committed. Uncommitted changes are not permanent, and might be rolled back at any time. This value provides the least isolation, and is not available for many database servers (such as Oracle, Sybase, MS-SQL, and InterBase).
- *ReadCommitted*: When the isolation level is *ReadCommitted*, only committed changes made by other transactions are visible. Although this setting protects your transaction from seeing uncommitted changes that may be rolled back, you may still receive an inconsistent view of the database state if another transaction is committed while you are in the process of reading. This level is available for all transactions except local transactions managed by the BDE.
- *RepeatableRead*: When the isolation level is *RepeatableRead*, your transaction is guaranteed to see a consistent state of the database data. Your transaction sees a single snapshot of the data. It cannot see any subsequent changes to data by other simultaneous transactions, even if they are committed. This isolation level guarantees that once your transaction reads a record, its view of that record will not change. At this level your transaction is most isolated from changes made by other transactions. This level is not available on some servers, such as Sybase and MS-SQL and is unavailable on local transactions managed by the BDE.

In addition, *TSQLConnection* lets you specify database-specific custom isolation levels. Custom isolation levels are defined by the *dbExpress* driver. See you driver documentation for details.

Note For a detailed description of how each isolation level is implemented, see your server documentation.

TDatabase and *TADOConnection* let you specify the transaction isolation level by setting the *TransIsolation* property. When you set *TransIsolation* to a value that is not supported by the database server, you get the next highest level of isolation (if available). If there is no higher level available, the connection component raises an exception when you try to start a transaction.

When using *TSQLConnection*, transaction isolation level is controlled by the *IsolationLevel* field of the transaction descriptor.

When using InterBase express, transaction isolation level is controlled by a transaction parameter.

Sending commands to the server

All database connection components except *TIBDatabase* let you execute SQL statements on the associated server by calling the *Execute* method. Although *Execute* can return a cursor when the statement is a SELECT statement, this use is not recommended. The preferred method for executing statements that return data is to use a dataset.

The *Execute* method is very convenient for executing simple SQL statements that do not return any records. Such statements include Data Definition Language (DDL) statements, which operate on or create a database's metadata, such as CREATE INDEX, ALTER TABLE, and DROP DOMAIN. Some Data Manipulation Language (DML) SQL statements also do not return a result set. The DML statements that perform an action on data but do not return a result set are: INSERT, DELETE, and UPDATE.

The syntax for the *Execute* method varies with the connection type:

- For *TDatabase*, *Execute* takes four parameters: a string that specifies a single SQL statement that you want to execute, a *TParams* object that supplies any parameter values for that statement, a boolean that indicates whether the statement should be cached because you will call it again, and a pointer to a BDE cursor that can be returned (It is recommended that you pass nil).
- For *TADOConnection*, there are two versions of *Execute.* The first takes a WideString that specifies the SQL statement and a second parameter that specifies a set of options that control whether the statement is executed asynchronously and whether it returns any records. This first syntax returns an interface for the returned records. The second syntax takes a WideString that specifies the SQL statement, a second parameter that returns the number of records affected when the statement executes, and a third that specifies options such as whether the statement executes asynchronously. Note that neither syntax provides for passing parameters.
- For *TSQLConnection*, *Execute* takes three parameters: a string that specifies a single SQL statement that you want to execute, a *TParams* object that supplies any parameter values for that statement, and a pointer that can receive a *TCustomSQLDataSet* that is created to return records.

Note *Execute* can only execute one SQL statement at a time. It is not possible to execute multiple SQL statements with a single call to *Execute*, as you can with SQL scripting utilities. To execute more than one statement, call *Execute* repeatedly.

It is relatively easy to execute a statement that does not include any parameters. For example, the following code executes a CREATE TABLE statement (DDL) without any parameters on a *TSQLConnection* component:

```
procedure TForm1.CreateTableButtonClick(Sender: TObject);
var
  SQLstmt: String;
begin
  SQLConnection1.Connected := True;
  SQLstmt := 'CREATE TABLE NewCusts ' +
    '( ' +
    '  CustNo INTEGER, ' +
    '  Company CHAR(40), ' +
    '  State CHAR(2), ' +
    '  PRIMARY KEY (CustNo) ' +
    ')';
  SQLConnection1.Execute(SQLstmt, nil, nil);
end;
```

To use parameters, you must create a *TParams* object. For each parameter value, use the *TParams.CreateParam* method to add a *TParam* object. Then use properties of *TParam* to describe the parameter and set its value.

This process is illustrated in the following example, which uses *TDatabase* to execute an INSERT statement. The INSERT statement has a single parameter named :*StateParam*. A *TParams* object (called *stmtParams*) is created to supply a value of "CA" for that parameter.

```
procedure TForm1.INSERT_WithParamsButtonClick(Sender: TObject);
var
  SQLstmt: String;
  stmtParams: TParams;
begin
  stmtParams := TParams.Create;
  try
    Database1.Connected := True;
    stmtParams.CreateParam(ftString, 'StateParam', ptInput);
    stmtParams.ParamByName('StateParam').AsString := 'CA';
    SQLstmt := 'INSERT INTO "Custom.db" '+
      '(CustNo, Company, State) ' +
      'VALUES (7777, "Robin Dabank Consulting", :StateParam)';
    Database1.Execute(SQLstmt, stmtParams, False, nil);
  finally
    stmtParams.Free;
  end;
end;
```

If the SQL statement includes a parameter but you do not supply a *TParam* object to provide its value, the SQL statement may cause an error when executed (this depends on the particular database back-end used). If a *TParam* object is provided but there is no corresponding parameter in the SQL statement, an exception is raised when the application attempts to use the *TParam*.

Working with associated datasets

All database connection components maintain a list of all datasets that use them to connect to a database. A connection component uses this list, for example, to close all of the datasets when it closes the database connection.

You can use this list as well, to perform actions on all the datasets that use a specific connection component to connect to a particular database.

Closing all datasets without disconnecting from the server

The connection component automatically closes all datasets when you close its connection. There may be times, however, when you want to close all datasets without disconnecting from the database server.

To close all open datasets without disconnecting from a server, you can use the *CloseDataSets* method.

For *TADOConnection* and *TIBDatabase*, calling *CloseDataSets* always leaves the connection open. For *TDatabase* and *TSQLConnection*, you must also set the *KeepConnection* property to *True*.

Iterating through the associated datasets

To perform any actions (other than closing them all) on all the datasets that use a connection component, use the *DataSets* and *DataSetCount* properties. *DataSets* is an indexed array of all datasets that are linked to the connection component. For all connection components except *TADOConnection*, this list includes only the active datasets. *TADOConnection* lists the inactive datasets as well. *DataSetCount* is the number of datasets in this array.

Note When you use a specialized client dataset to cache updates (as opposed to the generic client dataset, *TClientDataSet*), the *DataSets* property lists the internal dataset owned by the client dataset, not the client dataset itself.

You can use *DataSets* with *DataSetCount* to cycle through all currently active datasets in code. For example, the following code cycles through all active datasets and disables any controls that use the data they provide:

```
var
  I: Integer;
begin
  with MyDBConnection do
  begin
    for I := 0 to DataSetCount - 1 do
      DataSets[I].DisableControls;
  end;
end;
```

Note *TADOConnection* supports command objects as well as datasets. You can iterate through these much like you iterate through the datasets, by using the *Commands* and *CommandCount* properties.

Obtaining metadata

All database connection components can retrieve lists of metadata on the database server, although they vary in the types of metadata they retrieve. The methods that retrieve metadata fill a string list with the names of various entities available on the server. You can then use this information, for example, to let your users dynamically select a table at runtime.

You can use a *TADOConnection* component to retrieve metadata about the tables and stored procedures available on the ADO data store. You can then use this information, for example, to let your users dynamically select a table or stored procedure at runtime.

Listing available tables

The *GetTableNames* method copies a list of table names to an already-existing string list object. This can be used, for example, to fill a list box with table names that the user can then use to choose a table to open. The following line fills a listbox with the names of all tables on the database:

```
MyDBConnection.GetTableNames(ListBox1.Items, False);
```

GetTableNames has two parameters: the string list to fill with table names, and a boolean that indicates whether the list should include system tables, or ordinary tables. Note that not all servers use system tables to store metadata, so asking for system tables may result in an empty list.

Note For most database connection components, *GetTableNames* returns a list of all available non-system tables when the second parameter is *False*. For *TSQLConnection*, however, you have more control over what type is added to the list when you are not fetching only the names of system tables. When using *TSQLConnection*, the types of names added to the list are controlled by the *TableScope* property. *TableScope* indicates whether the list should contain any or all of the following: ordinary tables, system tables, synonyms, and views.

Listing the fields in a table

The *GetFieldNames* method fills an existing string list with the names of all fields (columns) in a specified table. *GetFieldNames* takes two parameters, the name of the table for which you want to list the fields, and an existing string list to be filled with field names:

```
MyDBConnection.GetFieldNames('Employee', ListBox1.Items);
```

Listing available stored procedures

To get a listing of all of the stored procedures contained in the database, use the *GetProcedureNames* method. This method takes a single parameter: an already-existing string list to fill:

```
MyDBConnection.GetProcedureNames(ListBox1.Items);
```

Note *GetProcedureNames* is only available for *TADOConnection* and *TSQLConnection*.

Listing available indexes

To get a listing of all indexes defined for a specific table, use the *GetIndexNames* method. This method takes two parameters: the table whose indexes you want, and an already-existing string list to fill:

```
SQLConnection1.GetIndexNames('Employee', ListBox1.Items);
```

Note *GetIndexNames* is only available for *TSQLConnection*, although most table-type datasets have an equivalent method.

Listing stored procedure parameters

To get a list of all parameters defined for a specific stored procedure, use the *GetProcedureParams* method. *GetProcedureParams* fills a *TList* object with pointers to parameter description records, where each record describes a parameter of a specified stored procedure, including its name, index, parameter type, field type, and so on.

GetProcedureParams takes two parameters: the name of the stored procedure, and an already-existing *TList* object to fill:

```
SQLConnection1.GetProcedureParams('GetInterestRate', List1);
```

You can convert the parameter descriptions that are added to the list into the more familiar *TParams* object by calling the global *LoadParamListItems*procedure. Because *GetProcedureParams* dynamically allocates the individual records, your application must free them when it is finished with the information. The global *FreeProcParams* routine can do this for you.

Note *GetProcedureParams* is only available for *TSQLConnection*.

Chapter

18

Understanding datasets

The fundamental unit for accessing data is the dataset family of objects. Your application uses datasets for all database access. A dataset object represents a set of records from a database organized into a logical table. These records may be the records from a single database table, or they may represent the results of executing a query or stored procedure.

All dataset objects that you use in your database applications descend from *TDataSet*, and they inherit data fields, properties, events, and methods from this class. This chapter describes the functionality of *TDataSet* that is inherited by the dataset objects you use in your database applications. You need to understand this shared functionality to use any dataset object.

TDataSet is a virtualized dataset, meaning that many of its properties and methods are **virtual** or **abstract**. A *virtual method* is a function or procedure declaration where the implementation of that method can be (and usually is) overridden in descendant objects. An *abstract method* is a function or procedure declaration without an actual implementation. The declaration is a prototype that describes the method (and its parameters and return type, if any) that must be implemented in all descendant dataset objects, but that might be implemented differently by each of them.

Because *TDataSet* contains **abstract** methods, you cannot use it directly in an application without generating a runtime error. Instead, you either create instances of the built-in *TDataSet* descendants and use them in your application, or you derive your own dataset object from *TDataSet* or its descendants and write implementations for all its **abstract** methods.

TDataSet defines much that is common to all dataset objects. For example, *TDataSet* defines the basic structure of all datasets: an array of *TField* components that correspond to actual columns in one or more database tables, lookup fields provided by your application, or calculated fields provided by your application. For information about *TField* components, see Chapter 19, “Working with field components.”

This chapter describes how to use the common database funtionality introduced by *TDataSet*. Bear in mind, however, that although *TDataSet* introduces the methods for this functionality, not all *TDataSet* dependants implement them. In particular, unidirectional datasets implement only a limited subset.

Using TDataSet descendants

TDataSet has several immediate descendants, each of which corresponds to a different data access mechanism. You do not work directly with any of these descendants. Rather, each descendant introduces the properties and methods for using a particular data access mechanism. These properties and methods are then exposed by descendant classes that are adapted to different types of server data. The immediate descendants of *TDataSet* include

- *TBDEDataSet*, which uses the Borland Database Engine (BDE) to communicate with the database server. The *TBDEDataSet* descendants you use are *TTable*, *TQuery*, *TStoredProc*, and *TNestedTable*. The unique features of BDE-enabled datasets are described in Chapter 20, “Using the Borland Database Engine”.
- *TCustomADODataSet*, which uses ActiveX Data Objects (ADO) to communicate with an OLEDB data store. The *TCustomADODataSet* descendants you use are *TADODataSet*, *TADOTable*, *TADOQuery*, and *TADOStoredProc*. The unique features of ADO-based datasets are described in Chapter 21, “Working with ADO components”.
- *TCustomSQLDataSet*, which uses dbExpress to communicate with a database server. The *TCustomSQLDataSet* descendants you use are *TSQLDataSet*, *TSQLTable*, *TSQLQuery*, and *TSQLStoredProc*. The unique features of dbExpress datasets are described in Chapter 22, “Using unidirectional datasets”.
- *TIBCustomDataSet*, which communicates directly with an InterBase database server. The *TIBCustomDataSet* descendants you use are *TIBDataSet*, *TIBTable*, *TIBQuery*, and *TIBStoredProc*.
- *TCustomClientDataSet*, which represents the data from another dataset component or the data from a dedicated file on disk. The *TCustomClientDataSet* descendants you use are *TClientDataSet*, which can connect to an external (source) dataset, and the client datasets that are specialized to a particular data access mechanism (*TBDEClientDataSet*, *TSQLClientDataSet*, and *TIBClientDataSet*), which use an internal source dataset. The unique features of client datasets are described in Chapter 23, “Using client datasets”.

Some pros and cons of the various data access mechanisms employed by these *TDataSet* descendants are described in “Using databases” on page 14-1.

In addition to the built-in datasets, you can create your own custom *TDataSet* descendants — for example to supply data from a process other than a database server, such as a spreadsheet. Writing custom datasets allows you the flexibility of managing the data using any method you choose, while still letting you use the VCL data controls to build your user interface. For more information about creating custom components, see Chapter 40, “Overview of component creation.”

Although each *TDataSet* descendant has its own unique properties and methods, some of the properties and methods introduced by descendant classes are the same as those introduced by other descendant classes that use another data access mechanism. For example, there are similarities between the “table” components (*TTable*, *TADOTable*, *TSQLTable*, and *TIBTable*). For information about the commonalities introduced by *TDataSet* descendants, see “Types of datasets” on page 18-23.

Determining dataset states

The *state*—or *mode*—of a dataset determines what can be done to its data. For example, when a dataset is closed, its state is *dsInactive*, meaning that nothing can be done to its data. At runtime, you can examine a dataset’s read-only *State* property to determine its current state. The following table summarizes possible values for the *State* property and what they mean:

Table 18.1 Values for the dataset State property

Value	State	Meaning
dsInactive	Inactive	DataSet closed. Its data is unavailable.
dsBrowse	Browse	DataSet open. Its data can be viewed, but not changed. This is the default state of an open dataset.
dsEdit	Edit	DataSet open. The current row can be modified. (not supported on unidirectional datasets)
dsInsert	Insert	DataSet open. A new row is inserted or appended. (not supported on unidirectional datasets)
dsSetKey	SetKey	DataSet open. Enables setting of ranges and key values used for ranges and *GotoKey* operations. (not supported by all datasets)
dsCalcFields	CalcFields	DataSet open. Indicates that an *OnCalcFields* event is under way. Prevents changes to fields that are not calculated.
dsCurValue	CurValue	DataSet open. Indicates that the CurValue property of fields is being fetched for an event handler that responds to errors in applying cached updates.
dsNewValue	NewValue	DataSet open. Indicates that the NewValue property of fields is being fetched for an event handler that responds to errors in applying cached updates.
dsOldValue	OldValue	DataSet open. Indicates that the OldValue property of fields is being fetched for an event handler that responds to errors in applying cached updates.
dsFilter	Filter	DataSet open. Indicates that a filter operation is under way. A restricted set of data can be viewed, and no data can be changed. (not supported on unidirectional datasets)
dsBlockRead	Block Read	DataSet open. Data-aware controls are not updated and events are not triggered when the current record changes.

Table 18.1 Values for the dataset State property (continued)

Value	State	Meaning
dsInternalCalc	Internal Calc	DataSet open. An *OnCalcFields* event is underway for calculated values that are stored with the record. (client datasets only)
dsOpening	Opening	DataSet is in the process of opening but has not finished. This state occurs when the dataset is opened for asynchronous fetching.

Typically, an application checks the dataset state to determine when to perform certain tasks. For example, you might check for the *dsEdit* or *dsInsert* state to ascertain whether you need to post updates.

Note Whenever a dataset's state changes, the *OnStateChange* event is called for any data source components associated with the dataset. For more information about data source components and *OnStateChange*, see "Responding to changes mediated by the data source" on page 15-4.

Opening and closing datasets

To read or write data in a dataset, an application must first open it. You can open a dataset in two ways,

- Set the *Active* property of the dataset to *True*, either at design time in the Object Inspector, or in code at runtime:

```
CustTable.Active := True;
```

- Call the *Open* method for the dataset at runtime,

```
CustQuery.Open;
```

When you open the dataset, the dataset first receives a *BeforeOpen* event, then it opens a cursor, populating itself with data, and finally, it receives an *AfterOpen* event.

The newly-opened dataset is in browse mode, which means your application can read the data and navigate through it.

You can close a dataset in two ways,

- Set the *Active* property of the dataset to *False*, either at design time in the Object Inspector, or in code at runtime,

```
CustQuery.Active := False;
```

- Call the *Close* method for the dataset at runtime,

```
CustTable.Close;
```

Just as the dataset receives *BeforeOpen* and *AfterOpen* events when you open it, it receives a *BeforeClose* and *AfterClose* event when you close it. handlers that respond to the *Close* method for a dataset. You can use these events, for example, to prompt the user to post pending changes or cancel them before closing the dataset. The following code illustrates such a handler:

```
procedure TForm1.CustTableVerifyBeforeClose(DataSet: TDataSet);
begin
  if (CustTable.State in [dsEdit, dsInsert]) then begin
    case MessageDlg('Post changes before closing?', mtConfirmation, mbYesNoCancel, 0) of
      mrYes:    CustTable.Post;   { save the changes }
      mrNo:     CustTable.Cancel; { abandon the changes}
      mrCancel: Abort;            { abort closing the dataset }
    end;
  end;
end;
```

Note You may need to close a dataset when you want to change certain of its properties, such as *TableName* on a *TTable* component. When you reopen the dataset, the new property value takes effect.

Navigating datasets

Each active dataset has a *cursor*, or pointer, to the current row in the dataset. The *current row* in a dataset is the one whose field values currently show in single-field, data-aware controls on a form, such as *TDBEdit*, *TDBLabel*, and *TDBMemo*. If the dataset supports editing, the current record contains the values that can be manipulated by edit, insert, and delete methods.

You can change the current row by moving the cursor to point at a different row. The following table lists methods you can use in application code to move to different records:

Table 18.2 Navigational methods of datasets

Method	Moves the cursor to
First	The first row in a dataset.
Last	The last row in a dataset. (not available for unidirectional datasets)
Next	The next row in a dataset.
Prior	The previous row in a dataset. (not available for unidirectional datasets)
MoveBy	A specified number of rows forward or back in a dataset.

The data-aware, visual component *TDBNavigator* encapsulates these methods as buttons that users can click to move among records at runtime. For information about the navigator component, see “Navigating and manipulating records” on page 15-28.

Whenever you change the current record using one of these methods (or by other methods that navigate based on a search criterion), the dataset receives two events: *BeforeScroll* (before leaving the current record) and *AfterScroll* (after arriving at the new record). You can use these events to update your user interface (for example, to update a status bar that indicates information about the current record).

TDataSet also defines two boolean properties that provide useful information when iterating through the records in a dataset.

Table 18.3 Navigational properties of datasets

Property	Description
Bof (Beginning-of-file)	*True*: the cursor is at the first row in the dataset.
	False: the cursor is not known to be at the first row in the dataset
Eof (End-of-file)	*True*: the cursor is at the last row in the dataset.
	False: the cursor is not known to be at the first row in the dataset

Using the First and Last methods

The *First* method moves the cursor to the first row in a dataset and sets the *Bof* property to *True*. If the cursor is already at the first row in the dataset, *First* does nothing.

For example, the following code moves to the first record in *CustTable*:

```
CustTable.First;
```

The *Last* method moves the cursor to the last row in a dataset and sets the *Eof* property to *True*. If the cursor is already at the last row in the dataset, *Last* does nothing.

The following code moves to the last record in *CustTable*:

```
CustTable.Last;
```

Note The *Last* method raises an exception in unidirectional datasets.

Tip While there may be programmatic reasons to move to the first or last rows in a dataset without user intervention, you can also enable your users to navigate from record to record using the *TDBNavigator* component. The navigator component contains buttons that, when active and visible, enable a user to move to the first and last rows of an active dataset. The *OnClick* events for these buttons call the *First* and *Last* methods of the dataset. For more information about making effective use of the navigator component, see “Navigating and manipulating records” on page 15-28.

Using the Next and Prior methods

The *Next* method moves the cursor forward one row in the dataset and sets the *Bof* property to *False* if the dataset is not empty. If the cursor is already at the last row in the dataset when you call *Next*, nothing happens.

For example, the following code moves to the next record in *CustTable*:

```
CustTable.Next;
```

The *Prior* method moves the cursor back one row in the dataset, and sets *Eof* to *False* if the dataset is not empty. If the cursor is already at the first row in the dataset when you call *Prior*, *Prior* does nothing.

For example, the following code moves to the previous record in *CustTable*:

```
CustTable.Prior;
```

Note The *Prior* method raises an exception in unidirectional datasets.

Using the MoveBy method

MoveBy lets you specify how many rows forward or back to move the cursor in a dataset. Movement is relative to the current record at the time that *MoveBy* is called. *MoveBy* also sets the *Bof* and *Eof* properties for the dataset as appropriate.

This function takes an integer parameter, the number of records to move. Positive integers indicate a forward move and negative integers indicate a backward move.

Note *MoveBy* raises an exception in unidirectional datasets if you use a negative argument.

MoveBy returns the number of rows it moves. If you attempt to move past the beginning or end of the dataset, the number of rows returned by *MoveBy* differs from the number of rows you requested to move. This is because *MoveBy* stops when it reaches the first or last record in the dataset.

The following code moves two records backward in *CustTable*:

```
CustTable.MoveBy(-2);
```

Note If your application uses *MoveBy* in a multi-user database environment, keep in mind that datasets are fluid. A record that was five records back a moment ago may now be four, six, or even an unknown number of records back if several users are simultaneously accessing the database and changing its data.

Using the Eof and Bof properties

Two read-only, runtime properties, *Eof* (End-of-file) and *Bof* (Beginning-of-file), are useful when you want to iterate through all records in a dataset.

Eof

When *Eof* is *True*, it indicates that the cursor is unequivocally at the last row in a dataset. *Eof* is set to *True* when an application

- Opens an empty dataset.
- Calls a dataset's *Last* method.
- Calls a dataset's *Next* method, and the method fails (because the cursor is currently at the last row in the dataset.
- Calls *SetRange* on an empty range or dataset.

Eof is set to *False* in all other cases; you should assume *Eof* is *False* unless one of the conditions above is met *and* you test the property directly.

Eof is commonly tested in a loop condition to control iterative processing of all records in a dataset. If you open a dataset containing records (or you call *First*) *Eof* is

False. To iterate through the dataset a record at a time, create a loop that steps through each record by calling *Next*, and terminates when *Eof* is *True*. *Eof* remains *False* until you call *Next* when the cursor is already on the last record.

The following code illustrates one way you might code a record-processing loop for a dataset called *CustTable*:

```
CustTable.DisableControls;
try
  CustTable.First; { Go to first record, which sets Eof False }
  while not CustTable.Eof do { Cycle until Eof is True }
  begin
    { Process each record here }
    ⋮
    CustTable.Next; { Eof False on success; Eof True when Next fails on last record }
  end;
finally
  CustTable.EnableControls;
end;
```

Tip This example also shows how to disable and enable data-aware visual controls tied to a dataset. If you disable visual controls during dataset iteration, it speeds processing because your application does not need to update the contents of the controls as the current record changes. After iteration is complete, controls should be enabled again to update them with values for the new current row. Note that enabling of the visual controls takes place in the **finally** clause of a **try...finally** statement. This guarantees that even if an exception terminates loop processing prematurely, controls are not left disabled.

Bof

When *Bof* is *True*, it indicates that the cursor is unequivocally at the first row in a dataset. *Bof* is set to *True* when an application

- Opens a dataset.
- Calls a dataset's *First* method.
- Calls a dataset's *Prior* method, and the method fails (because the cursor is currently at the first row in the dataset.
- Calls *SetRange* on an empty range or dataset.

Bof is set to *False* in all other cases; you should assume *Bof* is *False* unless one of the conditions above is met *and* you test the property directly.

Like *Eof*, *Bof* can be in a loop condition to control iterative processing of records in a dataset. The following code illustrates one way you might code a record-processing loop for a dataset called *CustTable*:

```
CustTable.DisableControls; { Speed up processing; prevent screen flicker }
try
  while not CustTable.Bof do { Cycle until Bof is True }
  begin
    { Process each record here }
    ⋮
```

```
      CustTable.Prior; { Bof False on success; Bof True when Prior fails on first record }
    end;
  finally
    CustTable.EnableControls; { Display new current row in controls }
  end;
```

Marking and returning to records

In addition to moving from record to record in a dataset (or moving from one record to another by a specific number of records), it is often also useful to mark a particular location in a dataset so that you can return to it quickly when desired. *TDataSet* introduces a bookmarking feature that consists of a *Bookmark* property and five bookmark methods.

TDataSet implements **virtual** bookmark methods. While these methods ensure that any dataset object derived from *TDataSet* returns a value if a bookmark method is called, the return values are merely defaults that do not keep track of the current location. *TDataSet* descendants vary in the level of support they provide for bookmarks. None of the dbExpress datasets add any support for bookmarks. ADO datasets can support bookmarks, depending on the underlying database tables. BDE datasets, InterBase express datasets, and client datasets always support bookmarks.

The Bookmark property

The *Bookmark* property indicates which bookmark among any number of bookmarks in your application is current. *Bookmark* is a string that identifies the current bookmark. Each time you add another bookmark, it becomes the current bookmark.

The GetBookmark method

To create a bookmark, you must declare a variable of type *TBookmark* in your application, then call *GetBookmark* to allocate storage for the variable and set its value to a particular location in a dataset. The *TBookmark* type is a Pointer.

The GotoBookmark and BookmarkValid methods

When passed a bookmark, *GotoBookmark* moves the cursor for the dataset to the location specified in the bookmark. Before calling *GotoBookmark*, you can call *BookmarkValid* to determine if the bookmark points to a record. *BookmarkValid* returns *True* if a specified bookmark points to a record.

The CompareBookmarks method

You can also call *CompareBookmarks* to see if a bookmark you want to move to is different from another (or the current) bookmark. If the two bookmarks refer to the same record (or if both are **nil**), *CompareBookmarks* returns 0.

The FreeBookmark method

FreeBookmark frees the memory allocated for a specified bookmark when you no longer need it. You should also call *FreeBookmark* before reusing an existing bookmark.

A bookmarking example

The following code illustrates one use of bookmarking:

```
procedure DoSomething (const Tbl: TTable)
var
  Bookmark: TBookmark;
begin
  Bookmark := Tbl.GetBookmark; { Allocate memory and assign a value }
  Tbl.DisableControls; { Turn off display of records in data controls }
  try
    Tbl.First; { Go to first record in table }
    while not Tbl.Eof do {Iterate through each record in table }
    begin
      { Do your processing here }
      ⋮
      Tbl.Next;
    end;
  finally
    Tbl.GotoBookmark(Bookmark);
    Tbl.EnableControls; { Turn on display of records in data controls, if necessary }
    Tbl.FreeBookmark(Bookmark); {Deallocate memory for the bookmark }
  end;
end;
```

Before iterating through records, controls are disabled. Should an error occur during iteration through records, the **finally** clause ensures that controls are always enabled and that the bookmark is always freed even if the loop terminates prematurely.

Searching datasets

If a dataset is not unidirectional, you can search against it using the *Locate* and *Lookup* methods. These methods enable you to search on any type of columns in any dataset.

Note Some *TDataSet* descendants introduce an additional family of methods for searching based on an index. For information about these additional methods, see “Using Indexes to search for records” on page 18-27.

Using Locate

Locate moves the cursor to the first row matching a specified set of search criteria. In its simplest form, you pass *Locate* the name of a column to search, a field value to match, and an options flag specifying whether the search is case-insensitive or if it can use partial-key matching. (Partial-key matching is when the criterion string need only be a prefix of the field value.) For example, the following code moves the cursor to the first row in the *CustTable* where the value in the *Company* column is “Professional Divers, Ltd.”:

```
var
  LocateSuccess: Boolean;
  SearchOptions: TLocateOptions;
begin
```

```
    SearchOptions := [loPartialKey];
    LocateSuccess := CustTable.Locate('Company', 'Professional Divers, Ltd.', SearchOptions);
  end;
```

If *Locate* finds a match, the first record containing the match becomes the current record. *Locate* returns *True* if it finds a matching record, *False* if it does not. If a search fails, the current record does not change.

The real power of *Locate* comes into play when you want to search on multiple columns and specify multiple values to search for. Search values are Variants, which means you can specify different data types in your search criteria. To specify multiple columns in a search string, separate individual items in the string with semicolons.

Because search values are Variants, if you pass multiple values, you must either pass a Variant array as an argument (for example, the return values from the *Lookup* method), or you must construct the Variant array in code using the *VarArrayOf* function. The following code illustrates a search on multiple columns using multiple search values and partial-key matching:

```
with CustTable do
  Locate('Company;Contact;Phone', VarArrayOf(['Sight Diver','P']), loPartialKey);
```

Locate uses the fastest possible method to locate matching records. If the columns to search are indexed and the index is compatible with the search options you specify, *Locate* uses the index.

Using Lookup

Lookup searches for the first row that matches specified search criteria. If it finds a matching row, it forces the recalculation of any calculated fields and lookup fields associated with the dataset, then returns one or more fields from the matching row. *Lookup* does not move the cursor to the matching row; it only returns values from it.

In its simplest form, you pass *Lookup* the name of field to search, the field value to match, and the field or fields to return. For example, the following code looks for the first record in the *CustTable* where the value of the *Company* field is “Professional Divers, Ltd.”, and returns the company name, a contact person, and a phone number for the company:

```
var
  LookupResults: Variant;
begin
  LookupResults := CustTable.Lookup('Company', 'Professional Divers, Ltd.',
     'Company;Contact; Phone');
end;
```

Lookup returns values for the specified fields from the first matching record it finds. Values are returned as Variants. If more than one return value is requested, *Lookup* returns a Variant array. If there are no matching records, *Lookup* returns a Null Variant. For more information about Variant arrays, see the online help.

The real power of *Lookup* comes into play when you want to search on multiple columns and specify multiple values to search for. To specify strings containing multiple columns or result fields, separate individual fields in the string items with semicolons.

Because search values are Variants, if you pass multiple values, you must either pass a Variant array as an argument (for example, the return values from the *Lookup* method), or you must construct the Variant array in code using the *VarArrayOf* function. The following code illustrates a lookup search on multiple columns:

```
var
  LookupResults: Variant;
begin
with CustTable do
  LookupResults := Lookup('Company; City', VarArrayOf(['Sight Diver', 'Christiansted']),
    'Company; Addr1; Addr2; State; Zip');
end;
```

Like *Locate*, *Lookup* uses the fastest possible method to locate matching records. If the columns to search are indexed, *Lookup* uses the index.

Displaying and editing a subset of data using filters

An application is frequently interested in only a subset of records from a dataset. For example, you may be interested in retrieving or viewing only those records for companies based in California in your customer database, or you may want to find a record that contains a particular set of field values. In each case, you can use filters to restrict an application's access to a subset of all records in the dataset.

With unidirectional datasets, you can only limit the records in the dataset by using a query that restricts the records in the dataset. With other *TDataSet* descendants, however, you can define a subset of the data that has already been fetched. To restrict an application's access to a subset of all records in the dataset, you can use filters.

A filter specifies conditions a record must meet to be displayed. Filter conditions can be stipulated in a dataset's *Filter* property or coded into its *OnFilterRecord* event handler. Filter conditions are based on the values in any specified number of fields in a dataset, regardless of whether those fields are indexed. For example, to view only those records for companies based in California, a simple filter might require that records contain a value in the State field of "CA".

Note Filters are applied to every record retrieved in a dataset. When you want to filter large volumes of data, it may be more efficient to use a query to restrict record retrieval, or to set a range on an indexed table rather than using filters.

Enabling and disabling filtering

Enabling filters on a dataset is a three-step process:

1. Create a filter.
2. Set filter options for string-based filter tests, if necessary.
3. Set the *Filtered* property to *True*.

When filtering is enabled, only those records that meet the filter criteria are available to an application. Filtering is always a temporary condition. You can turn off filtering by setting the *Filtered* property to *False*.

Creating filters

There are two ways to create a filter for a dataset:

- Specify simple filter conditions in the *Filter* property. *Filter* is especially useful for creating and applying filters at runtime.
- Write an *OnFilterRecord* event handler for simple or complex filter conditions. With *OnFilterRecord*, you specify filter conditions at design time. Unlike the *Filter* property, which is restricted to a single string containing filter logic, an *OnFilterRecord* event can take advantage of branching and looping logic to create complex, multi-level filter conditions.

The main advantage to creating filters using the *Filter* property is that your application can create, change, and apply filters dynamically, (for example, in response to user input). Its main disadvantages are that filter conditions must be expressible in a single text string, cannot make use of branching and looping constructs, and cannot test or compare its values against values not already in the dataset.

The strengths of the *OnFilterRecord* event are that a filter can be complex and variable, can be based on multiple lines of code that use branching and looping constructs, and can test dataset values against values outside the dataset, such as the text in an edit box. The main weakness of using *OnFilterRecord* is that you set the filter at design time and it cannot be modified in response to user input. (You can, however, create several filter handlers and switch among them in response to general application conditions.)

The following sections describe how to create filters using the *Filter* property and the *OnFilterRecord* event handler.

Setting the Filter property

To create a filter using the *Filter* property, set the value of the property to a string that contains the filter's test condition. For example, the following statement creates a filter that tests a dataset's *State* field to see if it contains a value for the state of California:

```
Dataset1.Filter := 'State = ' + QuotedStr('CA');
```

You can also supply a value for *Filter* based on text supplied by the user. For example, the following statement assigns the text in from edit box to *Filter*:

```
Dataset1.Filter := Edit1.Text;
```

You can, of course, create a string based on both hard-coded text and user-supplied data:

```
Dataset1.Filter := 'State = ' + QuotedStr(Edit1.Text);
```

Blank field values do not appear unless they are explicitly included in the filter:

```
Dataset1.Filter := 'State <> ''CA'' or State = BLANK';
```

Note After you specify a value for *Filter*, to apply the filter to the dataset, set the *Filtered* property to *True*.

Filters can compare field values to literals and to constants using the following comparison and logical operators:

Table 18.4 Comparison and logical operators that can appear in a filter

Operator	Meaning
<	Less than
>	Greater than
>=	Greater than or equal to
<=	Less than or equal to
=	Equal to
<>	Not equal to
AND	Tests two statements are both *True*
NOT	Tests that the following statement is not *True*
OR	Tests that at least one of two statements is *True*
+	Adds numbers, concatenates strings, ads numbers to date/time values (only available for some drivers)
-	Subtracts numbers, subtracts dates, or subtracts a number from a date (only available for some drivers)
*	Multiplies two numbers (only available for some drivers)
/	Divides two numbers (only available for some drivers)
*	wildcard for partial comparisons (*FilterOptions* must include *foPartialCompare*)

By using combinations of these operators, you can create fairly sophisticated filters. For example, the following statement checks to make sure that two test conditions are met before accepting a record for display:

```
(Custno > 1400) AND (Custno < 1500);
```

Note When filtering is on, user edits to a record may mean that the record no longer meets a filter's test conditions. The next time the record is retrieved from the dataset, it may therefore "disappear." If that happens, the next record that passes the filter condition becomes the current record.

Writing an OnFilterRecord event handler

You can write code to filter records using the *OnFilterRecord* events generated by the dataset for each record it retrieves. This event handler implements a test that determines if a record should be included in those that are visible to the application.

To indicate whether a record passes the filter condition, your *OnFilterRecord* handler sets its *Accept* parameter to *True* to include a record, or *False* to exclude it. For example, the following filter displays only those records with the State field set to “CA”:

```
procedure TForm1.Table1FilterRecord(DataSet: TDataSet; var Accept: Boolean);
begin
  Accept := DataSet['State'].AsString = 'CA';
end;
```

When filtering is enabled, an *OnFilterRecord* event is generated for each record retrieved. The event handler tests each record, and only those that meet the filter’s conditions are displayed. Because the *OnFilterRecord* event is generated for every record in a dataset, you should keep the event handler as tightly-coded as possible to avoid adversely affecting the performance.

Switching filter event handlers at runtime

You can code any number of *OnFilterRecord* event handlers and switch among them at runtime. For example, the following statements switch to an *OnFilterRecord* event handler called *NewYorkFilter*:

```
DataSet1.OnFilterRecord := NewYorkFilter;
Refresh;
```

Setting filter options

The *FilterOptions* property lets you specify whether a filter that compares string-based fields accepts records based on partial comparisons and whether string comparisons are case-sensitive. *FilterOptions* is a set property that can be an empty set (the default), or that can contain either or both of the following values:

Table 18.5 FilterOptions values

Value	Meaning
foCaseInsensitive	Ignore case when comparing strings.
foNoPartialCompare	Disable partial string matching; that is, don’t match strings that end with an asterisk (*).

For example, the following statements set up a filter that ignores case when comparing values in the *State* field:

```
FilterOptions := [foCaseInsensitive];
Filter := 'State = ' + QuotedStr('CA');
```

Navigating records in a filtered dataset

There are four dataset methods that navigate among records in a filtered dataset. The following table lists these methods and describes what they do:

Table 18.6 Filtered dataset navigational methods

Method	Purpose
FindFirst	Move to the first record that matches the current filter criteria. The search for the first matching record always begins at the first record in the unfiltered dataset.
FindLast	Move to the last record that matches the current filter criteria.
FindNext	Moves from the current record in the filtered dataset to the next one.
FindPrior	Move from the current record in the filtered dataset to the previous one.

For example, the following statement finds the first filtered record in a dataset:

```
DataSet1.FindFirst;
```

Provided that you set the *Filter* property or create an *OnFilterRecord* event handler for your application, these methods position the cursor on the specified record regardless of whether filtering is currently enabled. If you call these methods when filtering is not enabled, then they

- Temporarily enable filtering.
- Position the cursor on a matching record if one is found.
- Disable filtering.

Note If filtering is disabled and you do not set the *Filter* property or create an *OnFilterRecord* event handler, these methods do the same thing as *First*, *Last*, *Next*, and *Prior*.

All navigational filter methods position the cursor on a matching record (if one is found), make that record the current one, and return *True*. If a matching record is not found, the cursor position is unchanged, and these methods return *False*. You can check the status of the *Found* property to wrap these calls, and only take action when *Found* is *True*. For example, if the cursor is already on the last matching record in the dataset and you call *FindNext*, the method returns *False*, and the current record is unchanged.

Modifying data

You can use the following dataset methods to insert, update, and delete data if the read-only *CanModify* property is *True*. *CanModify* is *True* unless the dataset is unidirectional, the database underlying the dataset does not permit read and write privileges, or some other factor intervenes. (Intervening factors include the *ReadOnly* property on some datasets or the *RequestLive* property on *TQuery* components.)

Table 18.7 Dataset methods for inserting, updating, and deleting data

Method	Description
Edit	Puts the dataset into *dsEdit* state if it is not already in *dsEdit* or *dsInsert* states.
Append	Posts any pending data, moves current record to the end of the dataset, and puts the dataset in *dsInsert* state.
Insert	Posts any pending data, and puts the dataset in *dsInsert* state.
Post	Attempts to post the new or altered record to the database. If successful, the dataset is put in *dsBrowse* state; if unsuccessful, the dataset remains in its current state.
Cancel	Cancels the current operation and puts the dataset in *dsBrowse* state.
Delete	Deletes the current record and puts the dataset in *dsBrowse* state.

Editing records

A dataset must be in *dsEdit* mode before an application can modify records. In your code you can use the *Edit* method to put a dataset into *dsEdit* mode if the read-only *CanModify* property for the dataset is *True*.

When a dataset transitions to *dsEdit* mode, it first receives a *BeforeEdit* event. After the transition to edit mode is successfully completed, the dataset receives an *AfterEdit* event. Typically, these events are used for updating the user interface to indicate the current state of the dataset. If the dataset can't be put into edit mode for some reason, an *OnEditError* event occurs, where you can inform the user of the problem or try to correct the situation that prevented the dataset from entering edit mode.

On forms in your application, some data-aware controls can automatically put a dataset into *dsEdit* state if

- The control's *ReadOnly* property is *False* (the default),
- The *AutoEdit* property of the data source for the control is *True*, and
- *CanModify* is *True* for the dataset.

Note Even if a dataset is in *dsEdit* state, editing records may not succeed for SQL-based databases if your application's user does not have proper SQL access privileges.

Once a dataset is in *dsEdit* mode, a user can modify the field values for the current record that appears in any data-aware controls on a form. Data-aware controls for which editing is enabled automatically call *Post* when a user executes any action that changes the current record (such as moving to a different record in a grid).

If you have a navigator component on your form, users can cancel edits by clicking the navigator's Cancel button. Canceling edits returns a dataset to *dsBrowse* state.

In code, you must write or cancel edits by calling the appropriate methods. You write changes by calling *Post*. You cancel them by calling *Cancel*. In code, *Edit* and *Post* are often used together. For example,

```
with CustTable do
begin
  Edit;
```

```
    FieldValues['CustNo'] := 1234;
    Post;
  end;
```

In the previous example, the first line of code places the dataset in *dsEdit* mode. The next line of code assigns the number 1234 to the *CustNo* field of the current record. Finally, the last line writes, or posts, the modified record. If you are not caching updates, posting writes the change back to the database. If you are caching updates, the change is written to a temporary buffer, where it stays until the dataset's *ApplyUpdates* method is called.

Adding new records

A dataset must be in *dsInsert* mode before an application can add new records. In code, you can use the *Insert* or *Append* methods to put a dataset into *dsInsert* mode if the read-only *CanModify* property for the dataset is *True*.

When a dataset transitions to *dsInsert* mode, it first receives a *BeforeInsert* event. After the transition to insert mode is successfully completed, the dataset receives first an *OnNewRecord* event hand then an *AfterInsert* event. You can use these events, for example, to provide initial values to newly inserted records:

```
procedure TForm1.OrdersTableNewRecord(DataSet: TDataSet);
begin
  DataSet.FieldByName('OrderDate').AsDateTime := Date;
end;
```

On forms in your application, the data-aware grid and navigator controls can put a dataset into *dsInsert* state if

- The control's *ReadOnly* property is *False* (the default), and
- *CanModify* is *True* for the dataset.

Note Even if a dataset is in *dsInsert* state, adding records may not succeed for SQL-based databases if your application's user does not have proper SQL access privileges.

Once a dataset is in *dsInsert* mode, a user or application can enter values into the fields associated with the new record. Except for the grid and navigational controls, there is no visible difference to a user between *Insert* and *Append*. On a call to *Insert*, an empty row appears in a grid above what was the current record. On a call to *Append*, the grid is scrolled to the last record in the dataset, an empty row appears at the bottom of the grid, and the *Next* and *Last* buttons are dimmed on any navigator component associated with the dataset.

Data-aware controls for which inserting is enabled automatically call *Post* when a user executes any action that changes which record is current (such as moving to a different record in a grid). Otherwise you must call *Post* in your code.

Post writes the new record to the database, or, if you are caching updates, *Post* writes the record to an in-memory cache. To write cached inserts and appends to the database, call the dataset's *ApplyUpdates* method.

Inserting records

Insert opens a new, empty record before the current record, and makes the empty record the current record so that field values for the record can be entered either by a user or by your application code.

When an application calls *Post* (or *ApplyUpdates* when using cached updates), a newly inserted record is written to a database in one of three ways:

- For indexed Paradox and dBASE tables, the record is inserted into the dataset in a position based on its index.
- For unindexed Paradox and dBASE tables, the record is inserted into the dataset at its current position.
- For SQL databases, the physical location of the insertion is implementation-specific. If the table is indexed, the index is updated with the new record information.

Appending records

Append opens a new, empty record at the end of the dataset, and makes the empty record the current one so that field values for the record can be entered either by a user or by your application code.

When an application calls *Post* (or *ApplyUpdates* when using cached updates), a newly appended record is written to a database in one of three ways:

- For indexed Paradox and dBASE tables, the record is inserted into the dataset in a position based on its index.
- For unindexed Paradox and dBASE tables, the record is added to the end of the dataset.
- For SQL databases, the physical location of the append is implementation-specific. If the table is indexed, the index is updated with the new record information.

Deleting records

Use the *Delete* method to delete the current record in an active dataset. When the *Delete* method is called,

- The dataset receives a *BeforeDelete* event.
- The dataset attempts to delete the current record.
- The dataset returns to the *dsBrowse* state.
- The dataset receives an *AfterDelete* event.

If want to prevent the deletion in the *BeforeDelete* event handler, you can call the global *Abort* procedure:

```
procedure TForm1.TableBeforeDelete (Dataset: TDataset)begin
  if MessageDlg('Delete This Record?', mtConfirmation, mbYesNoCancel, 0) <> mrYes then
    Abort;
end;
```

If *Delete* fails, it generates an *OnDeleteError* event. If the *OnDeleteError* event handler can't correct the problem, the dataset remains in *dsEdit* state. If *Delete* succeeds, the dataset reverts to the *dsBrowse* state and the record that followed the deleted record becomes the current record.

If you are caching updates, the deleted record is not removed from the underlying database table until you call *ApplyUpdates*.

If you provide a navigator component on your forms, users can delete the current record by clicking the navigator's Delete button. In code, you must call *Delete* explicitly to remove the current record.

Posting data

After you finish editing a record, you must call the *Post* method to write out your changes. The *Post* method behaves differently, depending on the dataset's state and on whether you are caching updates.

- If you are not caching updates, and the dataset is in the *dsEdit* or *dsInsert* state, *Post* writes the current record to the database and returns the dataset to the *dsBrowse* state.
- If you are caching updates, and the dataset is in the *dsEdit* or *dsInsert* state, *Post* writes the current record to an internal cache and returns the dataset to the *dsBrowse* state. The edits are net written to the database until you call *ApplyUpdates*.
- If the dataset is in the *dsSetKey* state, *Post* returns the dataset to the *dsBrowse* state.

Regardless of the initial state of the dataset, *Post* generates *BeforePost* and *AfterPost* events, before and after writing the current changes. You can use these events to update the user interface, or prevent the dataset from posting changes by calling the *Abort* procedure. If the call to *Post* fails, the dataset receives an *OnPostError* event, where you can inform the user of the problem or attempt to correct it.

Posting can be done explicitly, or implicitly as part of another procedure. When an application moves off the current record, *Post* is called implicitly. Calls to the *First*, *Next*, *Prior*, and *Last* methods perform a *Post* if the table is in *dsEdit* or *dsInsert* modes. The *Append* and *Insert* methods also implicitly post any pending data.

Warning The *Close* method does not call *Post* implicitly. Use the *BeforeClose* event to post any pending edits explicitly.

Canceling changes

An application can undo changes made to the current record at any time, if it has not yet directly or indirectly called *Post*. For example, if a dataset is in *dsEdit* mode, and a user has changed the data in one or more fields, the application can return the record back to its original values by calling the *Cancel* method for the dataset. A call to *Cancel* always returns a dataset to *dsBrowse* state.

If the dataset was in *dsEdit* or *dsInsert* mode when your application called *Cancel*, it receives *BeforeCancel* and *AfterCancel* events before and after the current record is restored to its original values.

On forms, you can allow users to cancel edit, insert, or append operations by including the Cancel button on a navigator component associated with the dataset, or you can provide code for your own Cancel button on the form.

Modifying entire records

On forms, all data-aware controls except for grids and the navigator provide access to a single field in a record.

In code, however, you can use the following methods that work with entire record structures provided that the structure of the database tables underlying the dataset is stable and does not change. The following table summarizes the methods available for working with entire records rather than individual fields in those records:

Table 18.8 Methods that work with entire records

Method	Description
AppendRecord([array of values])	Appends a record with the specified column values at the end of a table; analogous to *Append*. Performs an implicit *Post*.
InsertRecord([array of values])	Inserts the specified values as a record before the current cursor position of a table; analogous to *Insert*. Performs an implicit *Post*.
SetFields([array of values])	Sets the values of the corresponding fields; analogous to assigning values to *TField*s. The application must perform an explicit *Post*.

These method take an array of values as an argument, where each value corresponds to a column in the underlying dataset. The values can be literals, variables, or NULL. If the number of values in an argument is less than the number of columns in a dataset, then the remaining values are assumed to be NULL.

For unindexed datasets, *AppendRecord* adds a record to the end of the dataset and *InsertRecord* inserts a record after the current cursor position. For indexed datasets, both methods place the record in the correct position in the table, based on the index. In both cases, the methods move the cursor to the record's position.

SetFields assigns the values specified in the array of parameters to fields in the dataset. To use *SetFields*, an application must first call *Edit* to put the dataset in *dsEdit* mode. To apply the changes to the current record, it must perform a *Post*.

If you use *SetFields* to modify some, but not all fields in an existing record, you can pass NULL values for fields you do not want to change. If you do not supply enough values for all fields in a record, SetFields assigns NULL values to them. NULL values overwrite any existing values already in those fields.

For example, suppose a database has a COUNTRY table with columns for Name, Capital, Continent, Area, and Population. If a *TTable* component called *CountryTable* were linked to the COUNTRY table, the following statement would insert a record into the COUNTRY table:

```
CountryTable.InsertRecord(['Japan', 'Tokyo', 'Asia']);
```

This statement does not specify values for Area and Population, so NULL values are inserted for them. The table is indexed on Name, so the statement would insert the record based on the alphabetic collation of "Japan".

To update the record, an application could use the following code:

```
with CountryTable do
begin
  if Locate('Name', 'Japan', loCaseInsensitive) then;
  begin
    Edit;
    SetFields(nil, nil, nil, 344567, 164700000);
    Post;
  end;
end;
```

This code assigns values to the Area and Population fields and then posts them to the database. The three NULL pointers act as place holders for the first three columns to preserve their current contents.

Calculating fields

Using the Fields editor, you can define calculated fields for your datasets. When a dataset contains calculated fields, you provide the code to calculate those field's values in an *OnCalcFields* event handler. For details on how to define calculated fields using the Fields editor, see "Defining a calculated field" on page 19-7.

The *AutoCalcFields* property determines when *OnCalcFields* is called. If *AutoCalcFields* is *True*, *OnCalcFields* is called when

- A dataset is opened.
- The dataset enters edit mode.
- A record is retrieved from the database.
- Focus moves from one visual component to another, or from one column to another in a data-aware grid control and the current record has been modified.

If *AutoCalcFields* is *False*, then *OnCalcFields* is not called when individual fields within a record are edited (the fourth condition above).

Caution *OnCalcFields* is called frequently, so the code you write for it should be kept short. Also, if *AutoCalcFields* is *True*, *OnCalcFields* should not perform any actions that modify the dataset (or a linked dataset if it is part of a master-detail relationship), because this leads to recursion. For example, if *OnCalcFields* performs a *Post*, and *AutoCalcFields* is *True*, then *OnCalcFields* is called again, causing another *Post*, and so on.

When *OnCalcFields* executes, a dataset enters *dsCalcFields* mode. This state prevents modifications or additions to the records except for the calculated fields the handler is designed to modify. The reason for preventing other modifications is because *OnCalcFields* uses the values in other fields to derive calculated field values. Changes to those other fields might otherwise invalidate the values assigned to calculated fields. After *OnCalcFields* is completed, the dataset returns to *dsBrowse* state.

Types of datasets

"Using TDataSet descendants" on page 18-2 classifies *TDataSet* descendants by the method they use to access their data. Another useful way to classify *TDataSet* descendants is to consider the type of server data they represent. Viewed this way, there are three basic classes of datasets:

- **Table-type datasets**: Table-type datasets represent a single table from the database server, including all of its rows and columns. Table-type datasets include *TTable*, *TADOTable*, *TSQLTable*, and *TIBTable*.

  Table-type datasets let you take advantage of indexes defined on the server. Because there is a one-to-one correspondence between database table and dataset, you can use server indexes that are defined for the database table. Indexes allow your application to sort the records in the table, speed searches and lookups, and can form the basis of a master/detail relationship. Some table-type datasets also take advantage of the one-to-one relationship between dataset and database table to let you perform table-level operations such as creating and deleting database tables.

- **Query-type datasets**: Query-type datasets represent a single SQL command, or query. Queries can represent the result set from executing a command (typically a SELECT statement), or they can execute a command that does not return any records (for example, an UPDATE statement). Query-type datasets include *TQuery*, *TADOQuery*, *TSQLQuery*, and *TIBQuery*.

  To use a query-type dataset effectively, you must be familiar with SQL and your server's SQL implementation, including limitations and extensions to the SQL-92 standard. If you are new to SQL, you may want to purchase a third party book that covers SQL in-depth. One of the best is *Understanding the New SQL: A Complete Guide*, by Jim Melton and Alan R. Simpson, Morgan Kaufmann Publishers.

- **Stored procedure-type datasets**: Stored procedure-type datasets represent a stored procedure on the database server. Stored procedure-type datasets include *TStoredProc*, *TADOStoredProc*, *TSQLStoredProc*, and *TIBStoredProc*.

  A stored procedure is a self-contained program written in the procedure and trigger language specific to the database system used. They typically handle frequently-repeated database-related tasks, and are especially useful for operations that act on large numbers of records or that use aggregate or mathematical functions. Using stored procedures typically improves the performance of a database application by:

  - Taking advantage of the server's usually greater processing power and speed.
  - Reducing network traffic by moving processing to the server.

Stored procedures may or may not return data. Those that return data may return it as a cursor (similar to the results of a SELECT query), as multiple cursors (effectively returning multiple datasets), or they may return data in output parameters. These differences depend in part on the server: Some servers do not allow stored procedures to return data, or only allow output parameters. Some servers do not support stored procedures at all. See your server documentation to determine what is available.

Note You can usually use a query-type dataset to execute stored procedures because most servers provide extensions to SQL for working with stored procedures. Each server, however, uses its own syntax for this. If you choose to use a query-type dataset instead of a stored procedure-type dataset, see your server documentation for the necessary syntax.

In addition to the datasets that fall neatly into these three categories, *TDataSet* has some descendants that fit into more than one category:

- *TADODataSet* and *TSQLDataSet* have a *CommandType* property that lets you specify whether they represent a table, query, or stored procedure. Property and method names are most similar to query-type datasets, although *TADODataSet* lets you specify an index like a table-type dataset.
- *TClientDataSet* represents the data from another dataset. As such, it can represent a table, query, or stored procedure. *TClientDataSet* behaves most like a table-type dataset, because of its index support. However, it also has some of the features of queries and stored procedures: the management of parameters and the ability to execute without retrieving a result set.
- Some other client datasets (*TBDEClientDataSet* and *TSQLClientDataSet*) have a *CommandType* property that lets you specify whether they represent a table, query, or stored procedure. Property and method names are like *TClientDataSet*, including parameter support, indexes, and the ability to execute without retrieving a result set.
- *TIBDataSet* can represent both queries and stored procedures. In fact, it can represent multiple queries and stored procedures simultaneously, with separate properties for each.

Using table-type datasets

To use a table-type dataset,

1. Place the appropriate dataset component in a data module or on a form, and set its *Name* property to a unique value appropriate to your application.
2. Identify the database server that contains the table you want to use. Each table-type dataset does this differently, but typically you specify a database connection component:
    - For *TTable*, specify a *TDatabase* component or a BDE alias using the *DatabaseName* property.

- For *TADOTable*, specify a *TADOConnection* component using the *Connection* property.
- For *TSQLTable*, specify a *TSQLConnection* component using the *SQLConnection* property.
- For *TIBTable*, specify a *TIBConnection* component using the *Database* property.

For information about using database connection components, see Chapter 17, "Connecting to databases".

3 Set the *TableName* property to the name of the table in the database. You can select tables from a drop-down list if you have already identified a database connection component.

4 Place a data source component in the data module or on the form, and set its *DataSet* property to the name of the dataset. The data source component is used to pass a result set from the dataset to data-aware components for display.

Advantages of using table-type datasets

The main advantage of using table-type datasets is the availability of indexes. Indexes enable your application to

- Sort the records in the dataset.
- Locate records quickly.
- Limit the records that are visible.
- Establish master/detail relationships.

In addition, the one-to-one relationship between table-type datasets and database tables enables many of them to be used for

- Controlling Read/write access to tables
- Creating and deleting tables
- Emptying tables
- Synchronizing tables

Sorting records with indexes

An index determines the display order of records in a table. Typically, records appear in ascending order based on a primary, or default, index. This default behavior does not require application intervention. If you want a different sort order, however, you must specify either

- An alternate index.
- A list of columns on which to sort (not available on servers that aren't SQL-based).

Indexes let you present the data from a table in different orders. On SQL-based tables, this sort order is implemented by using the index to generate an ORDER BY clause in a query that fetches the table's records. On other tables (such as Paradox and dBASE tables), the index is used by the data access mechanism to present records in the desired order.

Obtaining information about indexes

You application can obtain information about server-defined indexes from all table-type datasets. To obtain a list of available indexes for the dataset, call the *GetIndexNames* method. *GetIndexNames* fills a string list with valid index names. For example, the following code fills a listbox with the names of all indexes defined for the *CustomersTable* dataset:

```
CustomersTable.GetIndexNames(ListBox1.Items);
```

Note For Paradox tables, the primary index is unnamed, and is therefore not returned by *GetIndexNames*. You can still change the index back to a primary index on a Paradox table after using an alternative index, however, by setting the *IndexName* property to a blank string.

To obtain information about the fields of the current index, use the

- *IndexFieldCount* property, to determine the number of columns in the index.
- *IndexFields* property, to examine a list the field components for the columns that comprise the index.

The following code illustrates how you might use *IndexFieldCount* and *IndexFields* to iterate through a list of column names in an application:

```
var
  I: Integer;
  ListOfIndexFields: array[0 to 20} of string;
begin
with CustomersTable do
  begin
  for I := 0 to IndexFieldCount - 1 do
     ListOfIndexFields[I] := IndexFields[I].FieldName;
  end;
end;
```

Note *IndexFieldCount* is not valid for a dBASE table opened on an expression index.

Specifying an index with IndexName

Use the *IndexName* property to cause an index to be active. Once active, an index determines the order of records in the dataset. (It can also be used as the basis for a master-detail link, an index-based search, or index-based filtering.)

To activate an index, set the *IndexName* property to the name of the index. In some database systems, primary indexes do not have names. To activate one of these indexes, set *IndexName* to a blank string.

At design-time, you can select an index from a list of available indexes by clicking the property's ellipsis button in the Object Inspector. At runtime set *IndexName* using a ***String*** literal or variable. You can obtain a list of available indexes by calling the *GetIndexNames* method.

The following code sets the index for *CustomersTable* to *CustDescending*:

```
CustomersTable.IndexName := 'CustDescending';
```

Creating an index with IndexFieldNames

If there is no defined index that implements the sort order you want, you can create a pseudo-index using the *IndexFieldNames* property.

Note *IndexName* and *IndexFieldNames* are mutually exclusive. Setting one property clears values set for the other.

The value of *IndexFieldNames* is a string. To specify a sort order, list each column name to use in the order it should be used, and delimit the names with semicolons. Sorting is by ascending order only. Case-sensitivity of the sort depends on the capabilities of your server. See your server documentation for more information.

The following code sets the sort order for *PhoneTable* based on *LastName*, then *FirstName*:

```
PhoneTable.IndexFieldNames := 'LastName;FirstName';
```

Note If you use *IndexFieldNames* on Paradox and dBASE tables, the dataset attempts to find an index that uses the columns you specify. If it cannot find such an index, it raises an exception.

Using Indexes to search for records

You can search against any dataset using the *Locate* and *Lookup* methods of *TDataSet*. However, by explicitly using indexes, some table-type datasets can improve over the searching performance provided by the *Locate* and *Lookup* methods.

ADO datasets all support the *Seek* method, which moves to a record based on a set of field values for fields in the current index. *Seek* lets you specify where to move the cursor relative to the first or last matching record.

TTable and all types of client dataset support similar indexed-based searches, but use a combination of related methods. The following table summarizes the six related methods provided by *TTable* and client datasets to support index-based searches:

Table 18.9 Index-based search methods

Method	Purpose
EditKey	Preserves the current contents of the search key buffer and puts the dataset into *dsSetKey* state so your application can modify existing search criteria prior to executing a search.
FindKey	Combines the *SetKey* and *GotoKey* methods in a single method.
FindNearest	Combines the *SetKey* and *GotoNearest* methods in a single method.
GotoKey	Searches for the first record in a dataset that exactly matches the search criteria, and moves the cursor to that record if one is found.
GotoNearest	Searches on string-based fields for the closest match to a record based on partial key values, and moves the cursor to that record.
SetKey	Clears the search key buffer and puts the table into *dsSetKey* state so your application can specify new search criteria prior to executing a search.

GotoKey and *FindKey* are boolean functions that, if successful, move the cursor to a matching record and return *True*. If the search is unsuccessful, the cursor is not moved, and these functions return *False*.

GotoNearest and *FindNearest* always reposition the cursor either on the first exact match found or, if no match is found, on the first record that is greater than the specified search criteria.

Executing a search with Goto methods

To execute a search using *Goto* methods, follow these general steps:

1. Specify the index to use for the search. This is the same index that sorts the records in the dataset (see “Sorting records with indexes” on page 18-25). To specify the index, use the *IndexName* or *IndexFieldNames* property.
2. Open the dataset.
3. Put the dataset in *dsSetKey* state by calling the *SetKey* method.
4. Specify the value(s) to search on in the *Fields* property. *Fields* is a *TFields* object, which maintains an indexed list of field components you can access by specifying ordinal numbers corresponding to columns. The first column number in a dataset is 0.
5. Search for and move to the first matching record found with *GotoKey* or *GotoNearest*.

For example, the following code, attached to a button’s *OnClick* event, uses the *GotoKey* method to move to the first record where the first field in the index has a value that exactly matches the text in an edit box:

```
procedure TSearchDemo.SearchExactClick(Sender: TObject);
begin
  ClientDataSet1.SetKey;
  ClientDataSet1.Fields[0].AsString := Edit1.Text;
  if not ClientDataSet1.GotoKey then
    ShowMessage('Record not found');
end;
```

GotoNearest is similar. It searches for the nearest match to a partial field value. It can be used only for string fields. For example,

```
Table1.SetKey;
Table1.Fields[0].AsString := 'Sm';
Table1.GotoNearest;
```

If a record exists with “Sm” as the first two characters of the first indexed field’s value, the cursor is positioned on that record. Otherwise, the position of the cursor does not change and *GotoNearest* returns *False*.

Executing a search with Find methods

The *Find* methods do the same thing as the *Goto* methods, except that you do not need to explicitly put the dataset in *dsSetKey* state to specify the key field values on which to search. To execute a search using *Find* methods, follow these general steps:

1 Specify the index to use for the search. This is the same index that sorts the records in the dataset (see "Sorting records with indexes" on page 18-25). To specify the index, use the *IndexName* or *IndexFieldNames* property.

2 Open the dataset.

3 Search for and move to the first or nearest record with *FindKey* or *FindNearest*. Both methods take a single parameter, a comma-delimited list of field values, where each value corresponds to an indexed column in the underlying table.

Note *FindNearest* can only be used for string fields.

Specifying the current record after a successful search

By default, a successful search positions the cursor on the first record that matches the search criteria. If you prefer, you can set the *KeyExclusive* property to *True* to position the cursor on the next record after the first matching record.

By default, *KeyExclusive* is *False*, meaning that successful searches position the cursor on the first matching record.

Searching on partial keys

If the dataset has more than one key column, and you want to search for values in a subset of that key, set *KeyFieldCount* to the number of columns on which you are searching. For example, if the dataset's current index has three columns, and you want to search for values using just the first column, set *KeyFieldCount* to 1.

For table-type datasets with multiple-column keys, you can search only for values in contiguous columns, beginning with the first. For example, for a three-column key you can search for values in the first column, the first and second, or the first, second, and third, but not just the first and third.

Repeating or extending a search

Each time you call *SetKey* or *FindKey*, the method clears any previous values in the *Fields* property. If you want to repeat a search using previously set fields, or you want to add to the fields used in a search, call *EditKey* in place of *SetKey* and *FindKey*.

For example, suppose you have already executed a search of the Employee table based on the City field of the "CityIndex" index. Suppose further that "CityIndex" includes both the *City* and *Company* fields. To find a record with a specified company name in a specified city, use the following code:

```
Employee.KeyFieldCount := 2;
Employee.EditKey;
Employee['Company'] := Edit2.Text;
Employee.GotoNearest;
```

Limiting records with ranges

You can temporarily view and edit a subset of data for any dataset by using filters (see “Displaying and editing a subset of data using filters” on page 18-12). Some table-type datasets support an additional way to access a subset of available records, called ranges.

Ranges only apply to *TTable* and to client datasets. Despite their similarities, ranges and filters have different uses. The following topics discuss the differences between ranges and filters and how to use ranges.

Understanding the differences between ranges and filters

Both ranges and filters restrict visible records to a subset of all available records, but the way they do so differs. A range is a set of contiguously indexed records that fall between specified boundary values. For example, in an employee database indexed on last name, you might apply a range to display all employees whose last names are greater than “Jones” and less than “Smith”. Because ranges depend on indexes, you must set the current index to one that can be used to define the range. As with specifying an index to sort records, you can assign the index on which to define a range using either the *IndexName* or the *IndexFieldNames* property.

A filter, on the other hand, is any set of records that share specified data points, regardless of indexing. For example, you might filter an employee database to display all employees who live in California and who have worked for the company for five or more years. While filters can make use of indexes if they apply, filters are not dependent on them. Filters are applied record-by-record as an application scrolls through a dataset.

In general, filters are more flexible than ranges. Ranges, however, can be more efficient when datasets are large and the records of interest to an application are already blocked in contiguously indexed groups. For very large datasets, it may be still more efficient to use the WHERE clause of a query-type dataset to select data. For details on specifying a query, see “Using query-type datasets” on page 18-41.

Specifying Ranges

There are two mutually exclusive ways to specify a range:

- Specify the beginning and ending separately using *SetRangeStart* and *SetRangeEnd*.
- Specify both endpoints at once using *SetRange*.

Setting the beginning of a range

Call the *SetRangeStart* procedure to put the dataset into *dsSetKey* state and begin creating a list of starting values for the range. Once you call *SetRangeStart*, subsequent assignments to the *Fields* property are treated as starting index values to use when applying the range. Fields specified must apply to the current index.

For example, suppose your application uses a *TSQLClientDataSet* component named *Customers*, linked to the CUSTOMER table, and that you have created persistent field components for each field in the *Customers* dataset. CUSTOMER is indexed on its first column (*CustNo*). A form in the application has two edit components named *StartVal* and *EndVal*, used to specify start and ending values for a range. The following code can be used to create and apply a range:

```
with Customers do
begin
  SetRangeStart;
  FieldByName('CustNo').AsString := StartVal.Text;
  SetRangeEnd;
  if (Length(EndVal.Text) > 0) then
    FieldByName('CustNo').AsString := EndVal.Text;
  ApplyRange;
end;
```

This code checks that the text entered in *EndVal* is not null before assigning any values to *Fields*. If the text entered for *StartVal* is null, then all records from the beginning of the dataset are included, since all values are greater than null. However, if the text entered for *EndVal* is null, then no records are included, since none are less than null.

For a multi-column index, you can specify a starting value for all or some fields in the index. If you do not supply a value for a field used in the index, a null value is assumed when you apply the range. If you try to set a value for a field that is not in the index, the dataset raises an exception.

Tip To start at the beginning of the dataset, omit the call to *SetRangeStart*.

To finish specifying the start of a range, call *SetRangeEnd* or apply or cancel the range. For information about applying and canceling ranges, see “Applying or canceling a range” on page 18-33.

Setting the end of a range

Call the *SetRangeEnd* procedure to put the dataset into *dsSetKey* state and start creating a list of ending values for the range. Once you call *SetRangeEnd*, subsequent assignments to the *Fields* property are treated as ending index values to use when applying the range. Fields specified must apply to the current index.

Warning Always specify the ending values for a range, even if you want a range to end on the last record in the dataset. If you do not provide ending values, Delphi assumes the ending value of the range is a null value. A range with null ending values is always empty.

The easiest way to assign ending values is to call the *FieldByName* method. For example,

```
with Contacts do
begin
  SetRangeStart;
  FieldByName('LastName').AsString := Edit1.Text;
  SetRangeEnd;
  FieldByName('LastName').AsString := Edit2.Text;
  ApplyRange;
end;
```

As with specifying start of range values, if you try to set a value for a field that is not in the index, the dataset raises an exception.

To finish specifying the end of a range, apply or cancel the range. For information about applying and canceling ranges, see "Applying or canceling a range" on page 18-33.

Setting start- and end-range values

Instead of using separate calls to *SetRangeStart* and *SetRangeEnd* to specify range boundaries, you can call the *SetRange* procedure to put the dataset into *dsSetKey* state and set the starting and ending values for a range with a single call.

SetRange takes two constant array parameters: a set of starting values, and a set of ending values. For example, the following statement establishes a range based on a two-column index:

```
SetRange([Edit1.Text, Edit2.Text], [Edit3.Text, Edit4.Text]);
```

For a multi-column index, you can specify starting and ending values for all or some fields in the index. If you do not supply a value for a field used in the index, a null value is assumed when you apply the range. To omit a value for the first field in an index, and specify values for successive fields, pass a null value for the omitted field.

Always specify the ending values for a range, even if you want a range to end on the last record in the dataset. If you do not provide ending values, the dataset assumes the ending value of the range is a null value. A range with null ending values is always empty because the starting range is greater than or equal to the ending range.

Specifying a range based on partial keys

If a key is composed of one or more string fields, the *SetRange* methods support partial keys. For example, if an index is based on the *LastName* and *FirstName* columns, the following range specifications are valid:

```
Contacts.SetRangeStart;
Contacts['LastName'] := 'Smith';
Contacts.SetRangeEnd;
Contacts['LastName'] := 'Zzzzzz';
Contacts.ApplyRange;
```

This code includes all records in a range where *LastName* is greater than or equal to "Smith." The value specification could also be:

```
Contacts['LastName'] := 'Sm';
```

This statement includes records that have *LastName* greater than or equal to "Sm."

Including or excluding records that match boundary values

By default, a range includes all records that are greater than or equal to the specified starting range, and less than or equal to the specified ending range. This behavior is controlled by the *KeyExclusive* property. *KeyExclusive* is *False* by default.

If you prefer, you can set the *KeyExclusive* property for a dataset to *True* to exclude records equal to ending range. For example,

```
Contacts.KeyExclusive := True;
Contacts.SetRangeStart;
Contacts['LastName'] := 'Smith';
Contacts.SetRangeEnd;
Contacts['LastName'] := 'Tyler';
Contacts.ApplyRange;
```

This code includes all records in a range where *LastName* is greater than or equal to “Smith” and less than “Tyler”.

Modifying a range

Two functions enable you to modify the existing boundary conditions for a range: *EditRangeStart*, for changing the starting values for a range; and *EditRangeEnd*, for changing the ending values for the range.

The process for editing and applying a range involves these general steps:

1. Putting the dataset into *dsSetKey* state and modifying the starting index value for the range.
2. Modifying the ending index value for the range.
3. Applying the range to the dataset.

You can modify either the starting or ending values of the range, or you can modify both boundary conditions. If you modify the boundary conditions for a range that is currently applied to the dataset, the changes you make are not applied until you call *ApplyRange* again.

Editing the start of a range

Call the *EditRangeStart* procedure to put the dataset into *dsSetKey* state and begin modifying the current list of starting values for the range. Once you call *EditRangeStart*, subsequent assignments to the *Fields* property overwrite the current index values to use when applying the range.

Tip If you initially created a start range based on a partial key, you can use *EditRangeStart* to extend the starting value for a range. For more information about ranges based on partial keys, see “Specifying a range based on partial keys” on page 18-32.

Editing the end of a range

Call the *EditRangeEnd* procedure to put the dataset into *dsSetKey* state and start creating a list of ending values for the range. Once you call *EditRangeEnd*, subsequent assignments to the *Fields* property are treated as ending index values to use when applying the range.

Applying or canceling a range

When you call *SetRangeStart* or *EditRangeStart* to specify the start of a range, or *SetRangeEnd* or *EditRangeEnd* to specify the end of a range, the dataset enters the *dsSetKey* state. It stays in that state until you apply or cancel the range.

Applying a range

When you specify a range, the boundary conditions you define are not put into effect until you apply the range. To make a range take effect, call the *ApplyRange* method. *ApplyRange* immediately restricts a user's view of and access to data in the specified subset of the dataset.

Canceling a range

The *CancelRange* method ends application of a range and restores access to the full dataset. Even though canceling a range restores access to all records in the dataset, the boundary conditions for that range are still available so that you can reapply the range at a later time. Range boundaries are preserved until you provide new range boundaries or modify the existing boundaries. For example, the following code is valid:

```
⋮
MyTable.CancelRange;
⋮
{later on, use the same range again. No need to call SetRangeStart, etc.}
MyTable.ApplyRange;
⋮
```

Creating master/detail relationships

Table-type datasets can be linked into master/detail relationships. When you set up a master/detail relationship, you link two datasets so that all the records of one (the detail) always correspond to the single current record in the other (the master).

Table-type datasets support master/detail relationships in two very distinct ways:

- All table-type datasets can act as the detail of another dataset by linking cursors. This process is described in "Making the table a detail of another dataset" below.
- *TTable*, *TSQLTable*, and all client datasets can act as the master in a master/detail relationship that uses nested detail tables. This process is described in "Using nested detail tables" on page 18-36.

Each of these approaches has its unique advantages. Linking cursors lets you create master/detail relationships where the master table is any type of dataset. With nested details, the type of dataset that can act as the detail table is limited, but they provide for more options in how to display the data. If the master is a client dataset, nested details provide a more robust mechanism for applying cached updates.

Making the table a detail of another dataset

A table-type dataset's *MasterSource* and *MasterFields* properties can be used to establish one-to-many relationships between two datasets.

The *MasterSource* property is used to specify a data source from which the table gets data from the master table. This data source can be linked to any type of dataset. For instance, by specifying a query's data source in this property, you can link a client dataset as the detail of the query, so that the client dataset tracks events occurring in the query.

The dataset is linked to the master table based on its current index. Before you specify the fields in the master dataset that are tracked by the detail dataset, first specify the index in the detail dataset that starts with the corresponding fields. You can use either the *IndexName* or the *IndexFieldNames* property.

Once you specify the index to use, use the *MasterFields* property to indicate the column(s) in the master dataset that correspond to the index fields in the detail table. To link datasets on multiple column names, separate field names with semicolons:

```
Parts.MasterFields := 'OrderNo;ItemNo';
```

To help create meaningful links between two datasets, you can use the Field Link designer. To use the Field Link designer, double click on the *MasterFields* property in the Object Inspector after you have assigned a *MasterSource* and an index.

The following steps create a simple form in which a user can scroll through customer records and display all orders for the current customer. The master table is the *CustomersTable* table, and the detail table is *OrdersTable*. The example uses the BDE-based *TTable* component, but you can use the same methods to link any table-type datasets.

1 Place two *TTable* components and two *TDataSource* components in a data module.

2 Set the properties of the first *TTable* component as follows:

- *DatabaseName*: DBDEMOS
- *TableName*: CUSTOMER
- *Name*: CustomersTable

3 Set the properties of the second *TTable* component as follows:

- *DatabaseName*: DBDEMOS
- *TableName*: ORDERS
- *Name*: OrdersTable

4 Set the properties of the first *TDataSource* component as follows:

- *Name*: CustSource
- *DataSet*: CustomersTable

5 Set the properties of the second *TDataSource* component as follows:

- *Name*: OrdersSource
- *DataSet*: OrdersTable

6 Place two *TDBGrid* components on a form.

7 Choose File|Use Unit to specify that the form should use the data module.

8 Set the *DataSource* property of the first grid component to "CustSource", and set the *DataSource* property of the second grid to "OrdersSource".

9 Set the *MasterSource* property of *OrdersTable* to "CustSource". This links the CUSTOMER table (the master table) to the ORDERS table (the detail table).

10 Double-click the *MasterFields* property value box in the Object Inspector to invoke the Field Link Designer to set the following properties:

- In the Available Indexes field, choose *CustNo* to link the two tables by the *CustNo* field.
- Select *CustNo* in both the Detail Fields and Master Fields field lists.
- Click the Add button to add this join condition. In the Joined Fields list, "CustNo -> CustNo" appears.
- Choose OK to commit your selections and exit the Field Link Designer.

11 Set the *Active* properties of *CustomersTable* and *OrdersTable* to *True* to display data in the grids on the form.

12 Compile and run the application.

If you run the application now, you will see that the tables are linked together, and that when you move to a new record in the CUSTOMER table, you see only those records in the ORDERS table that belong to the current customer.

Using nested detail tables

A nested table is a detail dataset that is the value of a single dataset field in another (master) dataset. For datasets that represent server data, a nested detail dataset can only be used for a dataset field on the server. *TClientDataSet* components do not represent server data, but they can also contain dataset fields if you create a dataset for them that contains nested details, or if they receive data from a provider that is linked to the master table of a master/detail relationship.

Note For *TClientDataSet*, using nested detail sets is necessary if you want to apply updates from master and detail tables to a database server.

To use nested detail sets, the *ObjectView* property of the master dataset must be *True*. When your table-type dataset contains nested detail datasets, *TDBGrid* provides support for displaying the nested details in a popup window. For more information on how this works, see "Displaying dataset fields" on page 19-26.

Alternately, you can display and edit detail datasets in data-aware controls by using a separate dataset component for the detail set. At design time, create persistent fields for the fields in your (master) dataset, using the Fields Editor: right click the master dataset and choose Fields Editor. Add a new persistent field to your dataset by right-clicking and choosing Add Fields. Define your new field with type DataSet Field. In the Fields Editor, define the structure of the detail table. You must also add persistent fields for any other fields used in your master dataset.

The dataset component for the detail table is a dataset descendant of a type allowed by the master table. *TTable* components only allow *TNestedDataSet* components as nested datasets. *TSQLTable* components allow other *TSQLTable* components. *TClientDataset* components allow other client datasets. Choose a dataset of the appropriate type from the Component palette and add it to your form or data module. Set this detail dataset's *DataSetField* property to the persistent DataSet field in the master dataset. Finally, place a data source component on the form or data module and set its *DataSet* property to the detail dataset. Data-aware controls can use this data source to access the data in the detail set.

Controlling Read/write access to tables

By default when a table-type dataset is opened, it requests read and write access for the underlying database table. Depending on the characteristics of the underlying database table, the requested write privilege may not be granted (for example, when you request write access to an SQL table on a remote server and the server restricts the table's access to read only).

Note This is not true for *TClientDataSet*, which determines whether users can edit data from information that the dataset provider supplies with data packets. It is also not true for *TSQLTable*, which is a unidirectional dataset, and hence always read-only.

When the table opens, you can check the *CanModify* property to ascertain whether the underlying database (or the dataset provider) allows users to edit the data in the table. If *CanModify* is *False*, the application cannot write to the database. If *CanModify* is *True*, your application can write to the database provided the table's *ReadOnly* property is *False*.

ReadOnly determines whether a user can both view and edit data. When *ReadOnly* is *False* (the default), a user can both view and edit data. To restrict a user to viewing data, set *ReadOnly* to *True* before opening the table.

Note *ReadOnly* is implemented on all table-type datasets except *TSQLTable*, which is always read-only.

Creating and deleting tables

Some table-type datasets let you create and delete the underlying tables at design time or at runtime. Typically, database tables are created and deleted by a database administrator. However, it can be handy during application development and testing to create and destroy database tables that your application can use.

Creating tables

TTable and *TIBTable* both let you create the underlying database table without using SQL. Similarly, *TClientDataSet* lets you create a dataset when you are not working with a dataset provider. Using *TTable* and *TClientDataSet*, you can create the table at design time or runtime. *TIBTable* only lets you create tables at runtime.

Before you can create the table, you must be set properties to specify the structure of the table you are creating. In particular, you must specify

- The database that will host the new table. For *TTable*, you specify the database using the *DatabaseName* property. For *TIBTable*, you must use a *TIBDataBase* component, which is assigned to the *Database* property. (Client datasets do not use a database.)
- The type of database (*TTable* only). Set the *TableType* property to the desired type of table. For Paradox, dBASE, or ASCII tables, set *TableType* to *ttParadox*, *ttDBase*, or *ttASCII*, respectively. For all other table types, set *TableType* to *ttDefault*.

- The name of the table you want to create. Both *TTable* and *TIBTable* have a *TableName* property for the name of the new table. Client datasets do not use a table name, but you should specify the *FileName* property before you save the new table. If you create a table that duplicates the name of an existing table, the existing table and all its data are overwritten by the newly created table. The old table and its data cannot be recovered. To avoid overwriting an existing table, you can check the *Exists* property at runtime. *Exists* is only available on *TTable* and *TIBTable*.
- The fields for the new table. There are two ways to do this:
  - You can add field definitions to the *FieldDefs* property. At design time, double-click the *FieldDefs* property in the Object Inspector to bring up the collection editor. Use the collection editor to add, remove, or change the properties of the field definitions. At runtime, clear any existing field definitions and then use the *AddFieldDef* method to add each new field definition. For each new field definition, set the properties of the *TFieldDef* object to specify the desired attributes of the field.
  - You can use persistent field components instead. At design time, double-click on the dataset to bring up the *Fields* editor. In the Fields editor, right-click and choose the New Field command. Describe the basic properties of your field. Once the field is created, you can alter its properties in the Object Inspector by selecting the field in the Fields editor.
- Indexes for the new table (optional). At design time, double-click the *IndexDefs* property in the Object Inspector to bring up the collection editor. Use the collection editor to add, remove, or change the properties of index definitions. At runtime, clear any existing index definitions, and then use the *AddIndexDef* method to add each new index definition. For each new index definition, set the properties of the *TIndexDef* object to specify the desired attributes of the index.

Note You can't define indexes for the new table if you are using persistent field components instead of field definition objects.

To create the table at design time, right-click the dataset and choose Create Table (*TTable*) or Create Data Set (*TClientDataSet*). This command does not appear on the context menu until you have specified all the necessary information.

To create the table at runtime, call the *CreateTable* method (*TTable* and *TIBTable*) or the *CreateDataSet* method (*TClientDataSet*).

Note You can set up the definitions at design time and then call the *CreateTable* (or *CreateDataSet*) method at runtime to create the table. However, to do so you must indicate that the definitions specified at runtime should be saved with the dataset component. (by default, field and index definitions are generated dynamically at runtime). Specify that the definitions should be saved with the dataset by setting its *StoreDefs* property to *True*.

Tip If you are using *TTable*, you can preload the field definitions and index definitions of an existing table at design time. Set the *DatabaseName* and *TableName* properties to specify the existing table. Right click the table component and choose Update Table Definition. This automatically sets the values of the *FieldDefs* and *IndexDefs* properties to describe the fields and indexes of the existing table. Next, reset the *DatabaseName* and *TableName* to specify the table you want to create, canceling any prompts to rename the existing table.

Note When creating Oracle8 tables, you can't create object fields (ADT fields, array fields, and dataset fields).

The following code creates a new table at runtime and associates it with the DBDEMOS alias. Before it creates the new table, it verifies that the table name provided does not match the name of an existing table:

```
var
  TableFound: Boolean;
begin
  with TTable.Create(nil) do // create a temporary TTable component
  begin
    try
      { set properties of the temporary TTable component }
      Active := False;
      DatabaseName := 'DBDEMOS';
      TableName := Edit1.Text;
      TableType := ttDefault;
      { define fields for the new table }
      FieldDefs.Clear;
      with FieldDefs.AddFieldDef do begin
        Name := 'First';
        DataType := ftString;
        Size := 20;
        Required := False;
      end;
      with FieldDefs.AddFieldDef do begin
        Name := 'Second';
        DataType := ftString;
        Size := 30;
        Required := False;
      end;
      { define indexes for the new table }
      IndexDefs.Clear;
      with IndexDefs.AddIndexDef do begin
        Name := '';
        Fields := 'First';
        Options := [ixPrimary];
      end;
      TableFound := Exists; // check whether the table already exists
      if TableFound then
        if MessageDlg('Overwrite existing table ' + Edit1.Text + '?',
             mtConfirmation, mbYesNoCancel, 0) = mrYes then
          TableFound := False;
      if not TableFound then
        CreateTable; // create the table
    finally
      Free; // destroy the temporary TTable when done
    end;
  end;
end;
```

Deleting tables

TTable and *TIBTable* let you delete tables from the underlying database table without using SQL. To delete a table at runtime, call the dataset's *DeleteTable* method. For example, the following statement removes the table underlying a dataset:

```
CustomersTable.DeleteTable;
```

Caution When you delete a table with *DeleteTable*, the table and all its data are gone forever.

If you are using *TTable*, you can also delete tables at design time: Right-click the table component and select Delete Table from the context menu. The Delete Table menu pick is only present if the table component represents an existing database table (the *DatabaseName* and *TableName* properties specify an existing table).

Emptying tables

Many table-type datasets supply a single method that lets you delete all rows of data in the table.

- For *TTable* and *TIBTable*, you can delete all the records by calling the *EmptyTable* method at runtime:

```
PhoneTable.EmptyTable;
```

- For *TADOTable*, you can use the *DeleteRecords* method.

```
PhoneTable.DeleteRecords;
```

- For *TSQLTable*, you can use the *DeleteRecords* method as well. Note, however, that the *TSQLTable* version of *DeleteRecords* never takes any parameters.

```
PhoneTable.DeleteRecords;
```

- For client datasets, you can use the *EmptyDataSet* method.

```
PhoneTable.EmptyDataSet;
```

Note For tables on SQL servers, these methods only succeed if you have DELETE privilege for the table.

Caution When you empty a dataset, the data you delete is gone forever.

Synchronizing tables

If you have two or more datasets that represent the same database table but do not share a data source component, then each dataset has its own view on the data and its own current record. As users access records through each datasets, the components' current records will differ.

If the datasets are all instances of *TTable*, or all instances of *TIBTable*, or all client datasets, you can force the current record for each of these datasets to be the same by calling the *GotoCurrent* method. *GotoCurrent* sets its own dataset's current record to the current record of a matching dataset. For example, the following code sets the current record of *CustomerTableOne* to be the same as the current record of *CustomerTableTwo*:

```
CustomerTableOne.GotoCurrent(CustomerTableTwo);
```

Tip If your application needs to synchronize datasets in this manner, put the datasets in a data module and add the unit for the data module to the uses clause of each unit that accesses the tables.

To synchronize datasets from separate forms, you must add one form's unit to the uses clause of the other, and you must qualify at least one of the dataset names with its form name. For example:

```
CustomerTableOne.GotoCurrent(Form2.CustomerTableTwo);
```

Using query-type datasets

To use a query-type dataset,

1. Place the appropriate dataset component in a data module or on a form, and set its *Name* property to a unique value appropriate to your application.
2. Identify the database server to query. Each query-type dataset does this differently, but typically you specify a database connection component:
   - For *TQuery*, specify a *TDatabase* component or a BDE alias using the *DatabaseName* property.
   - For *TADOQuery*, specify a *TADOConnection* component using the *Connection* property.
   - For *TSQLQuery*, specify a *TSQLConnection* component using the *SQLConnection* property.
   - For *TIBQuery*, specify a *TIBConnection* component using the *Database* property.

   For information about using database connection components, see Chapter 17, "Connecting to databases".
3. Specify an SQL statement in the *SQL* property of the dataset, and optionally specify any parameters for the statement. For more information, see "Specifying the query" on page 18-42 and "Using parameters in queries" on page 18-43.
4. If the query data is to be used with visual data controls, add a data source component to the data module, and set its *DataSet* property to the query-type dataset. The data source component forwards the results of the query (called a *result set*) to data-aware components for display. Connect data-aware components to the data source using their *DataSource* and *DataField* properties.
5. Activate the query component. For queries that return a result set, use the *Active* property or the *Open* method. To execute queries that only perform an action on a table and return no result set, use the *ExecSQL* method at runtime. If you plan to execute the query more than once, you may want to call *Prepare* to initialize the data access layer and bind parameter values into the query. For information about preparing a query, see "Preparing queries" on page 18-47.

Specifying the query

For true query-type datasets, you use the *SQL* property to specify the SQL statement for the dataset to execute. Some datasets, such as *TADODataSet*, *TSQLDataSet*, and client datasets, use a *CommandText* property to accomplish the same thing.

Most queries that return records are SELECT commands. Typically, they define the fields to include, the tables from which to select those fields, conditions that limit what records to include, and the order of the resulting dataset. For example:

```
SELECT CustNo, OrderNo, SaleDate
FROM Orders
WHERE CustNo = 1225
ORDER BY SaleDate
```

Queries that do not return records include statements that use Data Definition Language (DDL) or Data Manipulation Language (DML) statements other than SELECT statements (For example, INSERT, DELETE, UPDATE, CREATE INDEX, and ALTER TABLE commands do not return any records). The language used in commands is server-specific, but usually compliant with the SQL-92 standard for the SQL language.

The SQL command you execute must be acceptable to the server you are using. Datasets neither evaluate the SQL nor execute it. They merely pass the command to the server for execution. In most cases, the SQL command must be only one complete SQL statement, although that statement can be as complex as necessary (for example, a SELECT statement with a WHERE clause that uses several nested logical operators such as AND and OR). Some servers also support “batch” syntax that permits multiple statements; if your server supports such syntax, you can enter multiple statements when you specify the query.

The SQL statements used by queries can be verbatim, or they can contain replaceable parameters. Queries that use parameters are called *parameterized queries*. When you use parameterized queries, the actual values assigned to the parameters are inserted into the query before you execute, or run, the query. Using parameterized queries is very flexible, because you can change a user’s view of and access to data on the fly at runtime without having to alter the SQL statement. For more information about parameterized queries, see “Using parameters in queries” on page 18-43.

Specifying a query using the SQL property

When using a true query-type dataset *(TQuery*, *TADOQuery*, *TSQLQuery*, or *TIBQuery)*, assign the query to the *SQL* property. The *SQL* property is a *TStrings* object. Each separate string in this *TStrings* object is a separate line of the query. Using multiple lines does not affect the way the query executes on the server, but can make it easier to modify and debug the query if you divide the statement into logical units:

```
MyQuery.Close;
MyQuery.SQL.Clear;
MyQuery.SQL.Add('SELECT CustNo, OrderNO, SaleDate');
MyQuery.SQL.Add(' FROM Orders');
MyQuery.SQL.Add('ORDER BY SaleDate');
MyQuery.Open;
```

The code below demonstrates modifying only a single line in an existing SQL statement. In this case, the ORDER BY clause already exists on the third line of the statement. It is referenced via the *SQL* property using an index of 2.

```
MyQuery.SQL[2] := ‘ORDER BY OrderNo’;
```

Note The dataset must be closed when you specify or modify the SQL property.

At design time, use the String List editor to specify the query. Click the ellipsis button by the *SQL* property in the Object Inspector to display the String List editor.

Note With some versions of Delphi, if you are using *TQuery*, you can also use the SQL Builder to construct a query based on a visible representation of tables and fields in a database. To use the SQL Builder, select the query component, right-click it to invoke the context menu, and choose Graphical Query Editor. To learn how to use SQL Builder, open it and use its online help.

Because the *SQL* property is a *TStrings* object, you can load the text of the query from a file by calling the *TStrings.LoadFromFile* method:

```
MyQuery.SQL.LoadFromFile('custquery.sql');
```

You can also use the *Assign* method of the *SQL* property to copy the contents of a string list object into the *SQL* property. The *Assign* method automatically clears the current contents of the *SQL* property before copying the new statement:

```
MyQuery.SQL.Assign(Memo1.Lines);
```

Specifying a query using the CommandText property

When using *TADODataSet*, *TSQLDataSet*, or a client dataset, assign the text of the query statement to the *CommandText* property:

```
MyQuery.CommandText := 'SELECT CustName, Address FROM Customer';
```

At design time, you can type the query directly into the Object Inspector, or, if the dataset already has an active connection to the database, you can click the elipsis button by the *CommandText* property to display the Command Text editor. The Command Text editor lists the available tables, and the fields in those tables, to make it easier to compose your queries.

Using parameters in queries

A parameterized SQL statement contains parameters, or variables, the values of which can be varied at design time or runtime. Parameters can replace data values, such as those used in a WHERE clause for comparisons, that appear in an SQL statement. Ordinarily, parameters stand in for data values passed to the statement. For example, in the following INSERT statement, values to insert are passed as parameters:

```
INSERT INTO Country (Name, Capital, Population)
VALUES (:Name, :Capital, :Population)
```

In this SQL statement, *:Name*, *:Capital*, and *:Population* are placeholders for actual values supplied to the statement at runtime by your application. Note that the names of parameters begin with a colon. The colon is required so that the parameter names can be distinguished from literal values. You can also include unnamed parameters by adding a question mark (?) to your query. Unnamed parameters are identified by position, because they do not have unique names.

Before the dataset can execute the query, you must supply values for any parameters in the query text. *TQuery*, *TIBQuery*, *TSQLQuery*, and client datasets use the *Params* property to store these values. *TADOQuery* uses the *Parameters* property instead. *Params* (or *Parameters*) is a collection of parameter objects (*TParam* or *TParameter*), where each object represents a single parameter. When you specify the text for the query, the dataset generates this set of parameter objects, and (depending on the dataset type) initializes any of their properties that it can deduce from the query.

Note You can suppress the automatic generation of parameter objects in response to changing the query text by setting the *ParamCheck* property to *False*. This is useful for data definition language (DDL) statements that contain parameters as part of the DDL statement that are not parameters for the query itself. For example, the DDL statement to create a stored procedure may define parameters that are part of the stored procedure. By setting *ParamCheck* to *False*, you prevent these parameters from being mistaken for parameters of the query.

Parameter values must be bound into the SQL statement before it is executed for the first time. Query components do this automatically for you even if you do not explicitly call the *Prepare* method before executing a query.

Tip It is a good programming practice to provide variable names for parameters that correspond to the actual name of the column with which it is associated. For example, if a column name is “Number,” then its corresponding parameter would be “:Number”. Using matching names is especially important if the dataset uses a datasource to obtain parameter values from another dataset. This process is described in “Establishing master/detail relationships using parameters” on page 18-46.

Supplying parameters at design time

At design time, you can specify parameter values using the parameter collection editor. To display the parameter collection editor, click on the ellipsis button for the *Params* or *Parameters* property in the Object Inspector. If the SQL statement does not contain any parameters, no objects are listed in the collection editor.

Note The parameter collection editor is the same collection editor that appears for other collection properties. Because the editor is shared with other properties, its right-click context menu contains the Add and Delete commands. However, they are never enabled for query parameters. The only way to add or delete parameters is in the SQL statement itself.

For each parameter, select it in the parameter collection editor. Then use the Object Inspector to modify its properties.

When using the *Params* property (*TParam* objects), you will want to inspect or modify the following:

- The *DataType* property lists the data type for the parameter’s value. For some datasets, this value may be correctly initialized. If the dataset did not deduce the type, *DataType* is *ftUnknown*, and you must change it to indicate the type of the parameter value.

The *DataType* property lists the logical data type for the parameter. In general, these data types conform to server data types. For specific logical type-to-server data type mappings, see the documentation for the data access mechanism (BDE, dbExpress, InterBase).

- The *ParamType* property lists the type of the selected parameter. For queries, this is always *ptInput*, because queries can only contain input parameters. If the value of *ParamType* is *ptUnknown*, change it to *ptInput*.
- The *Value* property specifies a value for the selected parameter. You can leave *Value* blank if your application supplies parameter values at runtime.

When using the *Parameters* property (*TParameter* objects), you will want to inspect or modify the following:

- The *DataType* property lists the data type for the parameter's value. For some data types, you must provide additional information:
    - The *NumericScale* property indicates the number of decimal places for numeric parameters.
    - The *Precision* property indicates the total number of digits for numeric parameters.
    - The *Size* property indicates the number of characters in string parameters.
- The *Direction* property lists the type of the selected parameter. For queries, this is always *pdInput*, because queries can only contain input parameters.
- The *Attributes* property controls the type of values the parameter will accept. *Attributes* may be set to a combination of *psSigned*, *psNullable*, and *psLong*.
- The *Value* property specifies a value for the selected parameter. You can leave *Value* blank if your application supplies parameter values at runtime.

Supplying parameters at runtime

To create parameters at runtime, you can use the

- *ParamByName* method to assign values to a parameter based on its name (not available for *TADOQuery*)
- *Params* or *Parameters* property to assign values to a parameter based on the parameter's ordinal position within the SQL statement.
- *Params.ParamValues* or *Parameters.ParamValues* property to assign values to one or more parameters in a single command line, based on the name of each parameter set.

The following code uses *ParamByName* to assign the text of an edit box to the :Capital parameter:

```
SQLQuery1.ParamByName('Capital').AsString := Edit1.Text;
```

The same code can be rewritten using the *Params* property, using an index of 0 (assuming the :Capital parameter is the first parameter in the SQL statement):

```
SQLQuery1.Params[0].AsString := Edit1.Text;
```

The command line below sets three parameters at once, using the *Params.ParamValues* property:

```
Query1.Params.ParamValues['Name;Capital;Continent'] :=
  VarArrayOf([Edit1.Text, Edit2.Text, Edit3.Text]);
```

Note that *ParamValues* uses Variants, avoiding the need to cast values.

Establishing master/detail relationships using parameters

To set up a master/detail relationship where the detail set is a query-type dataset, you must specify a query that uses parameters. These parameters refer to current field values on the master dataset. Because the current field values on the master dataset change dynamically at runtime, you must rebind the detail set's parameters every time the master record changes. Although you could write code to do this using an event handler, all query-type datasets except *TIBQuery* provide an easier mechanism using the *DataSource* property.

If parameter values for a parameterized query are not bound at design time or specified at runtime, query-type datasets attempt to supply values for them based on the *DataSource* property. *DataSource* identifies a different dataset that is searched for field names that match the names of unbound parameters. This search dataset can be any type of dataset. The search dataset must be created and populated before you create the detail dataset that uses it. If matches are found in the search dataset, the detail dataset binds the parameter values to the values of the fields in the current record pointed to by the data source.

To illustrate how this works, consider two tables: a customer table and an orders table. For every customer, the orders table contains a set of orders that the customer made. The Customer table includes an ID field that specifies a unique customer ID. The orders table includes a CustID field that specifies the ID of the customer who made an order.

The first step is to set up the Customer dataset:

1 Add a table-type dataset to your application and bind it to the Customer table.

2 Add a *TDataSource* component named *CustomerSource*. Set its *DataSet* property to the dataset added in step 1. This data source now represents the Customer dataset.

3 Add a query-type dataset and set its *SQL* property to

   ```
   SELECT CustID, OrderNo, SaleDate
   FROM Orders
   WHERE CustID = :ID
   ```

   Note that the name of the parameter is the same as the name of the field in the master (Customer) table.

4 Set the detail dataset's *DataSource* property to *CustomerSource*. Setting this property makes the detail dataset a linked query.

At runtime the *:ID* parameter in the SQL statement for the detail dataset is not assigned a value, so the dataset tries to match the parameter by name against a column in the dataset identified by *CustomersSource*. *CustomersSource* gets its data from the master dataset, which, in turn, derives its data from the Customer table. Because the Customer table contains a column called “ID,” the value from the *ID* field in the current record of the master dataset is assigned to the *:ID* parameter for the detail dataset’s SQL statement. The datasets are linked in a master-detail relationship. Each time the current record changes in the Customers dataset, the detail dataset’s SELECT statement executes to retrieve all orders based on the current customer id.

Preparing queries

Preparing a query is an optional step that precedes query execution. Preparing a query submits the SQL statement and its parameters, if any, to the data access layer and the database server for parsing, resource allocation, and optimization. In some datasets, the dataset may perform additional setup operations when preparing the query. These operations improve query performance, making your application faster, especially when working with updatable queries.

An application can prepare a query by setting the *Prepared* property to *True*. If you do not prepare a query before executing it, the dataset automatically prepares it for you each time you call *Open* or *ExecSQL*. Even though the dataset prepares queries for you, you can improve performance by explicitly preparing the dataset before you open it the first time.

```
CustQuery.Prepared := True;
```

When you explicitly prepare the dataset, the resources allocated for executing the statement are not freed until you set *Prepared* to *False*.

Set the *Prepared* property to *False* if you want to ensure that the dataset is re-prepared before it executes (for example, if you add a parameter).

Note When you change the text of the *SQL* property for a query, the dataset automatically closes and unprepares the query.

Executing queries that don’t return a result set

When a query returns a set of records (such as a SELECT query), you execute the query the same way you populate any dataset with records: by setting *Active* to *True* or calling the *Open* method.

However, often SQL commands do not return any records. Such commands include statements that use Data Definition Language (DDL) or Data Manipulation Language (DML) statements other than SELECT statements (For example, INSERT, DELETE, UPDATE, CREATE INDEX, and ALTER TABLE commands do not return any records).

For all query-type datasets, you can execute a query that does not return a result set by calling *ExecSQL*:

```
CustomerQuery.ExecSQL;  { query does not return a result set }
```

Tip If you are executing the query multiple times, it is a good idea to set the *Prepared* property to *True*.

Although the query does not return any records, you may want to know the number of records it affected (for example, the number of records deleted by a DELETE query). The *RowsAffected* property gives the number of affected records after a call to *ExecSQL*.

Tip When you do not know at design time whether the query returns a result set (for example, if the user supplies the query dynamically at runtime), you can code both types of query execution statements in a **try...except** block. Put a call to the *Open* method in the **try** clause. An action query is executed when the query is activated with the *Open* method, but an exception occurs in addition to that. Check the exception, and suppress it if it merely indicates the lack of a result set. (For example, *TQuery* indicates this by an *ENoResultSet* exception.)

Using unidirectional result sets

When a query-type dataset returns a result set, it also receives a cursor, or pointer to the first record in that result set. The record pointed to by the cursor is the currently active record. The current record is the one whose field values are displayed in data-aware components associated with the result set's data source. Unless you are using dbExpress, this cursor is bi-directional by default. A bi-directional cursor can navigate both forward and backward through its records. Bi-directional cursor support requires some additional processing overhead, and can slow some queries.

If you do not need to be able to navigate backward through a result set, *TQuery* and *TIBQuery* let you improve query performance by requesting a unidirectional cursor instead. To request a unidirectional cursor, set the *UniDirectional* property to *True*.

Set *UniDirectional* before preparing and executing a query. The following code illustrates setting *UniDirectional* prior to preparing and executing a query:

```
if not (CustomerQuery.Prepared) then
begin
  CustomerQuery.UniDirectional := True;
  CustomerQuery.Prepared := True;
end;
CustomerQuery.Open;  { returns a result set with a one-way cursor }
```

Note Do not confuse the *UniDirectional* property with a unidirectional dataset. Unidirectional datasets (*TSQLDataSet*, *TSQLTable*, *TSQLQuery*, and *TSQLStoredProc*) use dbExpress, which only returns unidirectional cursors. In addition to restricting the ability to navigate backwards, unidirectional datasets do not buffer records, and so have additional limitations (such as the inability to use filters).

Using stored procedure-type datasets

How your application uses a stored procedure depends on how the stored procedure was coded, whether and how it returns data, the specific database server used, or a combination of these factors.

In general terms, to access a stored procedure on a server, an application must:

1. Place the appropriate dataset component in a data module or on a form, and set its *Name* property to a unique value appropriate to your application.
2. Identify the database server that defines the stored procedure. Each stored procedure-type dataset does this differently, but typically you specify a database connection component:
   - For *TStoredProc*, specify a *TDatabase* component or a BDE alias using the *DatabaseName* property.
   - For *TADOStoredProc*, specify a *TADOConnection* component using the *Connection* property.
   - For *TSQLStoredProc*, specify a *TSQLConnection* component using the *SQLConnection* property.
   - For *TIBStoredProc*, specify a *TIBConnection* component using the *Database* property.

   For information about using database connection components, see Chapter 17, "Connecting to databases".
3. Specify the stored procedure to execute. For most stored procedure-type datasets, you do this by setting the *StoredProcName* property. The one exception is *TADOStoredProc*, which has a *ProcedureName* property instead.
4. If the stored procedure returns a cursor to be used with visual data controls, add a data source component to the data module, and set its *DataSet* property to the stored procedure-type dataset. Connect data-aware components to the data source using their *DataSource* and *DataField* properties.
5. Provide input parameter values for the stored procedure, if necessary. If the server does not provide information about all stored procedure parameters, you may need to provide additional input parameter information, such as parameter names and data types. For information about working with stored procedure parameters, see "Working with stored procedure parameters" on page 18-50.
6. Execute the stored procedure. For stored procedures that return a cursor, use the *Active* property or the *Open* method. To execute stored procedures that do not return any results or that only return output parameters, use the *ExecProc* method at runtime. If you plan to execute the stored procedure more than once, you may want to call *Prepare* to initialize the data access layer and bind parameter values into the stored procedure. For information about preparing a query, see "Executing stored procedures that don't return a result set" on page 18-53.
7. Process any results. These results can be returned as result and output parameters, or they can be returned as a result set that populates the stored procedure-type dataset. Some stored procedures return multiple cursors. For details on how to access the additional cursors, see "Fetching multiple result sets" on page 18-53.

Working with stored procedure parameters

There are four types of parameters that can be associated with stored procedures:

- *Input parameters*, used to pass values to a stored procedure for processing.
- *Output parameters*, used by a stored procedure to pass return values to an application.
- *Input/output parameters*, used to pass values to a stored procedure for processing, and used by the stored procedure to pass return values to the application.
- A *result parameter*, used by some stored procedures to return an error or status value to an application. A stored procedure can only return one result parameter.

Whether a stored procedure uses a particular type of parameter depends both on the general language implementation of stored procedures on your database server and on a specific instance of a stored procedure. For any server, individual stored procedures may or may not use input parameters. On the other hand, some uses of parameters are server-specific. For example, on MS-SQL Server and Sybase stored procedures always return a result parameter, but the InterBase implementation of a stored procedure never returns a result parameter.

Access to stored procedure parameters is provided by the *Params* property (in *TStoredProc*, *TSQLStoredProc*, *TIBStoredProc*) or the *Parameters* property (in *TADOStoredProc*). When you assign a value to the *StoredProcName* (or *ProcedureName*) property, the dataset automatically generates objects for each parameter of the stored procedure. For some datasets, if the stored procedure name is not specified until runtime, objects for each parameter must be programmatically created at that time. Not specifying the stored procedure and manually creating the *TParam* or *TParameter* objects allows a single dataset to be used with any number of available stored procedures.

Note Some stored procedures return a dataset in addition to output and result parameters. Applications can display dataset records in data-aware controls, but must separately process output and result parameters.

Setting up parameters at design time

You can specify stored procedure parameter values at design time using the parameter collection editor. To display the parameter collection editor, click on the ellipsis button for the *Params* or *Parameters* property in the Object Inspector.

Important You can assign values to input parameters by selecting them in the parameter collection editor and using the Object Inspector to set the *Value* property. However, do not change the names or data types for input parameters reported by the server. Otherwise, when you execute the stored procedure an exception is raised.

Some servers do not report parameter names or data types. In these cases, you must set up the parameters manually using the parameter collection editor. Right click and choose Add to add parameters. For each parameter you add, you must fully describe the parameter. Even if you do not need to add any parameters, you should check the properties of individual parameter objects to ensure that they are correct.

If the dataset has a *Params* property (*TParam* objects), the following properties must be correctly specified:

- The *Name* property indicates the name of the parameter as it is defined by the stored procedure.
- The *DataType* property gives the data type for the parameter's value. When using *TSQLStoredProc*, some data types require additional information:
  - The *NumericScale* property indicates the number of decimal places for numeric parameters.
  - The *Precision* property indicates the total number of digits for numeric parameters.
  - The *Size* property indicates the number of characters in string parameters.
- The *ParamType* property indicates the type of the selected parameter. This can be *ptInput* (for input parameters), *ptOutput* (for output parameters), *ptInputOutput* (for input/output parameters) or *ptResult* (for result parameters).
- The *Value* property specifies a value for the selected parameter. You can never set values for output and result parameters. These types of parameters have values set by the execution of the stored procedure. For input and input/output parameters, you can leave *Value* blank if your application supplies parameter values at runtime.

If the dataset uses a *Parameters* property (*TParameter* objects), the following properties must be correctly specified:

- The *Name* property indicates the name of the parameter as it is defined by the stored procedure.
- The *DataType* property gives the data type for the parameter's value. For some data types, you must provide additional information:
  - The *NumericScale* property indicates the number of decimal places for numeric parameters.
  - The *Precision* property indicates the total number of digits for numeric parameters.
  - The *Size* property indicates the number of characters in string parameters.
- The *Direction* property gives the type of the selected parameter. This can be *pdInput* (for input parameters), *pdOutput* (for output parameters), *pdInputOutput* (for input/output parameters) or *pdReturnValue* (for result parameters).
- The *Attributes* property controls the type of values the parameter will accept. *Attributes* may be set to a combination of *psSigned*, *psNullable*, and *psLong*.
- The *Value* property specifies a value for the selected parameter. Do not set values for output and result parameters. For input and input/output parameters, you can leave *Value* blank if your application supplies parameter values at runtime.

Using parameters at runtime

With some datasets, if the name of the stored procedure is not specified until runtime, no *TParam* objects are automatically created for parameters and they must be created programmatically. This can be done using the *TParam.Create* method or the *TParams.AddParam* method:

```
var
  P1, P2: TParam;
begin
  ...
  with StoredProc1 do begin
    StoredProcName := 'GET_EMP_PROJ';
    Params.Clear;
    P1 := TParam.Create(Params, ptInput);
    P2 := TParam.Create(Params, ptOutput);
    try
      Params[0].Name := ‘EMP_NO’;
      Params[1].Name := ‘PROJ_ID’;
      ParamByname(‘EMP_NO’).AsSmallInt := 52;
      ExecProc;
      Edit1.Text := ParamByname(‘PROJ_ID’).AsString;
    finally
      P1.Free;
      P2.Free;
    end;
  end;
  ...
end;
```

Even if you do not need to add the individual parameter objects at runtime, you may want to access individual parameter objects to assign values to input parameters and to retrieve values from output parameters. You can use the dataset’s *ParamByName* method to access individual parameters based on their names. For example, the following code sets the value of an input/output parameter, executes the stored procedure, and retrieves the returned value:

```
with SQLStoredProc1 do
begin
  ParamByName('IN_OUTVAR').AsInteger := 103;
  ExecProc;
  IntegerVar := ParamByName('IN_OUTVAR').AsInteger;
end;
```

Preparing stored procedures

As with query-type datasets, stored procedure-type datasets must be prepared before they execute the stored procedure. Preparing a stored procedure tells the data access layer and the database server to allocate resources for the stored procedure and to bind parameters. These operations can improve performance.

If you attempt to execute a stored procedure before preparing it, the dataset automatically prepares it for you, and then unprepares it after it executes. If you plan to execute a stored procedure a number of times, it is more efficient to explicitly prepare it by setting the Prepared property to *True*.

```
MyProc.Prepared := True;
```

When you explicitly prepare the dataset, the resources allocated for executing the stored procedure are not freed until you set *Prepared* to *False*.

Set the *Prepared* property to *False* if you want to ensure that the dataset is re-prepared before it executes (for example, if you change the parameters when using Oracle overloaded procedures).

Executing stored procedures that don't return a result set

When a stored procedure returns a cursor, you execute it the same way you populate any dataset with records: by setting *Active* to *True* or calling the *Open* method.

However, often stored procedures do not return any data, or only return results in output parameters. You can execute a stored procedure that does not return a result set by calling *ExecProc*. After executing the stored procedure, you can use the *ParamByName* method to read the value of the result parameter or of any output parameters:

```
MyStoredProcedure.ExecProc;  { does not return a result set }
Edit1.Text := MyStoredProcedure.ParamByName('OUTVAR').AsString;
```

Note *TADOStoredProc* does not have a *ParamByName* method. To obtain output parameter values when using ADO, access parameter objects using the *Parameters* property.

Tip If you are executing the procedure multiple times, it is a good idea to set the *Prepared* property to *True*.

Fetching multiple result sets

Some stored procedures return multiple sets of records. The dataset only fetches the first set when you open it. If you are using *TSQLStoredProc* or *TADOStoredProc*, you can access the other sets of records by calling the *NextRecordSet* method:

```
var
  DataSet2: TCustomSQLDataSet;
begin
  DataSet2 := SQLStoredProc1.NextRecordSet;
  ...
```

In *TSQLStoredProc, NextRecordSet* returns a newly created *TCustomSQLDataSet* component that provides access to the next set of records. In *TADOStoredProc*, *NextRecordset* returns an interface that can be assigned to the *RecordSet* property of an existing ADO dataset. For either class, the method returns the number of records in the returned dataset as an output parameter.

The first time you call *NextRecordSet*, it returns the second set of records. Calling *NextRecordSet* again returns a third dataset, and so on, until there are no more sets of records. When there are no additional cursors, *NextRecordSet* returns **nil**.

Chapter

19

Working with field components

This chapter describes the properties, events, and methods common to the *TField* object and its descendants. Field components represent individual fields (columns) in datasets. This chapter also describes how to use field components to control the display and editing of data in your applications.

Field components are always associated with a dataset. You never use a *TField* object directly in your applications. Instead, each field component in your application is a *TField* descendant specific to the datatype of a column in a dataset. Field components provide data-aware controls such as *TDBEdit* and *TDBGrid* access to the data in a particular column of the associated dataset.

Generally speaking, a single field component represents the characteristics of a single column, or field, in a dataset, such as its data type and size. It also represents the field's display characteristics, such as alignment, display format, and edit format. For example, a *TFloatField* component has four properties that directly affect the appearance of its data:

Table 19.1 TFloatField properties that affect data display

Property	Purpose
Alignment	Specifies whether data is displayed left-aligned, centered, or right-aligned.
DisplayWidth	Specifies the number of digits to display in a control at one time.
DisplayFormat	Specifies data formatting for display (such as how many decimal places to show).
EditFormat	Specifies how to display a value during editing.

As you scroll from record to record in a dataset, a field component lets you view and change the value for that field in the current record.

Field components have many properties in common with one another (such as *DisplayWidth* and *Alignment*), and they have properties specific to their data types (such as *Precision* for *TFloatField*). Each of these properties affect how data appears to an application's users on a form. Some properties, such as *Precision*, can also affect what data values the user can enter in a control when modifying or entering data.

All field components for a dataset are either *dynamic* (automatically generated for you based on the underlying structure of database tables), or *persistent* (generated based on specific field names and properties you set in the Fields editor). Dynamic and persistent fields have different strengths and are appropriate for different types of applications. The following sections describe dynamic and persistent fields in more detail and offer advice on choosing between them.

Dynamic field components

Dynamically generated field components are the default. In fact, all field components for any dataset start out as dynamic fields the first time you place a dataset on a data module, specify how that dataset fetches its data, and open it. A field component is *dynamic* if it is created automatically based on the underlying physical characteristics of the data represented by a dataset. Datasets generate one field component for each column in the underlying data. The exact *TField* descendant created for each column is determined by field type information received from the database or (for *TClientDataSet*) from a provider component.

Dynamic fields are temporary. They exist only as long as a dataset is open. Each time you reopen a dataset that uses dynamic fields, it rebuilds a completely new set of dynamic field components based on the current structure of the data underlying the dataset. If the columns in the underlying data change, then the next time you open a dataset that uses dynamic field components, the automatically generated field components are also changed to match.

Use dynamic fields in applications that must be flexible about data display and editing. For example, to create a database browsing tool such as SQL explorer, you must use dynamic fields because every database table has different numbers and types of columns. You might also want to use dynamic fields in applications where user interaction with data mostly takes place inside grid components and you know that the datasets used by the application change frequently.

To use dynamic fields in an application:

1. Place datasets and data sources in a data module.
2. Associate the datasets with data. This involves using a connection component or provider to connect to the source of the data and setting any properties that specify what data the dataset represents.
3. Associate the data sources with the datasets.
4. Place data-aware controls in the application's forms, add the data module to each uses clause for each form's unit, and associate each data-aware control with a data source in the module. In addition, associate a field with each data-aware control that requires one. Note that because you are using dynamic field components, there is no guarantee that any field name you specify will exist when the dataset is opened.
5. Open the datasets.

Aside from ease of use, dynamic fields can be limiting. Without writing code, you cannot change the display and editing defaults for dynamic fields, you cannot safely change the order in which dynamic fields are displayed, and you cannot prevent access to any fields in the dataset. You cannot create additional fields for the dataset, such as calculated fields or lookup fields, and you cannot override a dynamic field's default data type. To gain control and flexibility over fields in your database applications, you need to invoke the Fields editor to create persistent field components for your datasets.

Persistent field components

By default, dataset fields are dynamic. Their properties and availability are automatically set and cannot be changed in any way. To gain control over a field's properties and events you must create persistent fields for the dataset. Persistent fields let you

- Set or change the field's display or edit characteristics at design time or runtime.
- Create new fields, such as lookup fields, calculated fields, and aggregated fields, that base their values on existing fields in a dataset.
- Validate data entry.
- Remove field components from the list of persistent components to prevent your application from accessing particular columns in an underlying database.
- Define new fields to replace existing fields, based on columns in the table or query underlying a dataset.

At design time, you can—and should—use the Fields editor to create persistent lists of the field components used by the datasets in your application. Persistent field component lists are stored in your application, and do not change even if the structure of a database underlying a dataset is changed. Once you create persistent fields with the Fields editor, you can also create event handlers for them that respond to changes in data values and that validate data entries.

Note When you create persistent fields for a dataset, only those fields you select are available to your application at design time and runtime. At design time, you can always use the Fields editor to add or remove persistent fields for a dataset.

All fields used by a single dataset are either persistent or dynamic. You cannot mix field types in a single dataset. If you create persistent fields for a dataset, and then want to revert to dynamic fields, you must remove all persistent fields from the dataset. For more information about dynamic fields, see “Dynamic field components” on page 19-2.

Note One of the primary uses of persistent fields is to gain control over the appearance and display of data. You can also control the appearance of columns in data-aware grids. To learn about controlling column appearance in grids, see “Creating a customized grid” on page 15-16.

Creating persistent fields

Persistent field components created with the Fields editor provide efficient, readable, and type-safe programmatic access to underlying data. Using persistent field components guarantees that each time your application runs, it always uses and displays the same columns, in the same order even if the physical structure of the underlying database has changed. Data-aware components and program code that rely on specific fields always work as expected. If a column on which a persistent field component is based is deleted or changed, Delphi generates an exception rather than running the application against a nonexistent column or mismatched data.

To create persistent fields for a dataset:

1. Place a dataset in a data module.
2. Bind the dataset to its underlying data. This typically involves associating the dataset with a connection component or provider and specifying any properties to describe the data. For example, If you are using *TADODataSet*, you can set the *Connection* property to a properly configured *TADOConnection* component and set the *CommandText* property to a valid query.
3. Double-click the dataset component in the data module to invoke the Fields editor. The Fields editor contains a title bar, navigator buttons, and a list box.

   The title bar of the Fields editor displays both the name of the data module or form containing the dataset, and the name of the dataset itself. For example, if you open the *Customers* dataset in the *CustomerData* data module, the title bar displays 'CustomerData.Customers,' or as much of the name as fits.

   Below the title bar is a set of navigation buttons that let you scroll one-by-one through the records in an active dataset at design time, and to jump to the first or last record. The navigation buttons are dimmed if the dataset is not active or if the dataset is empty. If the dataset is unidirectional, the buttons for moving to the last record and the previous record are always dimmed.

   The list box displays the names of persistent field components for the dataset. The first time you invoke the Fields editor for a new dataset, the list is empty because the field components for the dataset are dynamic, not persistent. If you invoke the Fields editor for a dataset that already has persistent field components, you see the field component names in the list box.
4. Choose Add Fields from the Fields editor context menu.
5. Select the fields to make persistent in the Add Fields dialog box. By default, all fields are selected when the dialog box opens. Any fields you select become persistent fields.

The Add Fields dialog box closes, and the fields you selected appear in the Fields editor list box. Fields in the Fields editor list box are persistent. If the dataset is active, note, too, that the Next and (if the dataset is not unidirectional) Last navigation buttons above the list box are enabled.

From now on, each time you open the dataset, it no longer creates dynamic field components for every column in the underlying database. Instead it only creates persistent components for the fields you specified.

Each time you open the dataset, it verifies that each non-calculated persistent field exists or can be created from data in the database. If it cannot, the dataset raises an exception warning you that the field is not valid, and does not open the dataset.

Arranging persistent fields

The order in which persistent field components are listed in the Fields editor list box is the default order in which the fields appear in a data-aware grid component. You can change field order by dragging and dropping fields in the list box.

To change the order of fields:

1. Select the fields. You can select and order one or more fields at a time.
2. Drag the fields to a new location.

If you select a noncontiguous set of fields and drag them to a new location, they are inserted as a contiguous block. Within the block, the order of fields does not change.

Alternatively, you can select the field, and use *Ctrl+Up* and *Ctrl+Dn* to change an individual field's order in the list.

Defining new persistent fields

Besides making existing dataset fields into persistent fields, you can also create special persistent fields as additions to or replacements of the other persistent fields in a dataset.

New persistent fields that you create are only for display purposes. The data they contain at runtime are not retained either because they already exist elsewhere in the database, or because they are temporary. The physical structure of the data underlying the dataset is not changed in any way.

To create a new persistent field component, invoke the context menu for the Fields editor and choose New field. The New Field dialog box appears.

The New Field dialog box contains three group boxes: Field properties, Field type, and Lookup definition.

- The Field properties group box lets you enter general field component information. Enter the field name in the Name edit box. The name you enter here corresponds to the field component's *FieldName* property. The New Field dialog uses this name to build a component name in the Component edit box. The name that appears in the Component edit box corresponds to the field component's *Name* property and is only provided for informational purposes (*Name* is the identifier by which you refer to the field component in your source code). The dialog discards anything you enter directly in the Component edit box.

- The Type combo box in the Field properties group lets you specify the field component's data type. You must supply a data type for any new field component you create. For example, to display floating-point currency values in a field, select *Currency* from the drop-down list. Use the Size edit box to specify the maximum number of characters that can be displayed or entered in a string-based field, or the size of *Bytes* and *VarBytes* fields. For all other data types, Size is meaningless.
- The Field type radio group lets you specify the type of new field component to create. The default type is Data. If you choose Lookup, the Dataset and Source Fields edit boxes in the Lookup definition group box are enabled. You can also create Calculated fields, and if you are working with a client dataset, you can create InternalCalc fields or Aggregate fields. The following table describes these types of fields you can create:

Table 19.2 Special persistent field kinds

Field kind	Purpose
Data	Replaces an existing field (for example to change its data type)
Calculated	Displays values calculated at runtime by a dataset's *OnCalcFields* event handler.
Lookup	Retrieve values from a specified dataset at runtime based on search criteria you specify. (not supported by unidirectional datasets)
InternalCalc	Displays values calculated at runtime by a client dataset and stored with its data.
Aggregate	Displays a value summarizing the data in a set of records from a client dataset.

The Lookup definition group box is only used to create lookup fields. This is described more fully in "Defining a lookup field" on page 19-8.

Defining a data field

A data field replaces an existing field in a dataset. For example, for programmatic reasons you might want to replace a *TSmallIntField* with a *TIntegerField*. Because you cannot change a field's data type directly, you must define a new field to replace it.

Important Even though you define a new field to replace an existing field, the field you define must derive its data values from an existing column in a table underlying a dataset.

To create a replacement data field for a field in a table underlying a dataset, follow these steps:

1. Remove the field from the list of persistent fields assigned for the dataset, and then choose New Field from the context menu.
2. In the New Field dialog box, enter the name of an existing field in the database table in the Name edit box. Do not enter a new field name. You are actually specifying the name of the field from which your new field will derive its data.
3. Choose a new data type for the field from the Type combo box. The data type you choose should be different from the data type of the field you are replacing. You cannot replace a string field of one size with a string field of another size. Note that while the data type should be different, it must be compatible with the actual data type of the field in the underlying table.

4 Enter the size of the field in the Size edit box, if appropriate. Size is only relevant for fields of type *TStringField*, *TBytesField*, and *TVarBytesField*.

5 Select Data in the Field type radio group if it is not already selected.

6 Choose OK. The New Field dialog box closes, the newly defined data field replaces the existing field you specified in Step 1, and the component declaration in the data module or form's **type** declaration is updated.

To edit the properties or events associated with the field component, select the component name in the Field editor list box, then edit its properties or events with the Object Inspector. For more information about editing field component properties and events, see "Setting persistent field properties and events" on page 19-10.

Defining a calculated field

A calculated field displays values calculated at runtime by a dataset's *OnCalcFields* event handler. For example, you might create a string field that displays concatenated values from other fields.

To create a calculated field in the New Field dialog box:

1 Enter a name for the calculated field in the Name edit box. Do not enter the name of an existing field.

2 Choose a data type for the field from the Type combo box.

3 Enter the size of the field in the Size edit box, if appropriate. Size is only relevant for fields of type *TStringField*, *TBytesField*, and *TVarBytesField*.

4 Select Calculated or InternalCalc in the Field type radio group. InternalCalc is only available if you are working with a client dataset. The significant difference between these types of calculated fields is that the values calculated for an InternalCalc field are stored and retrieved as part of the client dataset's data.

5 Choose OK. The newly defined calculated field is automatically added to the end of the list of persistent fields in the Field editor list box, and the component declaration is automatically added to the form's or data module's **type** declaration.

6 Place code that calculates values for the field in the *OnCalcFields* event handler for the dataset. For more information about writing code to calculate field values, see "Programming a calculated field" on page 19-7.

Note To edit the properties or events associated with the field component, select the component name in the Field editor list box, then edit its properties or events with the Object Inspector. For more information about editing field component properties and events, see "Setting persistent field properties and events" on page 19-10.

Programming a calculated field

After you define a calculated field, you must write code to calculate its value. Otherwise, it always has a null value. Code for a calculated field is placed in the *OnCalcFields* event for its dataset.

To program a value for a calculated field:

1 Select the dataset component from the Object Inspector drop-down list.

2 Choose the Object Inspector Events page.

3 Double-click the *OnCalcFields* property to bring up or create a *CalcFields* procedure for the dataset component.

4 Write the code that sets the values and other properties of the calculated field as desired.

For example, suppose you have created a *CityStateZip* calculated field for the *Customers* table on the *CustomerData* data module. *CityStateZip* should display a company's city, state, and zip code on a single line in a data-aware control.

To add code to the *CalcFields* procedure for the *Customers* table, select the *Customers* table from the Object Inspector drop-down list, switch to the Events page, and double-click the *OnCalcFields* property.

The *TCustomerData.CustomersCalcFields* procedure appears in the unit's source code window. Add the following code to the procedure to calculate the field:

```
CustomersCityStateZip.Value := CustomersCity.Value + ', ' + CustomersState.Value
  + ' ' + CustomersZip.Value;
```

Note When writing the *OnCalcFields* event handler for an internally calculated field, you can improve performance by checking the client dataset's *State* property and only recomputing the value when *State* is *dsInternalCalc*. See "Using internally calculated fields in client datasets" on page 23-10 for details.

Defining a lookup field

A lookup field is a read-only field that displays values at runtime based on search criteria you specify. In its simplest form, a lookup field is passed the name of an existing field to search on, a field value to search for, and a different field in a lookup dataset whose value it should display.

For example, consider a mail-order application that enables an operator to use a lookup field to determine automatically the city and state that correspond to the zip code a customer provides. The column to search on might be called *ZipTable.Zip*, the value to search for is the customer's zip code as entered in *Order.CustZip*, and the values to return would be those for the *ZipTable.City* and *ZipTable.State* columns of the record where the value of *ZipTable.Zip* matches the current value in the *Order.CustZip* field.

Note Unidirectional datasets do not support lookup fields.

To create a lookup field in the New Field dialog box:

1 Enter a name for the lookup field in the Name edit box. Do not enter the name of an existing field.

2 Choose a data type for the field from the Type combo box.

3 Enter the size of the field in the Size edit box, if appropriate. Size is only relevant for fields of type *TStringField*, *TBytesField*, and *TVarBytesField*.

4 Select Lookup in the Field type radio group. Selecting Lookup enables the Dataset and Key Fields combo boxes.

5 Choose from the Dataset combo box drop-down list the dataset in which to look up field values. The lookup dataset must be different from the dataset for the field component itself, or a circular reference exception is raised at runtime. Specifying a lookup dataset enables the Lookup Keys and Result Field combo boxes.

6 Choose from the Key Fields drop-down list a field in the current dataset for which to match values. To match more than one field, enter field names directly instead of choosing from the drop-down list. Separate multiple field names with semicolons. If you are using more than one field, you must use persistent field components.

7 Choose from the Lookup Keys drop-down list a field in the lookup dataset to match against the Source Fields field you specified in step 6. If you specified more than one key field, you must specify the same number of lookup keys. To specify more than one field, enter field names directly, separating multiple field names with semicolons.

8 Choose from the Result Field drop-down list a field in the lookup dataset to return as the value of the lookup field you are creating.

When you design and run your application, lookup field values are determined before calculated field values are calculated. You can base calculated fields on lookup fields, but you cannot base lookup fields on calculated fields.

You can use the *LookupCache* property to hone the way lookup fields are determined. *LookupCache* determines whether the values of a lookup field are cached in memory when a dataset is first opened, or looked up dynamically every time the current record in the dataset changes. Set *LookupCache* to *True* to cache the values of a lookup field when the *LookupDataSet* is unlikely to change and the number of distinct lookup values is small. Caching lookup values can speed performance, because the lookup values for every set of *LookupKeyFields* values are preloaded when the *DataSet* is opened. When the current record in the *DataSet* changes, the field object can locate its *Value* in the cache, rather than accessing the *LookupDataSet*. This performance improvement is especially dramatic if the *LookupDataSet* is on a network where access is slow.

Tip You can use a lookup cache to provide lookup values programmatically rather than from a secondary dataset. Be sure that the *LookupDataSet* property is nil. Then, use the *LookupList* property's *Add* method to fill it with lookup values. Set the *LookupCache* property to *True*. The field will use the supplied lookup list without overwriting it with values from a lookup dataset.

If every record of *DataSet* has different values for *KeyFields*, the overhead of locating values in the cache can be greater than any performance benefit provided by the cache. The overhead of locating values in the cache increases with the number of distinct values that can be taken by *KeyFields*.

If *LookupDataSet* is volatile, caching lookup values can lead to inaccurate results. Call *RefreshLookupList* to update the values in the lookup cache. *RefreshLookupList* regenerates the *LookupList* property, which contains the value of the *LookupResultField* for every set of *LookupKeyFields* values.

When setting *LookupCache* at runtime, call *RefreshLookupList* to initialize the cache.

Defining an aggregate field

An aggregate field displays values from a maintained aggregate in a client dataset. An aggregate is a calculation that summarizes the data in a set of records. See "Using maintained aggregates" on page 23-11 for details about maintained aggregates.

To create an aggregate field in the New Field dialog box:

1. Enter a name for the aggregate field in the Name edit box. Do not enter the name of an existing field.
2. Choose aggregate data type for the field from the Type combo box.
3. Select Aggregate in the Field type radio group.
4. Choose OK. The newly defined aggregate field is automatically added to the client dataset and its *Aggregates* property is automatically updated to include the appropriate aggregate specification.
5. Place the calculation for the aggregate in the *ExprText* property of the newly created aggregate field. For more information about defining an aggregate, see "Specifying aggregates" on page 23-11.

Once a persistent *TAggregateField* is created, a *TDBText* control can be bound to the aggregate field. The *TDBText* control will then display the value of the aggregate field that is relevant to the current record of the underlying client data set.

Deleting persistent field components

Deleting a persistent field component is useful for accessing a subset of available columns in a table, and for defining your own persistent fields to replace a column in a table. To remove one or more persistent field components for a dataset:

1. Select the field(s) to remove in the Fields editor list box.
2. Press *Del*.

Note You can also delete selected fields by invoking the context menu and choosing Delete.

Fields you remove are no longer available to the dataset and cannot be displayed by data-aware controls. You can always recreate a persistent field component that you delete by accident, but any changes previously made to its properties or events is lost. For more information, see "Creating persistent fields" on page 19-4.

Note If you remove all persistent field components for a dataset, the dataset reverts to using dynamic field components for every column in the underlying database table.

Setting persistent field properties and events

You can set properties and customize events for persistent field components at design time. Properties control the way a field is displayed by a data-aware component, for example, whether it can appear in a *TDBGrid*, or whether its value can be modified. Events control what happens when data in a field is fetched, changed, set, or validated.

To set the properties of a field component or write customized event handlers for it, select the component in the Fields editor, or select it from the component list in the Object Inspector.

Setting display and edit properties at design time

To edit the display properties of a selected field component, switch to the Properties page on the Object Inspector window. The following table summarizes display properties that can be edited.

Table 19.3 Field component properties

Property	Purpose
Alignment	Left justifies, right justifies, or centers a field contents within a data-aware component.
ConstraintErrorMessage	Specifies the text to display when edits clash with a constraint condition.
CustomConstraint	Specifies a local constraint to apply to data during editing.
Currency	Numeric fields only. *True*: displays monetary values. *False* (default): does not display monetary values.
DisplayFormat	Specifies the format of data displayed in a data-aware component.
DisplayLabel	Specifies the column name for a field in a data-aware grid component.
DisplayWidth	Specifies the width, in characters, of a grid column that display this field.
EditFormat	Specifies the edit format of data in a data-aware component.
EditMask	Limits data-entry in an editable field to specified types and ranges of characters, and specifies any special, non-editable characters that appear within the field (hyphens, parentheses, and so on).
FieldKind	Specifies the type of field to create.
FieldName	Specifies the actual name of a column in the table from which the field derives its value and data type.
HasConstraints	Indicates whether there are constraint conditions imposed on a field.
ImportedConstraint	Specifies an SQL constraint imported from the Data Dictionary or an SQL server.
Index	Specifies the order of the field in a dataset.
LookupDataSet	Specifies the table used to look up field values when *Lookup* is *True*.
LookupKeyFields	Specifies the field(s) in the lookup dataset to match when doing a lookup.
LookupResultField	Specifies the field in the lookup dataset from which to copy values into this field.
MaxValue	Numeric fields only. Specifies the maximum value a user can enter for the field.
MinValue	Numeric fields only. Specifies the minimum value a user can enter for the field.
Name	Specifies the component name of the field component within Delphi.
Origin	Specifies the name of the field as it appears in the underlying database.
Precision	Numeric fields only. Specifies the number of significant digits.

Table 19.3 Field component properties (continued)

Property	Purpose
ReadOnly	*True*: Displays field values in data-aware controls, but prevents editing. *False* (the default): Permits display and editing of field values.
Size	Specifies the maximum number of characters that can be displayed or entered in a string-based field, or the size, in bytes, of *TBytesField* and *TVarBytesField* fields.
Tag	Long integer bucket available for programmer use in every component as needed.
Transliterate	*True* (default): specifies that translation to and from the respective locales will occur as data is transferred between a dataset and a database. *False*: Locale translation does not occur.
Visible	*True* (the default): Permits display of field in a data-aware grid. *False*: Prevents display of field in a data-aware grid component. User-defined components can make display decisions based on this property.

Not all properties are available for all field components. For example, a field component of type *TStringField* does not have *Currency*, *MaxValue*, or *DisplayFormat* properties, and a component of type *TFloatField* does not have a *Size* property.

While the purpose of most properties is straightforward, some properties, such as *Calculated*, require additional programming steps to be useful. Others, such as *DisplayFormat*, *EditFormat*, and *EditMask*, are interrelated; their settings must be coordinated. For more information about using *DisplayFormat*, *EditFormat*, and *EditMask*, see "Controlling and masking user input" on page 19-14.

Setting field component properties at runtime

You can use and manipulate the properties of field component at runtime. Access persistent field components by name, where the name can be obtained by concatenating the field name to the dataset name.

For example, the following code sets the *ReadOnly* property for the *CityStateZip* field in the *Customers* table to *True*:

```
CustomersCityStateZip.ReadOnly := True;
```

And this statement changes field ordering by setting the *Index* property of the *CityStateZip* field in the *Customers* table to 3:

```
CustomersCityStateZip.Index := 3;
```

Creating attribute sets for field components

When several fields in the datasets used by your application share common formatting properties (such as *Alignment*, *DisplayWidth*, *DisplayFormat*, *EditFormat*, *MaxValue*, *MinValue*, and so on), it is more convenient to set the properties for a single field, then store those properties as an attribute set in the Data Dictionary. Attribute sets stored in the data dictionary can be easily applied to other fields.

Note Attribute sets and the Data Dictionary are only available for BDE-enabled datasets.

To create an attribute set based on a field component in a dataset:

1 Double-click the dataset to invoke the Fields editor.

2 Select the field for which to set properties.

3 Set the desired properties for the field in the Object Inspector.

4 Right-click the Fields editor list box to invoke the context menu.

5 Choose Save Attributes to save the current field's property settings as an attribute set in the Data Dictionary.

The name for the attribute set defaults to the name of the current field. You can specify a different name for the attribute set by choosing Save Attributes As instead of Save Attributes from the context menu.

Once you have created a new attribute set and added it to the Data Dictionary, you can then associate it with other persistent field components. Even if you later remove the association, the attribute set remains defined in the Data Dictionary.

Note You can also create attribute sets directly from the SQL Explorer. When you create an attribute set using SQL Explorer, it is added to the Data Dictionary, but not applied to any fields. SQL Explorer lets you specify two additional attributes: a field type (such as *TFloatField*, *TStringField*, and so on) and a data-aware control (such as *TDBEdit*, *TDBCheckBox*, and so on) that is automatically placed on a form when a field based on the attribute set is dragged to the form. For more information, see the online help for the SQL Explorer.

Associating attribute sets with field components

When several fields in the datasets used by your application share common formatting properties (such as *Alignment*, *DisplayWidth*, *DisplayFormat*, *EditFormat*, *MaxValue*, *MinValue*, and so on), and you have saved those property settings as attribute sets in the Data Dictionary, you can easily apply the attribute sets to fields without having to recreate the settings manually for each field. In addition, if you later change the attribute settings in the Data Dictionary, those changes are automatically applied to every field associated with the set the next time field components are added to the dataset.

To apply an attribute set to a field component:

1 Double-click the dataset to invoke the Fields editor.

2 Select the field for which to apply an attribute set.

3 Invoke the context menu and choose Associate Attributes.

4 Select or enter the attribute set to apply from the Associate Attributes dialog box. If there is an attribute set in the Data Dictionary that has the same name as the current field, that set name appears in the edit box.

Important If the attribute set in the Data Dictionary is changed at a later date, you must reapply the attribute set to each field component that uses it. You can invoke the Fields editor and multi-select field components within a dataset when reapplying attributes.

Removing attribute associations

If you change your mind about associating an attribute set with a field, you can remove the association by following these steps:

1 Invoke the Fields editor for the dataset containing the field.

2 Select the field or fields from which to remove the attribute association.

3 Invoke the context menu for the Fields editor and choose Unassociate Attributes.

Important Unassociating an attribute set does not change any field properties. A field retains the settings it had when the attribute set was applied to it. To change these properties, select the field in the Fields editor and set its properties in the Object Inspector.

Controlling and masking user input

The *EditMask* property provides a way to control the type and range of values a user can enter into a data-aware component associated with *TStringField*, *TDateField*, *TTimeField*, and *TDateTimeField*, and *TSQLTimeStampField* components. You can use existing masks or create your own. The easiest way to use and create edit masks is with the Input Mask editor. You can, however, enter masks directly into the *EditMask* field in the Object Inspector.

Note For *TStringField* components, the *EditMask* property is also its display format.

To invoke the Input Mask editor for a field component:

1 Select the component in the Fields editor or Object Inspector.

2 Click the Properties page in the Object Inspector.

3 Double-click the values column for the EditMask field in the Object Inspector, or click the ellipsis button. The Input Mask editor opens.

The Input Mask edit box lets you create and edit a mask format. The Sample Masks grid lets you select from predefined masks. If you select a sample mask, the mask format appears in the Input Mask edit box where you can modify it or use it as is. You can test the allowable user input for a mask in the Test Input edit box.

The Masks button enables you to load a custom set of masks—if you have created one—into the Sample Masks grid for easy selection.

Using default formatting for numeric, date, and time fields

Delphi provides built-in display and edit format routines and intelligent default formatting for *TFloatField*, *TCurrencyField*, *TBCDField*, *TFMTBCDField*, *TIntegerField*, *TSmallIntField*, *TWordField*, *TDateField*, *TDateTimeField*, and *TTimeField*, and *TSQLTimeStampField* components. To use these routines, you need do nothing.

Default formatting is performed by the following routines:

Table 19.4 Field component formatting routines

Routine	Used by . . .
FormatFloat	*TFloatField*, *TCurrencyField*
FormatDateTime	*TDateField*, *TTimeField*, *TDateTimeField*,
SQLTimeStampToString	*TSQLTimeStampField*
FormatCurr	*TCurrencyField*, *TBCDField*
BcdToStrF	*TFMTBcdField*

Only format properties appropriate to the data type of a field component are available for a given component.

Default formatting conventions for date, time, currency, and numeric values are based on the Regional Settings properties in the Control Panel. For example, using the default settings for the United States, a *TFloatField* column with the *Currency* property set to *True* sets the *DisplayFormat* property for the value 1234.56 to $1234.56, while the *EditFormat* is 1234.56.

At design time or runtime, you can edit the *DisplayFormat* and *EditFormat* properties of a field component to override the default display settings for that field. You can also write *OnGetText* and *OnSetText* event handlers to do custom formatting for field components at runtime.

Handling events

Like most components, field components have events associated with them. Methods can be assigned as handlers for these events. By writing these handlers you can react to the occurrence of events that affect data entered in fields through data-aware controls and perform actions of your own design. The following table lists the events associated with field components:

Table 19.5 Field component events

Event	Purpose
OnChange	Called when the value for a field changes.
OnGetText	Called when the value for a field component is retrieved for display or editing.
OnSetText	Called when the value for a field component is set.
OnValidate	Called to validate the value for a field component whenever the value is changed because of an edit or insert operation.

OnGetText and *OnSetText* events are primarily useful to programmers who want to do custom formatting that goes beyond the built-in formatting functions. *OnChange* is useful for performing application-specific tasks associated with data change, such as enabling or disabling menus or visual controls. *OnValidate* is useful when you want to control data-entry validation in your application before returning values to a database server.

To write an event handler for a field component:

1. Select the component.
2. Select the Events page in the Object Inspector.
3. Double-click the Value field for the event handler to display its source code window.
4. Create or edit the handler code.

Working with field component methods at runtime

Field components methods available at runtime enable you to convert field values from one data type to another, and enable you to set focus to the first data-aware control in a form that is associated with a field component.

Controlling the focus of data-aware components associated with a field is important when your application performs record-oriented data validation in a dataset event handler (such as *BeforePost*). Validation may be performed on the fields in a record whether or not its associated data-aware control has focus. Should validation fail for a particular field in the record, you want the data-aware control containing the faulty data to have focus so that the user can enter corrections.

You control focus for a field's data-aware components with a field's *FocusControl* method. *FocusControl* sets focus to the first data-aware control in a form that is associated with a field. An event handler should call a field's *FocusControl* method before validating the field. The following code illustrates how to call the *FocusControl* method for the *Company* field in the *Customers* table:

```
CustomersCompany.FocusControl;
```

The following table lists some other field component methods and their uses. For a complete list and detailed information about using each method, see the entries for *TField* and its descendants in the online *VCL Reference*.

Table 19.6 Selected field component methods

Method	Purpose
AssignValue	Sets a field value to a specified value using an automatic conversion function based on the field's type.
Clear	Clears the field and sets its value to NULL.
GetData	Retrieves unformatted data from the field.
IsValidChar	Determines if a character entered by a user in a data-aware control to set a value is allowed for this field.
SetData	Assigns unformatted data to this field.

Displaying, converting, and accessing field values

Data-aware controls such as *TDBEdit* and *TDBGrid* automatically display the values associated with field components. If editing is enabled for the dataset and the controls, data-aware controls can also send new and changed values to the database. In general, the built-in properties and methods of data-aware controls enable them to connect to datasets, display values, and make updates without requiring extra programming on your part. Use them whenever possible in your database applications. For more information about data-aware control, see Chapter 15, "Using data controls."

Standard controls can also display and edit database values associated with field components. Using standard controls, however, may require additional programming on your part. For example, when using standard controls, your application is responsible for tracking when to update controls because field values change. If the dataset has a datasource component, you can use its events to help you do this. In particular, the *OnDataChange* event lets you know when you may need to update a control's value and the *OnStateChange* event can help you determine when to enable or disable controls. For more information on these events, see "Responding to changes mediated by the data source" on page 15-4.

The following topics discuss how to work with field values so that you can display them in standard controls.

Displaying field component values in standard controls

An application can access the value of a dataset column through the *Value* property of a field component. For example, the following *OnDataChange* event handler updates the text in a *TEdit* control because the value of the *CustomersCompany* field may have changed:

```
procedure TForm1.CustomersDataChange(Sender: TObject, Field: TField);
begin
  Edit3.Text := CustomersCompany.Value;
end;
```

This method works well for string values, but may require additional programming to handle conversions for other data types. Fortunately, field components have built-in properties for handling conversions.

Note You can also use Variants to access and set field values. For more information about using variants to access and set field values, see "Accessing field values with the default dataset property" on page 19-19.

Converting field values

Conversion properties attempt to convert one data type to another. For example, the *AsString* property converts numeric and Boolean values to string representations.

The following table lists field component conversion properties, and which properties are recommended for field components by field-component class:

	AsVariant	AsString	AsInteger	AsFloat AsCurrency AsBCD	AsDateTime AsSQLTimeStamp	AsBoolean
TStringField	yes	NA	yes	yes	yes	yes
TWideStringField	yes	yes	yes	yes	yes	yes
TIntegerField	yes	yes	NA	yes		
TSmallIntField	yes	yes	yes	yes		
TWordField	yes	yes	yes	yes		
TLargeintField	yes	yes	yes	yes		
TFloatField	yes	yes	yes	yes		
TCurrencyField	yes	yes	yes	yes		
TBCDField	yes	yes	yes	yes		
TFMTBCDField	yes	yes	yes	yes		
TDateTimeField	yes	yes		yes	yes	
TDateField	yes	yes		yes	yes	
TTimeField	yes	yes		yes	yes	
TSQLTimeStampField	yes	yes		yes	yes	
TBooleanField	yes	yes				
TBytesField	yes	yes				
TVarBytesField	yes	yes				
TBlobField	yes	yes				
TMemoField	yes	yes				
TGraphicField	yes	yes				
TVariantField	NA	yes	yes	yes	yes	yes
TAggregateField	yes	yes				

Note that some columns in the table refer to more than one conversion property (such as *AsFloat*, *AsCurrency*, and *AsBCD*). This is because all field data types that support one of those properties always support the others as well.

Note also that the *AsVariant* property can translate among all data types. For any data types not listed above, *AsVariant* is also available (and is, in fact, the only option). When in doubt, use *AsVariant*.

In some cases, conversions are not always possible. For example, *AsDateTime* can be used to convert a string to a date, time, or datetime format only if the string value is in a recognizable datetime format. A failed conversion attempt raises an exception.

In some other cases, conversion is possible, but the results of the conversion are not always intuitive. For example, what does it mean to convert a *TDateTimeField* value into a float format? *AsFloat* converts the date portion of the field to the number of days since 12/31/1899, and it converts the time portion of the field to a fraction of 24 hours. Table 19.7 lists permissible conversions that produce special results:

Table 19.7 Special conversion results

Conversion	Result
String to Boolean	Converts “True,” “False,” “Yes,” and “No” to Boolean. Other values raise exceptions.
Float to Integer	Rounds float value to nearest integer value.
DateTime or SQLTimeStamp to Float	Converts date to number of days since 12/31/1899, time to a fraction of 24 hours.
Boolean to String	Converts any Boolean value to “True” or “False.”

In other cases, conversions are not possible at all. In these cases, attempting a conversion also raises an exception.

Conversion always occurs before an assignment is made. For example, the following statement converts the value of *CustomersCustNo* to a string and assigns the string to the text of an edit control:

```
Edit1.Text := CustomersCustNo.AsString;
```

Conversely, the next statement assigns the text of an edit control to the *CustomersCustNo* field as an integer:

```
MyTableMyField.AsInteger := StrToInt(Edit1.Text);
```

Accessing field values with the default dataset property

The most general method for accessing a field’s value is to use Variants with the *FieldValues* property. For example, the following statement puts the value of an edit box into the *CustNo* field in the *Customers* table:

```
Customers.FieldValues['CustNo'] := Edit2.Text;
```

Because the *FieldValues* property is of type Variant, it automatically converts other datatypes into a Variant value.

For more information about Variants, see the online help.

Accessing field values with a dataset’s Fields property

You can access the value of a field with the *Fields* property of the dataset component to which the field belongs. *Fields* maintains an indexed list of all the fields in the dataset. Accessing field values with the *Fields* property is useful when you need to iterate over a number of columns, or if your application works with tables that are not available to you at design time.

To use the *Fields* property you must know the order of and data types of fields in the dataset. You use an ordinal number to specify the field to access. The first field in a dataset is numbered 0. Field values must be converted as appropriate using each field component's conversion properties. For more information about field component conversion properties, see "Converting field values" on page 19-17.

For example, the following statement assigns the current value of the seventh column (Country) in the *Customers* table to an edit control:

```
Edit1.Text := CustTable.Fields[6].AsString;
```

Conversely, you can assign a value to a field by setting the *Fields* property of the dataset to the desired field. For example:

```
begin
  Customers.Edit;
  Customers.Fields[6].AsString := Edit1.Text;
  Customers.Post;
end;
```

Accessing field values with a dataset's FieldByName method

You can also access the value of a field with a dataset's *FieldByName* method. This method is useful when you know the name of the field you want to access, but do not have access to the underlying table at design time.

To use *FieldByName*, you must know the dataset and name of the field you want to access. You pass the field's name as an argument to the method. To access or change the field's value, convert the result with the appropriate field component conversion property, such as *AsString* or *AsInteger*. For example, the following statement assigns the value of the *CustNo* field in the *Customers* dataset to an edit control:

```
Edit2.Text := Customers.FieldByName('CustNo').AsString;
```

Conversely, you can assign a value to a field:

```
begin
  Customers.Edit;
  Customers.FieldByName('CustNo').AsString := Edit2.Text;
  Customers.Post;
end;
```

Setting a default value for a field

You can specify how a default value for a field in a client dataset or a BDE-enabled dataset should be calculated at runtime using the *DefaultExpression* property. *DefaultExpression* can be any valid SQL value expression that does not refer to field values. If the expression contains literals other than numeric values, they must appear in quotes. For example, a default value of noon for a time field would be

```
'12:00:00'
```

including the quotes around the literal value.

Note If the underlying database table defines a default value for the field, the default you specify in *DefaultExpression* takes precedence. That is because *DefaultExpression* is applied when the dataset posts the record containing the field, before the edited record is applied to the database server.

Working with constraints

Field components in client datasets or BDE-enabled datasets can use SQL server constraints. In addition, your applications can create and use custom constraints for these datasets that are local to your application. All constraints are rules or conditions that impose a limit on the scope or range of values that a field can store.

Creating a custom constraint

A custom constraint is not imported from the server like other constraints. It is a constraint that you declare, implement, and enforce in your local application. As such, custom constraints can be useful for offering a prevalidation enforcement of data entry, but a custom constraint cannot be applied against data received from or sent to a server application.

To create a custom constraint, set the *CustomConstraint* property to specify a constraint condition, and set *ConstraintErrorMessage* to the message to display when a user violates the constraint at runtime.

CustomConstraint is an SQL string that specifies any application-specific constraints imposed on the field's value. Set *CustomConstraint* to limit the values that the user can enter into a field. *CustomConstraint* can be any valid SQL search expression such as

```
x > 0 and x < 100
```

The name used to refer to the value of the field can be any string that is not a reserved SQL keyword, as long as it is used consistently throughout the constraint expression.

Note Custom constraints are only available in BDE-enabled and client datasets.

Custom constraints are imposed in addition to any constraints to the field's value that come from the server. To see the constraints imposed by the server, read the *ImportedConstraint* property.

Using server constraints

Most production SQL databases use constraints to impose conditions on the possible values for a field. For example, a field may not permit NULL values, may require that its value be unique for that column, or that its values be greater than *0* and less than *150*. While you could replicate such conditions in your client applications, client datasets and BDE-enabled datasets offer the *ImportedConstraint* property to propagate a server's constraints locally.

ImportedConstraint is a read-only property that specifies an SQL clause that limits field values in some manner. For example:

```
Value > 0 and Value < 100
```

Do not change the value of *ImportedConstraint*, except to edit nonstandard or server-specific SQL that has been imported as a comment because it cannot be interpreted by the database engine.

To add additional constraints on the field value, use the *CustomConstraint* property. Custom constraints are imposed in addition to the imported constraints. If the server constraints change, the value of *ImportedConstraint* also changed but constraints introduced in the *CustomConstraint* property persist.

Removing constraints from the *ImportedConstraint* property will not change the validity of field values that violate those constraints. Removing constraints results in the constraints being checked by the server instead of locally. When constraints are checked locally, the error message supplied as the *ConstraintErrorMessage* property is displayed when violations are found, instead of displaying an error message from the server.

Using object fields

Object fields are fields that represent a composite of other, simpler data types. These include ADT (Abstract Data Type) fields, Array fields, DataSet fields, and Reference fields. All of these field types either contain or reference child fields or other data sets.

ADT fields and array fields are fields that contain child fields. The child fields of an ADT field can be any scalar or object type (that is, any other field type). These child fields may differ in type from each other. An array field contains an array of child fields, all of the same type.

Dataset and reference fields are fields that access other data sets. A dataset field provides access to a nested (detail) dataset and a reference field stores a pointer (reference) to another persistent object (ADT).

Table 19.8 Types of object field components

Component name	Purpose
TADTField	Represents an ADT (Abstract Data Type) field.
TArrayField	Represents an array field.
TDataSetField	Represents a field that contains a nested data set reference.
TReferenceField	Represents a REF field, a pointer to an ADT.

When you add fields with the Fields editor to a dataset that contains object fields, persistent object fields of the correct type are automatically created for you. Adding persistent object fields to a dataset automatically sets the dataset's *ObjectView* property to *True*, which instructs the dataset to store these fields hierarchically, rather than flattening them out as if the constituent child fields were separate, independent fields.

The following properties are common to all object fields and provide the functionality to handle child fields and datasets.

Table 19.9 Common object field descendant properties

Property	Purpose
Fields	Contains the child fields belonging to the object field.
ObjectType	Classifies the object field.
FieldCount	Number of child fields belonging to the object field.
FieldValues	Provides access to the values of the child fields.

Displaying ADT and array fields

Both ADT and array fields contain child fields that can be displayed through data-aware controls.

Data-aware controls such as *TDBEdit* that represent a single field value display child field values in an uneditable comma delimited string. In addition, if you set the control's *DataField* property to the child field instead of the object field itself, the child field can be viewed an edited just like any other normal data field.

A *TDBGrid* control displays ADT and array field data differently, depending on the value of the dataset's *ObjectView* property. When *ObjectView* is *False*, each child field appears in a single column. When *ObjectView* is *True*, an ADT or array field can be expanded and collapsed by clicking on the arrow in the title bar of the column. When the field is expanded, each child field appears in its own column and title bar, all below the title bar of the ADT or array itself. When the ADT or array is collapsed, only one column appears with an uneditable comma-delimited string containing the child fields.

Working with ADT fields

ADTs are user-defined types created on the server, and are similar to the record type. An ADT can contain most scalar field types, array fields, reference fields, and nested ADTs.

There are a variety of ways to access the data in ADT field types. These are illustrated in the following examples, which assign a child field value to an edit box called *CityEdit*, and use the following ADT structure,

```
Address
  Street
  City
  State
  Zip
```

Using persistent field components

The easiest way to access ADT field values is to use persistent field components. For the ADT structure above, the following persistent fields can be added to the *Customer* table using the Fields editor:

```
CustomerAddress: TADTField;
CustomerAddrStreet: TStringField;
CustomerAddrCity: TStringField;
CustomerAddrState: TStringField;
CustomerAddrZip: TStringField;
```

Given these persistent fields, you can simply access the child fields of an ADT field by name:

```
CityEdit.Text := CustomerAddrCity.AsString;
```

Although persistent fields are the easiest way to access ADT child fields, it is not possible to use them if the structure of the dataset is not known at design time. When accessing ADT child fields without using persistent fields, you must set the dataset's *ObjectView* property to *True*.

Using the dataset's FieldByName method

You can access the children of an ADT field using the dataset's *FieldByName* method by qualifying the name of the child field with the ADT field's name:

```
CityEdit.Text := Customer.FieldByName('Address.City').AsString;
```

Using the deteset's FieldValues property

You can also use qualified field names with a dataset's *FieldValues* property:

```
CityEdit.Text := Customer['Address.City'];
```

Note that you can omit the property name (*FieldValues*) because *FieldValues* is the dataset's default property.

Note Unlike other runtime methods for accessing ADT child field values, the *FieldValues* property works even if the dataset's *ObjectView* property is *False*.

Using the ADT field's FieldValues property

You can access the value of a child field with the *TADTField*'s *FieldValues* property. *FieldValues* accepts and returns a *Variant*, so it can handle and convert fields of any type. The index parameter is an integer value that specifies the offset of the field.

```
CityEdit.Text := TADTField(Customer.FieldByName('Address')).FieldValues[1];
```

Because *FieldValues* is the default property of *TADTField*, the property name (*FieldValues*) can be omitted. Thus, the following statement is equivalent to the one above:

```
CityEdit.Text := TADTField(Customer.FieldByName('Address'))[1];
```

Using the ADT field's Fields property

Each ADT field has a *Fields* property that is analogous to the *Fields* property of a dataset. Like the *Fields* property of a dataset, you can use it to access child fields by position:

```
CityEdit.Text := TADTField(Customer.FieldByName('Address')).Fields[1].AsString;
```

or by name:

```
CityEdit.Text :=
TADTField(Customer.FieldByName('Address')).Fields.FieldByName('City').AsString;
```

Working with array fields

Array fields consist of a set of fields of the same type. The field types can be scalar (for example, float, string), or non-scalar (an ADT), but an array field of arrays is not permitted. The SparseArrays property of *TDataSet* determines whether a unique *TField* object is created for each element of the array field.

There are a variety of ways to access the data in array field types. If you are not using persistent fields, the dataset's *ObjectView* property must be set to *True* before you can access the elements of an array field.

Using persistent fields

You can map persistent fields to the individual array elements in an array field. For example, consider an array field *TelNos_Array*, which is a six element array of strings. The following persistent fields created for the *Customer* table component represent the *TelNos_Array* field and its six elements:

```
CustomerTelNos_Array: TArrayField;
CustomerTelNos_Array0: TStringField;
CustomerTelNos_Array1: TStringField;
CustomerTelNos_Array2: TStringField;
CustomerTelNos_Array3: TStringField;
CustomerTelNos_Array4: TStringField;
CustomerTelNos_Array5: TStringField;
```

Given these persistent fields, the following code uses a persistent field to assign an array element value to an edit box named *TelEdit*.

```
TelEdit.Text := CustomerTelNos_Array0.AsString;
```

Using the array field's FieldValues property

You can access the value of a child field with the array field's *FieldValues* property. *FieldValues* accepts and returns a *Variant*, so it can handle and convert child fields of any type. For example,

```
TelEdit.Text := TArrayField(Customer.FieldByName('TelNos_Array')).FieldValues[1];
```

Because *FieldValues* is the default property of *TArrayField*, this can also be written

```
TelEdit.Text := TArrayField(Customer.FieldByName('TelNos_Array'))[1];
```

Using the array field's Fields property

TArrayField has a *Fields* property that you can use to access individual sub-fields. This is illustrated below, where an array field (*OrderDates*) is used to populate a list box with all non-null array elements:

```
for I := 0 to OrderDates.Size - 1 do
begin
  if not OrderDates.Fields[I].IsNull then
    OrderDateListBox.Items.Add(OrderDates[I]);
end;
```

Working with dataset fields

Dataset fields provide access to data stored in a nested dataset. The NestedDataSet property references the nested dataset. The data in the nested dataset is then accessed through the field objects of the nested dataset.

Displaying dataset fields

TDBGrid controls enable the display of data stored in data set fields. In a *TDBGrid* control, a dataset field is indicated in each cell of a dataset column with the string "(DataSet)", and at runtime an ellipsis button also exists to the right. Clicking on the ellipsis brings up a new form with a grid displaying the dataset associated with the current record's dataset field. This form can also be brought up programmatically with the DB grid's *ShowPopupEditor* method. For example, if the seventh column in the grid represents a dataset field, the following code will display the dataset associated with that field for the current record.

```
DBGrid1.ShowPopupEditor(DBGrid1.Columns[7]);
```

Accessing data in a nested dataset

A dataset field is not normally bound directly to a data aware control. Rather, since a nested data set is just that, a data set, the means to get at its data is via a *TDataSet* descendant. The type of dataset you use is determined by the parent dataset (the one with the dataset field.) For example, a BDE-enabled dataset uses *TNestedTable* to represent the data in its dataset fields, while client datasets use other client datasets.

To access the data in a dataset field,

1 Create a persistent *TDataSetField* object by invoking the Fields editor for the parent dataset.

2 Create a dataset to represent the values in that dataset field. It must be of a type compatible with the parent dataset.

3 Set that *DataSetField* property of the dataset created in step 2 to the persistent dataset field you created in step 1.

If the nested dataset field for the current record has a value, the detail dataset component will contain records with the nested data; otherwise, the detail dataset will be empty.

Before inserting records into a nested dataset, you should be sure to post the corresponding record in the master table, if it has just been inserted. If the inserted record is not posted, it will be automatically posted before the nested dataset posts.

Working with reference fields

Reference fields store a pointer or reference to another ADT object. This ADT object is a single record of another object table. Reference fields always refer to a single record in a dataset (object table). The data in the referenced object is actually returned in a nested dataset, but can also be accessed via the *Fields* property on the *TReferenceField*.

Displaying reference fields

In a *TDBGrid* control a reference field is designated in each cell of the dataset column, with (Reference) and, at runtime, an ellipsis button to the right. At runtime, clicking on the ellipsis brings up a new form with a grid displaying the object associated with the current record's reference field.

This form can also be brought up programmatically with the DB grid's *ShowPopupEditor* method. For example, if the seventh column in the grid represents a reference field, the following code will display the object associated with that field for the current record.

```
DBGrid1.ShowPopupEditor(DBGrid1.Columns[7]);
```

Accessing data in a reference field

You can access the data in a reference field in the same way you access a nested dataset:

1. Create a persistent *TDataSetField* object by invoking the Fields editor for the parent dataset.
2. Create a dataset to represent the value of that dataset field.
3. Set that *DataSetField* property of the dataset created in step 2 to the persistent dataset field you created in step 1.

If the reference is assigned, the reference dataset will contain a single record with the referenced data. If the reference is null, the reference dataset will be empty.

You can also use the reference field's Fields property to access the data in a reference field. For example, the following lines are equivalent and assign data from the reference field *CustomerRefCity* to an edit box called *CityEdit*:

```
CityEdit.Text := CustomerRefCity.Fields[1].AsString;
CityEdit.Text := CustomerRefCity.NestedDataSet.Fields[1].AsString;
```

When data in a reference field is edited, it is actually the referenced data that is modified.

To assign a reference field, you need to first use a SELECT statement to select the reference from the table, and then assign. For example:

```
var
  AddressQuery: TQuery;
  CustomerAddressRef: TReferenceField;
begin
  AddressQuery.SQL.Text := ‘SELECT REF(A) FROM AddressTable A WHERE A.City = ‘’San
  Francisco’’’;
  AddressQuery.Open;
  CustomerAddressRef.Assign(AddressQuery.Fields[0]);
end;
```

Chapter

20

Using the Borland Database Engine

The Borland Database Engine (BDE) is a data-access mechanism that can be shared by several applications. The BDE defines a powerful library of API calls that can create, restructure, fetch data from, update, and otherwise manipulate local and remote database servers. The BDE provides a uniform interface to access a wide variety of database servers, using drivers to connect to different databases. Depending on your version of Delphi, you can use the drivers for local databases (Paradox, dBASE, FoxPro, and Access), SQL Links drivers for remote database servers such as InterBase, Oracle, Sybase, Informix, Microsoft SQL server, and DB2, and an ODBC adapter that lets you supply your own ODBC drivers.

When deploying BDE-based applications, you must include the BDE with your application. While this increases the size of the application and the complexity of deployment, the BDE can be shared with other BDE-based applications and provides a broad range of support for database manipulation. Although you can use the BDE's API directly in your application, the components on the BDE page of the Component palette wrap most of this functionality for you.

Note For information on the BDE API, see its online help file, BDE32.hlp, which is installed in the directory where you install the Borland Database Engine.

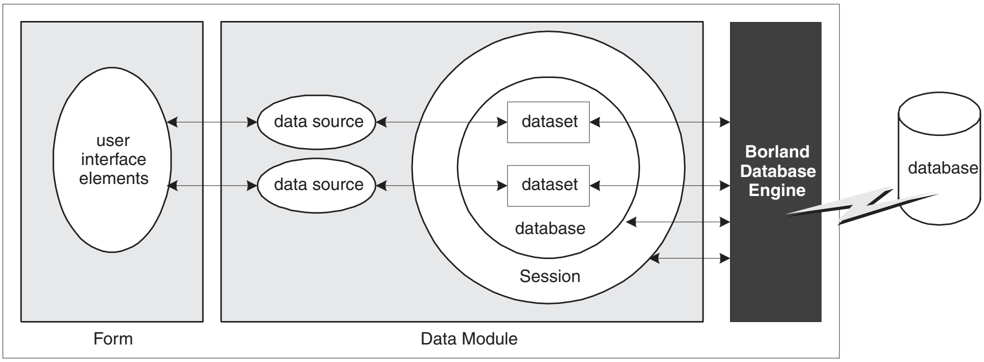
BDE-based architecture

When using the BDE, your application uses a variation of the general database architecture described in "Database architecture" on page 14-5. In addition to the user interface elements, datasource, and datasets common to all Delphi database applications, A BDE-based application can include

- One or more database components to control transactions and to manage database connections.
- One or more session components to isolate data access operations such as database connections, and to manage groups of databases.

The relationships between the components in a BDE-based application are illustrated in Figure 20.1:

Figure 20.1 Components in a BDE-based application



Using BDE-enabled datasets

BDE-enabled datasets use the Borland Database Engine (BDE) to access data. They inherit the common dataset capabilities described in Chapter 18, "Understanding datasets," using the BDE to provide the implementation. In addition, all BDE datasets add properties, events, and methods for

- Associating a dataset with database and session connections.
- Caching BLOBs.
- Obtaining a BDE handle.

There are three BDE-enabled datasets:

- *TTable*, a table-type dataset that represents all of the rows and columns of a single database table. See "Using table-type datasets" on page 18-24 for a description of features common to table-type datasets. See "Using TTable" on page 20-4 for a description of features unique to *TTable*.
- *TQuery*, a query-type dataset that encapsulates an SQL statement and enables applications to access the resulting records, if any. See "Using query-type datasets" on page 18-41 for a description of features common to query-type datasets. See "Using TQuery" on page 20-8 for a description of features unique to *TQuery*.
- *TStoredProc*, a stored procedure-type dataset that executes a stored procedure that is defined on a database server. See "Using stored procedure-type datasets" on page 18-48 for a description of features common to stored procedure-type datasets. See "Using TStoredProc" on page 20-11 for a description of features unique to *TStoredProc*.

Note In addition to the three types of BDE-enabled datasets, there is a BDE-based client dataset (*TBDEClientDataSet*) that can be used for caching updates. For information on caching updates, see "Using a client dataset to cache updates" on page 23-15.

Associating a dataset with database and session connections

In order for a BDE-enabled dataset to fetch data from a database server it needs to use both a database and a session.

- Databases represent connections to specific database servers. The database identifies a BDE driver, a particular database server that uses that driver, and a set of connection parameters for connecting to that database server. Each database is represented by a *TDatabase* component. You can either associate your datasets with a *TDatabase* component you add to a form or data module, or you can simply identify the database server by name and let Delphi generate an implicit database component for you. Using an explicitly-created *TDatabase* component is recommended for most applications, because the database component gives you greater control over how the connection is established, including the login process, and lets you create and use transactions.

  To associate a BDE-enabled dataset with a database, use the *DatabaseName* property. DatabaseName is a string that contains different information, depending on whether you are using an explicit database component and, if not, the type of database you are using:

  - If you are using an explicit *TDatabase* component, *DatabaseName* is the value of the *DatabaseName* property of the database component.
  - If you are want to use an implicit database component and the database has a BDE alias, you can specify a BDE alias as the value of *DatabaseName*. A BDE alias represents a database plus configuration information for that database. The configuration information associated with an alias differs by database type (Oracle, Sybase, InterBase, Paradox, dBASE, and so on). Use the BDE Administration tool or the SQL explorer to create and manage BDE aliases.
  - If you want to use an implicit database component for a Paradox or dBASE database, you can also use *DatabaseName* to simply specify the directory where the database tables are located.

- A session provides global management for a group of database connections in an application. When you add BDE-enabled datasets to your application, your application automatically contains a session component, named *Session*. As you add database and dataset components to the application, they are automatically associated with this default session. It also controls access to password protected Paradox files, and it specifies directory locations for sharing Paradox files over a network. You can control database connections and access to Paradox files using the properties, events, and methods of the session.

  You can use the default session to control all database connections in your application. Alternatively, you can add additional session components at design time or create them dynamically at runtime to control a subset of database connections in an application. To associate your dataset with an explicitly created session component, use the *SessionName* property. If you do not use explicit session components in your application, you do not have to provide a value for this property. Whether you use the default session or explicitly specify a session using the *SessionName* property, you can access the session associated with a dataset by reading the *DBSession* property.

Note If you use a session component, the *SessionName* property of a dataset must match the *SessionName* property for the database component with which the dataset is associated.

For more information about *TDatabase* and *TSession*, see “Connecting to databases with TDatabase” on page 20-12 and “Managing database sessions” on page 20-16.

Caching BLOBs

BDE-enabled datasets all have a *CacheBlobs* property that controls whether BLOB fields are cached locally by the BDE when an application reads BLOB records. By default, *CacheBlobs* is *True*, meaning that the BDE caches a local copy of BLOB fields. Caching BLOBs improves application performance by enabling the BDE to store local copies of BLOBs instead of fetching them repeatedly from the database server as a user scrolls through records.

In applications and environments where BLOBs are frequently updated or replaced, and a fresh view of BLOB data is more important than application performance, you can set *CacheBlobs* to *False* to ensure that your application always sees the latest version of a BLOB field.

Obtaining a BDE handle

You can use BDE-enabled datasets without ever needing to make direct API calls to the Borland Database Engine. The BDE-enabled datasets, in combination with database and session components, encapsulate much of the BDE functionality. However, if you need to make direct API calls to the BDE, you may need BDE handles for resources managed by the BDE. Many BDE APIs require these handles as parameters.

All BDE-enabled datasets include three read-only properties for accessing BDE handles at runtime:

- *Handle* is a handle to the BDE cursor that accesses the records in the dataset.
- *DBHandle* is a handle to the database that contains the underlying tables or stored procedure.
- *DBLocale* is a handle to the BDE language driver for the dataset. The locale controls the sort order and character set used for string data.

These properties are automatically assigned to a dataset when it is connected to a database server through the BDE. For more information about the BDE API, see the online help file, BDE32.HLP.

Using TTable

TTable encapsulates the full structure of and data in an underlying database table. It implements all of the basic functionality introduced by *TDataSet*, as well as all of the special features typical of table-type datasets. Before looking at the unique features introduced by *TTable*, you should familiarize yourself with the common database features described in “Understanding datasets,” including the section on table-type datasets that starts on page 18-24.

Because *TTable* is a BDE-enabled dataset, it must be associated with a database and a session. "Associating a dataset with database and session connections" on page 20-3 describes how you form these associations. Once the dataset is associated with a database and session, you can bind it to a particular database table by setting the *TableName* property and, if you are using a Paradox, dBASE, FoxPro, or comma-delimited ASCII text table, the *TableType* property.

Note The table must be closed when you change its association to a database, session, or database table, or when you set the *TableType* property. However, before you close the table to change these properties, first post or discard any pending changes. If cached updates are enabled, call the *ApplyUpdates* method to write the posted changes to the database.

TTable components are unique in the support they offer for local database tables (Paradox, dBASE, FoxPro, and comma-delimited ASCII text tables). The following topics describe the special properties and methods that implement this support.

In addition, *TTable* components can take advantage of the BDE's support for batch operations (table level operations to append, update, delete, or copy entire groups of records). This support is described in "Importing data from another table" on page 20-8.

Specifying the table type for local tables

If an application accesses Paradox, dBASE, FoxPro, or comma-delimited ASCII text tables, then the BDE uses the *TableType* property to determine the table's type (its expected structure). *TableType* is not used when *TTable* represents an SQL-based table on a database server.

By default *TableType* is set to *ttDefault*. When *TableType* is *ttDefault*, the BDE determines a table's type from its filename extension. Table 20.1 summarizes the file extensions recognized by the BDE and the assumptions it makes about a table's type:

Table 20.1 Table types recognized by the BDE based on file extension

Extension	Table type
No file extension	Paradox
.DB	Paradox
.DBF	dBASE
.TXT	ASCII text

If your local Paradox, dBASE, and ASCII text tables use the file extensions as described in Table 20.1, then you can leave *TableType* set to *ttDefault*. Otherwise, your application must set *TableType* to indicate the correct table type. Table 20.2 indicates the values you can assign to *TableType*:

Table 20.2 TableType values

Value	Table type
ttDefault	Table type determined automatically by the BDE
ttParadox	Paradox

Table 20.2 TableType values (continued)

Value	Table type
ttDBase	dBASE
ttFoxPro	FoxPro
ttASCII	Comma-delimited ASCII text

Controlling read/write access to local tables

Like any table-type dataset, *TTable* lets you control read and write access by your application using the *ReadOnly* property.

In addition, for Paradox, dBASE, and FoxPro tables, *TTable* can let you control read and write access to tables by other applications. The *Exclusive* property controls whether your application gains sole read/write access to a Paradox, dBASE, or FoxPro table. To gain sole read/write access for these table types, set the table component's *Exclusive* property to *True* before opening the table. If you succeed in opening a table for exclusive access, other applications cannot read data from or write data to the table. Your request for exclusive access is not honored if the table is already in use when you attempt to open it.

The following statements open a table for exclusive access:

```
CustomersTable.Exclusive := True; {Set request for exclusive lock}
CustomersTable.Active := True; {Now open the table}
```

Note You can attempt to set *Exclusive* on SQL tables, but some servers do not support exclusive table-level locking. Others may grant an exclusive lock, but permit other applications to read data from the table. For more information about exclusive locking of database tables on your server, see your server documentation.

Specifying a dBASE index file

For most servers, you use the methods common to all table-type datasets to specify an index. These methods are described in "Sorting records with indexes" on page 18-25.

For dBASE tables that use non-production index files or dBASE III PLUS-style indexes (*.NDX), however, you must use the *IndexFiles* and *IndexName* properties instead. Set the *IndexFiles* property to the name of the non-production index file or list the .NDX files. Then, specify one index in the *IndexName* property to have it actively sorting the dataset.

At design time, click the ellipsis button in the *IndexFiles* property value in the Object Inspector to invoke the Index Files editor. To add one non-production index file or .NDX file: click the Add button in the Index Files dialog and select the file from the Open dialog. Repeat this process once for each non-production index file or .NDX file. Click the OK button in the Index Files dialog after adding all desired indexes.

This same operation can be performed programmatically at runtime. To do this, access the *IndexFiles* property using properties and methods of string lists. When adding a new set of indexes, first call the *Clear* method of the table's *IndexFiles* property to remove any existing entries. Call the *Add* method to add each non-production index file or .NDX file:

```
with Table2.IndexFiles do begin
  Clear;
  Add('Bystate.ndx');
  Add('Byzip.ndx');
  Add('Fullname.ndx');
  Add('St_name.ndx');
end;
```

After adding any desired non-production or .NDX index files, the names of individual indexes in the index file are available, and can be assigned to the *IndexName* property. The index tags are also listed when using the *GetIndexNames* method and when inspecting index definitions through the *TIndexDef* objects in the *IndexDefs* property. Properly listed .NDX files are automatically updated as data is added, changed, or deleted in the table (regardless of whether a given index is used in the *IndexName* property).

In the example below, the *IndexFiles* for the *AnimalsTable* table component is set to the non-production index file ANIMALS.MDX, and then its *IndexName* property is set to the index tag called “NAME”:

```
AnimalsTable.IndexFiles.Add('ANIMALS.MDX');
AnimalsTable.IndexName := 'NAME';
```

Once you have specified the index file, using non-production or .NDX indexes works the same as any other index. Specifying an index name sorts the data in the table and makes it available for indexed-based searches, ranges, and (for non-production indexes) master-detail linking. See “Using table-type datasets” on page 18-24 for details on these uses of indexes.

There are two special considerations when using dBASE III PLUS-style .NDX indexes with *TTable* components. The first is that .NDX files cannot be used as the basis for master-detail links. The second is that when activating a .NDX index with the *IndexName* property, you must include the .NDX extension in the property value as part of the index name:

```
with Table1 do begin
  IndexName := 'ByState.NDX';
  FindKey(['CA']);
end;
```

Renaming local tables

To rename a Paradox or dBASE table at design time, right-click the table component and select Rename Table from the context menu.

To rename a Paradox or dBASE table at runtime, call the table’s *RenameTable* method. For example, the following statement renames the Customer table to CustInfo:

```
Customer.RenameTable(‘CustInfo’);
```

Importing data from another table

You can use a table component's *BatchMove* method to import data from another table. *BatchMove* can

- Copy records from another table into this table.
- Update records in this table that occur in another table.
- Append records from another table to the end of this table.
- Delete records in this table that occur in another table.

BatchMove takes two parameters: the name of the table from which to import data, and a mode specification that determines which import operation to perform. Table 20.3 describes the possible settings for the mode specification:

Table 20.3 BatchMove import modes

Value	Meaning
batAppend	Append all records from the source table to the end of this table.
batAppendUpdate	Append all records from the source table to the end of this table and update existing records in this table with matching records from the source table.
batCopy	Copy all records from the source table into this table.
batDelete	Delete all records in this table that also appear in the source table.
batUpdate	Update existing records in this table with matching records from the source table.

For example, the following code updates all records in the current table with records from the *Customer* table that have the same values for fields in the current index:

```
Table1.BatchMove('CUSTOMER.DB', batUpdate);
```

BatchMove returns the number of records it imports successfully.

Caution Importing records using the *batCopy* mode overwrites existing records. To preserve existing records use *batAppend* instead.

BatchMove performs only some of the batch operations supported by the BDE. Additional functions are available using the *TBatchMove* component. If you need to move a large amount of data between or among tables, use *TBatchMove* instead of calling a table's *BatchMove* method. For information about using *TBatchMove*, see "Using TBatchMove" on page 20-47.

Using TQuery

TQuery represents a single Data Definition Language (DDL) or Data Manipulation Language (DML) statement (For example, a SELECT, INSERT, DELETE, UPDATE, CREATE INDEX, or ALTER TABLE command). The language used in commands is server-specific, but usually compliant with the SQL-92 standard for the SQL language. *TQuery* implements all of the basic functionality introduced by *TDataSet*, as well as all of the special features typical of query-type datasets. Before looking at the unique features introduced by *TQuery*, you should familiarize yourself with the common database features described in "Understanding datasets," including the section on query-type datasets that starts on page 18-41.

Because *TQuery* is a BDE-enabled dataset, it must usually be associated with a database and a session. (The one exception is when you use the *TQuery* for a heterogeneous query.) "Associating a dataset with database and session connections" on page 20-3 describes how you form these associations. You specify the SQL statement for the query by setting the *SQL* property.

A TQuery component can access data in:

- Paradox or dBASE tables, using Local SQL, which is part of the BDE. Local SQL is a subset of the SQL-92 specification. Most DML is supported and enough DDL syntax to work with these types of tables. See the local SQL help, LOCALSQL.HLP, for details on supported SQL syntax.
- Local InterBase Server databases, using the InterBase engine. For information on InterBase's SQL-92 standard SQL syntax support and extended syntax support, see the InterBase *Language Reference.*
- Databases on remote database servers such as Oracle, Sybase, MS-SQL Server, Informix, DB2, and InterBase. You must install the appropriate SQL Link driver and client software (vendor-supplied) specific to the database server to access a remote server. Any standard SQL syntax supported by these servers is allowed. For information on SQL syntax, limitations, and extensions, see the documentation for your particular server.

Creating heterogeneous queries

TQuery supports heterogeneous queries against more than one server or table type (for example, data from an Oracle table and a Paradox table). When you execute a heterogeneous query, the BDE parses and processes the query using Local SQL. Because BDE uses Local SQL, extended, server-specific SQL syntax is not supported.

To perform a heterogeneous query, follow these steps:

1. Define separate BDE aliases for each database accessed in the query using the BDE BDE Administration tool or the SQL explorer.
2. Leave the *DatabaseName* property of the *TQuery* blank; the names of the databases used will be specified in the SQL statement.
3. In the SQL property, specify the SQL statement to execute. Precede each table name in the statement with the BDE alias for the table's database, enclosed in colons. This whole reference is then enclosed in quotation marks.
4. Set any parameters for the query in the *Params* property.
5. Call *Prepare* to prepare the query for execution prior to executing it for the first time.
6. Call *Open* or *ExecSQL* depending on the type of query you are executing.

For example, suppose you define an alias called *Oracle1* for an Oracle database that has a CUSTOMER table, and *Sybase1* for a Sybase database that has an ORDERS table. A simple query against these two tables would be:

```
SELECT Customer.CustNo, Orders.OrderNo
FROM ":Oracle1:CUSTOMER"
  JOIN ":Sybase1:ORDERS"
    ON (Customer.CustNo = Orders.CustNo)
WHERE (Customer.CustNo = 1503)
```

As an alternative to using a BDE alias to specify the database in a heterogeneous query, you can use a *TDatabase* component. Configure the *TDatabase* as normal to point to the database, set the *TDatabase.DatabaseName* to an arbitrary but unique value, and then use that value in the SQL statement instead of a BDE alias name.

Obtaining an editable result set

To request a result set that users can edit in data-aware controls, set a query component's *RequestLive* property to *True*. Setting *RequestLive* to *True* does not guarantee a live result set, but the BDE attempts to honor the request whenever possible. There are some restrictions on live result set requests, depending on whether the query uses the local SQL parser or a server's SQL parser.

- Queries where table names are preceded by a BDE database alias (as in heterogeneous queries) and queries executed against Paradox or dBASE are parsed by the BDE using Local SQL. When queries use the local SQL parser, the BDE offers expanded support for updatable, live result sets in both single table and multi-table queries. When using Local SQL, a live result set for a query against a single table or view is returned if the query does not contain any of the following:
  - DISTINCT in the SELECT clause
  - Joins (inner, outer, or UNION)
  - Aggregate functions with or without GROUP BY or HAVING clauses
  - Base tables or views that are not updatable
  - Subqueries
  - ORDER BY clauses not based on an index
- Queries against a remote database server are parsed by the server. If the *RequestLive* property is set to *True*, the SQL statement must abide by Local SQL standards in addition to any server-imposed restrictions because the BDE needs to use it for conveying data changes to the table. A live result set for a query against a single table or view is returned if the query does not contain any of the following:
  - A DISTINCT clause in the SELECT statement
  - Aggregate functions, with or without GROUP BY or HAVING clauses
  - References to more than one base table or updatable views (joins)
  - Subqueries that reference the table in the FROM clause or other tables

If an application requests and receives a live result set, the *CanModify* property of the query component is set to *True*. Even if the query returns a live result set, you may not be able to update the result set directly if it contains linked fields or you switch indexes before attempting an update. If these conditions exist, you should treat the result set as a read-only result set, and update it accordingly.

If an application requests a live result set, but the SELECT statement syntax does not allow it, the BDE returns either

- A read-only result set for queries made against Paradox or dBASE.
- An error code for SQL queries made against a remote server.

Updating read-only result sets

Applications can update data returned in a read-only result set if they are using cached updates.

If you are using a client dataset to cache updates, the client dataset or its associated provider can automatically generate the SQL for applying updates unless the query represents multiple tables. If the query represents multiple tables, you must indicate how to apply the updates:

- If all updates are applied to a single database table, you can indicate the underlying table to update in an *OnGetTableName* event handler.
- If you need more control over applying updates, you can associate the query with an update object (*TUpdateSQL*). A provider automatically uses this update object to apply updates:
  1. Associate the update object with the query by setting the query's *UpdateObject* property to the *TUpdateSQL* object you are using.
  2. Set the update object's *ModifySQL*, *InsertSQL*, and *DeleteSQL* properties to SQL statements that perform the appropriate updates for your query's data.

If you are using the BDE to cache updates, you must use an update object.

Note For more information on using update objects, see "Using update objects to update a dataset" on page 20-39.

Using TStoredProc

TStoredProc represents a stored procedure. It implements all of the basic functionality introduced by *TDataSet*, as well as most of the special features typical of stored procedure-type datasets. Before looking at the unique features introduced by *TStoredProc*, you should familiarize yourself with the common database features described in "Understanding datasets," including the section on stored procedure-type datasets that starts on page 18-48.

Because *TStoredProc* is a BDE-enabled dataset, it must be associated with a database and a session. "Associating a dataset with database and session connections" on page 20-3 describes how you form these associations. Once the dataset is associated with a database and session, you can bind it to a particular stored procedure by setting the *StoredProcName* property.

TStoredProc differs from other stored procedure-type datasets in the following ways:

- It gives you greater control over how to bind parameters.
- It provides support for Oracle overloaded stored procedures.

Binding parameters

When you prepare and execute a stored procedure, its input parameters are automatically bound to parameters on the server.

TStoredProc lets you use the *ParamBindMode* property to specify how parameters should be bound to the parameters on the server. By default *ParamBindMode* is set to *pbByName*, meaning that parameters from the stored procedure component are matched to those on the server by name. This is the easiest method of binding parameters.

Some servers also support binding parameters by ordinal value, the order in which the parameters appear in the stored procedure. In this case the order in which you specify parameters in the parameter collection editor is significant. The first parameter you specify is matched to the first input parameter on the server, the second parameter is matched to the second input parameter on the server, and so on. If your server supports parameter binding by ordinal value, you can set *ParamBindMode* to *pbByNumber*.

Tip If you want to set *ParamBindMode* to *pbByNumber*, you need to specify the correct parameter types in the correct order. You can view a server's stored procedure source code in the SQL Explorer to determine the correct order and type of parameters to specify.

Working with Oracle overloaded stored procedures
