Oracle servers allow overloading of stored procedures; overloaded procedures are different procedures with the same name. The stored procedure component's *Overload* property enables an application to specify the procedure to execute.

If *Overload* is zero (the default), there is assumed to be no overloading. If *Overload* is one (1), then the stored procedure component executes the first stored procedure it finds on the Oracle server that has the overloaded name; if it is two (2), it executes the second, and so on.

Note Overloaded stored procedures may take different input and output parameters. See your Oracle server documentation for more information.

Connecting to databases with TDatabase

When a Delphi application uses the Borland Database Engine (BDE) to connect to a database, that connection is encapsulated by a *TDatabase* component. A database component represents the connection to a single database in the context of a BDE session.

TDatabase performs many of the same tasks as and shares many common properties, methods, and events with other database connection components. These commonalities are described in Chapter 17, "Connecting to databases."

In addition to the common properties, methods, and events, *TDatabase* introduces many BDE-specific features. These features are described in the following topics.

Associating a database component with a session

All database components must be associated with a BDE session. Use the *SessionName*, establish this association. When you first create a database component at design time, *SessionName* is set to "Default", meaning that it is associated with the default session component that is referenced by the global *Session* variable.

Multi-threaded or reentrant BDE applications may require more than one session. If you need to use multiple sessions, add *TSession* components for each session. Then, associate your dataset with a session component by setting the *SessionName* property to a session component's *SessionName* property.

At runtime, you can access the session component with which the database is associated by reading the *Session* property. If *SessionName* is blank or "Default", then the *Session* property references the same *TSession* instance referenced by the global *Session* variable. *Session* enables applications to access the properties, methods, and events of a database component's parent session component without knowing the session's actual name.

For more information about BDE sessions, see "Managing database sessions" on page 20-16.

If you are using an implicit database component, the session for that database component is the one specified by the dataset's *SessionName* property.

Understanding database and session component interactions

In general, session component properties provide global, default behaviors that apply to all implicit database components created at runtime. For example, the controlling session's *KeepConnections* property determines whether a database connection is maintained even if its associated datasets are closed (the default), or if the connections are dropped when all its datasets are closed. Similarly, the default *OnPassword* event for a session guarantees that when an application attempts to attach to a database on a server that requires a password, it displays a standard password prompt dialog box.

Session methods apply somewhat differently. *TSession* methods affect all database components, regardless of whether they are explicitly created or instantiated implicitly by a dataset. For example, the session method *DropConnections* closes all datasets belonging to a session's database components, and then drops all database connections, even if the *KeepConnection* property for individual database components is *True*.

Database component methods apply only to the datasets associated with a given database component. For example, suppose the database component *Database1* is associated with the default session. *Database1.CloseDataSets()* closes only those datasets associated with *Database1*. Open datasets belonging to other database components within the default session remain open.

Identifying the database

AliasName and *DriverName* are mutually exclusive properties that identify the database server to which the *TDatabase* component connects.

- *AliasName* specifies the name of an existing BDE alias to use for the database component. The alias appears in subsequent drop-down lists for dataset components so that you can link them to a particular database component. If you specify *AliasName* for a database component, any value already assigned to *DriverName* is cleared because a driver name is always part of a BDE alias.

  You create and edit BDE aliases using the Database Explorer or the BDE Administration utility. For more information about creating and maintaining BDE aliases, see the online documentation for these utilities.

- *DriverName* is the name of a BDE driver. A driver name is one parameter in a BDE alias, but you may specify a driver name instead of an alias when you create a local BDE alias for a database component using the *DatabaseName* property. If you specify *DriverName*, any value already assigned to *AliasName* is cleared to avoid potential conflicts between the driver name you specify and the driver name that is part of the BDE alias identified in *AliasName*.

DatabaseName lets you provide your own name for a database connection. The name you supply is in addition to *AliasName* or *DriverName*, and is local to your application. *DatabaseName* can be a BDE alias, or, for Paradox and dBASE files, a fully-qualified path name. Like *AliasName*, *DatabaseName* appears in subsequent drop-down lists for dataset components to let you link them to database components.

At design time, to specify a BDE alias, assign a BDE driver, or create a local BDE alias, double-click a database component to invoke the Database Properties editor.

You can enter a *DatabaseName* in the Name edit box in the properties editor. You can enter an existing BDE alias name in the Alias name combo box for the *Alias* property, or you can choose from existing aliases in the drop-down list. The Driver name combo box enables you to enter the name of an existing BDE driver for the *DriverName* property, or you can choose from existing driver names in the drop-down list.

Note The Database Properties editor also lets you view and set BDE connection parameters, and set the states of the *LoginPrompt* and *KeepConnection* properties. For information on connection parameters, see “Setting BDE alias parameters” below. For information on *LoginPrompt*, see “Controlling server login” on page 17-4. For information on *KeepConnection* see “Opening a connection using TDatabase” on page 20-15.

Setting BDE alias parameters

At design time you can create or edit connection parameters in three ways:

- Use the Database Explorer or BDE Administration utility to create or modify BDE aliases, including parameters. For more information about these utilities, see their online Help files.
- Double-click the *Params* property in the Object Inspector to invoke the String List editor.
- Double-click a database component in a data module or form to invoke the Database Properties editor.

All of these methods edit the *Params* property for the database component. *Params* is a string list containing the database connection parameters for the BDE alias associated with a database component. Some typical connection parameters include path statement, server name, schema caching size, language driver, and SQL query mode.

When you first invoke the Database Properties editor, the parameters for the BDE alias are not visible. To see the current settings, click Defaults. The current parameters are displayed in the Parameter overrides memo box. You can edit existing entries or add new ones. To clear existing parameters, click Clear. Changes you make take effect only when you click OK.

At runtime, an application can set alias parameters only by editing the *Params* property directly. For more information about parameters specific to using SQL Links drivers with the BDE, see your online SQL Links help file.

Opening a connection using TDatabase

As with all database connection components, to connect to a database using *TDatabase*, you set the *Connected* property to *True* or call the *Open* method. This process is described in "Connecting to a database server" on page 17-3. Once a database connection is established the connection is maintained as long as there is at least one active dataset. When there are no more active datasets, the connection is dropped unless the database component's *KeepConnection* property is *True*.

When you connect to a remote database server from an application, the application uses the BDE and the Borland SQL Links driver to establish the connection. (The BDE can also communicate with an ODBC driver that you supply.) You need to configure the SQL Links or ODBC driver for your application prior to making the connection. SQL Links and ODBC parameters are stored in the *Params* property of a database component. For information about SQL Links parameters, see the online *SQL Links User's Guide*. To edit the *Params* property, see "Setting BDE alias parameters" on page 20-14.

Working with network protocols

As part of configuring the appropriate SQL Links or ODBC driver, you may need to specify the network protocol used by the server, such as SPX/IPX or TCP/IP, depending on the driver's configuration options. In most cases, network protocol configuration is handled using a server's client setup software. For ODBC it may also be necessary to check the driver setup using the ODBC driver manager.

Establishing an initial connection between client and server can be problematic. The following troubleshooting checklist should be helpful if you encounter difficulties:

- Is your server's client-side connection properly configured?
- Are the DLLs for your connection and database drivers in the search path?
- If you are using TCP/IP:
  - Is your TCP/IP communications software installed? Is the proper WINSOCK.DLL installed?
  - Is the server's IP address registered in the client's HOSTS file?

- Is the Domain Name Services (DNS) properly configured?
- Can you ping the server?

For more troubleshooting information, see the online *SQL Links User's Guide* and your server documentation.

Using ODBC

An application can use ODBC data sources (for example, Btrieve). An ODBC driver connection requires

- A vendor-supplied ODBC driver.
- The Microsoft ODBC Driver Manager.
- The BDE Administration utility.

To set up a BDE alias for an ODBC driver connection, use the BDE Administration utility. For more information, see the BDE Administration utility's online help file.

Using database components in data modules

You can safely place database components in data modules. If you put a data module that contains a database component into the Object Repository, however, and you want other users to be able to inherit from it, you must set the *HandleShared* property of the database component to *True* to prevent global name space conflicts.

Managing database sessions

An BDE-based application's database connections, drivers, cursors, queries, and so on are maintained within the context of one or more BDE sessions. Sessions isolate a set of database access operations, such as database connections, without the need to start another instance of the application.

All BDE-based database applications automatically include a default session component, named *Session*, that encapsulates the default BDE session. When database components are added to the application, they are automatically associated with the default session (note that its *SessionName* is "Default"). The default session provides global control over all database components not associated with another session, whether they are implicit (created by the session at runtime when you open a dataset that is not associated with a database component you create) or persistent (explicitly created by your application). The default session is not visible in your data module or form at design time, but you can access its properties and methods in your code at runtime.

To use the default session, you need write no code unless your application must

- Explicitly activate or deactivate a session, enabling or disabling the session's databases' ability to open.
- Modify the properties of the session, such as specifying default properties for implicitly generated database components.

- Execute a session's methods, such as managing database connections (for example opening and closing database connections in response to user actions).
- Respond to session events, such as when the application attempts to access a password-protected Paradox or dBASE table.
- Set Paradox directory locations such as the *NetFileDir* property to access Paradox tables on a network and the *PrivateDir* property to a local hard drive to speed performance.
- Manage the BDE aliases that describe possible database connection configurations for databases and datasets that use the session.

Whether you add database components to an application at design time or create them dynamically at runtime, they are automatically associated with the default session unless you specifically assign them to a different session. If you open a dataset that is not associated with a database component, Delphi automatically

- Creates a database component for it at runtime.
- Associates the database component with the default session.
- Initializes some of the database component's key properties based on the default session's properties. Among the most important of these properties is *KeepConnections*, which determines when database connections are maintained or dropped by an application.

The default session provides a widely applicable set of defaults that can be used as is by most applications. You need only associate a database component with an explicitly named session if the component performs a simultaneous query against a database already opened by the default session. In this case, each concurrent query must run under its own session. Multi-threaded database applications also require multiple sessions, where each thread has its own session.

Applications can create additional session components as needed. BDE-based database applications automatically include a session list component, named *Sessions*, that you can use to manage all of your session components. For more information about managing multiple sessions see, "Managing multiple sessions" on page 20-28.

You can safely place session components in data modules. If you put a data module that contains one or more session components into the Object Repository, however, make sure to set the *AutoSessionName* property to *True* to avoid namespace conflicts when users inherit from it.

Activating a session

Active is a Boolean property that determines if database and dataset components associated with a session are open. You can use this property to read the current state of a session's database and dataset connections, or to change it. If *Active* is *False* (the default), all databases and datasets associated with the session are closed. If *True*, databases and datasets are open.

A session is activated when it is first created, and subsequently, whenever its *Active* property is changed to *True* from *False* (for example, when a database or dataset is associated with a session is opened and there are currently no other open databases or datasets). Setting *Active* to *True* triggers a session's *OnStartup* event, registers the paradox directory locations with the BDE, and registers the *ConfigMode* property, which determines what BDE aliases are available within the session. You can write an *OnStartup* event handler to initialize the *NetFileDir*, *PrivateDir*, and *ConfigMode* properties before they are registered with the BDE, or to perform other specific session start-up activities. For information about the *NetFileDir* and *PrivateDir* properties, see "Specifying Paradox directory locations" on page 20-24. For information about ConfigMode, see "Working with BDE aliases" on page 20-24.

Once a session is active, you can open its database connections by calling the *OpenDatabase* method.

For session components you place in a data module or form, setting *Active* to *False* when there are open databases or datasets closes them. At runtime, closing databases and datasets may trigger events associated with them.

Note You cannot set *Active* to *False* for the default session at design time. While you can close the default session at runtime, it is not recommended.

You can also use a session's *Open* and *Close* methods to activate or deactivate sessions other than the default session at runtime. For example, the following single line of code closes all open databases and datasets for a session:

```
Session1.Close;
```

This code sets Session1's *Active* property to *False*. When a session's *Active* property is *False*, any subsequent attempt by the application to open a database or dataset resets *Active* to *True* and calls the session's *OnStartup* event handler if it exists. You can also explicitly code session reactivation at runtime. The following code reactivates *Session1*:

```
Session1.Open;
```

Note If a session is active you can also open and close individual database connections. For more information, see "Closing database connections" on page 20-19.

Specifying default database connection behavior

KeepConnections provides the default value for the *KeepConnection* property of implicit database components created at runtime. *KeepConnection* specifies what happens to a database connection established for a database component when all its datasets are closed. If *True* (the default), a constant, or *persistent*, database connection is maintained even if no dataset is active. If *False*, a database connection is dropped as soon as all its datasets are closed.

Note Connection persistence for a database component you explicitly place in a data module or form is controlled by that database component's *KeepConnection* property. If set differently, *KeepConnection* for a database component always overrides the *KeepConnections* property of the session. For more information about controlling individual database connections within a session, see "Managing database connections" on page 20-19.

KeepConnections should be set to *True* for applications that frequently open and close all datasets associated with a database on a remote server. This setting reduces network traffic and speeds data access because it means that a connection need only be opened and closed once during the lifetime of the session. Otherwise, every time the application closes or reestablishes a connection, it incurs the overhead of attaching and detaching the database.

Note Even when *KeepConnections* is *True* for a session, you can close and free inactive database connections for all implicit database components by calling the *DropConnections* method. For more information about *DropConnections*, see "Dropping inactive database connections" on page 20-20.

Managing database connections

You can use a session component to manage the database connections within it. The session component includes properties and methods you can use to

- Open database connections.
- Close database connections.
- Close and free all inactive temporary database connections.
- Locate specific database connections.
- Iterate through all open database connections.

Opening database connections

To open a database connection within a session, call the *OpenDatabase* method. *OpenDatabase* takes one parameter, the name of the database to open. This name is a BDE alias or the name of a database component. For Paradox or dBASE, the name can also be a fully qualified path name. For example, the following statement uses the default session and attempts to open a database connection for the database pointed to by the DBDEMOS alias:

```
var
  DBDemosDatabase: TDatabase;
begin
  DBDemosDatabase := Session.OpenDatabase('DBDEMOS');
  ...
```

OpenDatabase actives the session if it is not already active, and then checks if the specified database name matches the *DatabaseName* property of any database components for the session. If the name does not match an existing database component, *OpenDatabase* creates a temporary database component using the specified name. Finally, *OpenDatabase* calls the *Open* method of the database component to connect to the server. Each call to *OpenDatabase* increments a reference count for the database by 1. As long as this reference count remains greater than 0, the database is open.

Closing database connections

To close an individual database connection, call the *CloseDatabase* method. When you call *CloseDatabase*, the reference count for the database, which is incremented when you call *OpenDatabase*, is decremented by 1. When the reference count for a database is 0, the database is closed. *CloseDatabase* takes one parameter, the database to close. If you opened the database using the *OpenDatabase* method, this parameter can be set to the return value of *OpenDatabase*.

```
Session.CloseDatabase(DBDemosDatabase);
```

If the specified database name is associated with a temporary (implicit) database component, and the session's *KeepConnections* property is *False*, the database component is freed, effectively closing the connection.

Note If *KeepConnections* is *False* temporary database components are closed and freed automatically when the last dataset associated with the database component is closed. An application can always call *CloseDatabase* prior to that time to force closure. To free temporary database components when *KeepConnections* is *True*, call the database component's *Close* method, and then call the session's *DropConnections* method.

Note Calling *CloseDatabase* for a persistent database component does not actually close the connection. To close the connection, call the database component's *Close* method directly.

There are two ways to close all database connections within the session:

- Set the *Active* property for the session to *False*.
- Call the *Close* method for the session.

When you set *Active* to *False*, Delphi automatically calls the *Close* method. *Close* disconnects from all active databases by freeing temporary database components and calling each persistent database component's *Close* method. Finally, *Close* sets the session's BDE handle to **nil**.

Dropping inactive database connections

If the *KeepConnections* property for a session is *True* (the default), then database connections for temporary database components are maintained even if all the datasets used by the component are closed. You can eliminate these connections and free all inactive temporary database components for a session by calling the *DropConnections* method. For example, the following code frees all inactive, temporary database components for the default session:

```
Session.DropConnections;
```

Temporary database components for which one or more datasets are active are not dropped or freed by this call. To free these components, call *Close*.

Searching for a database connection

Use a session's *FindDatabase* method to determine whether a specified database component is already associated with a session. *FindDatabase* takes one parameter, the name of the database to search for. This name is a BDE alias or database component name. For Paradox or dBASE, it can also be a fully-qualified path name.

FindDatabase returns the database component if it finds a match. Otherwise it returns **nil**.

The following code searches the default session for a database component using the DBDEMOS alias, and if it is not found, creates one and opens it:

```
var
  DB: TDatabase;
begin
  DB := Session.FindDatabase('DBDEMOS');
```

```
    if (DB = nil) then                          { database doesn't exist for session so,}
      DB := Session.OpenDatabase('DBDEMOS');    { create and open it}
    if Assigned(DB) and DB.Connected then begin
      DB.StartTransaction;
      ...
    end;
  end;
```

Iterating through a session's database components

You can use two session component properties, *Databases* and *DatabaseCount*, to cycle through all the active database components associated with a session.

Databases is an array of all currently active database components associated with a session. *DatabaseCount* is the number of databases in that array. As connections are opened or closed during a session's life-span, the values of *Databases* and *DatabaseCount* change. For example, if a session's *KeepConnections* property is *False* and all database components are created as needed at runtime, each time a unique database is opened, *DatabaseCount* increases by one. Each time a unique database is closed, *DatabaseCount* decreases by one. If *DatabaseCount* is zero, there are no currently active database components for the session.

The following example code sets the *KeepConnection* property of each active database in the default session to *True*:

```
var
  MaxDbCount: Integer;
begin
  with Session do
    if (DatabaseCount > 0) then
      for MaxDbCount := 0 to (DatabaseCount - 1) do
        Databases[MaxDbCount].KeepConnection := True;
end;
```

Working with password-protected Paradox and dBASE tables

A session component can store passwords for password-protected Paradox and dBASE tables. Once you add a password to the session, your application can open tables protected by that password. Once you remove the password from the session, your application can't open tables that use the password until you add it again.

Using the AddPassword method

The *AddPassword* method provides an optional way for an application to provide a password for a session prior to opening an encrypted Paradox or dBASE table that requires a password for access. If you do not add the password to the session, when your application attempts to open a password-protected table, a dialog box prompts the user for a password.

AddPassword takes one parameter, a string containing the password to use. You can call *AddPassword* as many times as necessary to add passwords (one at a time) to access tables protected with different passwords.

```
var
  Passwrd: String;
begin
  Passwrd := InputBox('Enter password', 'Password:', '');
  Session.AddPassword(Passwrd);
  try
    Table1.Open;
  except
    ShowMessage('Could not open table!');
    Application.Terminate;
  end;
end;
```

Note Use of the *InputBox* function, above, is for demonstration purposes. In a real-world application, use password entry facilities that mask the password as it is entered, such as the *PasswordDialog* function or a custom form.

The Add button of the *PasswordDialog* function dialog has the same effect as the *AddPassword* method.

```
if PasswordDialog(Session) then
  Table1.Open
else
  ShowMessage('No password given, could not open table!');
end;
```

Using the RemovePassword and RemoveAllPasswords methods

RemovePassword deletes a previously added password from memory. *RemovePassword* takes one parameter, a string containing the password to delete.

```
Session.RemovePassword(‘secret’);
```

RemoveAllPasswords deletes all previously added passwords from memory.

```
Session.RemoveAllPasswords;
```

Using the GetPassword method and OnPassword event

The *OnPassword* event allows you to control how your application supplies passwords for Paradox and dBASE tables when they are required. Provide a handler for the *OnPassword* event if you want to override the default password handling behavior. If you do not provide a handler, Delphi presents a default dialog for entering a password and no special behavior is provided—the table open attempt either succeeds or an exception is raised.

If you provide a handler for the *OnPassword* event, do two things in the event handler: call the *AddPassword* method and set the event handler’s *Continue* parameter to *True*. The *AddPassword* method passes a string to the session to be used as a password for the table. The *Continue* parameter indicates to Delphi that no further password prompting need be done for this table open attempt. The default value for *Continue* is *False*, and so requires explicitly setting it to *True*. If *Continue* is *False* after the event handler has finished executing, an *OnPassword* event fires again—even if a valid password has been passed using *AddPassword*. If *Continue* is *True* after execution of the event handler and the string passed with *AddPassword* is not the valid password, the table open attempt fails and an exception is raised.

OnPassword can be triggered by two circumstances. The first is an attempt to open a password-protected table (dBASE or Paradox) when a valid password has not already been supplied to the session. (If a valid password for that table has already been supplied, the *OnPassword* event does not occur.)

The other circumstance is a call to the *GetPassword* method. *GetPassword* either generates an *OnPassword* event, or, if the session does not have an *OnPassword* event handler, displays a default password dialog. It returns *Tru*e if the *OnPassword* event handler or default dialog added a password to the session, and *False* if no entry at all was made.

In the following example, the *Password* method is designated as the *OnPassword* event handler for the default session by assigning it to the global *Session* object's *OnPassword* property.

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  Session.OnPassword := Password;
end;
```

In the *Password* method, the *InputBox* function prompts the user for a password. The *AddPassword* method then programmatically supplies the password entered in the dialog to the session.

```
procedure TForm1.Password(Sender: TObject; var Continue: Boolean);
var
  Passwrd: String;
begin
  Passwrd := InputBox('Enter password', 'Password:', '');
  Continue := (Passwrd > '');
  Session.AddPassword(Passwrd);
end;
```

The *OnPassword* event (and thus the *Password* event handler) is triggered by an attempt to open a password-protected table, as demonstrated below. Even though the user is prompted for a password in the handler for the *OnPassword* event, the table open attempt can still fail if they enter an invalid password or something else goes wrong.

```
procedure TForm1.OpenTableBtnClick(Sender: TObject);
const
  CRLF = #13 + #10;
begin
  try
    Table1.Open;                              { this line triggers the OnPassword event }
  except
    on E:Exception do begin                            { exception if cannot open table }
      ShowMessage('Error!' + CRLF +             { display error explaining what happened }
        E.Message + CRLF +
        'Terminating application...');
      Application.Terminate;                                      { end the application }
    end;
  end;
end;
```

Specifying Paradox directory locations

Two session component properties, *NetFileDir* and *PrivateDir*, are specific to applications that work with Paradox tables.

NetFileDir specifies the directory that contains the Paradox network control file, PDOXUSRS.NET. This file governs sharing of Paradox tables on network drives. All applications that need to share Paradox tables must specify the same directory for the network control file (typically a directory on a network file server). Delphi derives a value for *NetFileDir* from the Borland Database Engine (BDE) configuration file for a given database alias. If you set *NetFileDir* yourself, the value you supply overrides the BDE configuration setting, so be sure to validate the new value.

At design time, you can specify a value for *NetFileDir* in the Object Inspector. You can also set or change *NetFileDir* in code at runtime. The following code sets *NetFileDir* for the default session to the location of the directory from which your application runs:

```
Session.NetFileDir := ExtractFilePath(Application.EXEName);
```

Note *NetFileDir* can only be changed when an application does not have any open Paradox files. If you change *NetFileDir* at runtime, verify that it points to a valid network directory that is shared by your network users.

PrivateDir specifies the directory for storing temporary table processing files, such as those generated by the BDE to handle local SQL statements. If no value is specified for the *PrivateDir* property, the BDE automatically uses the current directory at the time it is initialized. If your application runs directly from a network file server, you can improve application performance at runtime by setting *PrivateDir* to a user's local hard drive before opening the database.

Note Do not set *PrivateDir* at design time and then open the session in the IDE. Doing so generates a Directory is busy error when running your application from the IDE.

The following code changes the setting of the default session's *PrivateDir* property to a user's C:\TEMP directory:

```
Session.PrivateDir := 'C:\TEMP';
```

Important Do not set *PrivateDir* to a root directory on a drive. Always specify a subdirectory.

Working with BDE aliases

Each database component associated with a session has a BDE alias (although optionally a fully-qualified path name may be substituted for an alias when accessing Paradox and dBASE tables). A session can create, modify, and delete aliases during its lifetime.

The *AddAlias* method creates a new BDE alias for an SQL database server. *AddAlias* takes three parameters: a string containing a name for the alias, a string that specifies the SQL Links driver to use, and a string list populated with parameters for the alias. For example, the following statements use *AddAlias* to add a new alias for accessing an InterBase server to the default session:

```
var
  AliasParams: TStringList;
begin
  AliasParams := TStringList.Create;
```

```
    try
      with AliasParams do begin
        Add('OPEN MODE=READ');
        Add('USER NAME=TOMSTOPPARD');
        Add('SERVER NAME=ANIMALS:/CATS/PEDIGREE.GDB');
      end;
      Session.AddAlias('CATS', 'INTRBASE', AliasParams);
      ...
    finally
      AliasParams.Free;
    end;
  end;
```

AddStandardAlias creates a new BDE alias for Paradox, dBASE, or ASCII tables. *AddStandardAlias* takes three string parameters: the name for the alias, the fully-qualified path to the Paradox or dBASE table to access, and the name of the default driver to use when attempting to open a table that does not have an extension. For example, the following statement uses *AddStandardAlias* to create a new alias for accessing a Paradox table:

```
AddStandardAlias('MYDBDEMOS', 'C:\TESTING\DEMOS\', 'Paradox');
```

When you add an alias to a session, the BDE stores a copy of the alias in memory, where it is only available to this session and any other sessions with *cfmPersistent* included in the *ConfigMode* property. *ConfigMode* is a set that describes which types of aliases can be used by the databases in the session. The default setting is *cmAll*, which translates into the set [*cfmVirtual*, *cfmPersistent*, *cfmSession*]. If *ConfigMode* is *cmAll*, a session can see all aliases created within the session (*cfmSession*), all aliases in the BDE configuration file on a user's system (*cfmPersistent*), and all aliases that the BDE maintains in memory (*cfmVirtual*). You can change *ConfigMode* to restrict what BDE aliases the databases in a session can use. For example, setting *ConfigMode* to *cfmSession* restricts a session's view of aliases to those created within the session. All other aliases in the BDE configuration file and in memory are not available.

To make a newly created alias available to all sessions and to other applications, use the session's *SaveConfigFile* method. *SaveConfigFile* writes aliases in memory to the BDE configuration file where they can be read and used by other BDE-enabled applications.

After you create an alias, you can make changes to its parameters by calling *ModifyAlias*. *ModifyAlias* takes two parameters: the name of the alias to modify and a string list containing the parameters to change and their values. For example, the following statements use *ModifyAlias* to change the OPEN MODE parameter for the CATS alias to READ/WRITE in the default session:

```
var
  List: TStringList;
begin
  List := TStringList.Create;
  with List do begin
    Clear;
    Add('OPEN MODE=READ/WRITE');
  end;
  Session.ModifyAlias('CATS', List);
  List.Free;
  ...
```

To delete an alias previously created in a session, call the *DeleteAlias* method. *DeleteAlias* takes one parameter, the name of the alias to delete. *DeleteAlias* makes an alias unavailable to the session.

Note *DeleteAlias* does not remove an alias from the BDE configuration file if the alias was written to the file by a previous call to *SaveConfigFile*. To remove the alias from the configuration file after calling *DeleteAlias*, call *SaveConfigFile* again.

Session components provide five methods for retrieving information about a BDE aliases, including parameter information and driver information. They are:

- *GetAliasNames*, to list the aliases to which a session has access.
- *GetAliasParams*, to list the parameters for a specified alias.
- *GetAliasDriverName*, to return the name of the BDE driver used by the alias.
- *GetDriverNames*, to return a list of all BDE drivers available to the session.
- *GetDriverParams*, to return driver parameters for a specified driver.

For more information about using a session's informational methods, see "Retrieving information about a session" below. For more information about BDE aliases and the SQL Links drivers with which they work, see the BDE online help, BDE32.HLP.

Retrieving information about a session

You can retrieve information about a session and its database components by using a session's informational methods. For example, one method retrieves the names of all aliases known to the session, and another method retrieves the names of tables associated with a specific database component used by the session. Table 20.4 summarizes the informational methods to a session component:

Table 20.4 Database-related informational methods for session components

Method	Purpose
GetAliasDriverName	Retrieves the BDE driver for a specified alias of a database.
GetAliasNames	Retrieves the list of BDE aliases for a database.
GetAliasParams	Retrieves the list of parameters for a specified BDE alias of a database.
GetConfigParams	Retrieves configuration information from the BDE configuration file.
GetDatabaseNames	Retrieves the list of BDE aliases and the names of any *TDatabase* components currently in use.
GetDriverNames	Retrieves the names of all currently installed BDE drivers.
GetDriverParams	Retrieves the list of parameters for a specified BDE driver.
GetStoredProcNames	Retrieves the names of all stored procedures for a specified database.
GetTableNames	Retrieves the names of all tables matching a specified pattern for a specified database.
GetFieldNames	Retrieves the names of all fields in a specified table in a specified database.

Except for *GetAliasDriverName*, these methods return a set of values into a string list declared and maintained by your application. (*GetAliasDriverName* returns a single string, the name of the current BDE driver for a particular database component used by the session.)

For example, the following code retrieves the names of all database components and aliases known to the default session:

```
var
  List: TStringList;
begin
  List := TStringList.Create;
  try
    Session.GetDatabaseNames(List);
    ...
  finally
    List.Free;
  end;
end;
```

Creating additional sessions

You can create sessions to supplement the default session. At design time, you can place additional sessions on a data module (or form), set their properties in the Object Inspector, write event handlers for them, and write code that calls their methods. You can also create sessions, set their properties, and call their methods at runtime.

Note Creating additional sessions is optional unless an application runs concurrent queries against a database or the application is multi-threaded.

To enable dynamic creation of a session component at runtime, follow these steps:

1. Declare a *TSession* variable.
2. Instantiate a new session by calling the *Create* method. The constructor sets up an empty list of database components for the session, sets the *KeepConnections* property to *True*, and adds the session to the list of sessions maintained by the application's session list component.
3. Set the *SessionName* property for the new session to a unique name. This property is used to associate database components with the session. For more information about the *SessionName* property, see "Naming a session" on page 20-28.
4. Activate the session and optionally adjust its properties.

You can also create and open sessions using the *OpenSession* method of *TSessionList*. Using *OpenSession* is safer than calling *Create*, because *OpenSession* only creates a session if it does not already exist. For information about *OpenSession*, see "Managing multiple sessions" on page 20-28.

The following code creates a new session component, assigns it a name, and opens the session for database operations that follow (not shown here). After use, it is destroyed with a call to the *Free* method.

Note Never delete the default session.

```
var
  SecondSession: TSession;
begin
  SecondSession := TSession.Create(Form1);
  with SecondSession do
    try
```

```
      SessionName := 'SecondSession';
      KeepConnections := False;
      Open;
      ...
    finally
      SecondSession.Free;
    end;
end;
```

Naming a session

A session’s *SessionName* property is used to name the session so that you can associate databases and datasets with it. For the default session, *SessionName* is “Default,” For each additional session component you create, you must set its *SessionName* property to a unique value.

Database and dataset components have *SessionName* properties that correspond to the *SessionName* property of a session component. If you leave the *SessionName* property blank for a database or dataset component it is automatically associated with the default session. You can also set *SessionName* for a database or dataset component to a name that corresponds to the *SessionName* of a session component you create.

The following code uses the *OpenSession* method of the default *TSessionList* component, *Sessions*, to open a new session component, sets its *SessionName* to “InterBaseSession,” activate the session, and associate an existing database component *Database1* with that session:

```
var
  IBSession: TSession;
  ...
begin
  IBSession := Sessions.OpenSession('InterBaseSession');
  Database1.SessionName := 'InterBaseSession';
end;
```

Managing multiple sessions

If you create a single application that uses multiple threads to perform database operations, you must create one additional session for each thread. The BDE page on the Component palette contains a session component that you can place in a data module or on a form at design time.

Important When you place a session component, you must also set its *SessionName* property to a unique value so that it does not conflict with the default session’s *SessionName* property.

Placing a session component at design time presupposes that the number of threads (and therefore sessions) required by the application at runtime is static. More likely, however, is that an application needs to create sessions dynamically. To create sessions dynamically, call the *OpenSession* method of the global *Sessions* object at runtime.

OpenSession requires a single parameter, a name for the session that is unique across all session names for the application. The following code dynamically creates and activates a new session with a uniquely generated name:

```
Sessions.OpenSession('RunTimeSession' + IntToStr(Sessions.Count + 1));
```

This statement generates a unique name for a new session by retrieving the current number of sessions, and adding one to that value. Note that if you dynamically create and destroy sessions at runtime, this example code will not work as expected. Nevertheless, this example illustrates how to use the properties and methods of *Sessions* to manage multiple sessions.

Sessions is a variable of type *TSessionList* that is automatically instantiated for BDE-based database applications. You use the properties and methods of *Sessions* to keep track of multiple sessions in a multi-threaded database application. Table 20.5 summarizes the properties and methods of the *TSessionList* component:

Table 20.5 TSessionList properties and methods

Property or Method	Purpose
Count	Returns the number of sessions, both active and inactive, in the session list.
FindSession	Searches for a session with a specified name and returns a pointer to it, or **nil** if there is no session with the specified name. If passed a blank session name, *FindSession* returns a pointer to the default session, *Session*.
GetSessionNames	Populates a string list with the names of all currently instantiated session components. This procedure always adds at least one string, “Default” for the default session.
List	Returns the session component for a specified session name. If there is no session with the specified name, an exception is raised.
OpenSession	Creates and activates a new session or reactivates an existing session for a specified session name.
Sessions	Accesses the session list by ordinal value.

As an example of using *Sessions* properties and methods in a multi-threaded application, consider what happens when you want to open a database connection. To determine if a connection already exists, use the *Sessions* property to walk through each session in the sessions list, starting with the default session. For each session component, examine its *Databases* property to see if the database in question is open. If you discover that another thread is already using the desired database, examine the next session in the list.

If an existing thread is not using the database, then you can open the connection within that session.

If, on the other hand, all existing threads are using the database, you must open a new session in which to open another database connection.

If you are replicating a data module that contains a session in a multi-threaded application, where each thread contains its own copy of the data module, you can use the *AutoSessionName* property to make sure that all datasets in the data module use the correct session. Setting *AutoSessionName* to *True* causes the session to generate its own unique name dynamically when it is created at runtime. It then assigns this name to every dataset in the data module, overriding any explicitly set session names. This ensures that each thread has its own session, and each dataset uses the session in its own data module.

Using transactions with the BDE

By default, the BDE provides implicit transaction control for your applications. When an application is under implicit transaction control, a separate transaction is used for each record in a dataset that is written to the underlying database. Implicit transactions guarantee both a minimum of record update conflicts and a consistent view of the database. On the other hand, because each row of data written to a database takes place in its own transaction, implicit transaction control can lead to excessive network traffic and slower application performance. Also, implicit transaction control will not protect logical operations that span more than one record.

If you explicitly control transactions, you can choose the most effective times to start, commit, and roll back your transactions. When you develop applications in a multi-user environment, particularly when your applications run against a remote SQL server, you should control transactions explicitly.

There are two mutually exclusive ways to control transactions explicitly in a BDE-based database application:

- Use the database component to control transactions. The main advantage to using the methods and properties of a database component is that it provides a clean, portable application that is not dependent on a particular database or server. This type of transaction control is supported by all database connection components, and described in “Managing transactions” on page 17-5
- Use passthrough SQL in a query component to pass SQL statements directly to remote SQL or ODBC servers. The main advantage to passthrough SQL is that you can use the advanced transaction management capabilities of a particular database server, such as schema caching. To understand the advantages of your server’s transaction management model, see your database server documentation. For more information about using passthrough SQL, see “Using passthrough SQL” below.

When working with local databases, you can only use the database component to create explicit transactions (local databases do not support passthrough SQL). However, there are limitations to using local transactions. For more information on using local transactions, see “Using local transactions” on page 20-31.

Note You can minimize the number of transactions you need by caching updates. For more information about cached updates, see “Using a client dataset to cache updates” on page 23-15 and “Using the BDE to cache updates” on page 20-32.

Using passthrough SQL

With passthrough SQL, you use a *TQuery*, *TStoredProc*, or *TUpdateSQL* component to send an SQL transaction control statement directly to a remote database server. The BDE does not process the SQL statement. Using passthrough SQL enables you to take direct advantage of the transaction controls offered by your server, especially when those controls are non-standard.

To use passthrough SQL to control a transaction, you must

- Install the proper SQL Links drivers. If you chose the “Typical” installation when installing Delphi, all SQL Links drivers are already properly installed.
- Configure your network protocol. See your network administrator for more information.
- Have access to a database on a remote server.
- Set SQLPASSTHRU MODE to NOT SHARED using the SQL Explorer. SQLPASSTHRU MODE specifies whether the BDE and passthrough SQL statements can share the same database connections. In most cases, SQLPASSTHRU MODE is set to SHARED AUTOCOMMIT. However, you can’t share database connections when using transaction control statements. For more information about SQLPASSTHRU modes, see the help file for the BDE Administration utility.

Note When SQLPASSTHRU MODE is NOT SHARED, you must use separate database components for datasets that pass SQL transaction statements to the server and datasets that do not.

Using local transactions

The BDE supports local transactions against Paradox, dBASE, Access, and FoxPro tables. From a coding perspective, there is no difference to you between a local transaction and a transaction against a remote database server.

Note When using transactions with local Paradox, dBASE, Access, and FoxPro tables, set *TransIsolation* to *tiDirtyRead* instead of using the default value of *tiReadCommitted*. A BDE error is returned if *TransIsolation* is set to anything but *tiDirtyRead* for local tables.

When a transaction is started against a local table, updates performed against the table are logged. Each log record contains the old record buffer for a record. When a transaction is active, records that are updated are locked until the transaction is committed or rolled back. On rollback, old record buffers are applied against updated records to restore them to their pre-update states.

Local transactions are more limited than transactions against SQL servers or ODBC drivers. In particular, the following limitations apply to local transactions:

- Automatic crash recovery is not provided.
- Data definition statements are not supported.
- Transactions cannot be run against temporary tables.
- *TransIsolation* level must only be set to *tiDirtyRead*.
- For Paradox, local transactions can only be performed on tables with valid indexes. Data cannot be rolled back on Paradox tables that do not have indexes.
- Only a limited number of records can be locked and modified. With Paradox tables, you are limited to 255 records. With dBASE the limit is 100.

- Transactions cannot be run against the BDE ASCII driver.
- Closing a cursor on a table during a transaction rolls back the transaction unless:
  - Several tables are open.
  - The cursor is closed on a table to which no changes were made.

Using the BDE to cache updates

The recommended approach for caching updates is to use a client dataset (*TBDEClientDataSet*) or to connect the BDE-dataset to a client dataset using a dataset provider. The advantages of using a client dataset are discussed in "Using a client dataset to cache updates" on page 23-15.

For simple cases, however, you may choose to use the BDE to cache updates instead. BDE-enabled datasets and *TDatabase* components provide built-in properties, methods, and events for handling cached updates. Most of these correspond directly to the properties, methods, and events that you use with client datasets and dataset providers when using a client dataset to cache updates. The following table lists these properties, events, and methods and the corresponding properties, methods and events on *TBDEClientDataSet*:

Table 20.6 Properties, methods, and events for cached updates

On BDE-enabled datasets (or TDatabase)	On TBDEClientDataSet	Purpose
CachedUpdates	Not needed for client datasets, which always cache updates.	Determines whether cached updates are in effect for the dataset.
UpdateObject	Use a *BeforeUpdateRecord* event handler, or, if using *TClientDataSet*, use the *UpdateObject* property on the BDE-enabled source dataset.	Specifies the update object for updating read-only datasets.
UpdatesPending	*ChangeCount*	Indicates whether the local cache contains updated records that need to be applied to the database.
UpdateRecordTypes	*StatusFilter*	Indicates the kind of updated records to make visible when applying cached updates.
UpdateStatus	*UpdateStatus*	Indicates if a record is unchanged, modified, inserted, or deleted.
OnUpdateError	*OnReconcileError*	An event for handling update errors on a record-by-record basis.
OnUpdateRecord	*BeforeUpdateRecord*	An event for processing updates on a record-by-record basis.
ApplyUpdates *ApplyUpdates* (database)	*ApplyUpdates*	Applies records in the local cache to the database.

Table 20.6 Properties, methods, and events for cached updates (continued)

On BDE-enabled datasets (or TDatabase)	On TBDEClientDataSet	Purpose
CancelUpdates	*CancelUpdates*	Removes all pending updates from the local cache without applying them.
CommitUpdates	*Reconcile*	Clears the update cache following successful application of updates.
FetchAll	*GetNextPacket* (and *PacketRecords*)	Copies database records to the local cache for editing and updating.
RevertRecord	*RevertRecord*	Undoes updates to the current record if updates are not yet applied.

For an overview of the cached update process, see "Overview of using cached updates" on page 23-16.

Note Even if you are using a client dataset to cache updates, you may want to read the section about update objects on page 20-39. You can use update objects in the *BeforeUpdateRecord* event handler of *TBDEClientDataSet* or *TDataSetProvider* to apply updates from stored procedures or multi-table queries.

Enabling BDE-based cached updates

To use the BDE for cached updates, the BDE-enabled dataset must indicate that it should cache updates. This is specified by setting the *CachedUpdates* property to *True*. When you enable cached updates, a copy of all records is cached in local memory. Users view and edit this local copy of data. Changes, insertions, and deletions are also cached in memory. They accumulate in memory until the application applies those changes to the database server. If changed records are successfully applied to the database, the record of those changes are freed in the cache.

The dataset caches all updates until you set *CachedUpdates* to *False*. Applying cached updates does not disable further cached updates; it only writes the current set of changes to the database and clears them from memory. Canceling the updates by calling *CancelUpdates* removes all the changes currently in the cache, but does not stop the dataset from caching any subsequent changes.

Note If you disable cached updates by setting *CachedUpdates* to *False*, any pending changes that you have not yet applied are discarded without notification. To prevent losing changes, test the *UpdatesPending* property before disabling cached updates.

Applying BDE-based cached updates

Applying updates is a two-phase process that should occur in the context of a database component's transaction so that your application can recover gracefully from errors. For information about transaction handling with database components, see "Managing transactions" on page 17-5.

When applying updates under database transaction control, the following events take place:

1. A database transaction starts.
2. Cached updates are written to the database (phase 1). If you provide it, an *OnUpdateRecord* event is triggered once for each record written to the database. If an error occurs when a record is applied to the database, the *OnUpdateError* event is triggered if you provide one.
3. The transaction is committed if writes are successful or rolled back if they are not:

   If the database write is successful:

   - Database changes are committed, ending the database transaction.
   - Cached updates are committed, clearing the internal cache buffer (phase 2).

   If the database write is unsuccessful:

   - Database changes are rolled back, ending the database transaction.
   - Cached updates are not committed, remaining intact in the internal cache.

For information about creating and using an *OnUpdateRecord* event handler, see "Creating an OnUpdateRecord event handler" on page 20-36. For information about handling update errors that occur when applying cached updates, see "Handling cached update errors" on page 20-37.

Note Applying cached updates is particularly tricky when you are working with multiple datasets linked in a master/detail relationship because the order in which you apply updates to each dataset is significant. Usually, you must update master tables before detail tables, except when handling deleted records, where this order must be reversed. Because of this difficulty, it is strongly recommended that you use client datasets when caching updates in a master/detail form. Client datasets automatically handle all ordering issues with master/detail relationships.

There are two ways to apply BDE-based updates:

- You can apply updates using a database component by calling its *ApplyUpdates* method. This method is the simplest approach, because the database handles all details of managing a transaction for the update process and of clearing the dataset's cache when updating is complete.
- You can apply updates for a single dataset by calling the dataset's *ApplyUpdates* and *CommitUpdates* methods. When applying updates at the dataset level you must explicitly code the transaction that wraps the update process as well as explicitly call *CommitUpdates* to commit updates from the cache.

Important To apply updates from a stored procedure or an SQL query that does not return a live result set, you must use *TUpdateSQL* to specify how to perform updates. For updates to joins (queries involving two or more tables), you must provide one *TUpdateSQL* object for each table involved, and you must use the *OnUpdateRecord* event handler to invoke these objects to perform the updates. See "Using update objects to update a dataset" on page 20-39 for details.

Applying cached updates using a database

To apply cached updates to one or more datasets in the context of a database connection, call the database component's *ApplyUpdates* method. The following code applies updates to the *CustomersQuery* dataset in response to a button click event:

```
procedure TForm1.ApplyButtonClick(Sender: TObject);
begin
  // for local databases such as Paradox, dBASE, and FoxPro
  // set TransIsolation to DirtyRead
  if not (Database1.IsSQLBased) and not (Database1.TransIsolation = tiDirtyRead) then
    Database1.TransIsolation := tiDirtyRead;
  Database1.ApplyUpdates([CustomersQuery]);
end;
```

The above sequence writes cached updates to the database in the context of an automatically-generated transaction. If successful, it commits the transaction and then commits the cached updates. If unsuccessful, it rolls back the transaction and leaves the update cache unchanged. In this latter case, you should handle cached update errors through a dataset's *OnUpdateError* event. For more information about handling update errors, see "Handling cached update errors" on page 20-37.

The main advantage to calling a database component's *ApplyUpdates* method is that you can update any number of dataset components that are associated with the database. The parameter for the *ApplyUpdates* method for a database is an array of *TDBDataSet*. For example, the following code applies updates for two queries:

```
if not (Database1.IsSQLBased) and not (Database1.TransIsolation = tiDirtyRead) then
  Database1.TransIsolation := tiDirtyRead;
Database1.ApplyUpdates([CustomerQuery, OrdersQuery]);
```

Applying cached updates with dataset component methods

You can apply updates for individual BDE-enabled datasets directly using the dataset's *ApplyUpdates* and *CommitUpdates* methods. Each of these methods encapsulate one phase of the update process:

1. *ApplyUpdates* writes cached changes to a database (phase 1).
2. *CommitUpdates* clears the internal cache when the database write is successful (phase 2).

The following code illustrates how you apply updates within a transaction for the *CustomerQuery* dataset:

```
procedure TForm1.ApplyButtonClick(Sender: TObject)
begin
  Database1.StartTransaction;
  try
    if not (Database1.IsSQLBased) and not (Database1.TransIsolation = tiDirtyRead) then
      Database1.TransIsolation := tiDirtyRead;
    CustomerQuery.ApplyUpdates;              { try to write the updates to the database }
    Database1.Commit;                                   { on success, commit the changes }
  except
    Database1.Rollback;                                   { on failure, undo any changes }
```

```
      raise;              { raise the exception again to prevent a call to CommitUpdates }
    end;
    CustomerQuery.CommitUpdates;                    { on success, clear the internal cache }
  end;
```

If an exception is raised during the *ApplyUpdates* call, the database transaction is rolled back. Rolling back the transaction ensures that the underlying database table is not changed. The *raise* statement inside the try...except block re*raises* the exception, thereby preventing the call to *CommitUpdates*. Because *CommitUpdates* is not called, the internal cache of updates is not cleared so that you can handle error conditions and possibly retry the update.

Creating an OnUpdateRecord event handler

When a BDE-enabled dataset applies its cached updates, it iterates through the changes recorded in its cache, attempting to apply them to the corresponding records in the base table. As the update for each changed, deleted, or newly inserted record is about to be applied, the dataset component's *OnUpdateRecord* event fires.

Providing a handler for the *OnUpdateRecord* event allows you to perform actions just before the current record's update is actually applied. Such actions can include special data validation, updating other tables, special parameter substitution, or executing multiple update objects. A handler for the *OnUpdateRecord* event affords you greater control over the update process.

Here is the skeleton code for an *OnUpdateRecord* event handler:

```
procedure TForm1.DataSetUpdateRecord(DataSet: TDataSet;
 UpdateKind: TUpdateKind; var UpdateAction: TUpdateAction);
begin
  { perform updates here... }
end;
```

The *DataSet* parameter specifies the cached dataset with updates.

The *UpdateKind* parameter indicates the type of update that needs to be performed for the current record. Values for *UpdateKind* are *ukModify*, *ukInsert*, and *ukDelete*. If you are using an update object, you need to pass this parameter to the update object when applying the update. You may also need to inspect this parameter if your handler performs any special processing based on the kind of update.

The *UpdateAction* parameter indicates whether you applied the update. Values for *UpdateAction* are *uaFail* (the default), *uaAbort*, *uaSkip*, *uaRetry*, *uaApplied*. If your event handler successfully applies the update, change this parameter to *uaApplied* before exiting. If you decide not to update the current record, change the value to *uaSkip* to preserve unapplied changes in the cache. If you do not change the value for *UpdateAction*, the entire update operation for the dataset is aborted and an exception is raised. You can suppress the error message (raising a silent exception) by changing *UpdateAction* to *uaAbort*.

In addition to these parameters, you will typically want to make use of the *OldValue* and *NewValue* properties for the field component associated with the current record. *OldValue* gives the original field value that was fetched from the database. It can be useful in locating the database record to update. *NewValue* is the edited value in the update you are trying to apply.

Important An *OnUpdateRecord* event handler, like an *OnUpdateError* or *OnCalcFields* event handler, should never call any methods that change the current record in a dataset.

The following example illustrates how to use these parameters and properties. It uses a *TTable* component named *UpdateTable* to apply updates. In practice, it is easier to use an update object, but using a table illustrates the possibilities more clearly.

```
procedure TForm1.EmpAuditUpdateRecord(DataSet: TDataSet;
  UpdateKind: TUpdateKind; var UpdateAction: TUpdateAction);
begin
  if UpdateKind = ukInsert then
    UpdateTable.AppendRecord([DataSet.Fields[0].NewValue, DataSet.Fields[1].NewValue])
  else
    if UpdateTable.Locate('KeyField', VarToStr(DataSet.Fields[1].OldValue), []) then
      case UpdateKind of
        ukModify:
          begin
            UpdateTable.Edit;
            UpdateTable.Fields[1].AsString := VarToStr(DataSet.Fields[1].NewValue);
            UpdateTable.Post;
          end;
        ukInsert:
          begin
            UpdateTable.Insert;
            UpdateTable.Fields[1].AsString := VarToStr(DataSet.Fields[1].NewValue);
            UpdateTable.Post;
          end;
        ukDelete: UpdateTable.Delete;
      end;
        UpdateAction := uaApplied;
end;
```

Handling cached update errors

The Borland Database Engine (BDE) specifically checks for user update conflicts and other conditions when attempting to apply updates, and reports any errors. The dataset component's *OnUpdateError* event enables you to catch and respond to errors. You should create a handler for this event if you use cached updates. If you do not, and an error occurs, the entire update operation fails.

Here is the skeleton code for an *OnUpdateError* event handler:

```
procedure TForm1.DataSetUpdateError(DataSet: TDataSet; E: EDatabaseError;
  UpdateKind: TUpdateKind; var UpdateAction: TUpdateAction);
begin
  { ... perform update error handling here ... }
end;
```

DataSet references the dataset to which updates are applied. You can use this dataset to access new and old values during error handling. The original values for fields in each record are stored in a read-only *TField* property called *OldValue*. Changed values are stored in the analogous *TField* property *NewValue*. These values provide the only way to inspect and change update values in the event handler.

Warning Do not call any dataset methods that change the current record (such as *Next* and *Prior*). Doing so causes the event handler to enter an endless loop.

The *E* parameter is usually of type *EDBEngineError*. From this exception type, you can extract an error message that you can display to users in your error handler. For example, the following code could be used to display the error message in the caption of a dialog box:

```
ErrorLabel.Caption := E.Message;
```

This parameter is also useful for determining the actual cause of the update error. You can extract specific error codes from *EDBEngineError*, and take appropriate action based on it.

The *UpdateKind* parameter describes the type of update that generated the error. Unless your error handler takes special actions based on the type of update being carried out, your code probably will not make use of this parameter.

The following table lists possible values for *UpdateKind*:

Table 20.7 UpdateKind values

Value	Meaning
ukModify	Editing an existing record caused an error.
ukInsert	Inserting a new record caused an error.
ukDelete	Deleting an existing record caused an error.

UpdateAction tells the BDE how to proceed with the update process when your event handler exits. When your update error handler is first called, the value for this parameter is always set to *uaFail*. Based on the error condition for the record that caused the error and what you do to correct it, you typically set *UpdateAction* to a different value before exiting the handler:

- If your error handler can correct the error condition that caused the handler to be invoked, set *UpdateAction* to the appropriate action to take on exit. For error conditions you correct, set *UpdateAction* to *uaRetry* to apply the update for the record again.
- When set to *uaSkip*, the update for the row that caused the error is skipped, and the update for the record remains in the cache after all other updates are completed.
- Both *uaFail* and *uaAbort* cause the entire update operation to end. *uaFail* raises an exception and displays an error message. *uaAbort* raises a silent exception (does not display an error message).

The following code shows an *OnUpdateError* event handler that checks to see if the update error is related to a key violation, and if it is, it sets the *UpdateAction* parameter to *uaSkip*:

```
{ Add 'Bde' to your uses clause for this example }
if (E is EDBEngineError) then
  with EDBEngineError(E) do begin
    if Errors[ErrorCount - 1].ErrorCode = DBIERR_KEYVIOL then
      UpdateAction := uaSkip                      { key violation, just skip this record }
    else
      UpdateAction := uaAbort;              { don't know what's wrong, abort the update }
  end;
```

Note If an error occurs during the application of cached updates, an exception is *raised* and an error message displayed. Unless the *ApplyUpdates* is called from within a try...except construct, an error message to the user displayed from inside your *OnUpdateError* event handler may cause your application to display the same error message twice. To prevent error message duplication, set *UpdateAction* to *uaAbort* to turn off the system-generated error message display.

Using update objects to update a dataset

When the BDE-enabled dataset represents a stored procedure or a query that is not "live", it is not possible to apply updates directly from the dataset. Such datasets may also cause a problem when you use a client dataset to cache updates. Whether you are using the BDE or a client dataset to cache updates, you can handle these problem datasets by using an update object:

1. If you are using a client dataset, use an external provider component with *TClientDataSet* rather than *TBDEClientDataSet*. This is so you can set the *UpdateObject* property of the BDE-enabled source dataset (step 3).
2. Add a *TUpdateSQL* component to the same data module as the BDE-enabled dataset.
3. Set the BDE-enabled dataset component's *UpdateObject* property to the *TUpdateSQL* component in the data module.
4. Specify the SQL statements needed to perform updates using the update object's *ModifySQL*, *InsertSQL*, and *DeleteSQL* properties. You can use the Update SQL editor to help you compose these statements.
5. Close the dataset.
6. Set the dataset component's *CachedUpdates* property to *True* or link the dataset to the client dataset using a dataset provider.
7. Reopen the dataset.

Note Sometimes, you need to use multiple update objects. For example, when updating a multi-table join or a stored procedure that represents data from multiple datasets, you must provide one *TUpdateSQL* object for each table you want to update. When using multiple update objects, you can't simply associate the update object with the dataset by setting the *UpdateObject* property. Instead, you must manually call the update object from an *OnUpdateRecord* event handler (when using the BDE to cache updates) or a *BeforeUpdateRecord* event handler (when using a client dataset).

The update object actually encapsulates three *TQuery* components. Each of these query components perform a single update task. One query component provides an SQL UPDATE statement for modifying existing records; a second query component provides an INSERT statement to add new records to a table; and a third component provides a DELETE statement to remove records from a table.

When you place an update component in a data module, you do not see the query components it encapsulates. They are created by the update component at runtime based on three update properties for which you supply SQL statements:

- *ModifySQL* specifies the UPDATE statement.
- *InsertSQL* specifies the INSERT statement.
- *DeleteSQL* specifies the DELETE statement.

At runtime, when the update component is used to apply updates, it:

1. Selects an SQL statement to execute based on whether the current record is modified, inserted, or deleted.
2. Provides parameter values to the SQL statement.
3. Prepares and executes the SQL statement to perform the specified update.

Creating SQL statements for update components

To update a record in an associated dataset, an update object uses one of three SQL statements. Each update object can only update a single table, so the object's update statements must each reference the same base table.

The three SQL statements delete, insert, and modify records cached for update. You must provide these statements as update object's *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties. You can provide these values at design time or at runtime. For example, the following code specifies a value for the *DeleteSQL* property at runtime:

```
with UpdateSQL1.DeleteSQL do begin
  Clear;
  Add('DELETE FROM Inventory I');
  Add('WHERE (I.ItemNo = :OLD_ItemNo)');
end;
```

At design time, you can use the Update SQL editor to help you compose the SQL statements that apply updates.

Update objects provide automatic parameter binding for parameters that reference the dataset's original and updated field values. Typically, therefore, you insert parameters with specially formatted names when you compose the SQL statements. For information on using these parameters, see "Understanding parameter substitution in update SQL statements" on page 20-41.

Using the Update SQL editor

To create the SQL statements for an update component,

1. Using the Object Inspector, select the name of the update object from the drop-down list for the dataset's *UpdateObject* property. This step ensures that the Update SQL editor you invoke in the next step can determine suitable default values to use for SQL generation options.
2. Right-click the update object and select UpdateSQL Editor from the context menu. This displays the Update SQL editor. The editor creates SQL statements for the update object's *ModifySQL*, *InsertSQL*, and *DeleteSQL* properties based on the underlying data set and on the values you supply to it.

The Update SQL editor has two pages. The Options page is visible when you first invoke the editor. Use the Table Name combo box to select the table to update. When you specify a table name, the Key Fields and Update Fields list boxes are populated with available columns.

The Update Fields list box indicates which columns should be updated. When you first specify a table, all columns in the Update Fields list box are selected for inclusion. You can multi-select fields as desired.

The Key Fields list box is used to specify the columns to use as keys during the update. For Paradox, dBASE, and FoxPro the columns you specify here must correspond to an existing index, but this is not a requirement for remote SQL databases. Instead of setting Key Fields you can click the Primary Keys button to choose key fields for the update based on the table's primary index. Click Dataset Defaults to return the selection lists to the original state: all fields selected as keys and all selected for update.

Check the Quote Field Names check box if your server requires quotation marks around field names.

After you specify a table, select key columns, and select update columns, click Generate SQL to generate the preliminary SQL statements to associate with the update component's *ModifySQL*, *InsertSQL*, and *DeleteSQL* properties. In most cases you will want or need to fine tune the automatically generated SQL statements.

To view and modify the generated SQL statements, select the SQL page. If you have generated SQL statements, then when you select this page, the statement for the *ModifySQL* property is already displayed in the SQL Text memo box. You can edit the statement in the box as desired.

Important Keep in mind that generated SQL statements are starting points for creating update statements. You may need to modify these statements to make them execute correctly. For example, when working with data that contains NULL values, you need to modify the WHERE clause to read

```
WHERE field IS NULL
```

rather then using the generated field variable. Test each of the statements directly yourself before accepting them.

Use the Statement Type radio buttons to switch among generated SQL statements and edit them as desired.

To accept the statements and associate them with the update component's SQL properties, click OK.

Understanding parameter substitution in update SQL statements

Update SQL statements use a special form of parameter substitution that enables you to substitute old or new field values in record updates. When the Update SQL editor generates its statements, it determines which field values to use. When you write the update SQL, you specify the field values to use.

When the parameter name matches a column name in the table, the new value in the field in the cached update for the record is automatically used as the value for the parameter. When the parameter name matches a column name prefixed by the string

"OLD_", then the old value for the field will be used. For example, in the update SQL statement below, the parameter :LastName is automatically filled with the new field value in the cached update for the inserted record.

```
INSERT INTO Names
(LastName, FirstName, Address, City, State, Zip)
VALUES (:LastName, :FirstName, :Address, :City, :State, :Zip)
```

New field values are typically used in the *InsertSQL* and *ModifySQL* statements. In an update for a modified record, the new field value from the update cache is used by the UPDATE statement to replace the old field value in the base table updated.

In the case of a deleted record, there are no new values, so the *DeleteSQL* property uses the ":OLD_FieldName" syntax. Old field values are also normally used in the WHERE clause of the SQL statement for a modified or deletion update to determine which record to update or delete.

In the WHERE clause of an UPDATE or DELETE update SQL statement, supply at least the minimal number of parameters to uniquely identify the record in the base table that is updated with the cached data. For instance, in a list of customers, using just a customer's last name may not be sufficient to uniquely identify the correct record in the base table; there may be a number of records with "Smith" as the last name. But by using parameters for last name, first name, and phone number could be a distinctive enough combination. Even better would be a unique field value like a customer number.

Note If you create SQL statements that contain parameters that do not refer the edited or original field values, the update object does not know how to bind their values. You can, however, do this manually, using the update object's *Query* property. See "Using an update component's Query property" on page 20-46 for details.

Composing update SQL statements

At design time, you can use the Update SQL editor to write the SQL statements for the *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties. If you do not use the Update SQL editor, or if you want to modify the generated statements, you should keep in mind the following guidelines when writing statements to delete, insert, and modify records in the base table.

The *DeleteSQL* property should contain only an SQL statement with the DELETE command. The base table to be updated must be named in the FROM clause. So that the SQL statement only deletes the record in the base table that corresponds to the record deleted in the update cache, use a WHERE clause. In the WHERE clause, use a parameter for one or more fields to uniquely identify the record in the base table that corresponds to the cached update record. If the parameters are named the same as the field and prefixed with "OLD_", the parameters are automatically given the values from the corresponding field from the cached update record. If the parameter are named in any other manner, you must supply the parameter values.

```
DELETE FROM Inventory I
WHERE (I.ItemNo = :OLD_ItemNo)
```

Some table types might not be able to find the record in the base table when fields used to identify the record contain NULL values. In these cases, the delete update fails for those records. To accommodate this, add a condition for those fields that might contain NULLs using the IS NULL predicate (in addition to a condition for a non-NULL value). For example, when a FirstName field may contain a NULL value:

```
DELETE FROM Names
WHERE (LastName = :OLD_LastName) AND
  ((FirstName = :OLD_FirstName) OR (FirstName IS NULL))
```

The *InsertSQL* statement should contain only an SQL statement with the INSERT command. The base table to be updated must be named in the INTO clause. In the VALUES clause, supply a comma-separated list of parameters. If the parameters are named the same as the field, the parameters are automatically given the value from the cached update record. If the parameter are named in any other manner, you must supply the parameter values. The list of parameters supplies the values for fields in the newly inserted record. There must be as many value parameters as there are fields listed in the statement.

```
INSERT INTO Inventory
(ItemNo, Amount)
VALUES (:ItemNo, 0)
```

The *ModifySQL* statement should contain only an SQL statement with the UPDATE command. The base table to be updated must be named in the FROM clause. Include one or more value assignments in the SET clause. If values in the SET clause assignments are parameters named the same as fields, the parameters are automatically given values from the fields of the same name in the updated record in the cache. You can assign additional field values using other parameters, as long as the parameters are not named the same as any fields and you manually supply the values. As with the *DeleteSQL* statement, supply a WHERE clause to uniquely identify the record in the base table to be updated using parameters named the same as the fields and prefixed with "OLD_". In the update statement below, the parameter :ItemNo is automatically given a value and :Price is not.

```
UPDATE Inventory I
SET I.ItemNo = :ItemNo, Amount = :Price
WHERE (I.ItemNo = :OLD_ItemNo)
```

Considering the above update SQL, take an example case where the application end-user modifies an existing record. The original value for the ItemNo field is 999. In a grid connected to the cached dataset, the end-user changes the ItemNo field value to 123 and Amount to 20. When the ApplyUpdates method is invoked, this SQL statement affects all records in the base table where the ItemNo field is 999, using the old field value in the parameter :OLD_ItemNo. In those records, it changes the ItemNo field value to 123 (using the parameter :ItemNo, the value coming from the grid) and Amount to 20.

Using multiple update objects

When more than one base table referenced in the update dataset needs to be updated, you need to use multiple update objects: one for each base table updated. Because the dataset component's *UpdateObject* only allows one update object to be associated with the dataset, you must associate each update object with a dataset by setting its *DataSet* property to the name of the dataset.

Tip When using multiple update objects, you can use *TBDEClientDataSet* instead of *TClientDataSet* with an external provider. This is because you do not need to set the source dataset's *UpdateObject* property.

The *DataSet* property for update objects is not available at design time in the Object Inspector. You can only set this property at runtime.

```
UpdateSQL1.DataSet := Query1;
```

The update object uses this dataset to obtain original and updated field values for parameter substitution and, if it is a BDE-enabled dataset, to identify the session and database to use when applying the updates. So that parameter substitution will work correctly, the update object's *DataSet* property must be the dataset that contains the updated field values. When using the BDE-enabled dataset to cache updates, this is the BDE-enabled dataset itself. When using a client dataset, this is a client dataset that is provided as a parameter to the *BeforeUpdateRecord* event handler.

When the update object has not been assigned to the dataset's *UpdateObject* property, its SQL statements are not automatically executed when you call *ApplyUpdates*. To update records, you must manually call the update object from an *OnUpdateRecord* event handler (when using the BDE to cache updates) or a *BeforeUpdateRecord* event handler (when using a client dataset). In the event handler, the minimum actions you need to take are

- If you are using a client dataset to cache updates, you must be sure that the updates object's *DatabaseName* and *SessionName* properties are set to the *DatabaseName* and *SessionName* properties of the source dataset.
- The event handler must call the update object's *ExecSQL* or *Apply* method. This invokes the update object for each record that requires updating. For more information about executing update statements, see "Executing the SQL statements" below.
- Set the event handler's *UpdateAction* parameter to *uaApplied* (*OnUpdateRecord*) or the *Applied* parameter to *True* (*BeforeUpdateRecord*).

You may optionally perform data validation, data modification, or other operations that depend on each record's update.

Warning If you call an update object's *ExecSQL* or *Apply* method in an *OnUpdateRecord* event handler, be sure that you do not set the dataset's *UpdateObject* property to that update object. Otherwise, this will result in a second attempt to apply each record's update.

Executing the SQL statements

When you use multiple update objects, you do not associate the update objects with a dataset by setting its *UpdateObject* property. As a result, the appropriate statements are not automatically executed when you apply updates. Instead, you must explicitly invoke the update object in code.

There are two ways to invoke the update object. Which way you choose depends on whether the SQL statement uses parameters to represent field values:

- If the SQL statement to execute uses parameters, call the *Apply* method.

- If the SQL statement to execute does not use parameters, it is more efficient to call the *ExecSQL* method.

Note If the SQL statement uses parameters other than the built-in types (for the original and updated field values), you must manually supply parameter values instead of relying on the parameter substitution provided by the *Apply* method. See "Using an update component's Query property" on page 20-46 for information on manually providing parameter values.

For information about the default parameter substitution for parameters in an update object's SQL statements, see "Understanding parameter substitution in update SQL statements" on page 20-41.

Calling the Apply method

The *Apply* method for an update component manually applies updates for the current record. There are two steps involved in this process:

1. Initial and edited field values for the record are bound to parameters in the appropriate SQL statement.
2. The SQL statement is executed.

Call the *Apply* method to apply the update for the current record in the update cache. The *Apply* method is most often called from within a handler for the dataset's *OnUpdateRecord* event or from a provider's *BeforeUpdateRecord* event handler.

Warning If you use the dataset's *UpdateObject* property to associate dataset and update object, *Apply* is called automatically. In that case, do not call *Apply* in an *OnUpdateRecord* event handler as this will result in a second attempt to apply the current record's update.

OnUpdateRecord event handlers indicate the type of update that needs to be applied with an *UpdateKind* parameter of type *TUpdateKind*. You must pass this parameter to the *Apply* method to indicate which update SQL statement to use. The following code illustrates this using a *BeforeUpdateRecord* event handler:

```
procedure TForm1.BDEClientDataSet1BeforeUpdateRecord(Sender: TObject; SourceDS: TDataSet;
          DeltaDS: TCustomClientDataSet; UpdateKind: TUpdateKind; var Applied: Boolean);
begin
  with UpdateSQL1 do
  begin
    DataSet := DeltaDS;
    DatabaseName := (SourceDS as TDBDataSet).DatabaseName;
    SessionName := (SourceDS as TDBDataSet).SessionName;
    Apply(UpdateKind);
    Applied := True;
  end;
end;
```

Calling the ExecSQL method

The *ExecSQL* method for an update component manually applies updates for the current record. Unlike the *Apply* method, *ExecSQL* does not bind parameters in the SQL statement before executing it. The *ExecSQL* method is most often called from within a handler for the *OnUpdateRecord* event (when using the BDE) or the *BeforeUpdateRecord* event (when using a client dataset).

Because *ExecSQL* does not bind parameter values, it is used primarily when the update object's SQL statements do not include parameters. You can use *Apply* instead, even when there are no parameters, but *ExecSQL* is more efficient because it does not check for parameters.

If the SQL statements include parameters, you can still call *ExecSQL*, but only after explicitly binding parameters. If you are using the BDE to cache updates, you can explicitly bind parameters by setting the update object's *DataSet* property and then calling its *SetParams* method. When using a client dataset to cache updates, you must supply parameters to the underlying query object maintained by *TUpdateSQL*. For information on how to do this, see "Using an update component's Query property" on page 20-46.

Warning If you use the dataset's *UpdateObject* property to associate dataset and update object, *ExecSQL* is called automatically. In that case, do not call *ExecSQL* in an *OnUpdateRecord* or *BeforeUpdateRecord* event handler as this will result in a second attempt to apply the current record's update.

OnUpdateRecord and *BeforeUpdateRecord* event handlers indicate the type of update that needs to be applied with an *UpdateKind* parameter of type *TUpdateKind*. You must pass this parameter to the *ExecSQL* method to indicate which update SQL statement to use. The following code illustrates this using a *BeforeUpdateRecord* event handler:

```
procedure TForm1.BDEClientDataSet1BeforeUpdateRecord(Sender: TObject; SourceDS: TDataSet;
         DeltaDS: TCustomClientDataSet; UpdateKind: TUpdateKind; var Applied: Boolean);
begin
  with UpdateSQL1 do
  begin
    DatabaseName := (SourceDS as TDBDataSet).DatabaseName;
    SessionName := (SourceDS as TDBDataSet).SessionName;
    ExecSQL(UpdateKind);
    Applied := True;
  end;
end;
```

If an exception is raised during the execution of the update program, execution continues in the *OnUpdateError* event, if it is defined.

Using an update component's Query property

The *Query* property of an update component provides access to the query components that implement its *DeleteSQL*, *InsertSQL*, and *ModifySQL* statements. In most applications, there is no need to access these query components directly: you can use the *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties to specify the statements these queries execute, and execute them by calling the update object's *Apply* or *ExecSQL* method. There are times, however, when you may need to directly manipulate the query component. In particular, the *Query* property is useful when you want to supply your own values for parameters in the SQL statements rather than relying on the update object's automatic parameter binding to old and new field values.

Note The *Query* property is only accessible at runtime.

The *Query* property is indexed on a *TUpdateKind* value:

- Using an index of *ukModify* accesses the query that updates existing records.
- Using an index of *ukInsert* accesses the query that inserts new records.
- Using an index of *ukDelete* accesses the query that deletes records.

The following shows how to use the *Query* property to supply parameter values that can't be bound automatically:

```
procedure TForm1.BDEClientDataSet1BeforeUpdateRecord(Sender: TObject; SourceDS: TDataSet;
          DeltaDS: TCustomClientDataSet; UpdateKind: TUpdateKind; var Applied: Boolean);
begin
  UpdateSQL1.DataSet := DeltaDS; { required for the automatic parameter substitution }
  with UpdateSQL1.Query[UpdateKind] do
  begin
    { Make sure the query has the correct DatabaseName and SessionName }
    DatabaseName := (SourceDS as TDBDataSet).DatabaseName;
    SessionName := (SourceDS as TDBDataSet).SessionName;
    ParamByName('TimeOfUpdate').Value = Now;
  end;
  UpdateSQL1.Apply(UpdateKind); { now perform automatic substitutions and execute }
  Applied := True;
end;
```

Using TBatchMove

TBatchMove encapsulates Borland Database Engine (BDE) features that let you to duplicate a dataset, append records from one dataset to another, update records in one dataset with records from another dataset, and delete records from one dataset that match records in another dataset. *TBatchMove* is most often used to:

- Download data from a server to a local data source for analysis or other operations.
- Move a desktop database into tables on a remote server as part of an upsizing operation.

A batch move component can create tables on the destination that correspond to the source tables, automatically mapping the column names and data types as appropriate.

Creating a batch move component

To create a batch move component:

1. Place a table or query component for the dataset from which you want to import records (called the *Source* dataset) on a form or in a data module.
2. Place the dataset to which to move records (called the *Destination* dataset) on the form or data module.

3 Place a *TBatchMove* component from the BDE page of the Component palette in the data module or form, and set its *Name* property to a unique value appropriate to your application.

4 Set the *Source* property of the batch move component to the name of the table from which to copy, append, or update records. You can select tables from the drop-down list of available dataset components.

5 Set the *Destination* property to the dataset to create, append to, or update. You can select a destination table from the drop-down list of available dataset components.

- If you are appending, updating, or deleting, *Destination* must represent an existing database table.
- If you are copying a table and *Destination* represents an existing table, executing the batch move overwrites all of the current data in the destination table.
- If you are creating an entirely new table by copying an existing table, the resulting table has the name specified in the *Name* property of the table component to which you are copying. The resulting table type will be of a structure appropriate to the server specified by the *DatabaseName* property.

6 Set the *Mode* property to indicate the type of operation to perform. Valid operations are *batAppend* (the default), *batUpdate*, *batAppendUpdate*, *batCopy*, and *batDelete*. For information about these modes, see “Specifying a batch move mode” on page 20-49.

7 Optionally set the *Transliterate* property. If *Transliterate* is *True* (the default), character data is translated from the *Source* dataset’s character set to the *Destination* dataset’s character set as necessary.

8 Optionally set column mappings using the *Mappings* property. You need not set this property if you want batch move to match columns based on their position in the source and destination tables. For more information about mapping columns, see “Mapping data types” on page 20-50.

9 Optionally specify the *ChangedTableName*, *KeyViolTableName*, and *ProblemTableName* properties. Batch move stores problem records it encounters during the batch operation in the table specified by *ProblemTableName*. If you are updating a Paradox table through a batch move, key violations can be reported in the table you specify in *KeyViolTableName*. *ChangedTableName* lists all records that changed in the destination table as a result of the batch move operation. If you do not specify these properties, these error tables are not created or used. For more information about handling batch move errors, see “Handling batch move errors” on page 20-51.

Specifying a batch move mode

The *Mode* property specifies the operation a batch move component performs:

Table 20.8 Batch move modes

Property	Purpose
batAppend	Append records to the destination table.
batUpdate	Update records in the destination table with matching records from the source table. Updating is based on the current index of the destination table.
batAppendUpdate	If a matching record exists in the destination table, update it. Otherwise, append records to the destination table.
batCopy	Create the destination table based on the structure of the source table. If the destination table already exists, it is dropped and recreated.
batDelete	Delete records in the destination table that match records in the source table.

Appending records

To append data, the destination dataset must represent an existing table. During the append operation, the BDE converts data to appropriate data types and sizes for the destination dataset if necessary. If a conversion is not possible, an exception is thrown and the data is not appended.

Updating records

To update data, the destination dataset must represent an existing table and must have an index defined that enables records to be matched. If the primary index fields are used for matching, records with index fields in the destination dataset that match index fields records in the source dataset are overwritten with the source data. During the update operation, the BDE converts data to appropriate data types and sizes for the destination dataset if necessary.

Appending and updating records

To append and update data the destination dataset must represent an existing table and must have an index defined that enables records to be matched. If the primary index fields are used for matching, records with index fields in the destination dataset that match index fields records in the source dataset are overwritten with the source data. Otherwise, data from the source dataset is appended to the destination dataset. During append and update operations, the BDE converts data to appropriate data types and sizes for the destination dataset, if necessary.

Copying datasets

To copy a source dataset, the destination dataset should not represent an exist table. If it does, the batch move operation overwrites the existing table with a copy of the source dataset.

If the source and destination datasets are maintained by different types of database engines, for example, Paradox and InterBase, the BDE creates a destination dataset with a structure as close as possible to that of the source dataset and automatically performs data type and size conversions as necessary.

Note *TBatchMove* does not copy metadata structures such as indexes, constraints, and stored procedures. You must recreate these metadata objects on your database server or through the SQL Explorer as appropriate.

Deleting records

To delete data in the destination dataset, it must represent an existing table and must have an index defined that enables records to be matched. If the primary index fields are used for matching, records with index fields in the destination dataset that match index fields records in the source dataset are deleted in the destination table.

Mapping data types

In *batAppend* mode, a batch move component creates the destination table based on the column data types of the source table. Columns and types are matched based on their position in the source and destination tables. That is, the first column in the source is matched with the first column in the destination, and so on.

To override the default column mappings, use the *Mappings* property. *Mappings* is a list of column mappings (one per line). This listing can take one of two forms. To map a column in the source table to a column of the same name in the destination table, you can use a simple listing that specifies the column name to match. For example, the following mapping specifies that a column named *ColName* in the source table should be mapped to a column of the same name in the destination table:

```
ColName
```

To map a column named *SourceColName* in the source table to a column named *DestColName* in the destination table, the syntax is as follows:

```
DestColName = SourceColName
```

If source and destination column data types are not the same, a batch move operation attempts a “best fit”. It trims character data types, if necessary, and attempts to perform a limited amount of conversion, if possible. For example, mapping a CHAR(10) column to a CHAR(5) column will result in trimming the last five characters from the source column.

As an example of conversion, if a source column of character data type is mapped to a destination of integer type, the batch move operation converts a character value of ‘5’ to the corresponding integer value. Values that cannot be converted generate errors. For more information about errors, see “Handling batch move errors” on page 20-51.

When moving data between different table types, a batch move component translates data types as appropriate based on the dataset’s server types. See the BDE online help file for the latest tables of mappings among server types.

Note To batch move data to an SQL server database, you must have that database server and a version of Delphi with the appropriate SQL Link installed, or you can use ODBC if you have the proper third party ODBC drivers installed.

Executing a batch move

Use the *Execute* method to execute a previously prepared batch operation at runtime. For example, if *BatchMoveAdd* is the name of a batch move component, the following statement executes it:

```
BatchMoveAdd.Execute;
```

You can also execute a batch move at design time by right clicking the mouse on a batch move component and choosing Execute from the context menu.

The *MovedCount* property keeps track of the number of records that are moved when a batch move executes.

The *RecordCount* property specifies the maximum number of records to move. If *RecordCount* is zero, all records are moved, beginning with the first record in the source dataset. If *RecordCount* is a positive number, a maximum of *RecordCount* records are moved, beginning with the current record in the source dataset. If *RecordCount* is greater than the number of records between the current record in the source dataset and its last record, the batch move terminates when the end of the source dataset is reached. You can examine *MoveCount* to determine how many records were actually transferred.

Handling batch move errors

There are two types of errors that can occur in a batch move operation: data type conversion errors and integrity violations. *TBatchMove* has a number of properties that report on and control error handling.

The *AbortOnProblem* property specifies whether to abort the operation when a data type conversion error occurs. If *AbortOnProblem* is *True*, the batch move operation is canceled when an error occurs. If *False*, the operation continues. You can examine the table you specify in the *ProblemTableName* to determine which records caused problems.

The *AbortOnKeyViol* property indicates whether to abort the operation when a Paradox key violation occurs.

The *ProblemCount* property indicates the number of records that could not be handled in the destination table without a loss of data. If *AbortOnProblem* is *True*, this number is one, since the operation is aborted when an error occurs.

The following properties enable a batch move component to create additional tables that document the batch move operation:

- *ChangedTableName*, if specified, creates a local Paradox table containing all records in the destination table that changed as a result of an update or delete operation.
- *KeyViolTableName,* if specified, creates a local Paradox table containing all records from the source table that caused a key violation when working with a Paradox table. If *AbortOnKeyViol* is *True*, this table will contain at most one entry since the operation is aborted on the first problem encountered.

- *ProblemTableName,* if specified, creates a local Paradox table containing all records that could not be posted in the destination table due to data type conversion errors. For example, the table could contain records from the source table whose data had to be trimmed to fit in the destination table. If *AbortOnProblem* is *True*, there is at most one record in this table since the operation is aborted on the first problem encountered.

Note If *ProblemTableName* is not specified, the data in the record is trimmed and placed in the destination table.

The Data Dictionary

When you use the BDE to access your data, your application has access to the Data Dictionary. The Data Dictionary provides a customizable storage area, independent of your applications, where you can create extended field attribute sets that describe the content and appearance of data.

For example, if you frequently develop financial applications, you may create a number of specialized field attribute sets describing different display formats for currency. When you create datasets for your application at design time, rather than using the Object Inspector to set the currency fields in each dataset by hand, you can associate those fields with an extended field attribute set in the data dictionary. Using the data dictionary ensures a consistent data appearance within and across the applications you create.

In a client/server environment, the Data Dictionary can reside on a remote server for additional sharing of information.

To learn how to create extended field attribute sets from the Fields editor at design time, and how to associate them with fields throughout the datasets in your application, see “Creating attribute sets for field components” on page 19-12. To learn more about creating a data dictionary and extended field attributes with the SQL and Database Explorers, see their respective online help files.

A programming interface to the Data Dictionary is available in the drintf unit (located in the lib directory). This interface supplies the following methods:

Table 20.9 Data Dictionary interface

Routine	Use
DictionaryActive	Indicates if the data dictionary is active.
DictionaryDeactivate	Deactivates the data dictionary.
IsNullID	Indicates whether a given ID is a null ID
FindDatabaseID	Returns the ID for a database given its alias.
FindTableID	Returns the ID for a table in a specified database.
FindFieldID	Returns the ID for a field in a specified table.
FindAttrID	Returns the ID for a named attribute set.
GetAttrName	Returns the name an attribute set given its ID.
GetAttrNames	Executes a callback for each attribute set in the dictionary.

Table 20.9 Data Dictionary interface (continued)

Routine	Use
GetAttrID	Returns the ID of the attribute set for a specified field.
NewAttr	Creates a new attribute set from a field component.
UpdateAttr	Updates an attribute set to match the properties of a field.
CreateField	Creates a field component based on stored attributes.
UpdateField	Changes the properties of a field to match a specified attribute set.
AssociateAttr	Associates an attribute set with a given field ID.
UnassociateAttr	Removes an attribute set association for a field ID.
GetControlClass	Returns the control class for a specified attribute ID.
QualifyTableName	Returns a fully qualified table name (qualified by user name).
QualifyTableNameByName	Returns a fully qualified table name (qualified by user name).
HasConstraints	Indicates whether the dataset has constraints in the dictionary.
UpdateConstraints	Updates the imported constraints of a dataset.
UpdateDataset	Updates a dataset to the current settings and constraints in the dictionary.

Tools for working with the BDE

One advantage of using the BDE as a data access mechanism is the wealth of supporting utilities that ship with Delphi. These utilities include:

- **SQL Explorer** and **Database Explorer**: Delphi ships with one of these two applications, depending on which version you have purchased. Both Explorers enable you to
  - Examine existing database tables and structures. The SQL Explorer lets you examine and query remote SQL databases.
  - Populate tables with data
  - Create extended field attribute sets in the Data Dictionary or associate them with fields in your application.
  - Create and manage BDE aliases.

  SQL Explorer lets you do the following as well:
  - Create SQL objects such as stored procedures on remote database servers.
  - View the reconstructed text of SQL objects on remote database servers.
  - Run SQL scripts.
- **SQL Monitor**: SQL Monitor lets you watch all of the communication that passes between the remote database server and the BDE. You can filter the messages you want to watch, limiting them to only the categories of interest. SQL Monitor is most useful when debugging your application.

- **BDE Administration utility:** The BDE Administration utility lets you add new database drivers, configure the defaults for existing drivers, and create new BDE aliases.
- **Database Desktop**: If you are using Paradox or dBASE tables, Database Desktop lets you view and edit their data, create new tables, and restructure existing tables. Using Database Desktop affords you more control than using the methods of a *TTable* component (for example, it allows you to specify validity checks and language drivers). It provides the only mechanism for restructuring Paradox and dBASE tables other than making direct calls the BDE's API.

Chapter 21

Working with ADO components

The *ADOExpress* components provide data access through the ADO framework. ADO, (Microsoft ActiveX Data Objects) is a set of COM objects that access data through an OLE DB provider. The Delphi *ADOExpress* components encapsulate these ADO objects in the Delphi database architecture.

The ADO layer of an ADO-based application consists of Microsoft ADO 2.1, an OLE DB provider or ODBC driver for the data store access, client software for the specific database system used (in the case of SQL databases), a database back-end system accessible to the application (for SQL database systems), and a database. All of these must be accessible to the ADO-based application for it to be fully functional.

The ADO objects that figure most prominently are the Connection, Command, and Recordset objects. These ADO objects are wrapped by the *TADOConnection*, *TADOCommand*, and ADO dataset components. The ADO framework includes other "helper" objects, like the Field and Properties objects, but these are typically not used directly in Delphi applications and are not wrapped by dedicated components.

This chapter presents the *ADOExpress* components and discusses the unique features they add to the common Delphi database architecture. Before reading about the features peculiar to the *ADOExpress* components, you should familiarize yourself with the common features of database connection components and datasets described in Chapter 17, "Connecting to databases" and Chapter 18, "Understanding datasets."

Overview of ADO components

The ADO page of the component palette hosts the *ADOExpress* components. These components let you connect to an ADO data store, execute commands, and retrieve data from tables in databases using the ADO framework. They require ADO 2.1 (or higher) to be installed on the host computer. Additionally, client software for the target database system (such as Microsoft SQL Server) must be installed, as well as an OLE DB driver or ODBC driver specific to the particular database system.

Most *ADOExpress* components have direct counterparts in the components available for other data access mechanisms: a database connection component (*TADOConnection*) and various types of datasets. In addition, *ADOExpress* includes *TADOCommand*, a simple component that is not a dataset but which represents an SQL command to be executed on the ADO data store.

The following table lists the ADO components.

Table 21.1 ADO components

Component	Use
TADOConnection	A database connection component that establishes a connection with an ADO data store; multiple ADO dataset and command components can share this connection to execute commands, retrieve data, and operate on metadata.
TADODataSet	The primary dataset for retrieving and operating on data; *TADODataSet* can retrieve data from a single or multiple tables; can connect directly to a data store or use a *TADOConnection* component.
TADOTable	A table-type dataset for retrieving and operating on a recordset produced by a single database table; *TADOTable* can connect directly to a data store or use a *TADOConnection* component.
TADOQuery	A query-type dataset for retrieving and operating on a recordset produced by a valid SQL statement; *TADOQuery* can also execute data definition language (DDL) SQL statements. It can connect directly to a data store or use a *TADOConnection* component
TADOStoredProc	A stored procedure-type dataset for executing stored procedures; *TADOStoredProc* executes stored procedures that may or may not retrieve data. It can connect directly to a data store or use a *TADOConnection* component.
TADOCommand	A simple component for executing commands (SQL statements that do not return result sets); *TADOCommand* can be used with a supporting dataset component, or retrieve a dataset from a table; It can connect directly to a data store or use a *TADOConnection* component.

Connecting to ADO data stores

Delphi ADO-based applications use Microsoft ActiveX Data Objects (ADO) 2.1 to interact with an OLE DB provider that connects to a data store and accesses its data. One of the items a data store can represent is a database. An ADO-based application requires that ADO 2.1 be installed on the client computer. ADO and OLE DB is supplied by Microsoft and installed with Windows.

An ADO provider represents one of a number of types of access, from native OLE DB drivers to ODBC drivers. These drivers must be installed on the client computer. OLE DB drivers for various database systems are supplied by the database vendor or by a third-party. If the application uses an SQL database, such as Microsoft SQL Server or Oracle, the client software for that database system must also be installed on the client computer. Client software is supplied by the database vendor and installed from the database systems CD (or disk).

To connect your application with the data store, use an ADO connection component (*TADOConnection*). Configure the ADO connection component to use one of the available ADO providers. Although *TADOConnection* is not strictly required, because ADO command and dataset components can establish connections directly using their *ConnectionString* property, you can use *TADOConnection* to share a single connection among several ADO components. This can reduce resource consumption, and allows you to create transactions that span multiple datasets.

Like other database connection components, *TADOConnection* provides support for

- Controlling connections
- Controlling server login
- Managing transactions
- Working with associated datasets
- Sending commands to the server
- Obtaining metadata

In addition to these features that are common to all database connection components, *TADOConnection* provides its own support for

- A wide range of options you can use to fine-tune the connection.
- The ability to list the command objects that use the connection.
- Additional events when performing common tasks.

Connecting to a data store using TADOConnection

One or more ADO dataset and command components can share a single connection to a data store by using *TADOConnection*. To do so, associated dataset and command components with the connection component through their *Connection* properties. At design-time, select the desired connection component from the drop-down list for the *Connection* property in the Object Inspector. At runtime, assign the reference to the *Connection* property. For example, the following line associates a *TADODataSet* component with a *TADOConnection* component.

```
ADODataSet1.Connection := ADOConnection1;
```

The connection component represents an ADO connection object. Before you can use the connection object to establish a connection, you must identify the data store to which you want to connect. Typically, you provide information using the *ConnectionString* property. *ConnectionString* is a semicolon delimited string that lists one or more named connection parameters. These parameters identify the data store by specifying either the name of a file that contains the connection information or the name of an ADO provider and a reference identifying the data store. Use the following, predefined parameter names to supply this information:

Parameter	Description
Provider	The name of a local ADO provider to use for the connection.
Data Source	The name of the data store.
File name	The name of a file containing connection information.
Remote Provider	The name of an ADO provider that resides on a remote machine.
Remote Server	The name of the remote server when using a remote provider.

Thus, a typical value of *ConnectionString* has the form

```
Provider=MSDASQL.1;Data Source=MQIS
```

Note The connection parameters in *ConnectionString* do not need to include the *Provider* or *Remote Provider* parameter if you specify an ADO provider using the *Provider* property. Similarly, you do not need to specify the *Data Source* parameter if you use the *DefaultDatabase* property.

In addition, to the parameters listed above, *ConnectionString* can include any connection parameters peculiar to the specific ADO provider you are using. These additional connection parameters can include user ID and password if you want to hardcode the login information.

At design-time, you can use the Connection String Editor to build a connection string by selecting connection elements (like the provider and server) from lists. Click the ellipsis button for the *ConnectionString* property in the Object Inspector to launch the Connection String Editor, which is an ActiveX property editor supplied by ADO.

Once you have specified the *ConnectionString* property (and, optionally, the *Provider* property), you can use the ADO connection component to connect to or disconnect from the ADO data store, although you may first want to use other properties to fine-tune the connection. When connecting to or disconnecting from the data store, *TADOConnection* lets you respond to a few additional events beyond those common to all database connection components. These additional events are described in "Events when establishing a connection" on page 21-7 and "Events when disconnecting" on page 21-8.

Note If you do not explicitly activate the connection by setting the connection component's *Connected* property to *True*, it automatically establishes the connection when the first dataset component is opened or the first time you use an ADO command component to execute a command.

Accessing the connection object

Use the *ConnectionObject* property of *TADOConnection* to access the underlying ADO connection object. Using this reference it is possible to access properties and call methods of the underlying ADO Connection object.

Using the underlying ADO Connection object requires a good working knowledge of ADO objects in general and the ADO Connection object in particular. It is not recommended that you use the Connection object unless you are familiar with Connection object operations. Consult the Microsoft Data Access SDK help for specific information on using ADO Connection objects.

Fine-tuning a connection

One advantage of using *TADOConnection* for establishing the connection to a data store instead of simply supplying a connection string for your ADO command and dataset components, is that it provides a greater degree of control over the conditions and attributes of the connection.

Forcing asynchronous connections

Use the *ConnectOptions* property to force the connection to be asynchronous. Asynchronous connections allow your application to continue processing without waiting for the connection to be completely opened.

By default, *ConnectionOptions* is set to *coConnectUnspecified* which allows the server to decide the best type of connection. To explicitly make the connection asynchronous, set *ConnectOptions* to *coAsyncConnect*.

The example routines below enable and disable asynchronous connections in the specified connection component:

```
procedure TForm1.AsyncConnectButtonClick(Sender: TObject);
begin
  with ADOConnection1 do begin
    Close;
    ConnectOptions := coAsyncConnect;
    Open;
  end;
end;
```

```
procedure TForm1.ServerChoiceConnectButtonClick(Sender: TObject);
begin
  with ADOConnection1 do begin
    Close;
    ConnectOptions := coConnectUnspecified;
    Open;
  end;
end;
```

Controlling timeouts

You can control the amount of time that can elapse before attempted commands and connections are considered failed and are aborted using the *ConnectionTimeout* and *CommandTimeout* properties.

ConnectionTimeout specifies the amount of time, in seconds, before an attempt to connect to the data store times out. If the connection does not successfully compile prior to expiration of the time specified in *ConnectionTimeout*, the connection attempt is canceled:

```
with ADOConnection1 do begin
  ConnectionTimeout := 10 {seconds};
  Open;
end;
```

CommandTimeout specifies the amount of time, in seconds, before an attempted command times out. If a command initiated by a call to the *Execute* method does not successfully complete prior to expiration of the time specified in *CommandTimeout*, the command is canceled and ADO generates an exception:

```
with ADOConnection1 do begin
  CommandTimeout := 10 {seconds};
  Execute('DROP TABLE Employee1997', cmdText, []);
end;
```

Indicating the types of operations the connection supports

ADO connections are established using a specific mode, similar to the mode you use when opening a file. The connection mode determines the permissions available to the connection, and hence the types of operations (such as reading and writing) that can be performed using that connection.

Use the *Mode* property to indicate the connection mode. The possible values are listed in Table 21.2:

Table 21.2 ADO connection modes

Connect Mode	Meaning
cmUnknown	Permissions are not yet set for the connection or cannot be determined.
cmRead	Read-only permissions are available to the connection.
cmWrite	Write-only permissions are available to the connection.
cmReadWrite	Read/write permissions are available to the connection.
cmShareDenyRead	Prevents others from opening connections with read permissions.
cmShareDenyWrite	Prevents others from opening connection with write permissions.
cmShareExclusive	Prevents others from opening connection.
cmShareDenyNone	Prevents others from opening connection with any permissions.

The possible values for *Mode* correspond to the *ConnectModeEnum* values of the *Mode* property on the underlying ADO connection object. See the Microsoft Data Access SDK help for more information on these values.

Specifying whether the connection automatically initiates transactions

Use the *Attributes* property to control the connection component's use of retaining commits and retaining aborts. When the connection component uses retaining commits, then every time your application commits a transaction, a new transaction is automatically started. When the connection component uses retaining aborts, then every time your application rolls back a transaction, a new transaction is automatically started.

Attributes is a set that can contain one, both, or neither of the constants *xaCommitRetaining* and *xaAbortRetaining*. When *Attributes* contains *xaCommitRetaining*, the connection uses retaining commits. When *Attributes* contains *xaAbortRetaining*, it uses retaining aborts.

Check whether either retaining commits or retaining aborts is enabled using the *in* operator. Enable retaining commits or aborts by adding the appropriate value to the attributes property; disable them by subtracting the value. The example routines below respectively enable and disable retaining commits in an ADO connection component.

```
procedure TForm1.RetainingCommitsOnButtonClick(Sender: TObject);
begin
  with ADOConnection1 do begin
    Close;
    if not (xaCommitRetaining in Attributes) then
      Attributes := (Attributes + [xaCommitRetaining])
    Open;
  end;
end;

procedure TForm1.RetainingCommitsOffButtonClick(Sender: TObject);
begin
  with ADOConnection1 do begin
    Close;
    if (xaCommitRetaining in Attributes) then
      Attributes := (Attributes - [xaCommitRetaining]);
    Open;
  end;
end;
```

Accessing the connection's commands

Like other database connection components, you can access the datasets associated with the connection using the *DataSets* and *DataSetCount* properties. However, *ADOExpress* also includes *TADOCommand* objects, which are not datasets, but which maintain a similar relationship to the connection component.

You can use the *Commands* and *CommandCount* properties of *TADOConnection* to access the associated ADO command objects in the same way you use the *DataSets* and *DataSetCount* properties to access the associated datasets. Unlike *DataSets* and *DataSetCount*, which only list active datasets, *Commands* and *CommandCount* provide references to all *TADOCommand* components associated with the connection component.

Commands is a zero-based array of references to ADO command components. *CommandCount* provides a total count of all of the commands listed in *Commands*. You can use theses properties together to iterate through all the commands that use a connection component, as illustrated in the following code*:*

```
var
  i: Integer
begin
  for i := 0 to (ADOConnection1.CommandCount - 1) do
    ADOConnection1.Commands[i].Execute;
end;
```

ADO connection events

In addition to the usual events that occur for all database connection components, *TADOConnection* generates a number of additional events that occur during normal usage.

Events when establishing a connection

In addition to the *BeforeConnect* and *AfterConnect* events that are common to all database connection components, *TADOConnection* also generates an *OnWillConnect* and *OnConnectComplete* event when establishing a connection. These events occur after the *BeforeConnect* event.

- *OnWillConnect* occurs before the ADO provider establishes a connection. It lets you make last minute changes to the connection string, provide a user name and password if you are handling your own login support, force an asynchronous connection, or even cancel the connection before it is opened.
- *OnConnectComplete* occurs after the connection is opened. Because *TADOConnection* can represent asynchronous connections, you should use *OnConnectComplete*, which occurs after the connection is opened or has failed due to an error condition, instead of the *AfterConnect* event, which occurs after the connection component instructs the ADO provider to open a connection, but not necessarily after the connection is opened.

Events when disconnecting

In addition to the *BeforeDisconnect* and *AfterDisconnect* events common to all database connection components, *TADOConnection* also generates an *OnDisconnect* event after closing a connection. *OnDisconnect* occurs after the connection is closed but before any associated datasets are closed and before the *AfterDisconnect* event.

Events when managing transactions

The ADO connection component provides a number of events for detecting when transaction-related processes have been completed. These events indicate when a transaction process initiated by a *BeginTrans*, *CommitTrans*, and *RollbackTrans* method has been successfully completed at the data store.

- The *OnBeginTransComplete* event occurs when the data store has successfully started a transaction after a call to the *BeginTrans* method.
- The *OnCommitTransComplete* event occurs after a transaction is successfully committed due to a call to *CommitTrans*.
- The *OnRollbackTransComplete* event occurs after a transaction is successfully aborted due to a call to *RollbackTrans*.

Other events

ADO connection components introduce two additional events you can use to respond to notifications from the underlying ADO connection object:

- The *OnExecuteComplete* event occurs after the connection component executes a command on the data store (for example, after calling the *Execute* method). *OnExecuteComplete* indicates whether the execution was successful.
- The *OnInfoMessage* event occurs when the underlying connection object provides detailed information after an operation is completed. The *OnInfoMessage* event handler receives the interface to an ADO Error object that contains the detailed information and a status code indicating whether the operation was successful.

Using ADO datasets

ADO dataset components encapsulate the ADO Recordset object. They inherit the common dataset capabilities described in Chapter 18, “Understanding datasets,” using ADO to provide the implementation. In order to use an ADO dataset, you must familiarize yourself with these common features.

In addition to the common dataset features, all ADO datasets add properties, events, and methods for

- Connecting to an ADO datastore.
- Accessing the underlying Recordset object.
- Filtering records based on bookmarks.
- Fetching records asynchronously.
- Performing batch updates (caching updates).
- Using files on disk to store data.

There are four ADO datasets:

- *TADOTable*, a table-type dataset that represents all of the rows and columns of a single database table. See “Using table-type datasets” on page 18-24 for information on using *TADOTable* and other table-type datasets.
- *TADOQuery*, a query-type dataset that encapsulates an SQL statement and enables applications to access the resulting records, if any. See “Using query-type datasets” on page 18-41 for information on using *TADOQuery* and other query-type datasets.
- *TADOStoredProc*, a stored procedure-type dataset that executes a stored procedure defined on a database server. See “Using stored procedure-type datasets” on page 18-48 for information on using *TADOStoredProc* and other stored procedure-type datasets.
- *TADODataSet*, a general-purpose dataset that includes the capabilities of the other three types. See “Using TADODataSet” on page 21-15 for a description of features unique to *TADODataSet*.

Note When using ADO to access database information, you do not need to use a dataset such as *TADOQuery* to represent SQL commands that do not return a cursor. Instead, you can use *TADOCommand*, a simple component that is not a dataset. For details on *TADOCommand*, see “Using Command objects” on page 21-16.

Connecting an ADO dataset to a data store

ADO datasets can connect to an ADO data store either collectively or individually.

When connecting datasets collectively, set the *Connection* property of each dataset to a *TADOConnection* component. Each dataset then uses the ADO connection component’s connection.

```
ADODataSet1.Connection := ADOConnection1;
ADODataSet2.Connection := ADOConnection1;
...
```

Among the advantages of connecting datasets collectively are:

- The datasets share the connection object's attributes.
- Only one connection need be set up: that of the *TADOConnection*.
- The datasets can participate in transactions.

For more information on using *TADOConnection* see "Connecting to ADO data stores" on page 21-2.

When connecting datasets individually, set the *ConnectionString* property of each dataset. Each dataset that uses *ConnectionString* establishes its own connection to the data store, independent of any other dataset connection in the application.

The *ConnectionString* property of ADO datasets works the same way as the *ConnectionString* property of *TADOConnection*: it is a set of semicolon-delimited connection parameters such as the following:

```
ADODataSet1.ConnectionString := 'Provider=YourProvider;Password=SecretWord;' +
  'User ID=JaneDoe;SERVER=PURGATORY;UID=JaneDoe;PWD=SecretWord;' +
  'Initial Catalog=Employee';
```

At design time you can use the Connection String Editor to help you build the connection string. For more information about connection strings, see "Connecting to a data store using TADOConnection" on page 21-3.

Working with record sets

The *Recordset* property provides direct access to the ADO recordset object underlying the dataset component. Using this object, it is possible to access properties and call methods of the recordset object from an application. Use of *Recordset* to directly access the underlying ADO recordset object requires a good working knowledge of ADO objects in general and the ADO recordset object in specific. Using the recordset object directly is not recommended unless you are familiar with recordset object operations. Consult the Microsoft Data Access SDK help for specific information on using ADO recordset objects.

The *RecordsetState* property indicates the current state of the underlying recordset object. *RecordsetState* corresponds to the *State* property of the ADO recordset object. The value of *RecordsetState* is either *stOpen, stExecuting,* or *stFetching*. (*TObjectState*, the type of the *RecordsetState* property, defines other values, but only *stOpen*, *stExecuting,* and *stFetching* pertain to recordsets.) A value of *stOpen* indicates that the recordset is currently idle. A value of *stExecuting* indicates that it is executing a command. A value of *stFetching* indicates that it is fetching rows from the associated table (or tables).

Use *RecordsetState* values to perform actions dependent on the current state of the dataset. For example, a routine that updates data might check the *RecordsetState* property to see whether the dataset is active and not in the process of other activities such as connecting or fetching data.

Filtering records based on bookmarks

ADO datasets support the common dataset feature of using bookmarks to mark and return to specific records. Also like other datasets, ADO datasets let you use filters to limit the available records in the dataset. ADO datasets provide an additional feature that combines these two common dataset features: the ability to filter on a set of records identified by bookmarks.

To filter on a set of bookmarks,

1. Use the *Bookmark* method to mark the records you want to include in the filtered dataset.
2. Call the *FilterOnBookmarks* method to filter the dataset so that only the bookmarked records appear.

This process is illustrated below:

```
procedure TForm1.Button1Click(Sender: TObject);
var
  BM1, BM2: TBookmarkStr;
begin
  with ADODataSet1 do begin
    BM1 := Bookmark;
    BMList.Add(Pointer(BM1));
    MoveBy(3);
    BM2 := Bookmark;
    BMList.Add(Pointer(BM2));
    FilterOnBookmarks([BM1, BM2]);
  end;
end;
```

Note that the example above also adds the bookmarks to a list object named BMList. This is necessary so that the application can later free the bookmarks when they are no longer needed.

For details on using bookmarks, see “Marking and returning to records” on page 18-9. For details on other types of filters, see “Displaying and editing a subset of data using filters” on page 18-12.

Fetching records asynchronously

Unlike other datasets, ADO datasets can fetch their data asynchronously. This allows your application to continue performing other tasks while the dataset populates itself with data from the data store.

To control whether the dataset fetches data asynchronously, if it fetches data at all, use the *ExecuteOptions* property. *ExecuteOptions* governs how the dataset fetches its records when you call *Open* or set *Active* to *True*. If the dataset represents a query or stored procedure that does not return any records, ExecuteOptions governs how the query or stored procedure is executed when you call *ExecSQL* or *ExecProc*.

ExecuteOptions is a set that includes zero or more of the following values:

Table 21.3 Execution options for ADO datasets

Execute Option	Meaning
eoAsyncExecute	The command or data fetch operation is executed asynchronously.
eoAsyncFetch	The dataset first fetches the number of records specified by the *CacheSize* property synchronously, then fetches any remaining rows asynchronously.
eoAsyncFetchNonBlocking	Asynchronous data fetches or command execution do not block the current thread of execution.
eoExecuteNoRecords	A command or stored procedure that does not return data. If any rows are retrieved, they are discarded and not returned.

Using batch updates

One approach for caching updates is to connect the ADO dataset to a client dataset using a dataset provider. This approach is discussed in "Using a client dataset to cache updates" on page 23-15.

However, ADO dataset components provide their own support for cached updates, which they call batch updates. The following table lists the correspondences between caching updates using a client dataset and using the batch updates features:

Table 21.4 Comparison of ADO and client dataset cached updates

ADO dataset	TClientDataSet	Description
LockType	Not used: client datasets always cache updates	Specifies whether the dataset is opened in batch update mode.
CursorType	Not used: client datasets always work with an in-memory snapshot of data	Specifies how isolated the ADO dataset is from changes on the server.
RecordStatus	UpdateStatus	Indicates what update, if any, has occurred on the current row. *RecordStatus* provides more information than *UpdateStatus*.
FilterGroup	StatusFilter	Specifies which type of records are available. *FilterGroup* provides a wider variety of information.
UpdateBatch	ApplyUpdates	Applies the cached updates back to the database server. Unlike *ApplyUpdates*, *UpdateBatch* lets you limit the types of updates to be applied.
CancelBatch	CancelUpdates	Discards pending updates, reverting to the original values. Unlike *CancelUpdates*, *CancelBatch* lets you limit the types of updates to be canceled.

Using the batch updates features of ADO dataset components is a matter of:

- Opening the dataset in batch update mode
- Inspecting the update status of individual rows
- Filtering multiple rows based on update status
- Applying the batch updates to base tables
- Canceling batch updates

Opening the dataset in batch update mode

To open an ADO dataset in batch update mode, it must meet these criteria:

1. The component's *CursorType* property must be *ctKeySet* (the default property value) or *ctStatic*.
2. The *LockType* property must be *ltBatchOptimistic*.
3. The command must be a SELECT query.

Before activating the dataset component, set the *CursorType* and *LockType* properties as indicated above. Assign a SELECT statement to the component's *CommandText* property (for *TADODataSet*) or the *SQL* property (for *TADOQuery*). For *TADOStoredProc* components, set the *ProcedureName* to the name of a stored procedure that returns a result set. These properties can be set at design-time through the Object Inspector or programmatically at runtime. The example below shows the preparation of a *TADODataSet* component for batch update mode.

```
with ADODataSet1 do begin
  CursorLocation := clUseClient;
  CursorType := ctStatic;
  LockType := ltBatchOptimistic;
  CommandType := cmdText;
  CommandText := 'SELECT * FROM Employee';
  Open;
end;
```

After a dataset has been opened in batch update mode, all changes to the data are cached rather than applied directly to the base tables.

Inspecting the update status of individual rows

Determine the update status of a given row by making it current and then inspecting the *RecordStatus* property of the ADO data component. *RecordStatus* reflects the update status of the current row and only that row.

```
case ADOQuery1.RecordStatus of
  rsUnmodified: StatusBar1.Panels[0].Text := 'Unchanged record';
  rsModified:   StatusBar1.Panels[0].Text := 'Changed record';
  rsDeleted:    StatusBar1.Panels[0].Text := 'Deleted record';
  rsNew:        StatusBar1.Panels[0].Text := 'New record';
end;
```

Filtering multiple rows based on update status

Filter a recordset to show only those rows that belong to a group of rows with the same update status using the *FilterGroup* property. Set *FilterGroup* to the *TFilterGroup* constant that represents the update status of rows to display. A value of *fgNone* (the default value for this property) specifies that no filtering is applied and all rows are visible regardless of update status (except rows marked for deletion). The example below causes only pending batch update rows to be visible.

```
FilterGroup := fgPendingRecords;
Filtered := True;
```

Note For the *FilterGroup* property to have an effect, the ADO dataset component's *Filtered* property must be set to *True*.

Applying the batch updates to base tables

Apply pending data changes that have not yet been applied or canceled by calling the *UpdateBatch* method. Rows that have been changed and are applied have their changes put into the base tables on which the recordset is based. A cached row marked for deletion causes the corresponding base table row to be deleted. A record insertion (exists in the cache but not the base table) is added to the base table. Modified rows cause the columns in the corresponding rows in the base tables to be changed to the new column values in the cache.

Used alone with no parameter, *UpdateBatch* applies all pending updates. A *TAffectRecords* value can optionally be passed as the parameter for *UpdateBatch*. If any value except *arAll* is passed, only a subset of the pending changes are applied. Passing *arAll* is the same as passing no parameter at all and causes all pending updates to be applied. The example below applies only the currently active row to be applied:

```
ADODataSet1.UpdateBatch(arCurrent);
```

Canceling batch updates

Cancel pending data changes that have not yet been canceled or applied by calling the *CancelBatch* method. When you cancel pending batch updates, field values on rows that have been changed revert to the values that existed prior to the last call to *CancelBatch* or *UpdateBatch*, if either has been called, or prior to the current pending batch of changes.

Used alone with no parameter, *CancelBatch* cancels all pending updates. A *TAffectRecords* value can optionally be passed as the parameter for *CancelBatch*. If any value except *arAll* is passed, only a subset of the pending changes are canceled. Passing *arAll* is the same as passing no parameter at all and causes all pending updates to be canceled. The example below cancels all pending changes:

```
ADODataSet1.CancelBatch;
```

Loading data from and saving data to files

The data retrieved via an ADO dataset component can be saved to a file for later retrieval on the same or a different computer. The data is saved in one of two proprietary formats: ADTG or XML. These two file formats are the only formats supported by ADO. However, both formats are not necessarily supported in all versions of ADO. Consult the ADO documentation for the version you are using to determine what save file formats are supported.

Save the data to a file using the *SaveToFile* method. *SaveToFile* takes two parameters, the name of the file to which data is saved, and, optionally, the format (ADTG or XML) in which to save the data. Indicate the format for the saved file by setting the *Format* parameter to *pfADTG* or *pfXML*. If the file specified by the *FileName* parameter already exists, *SaveToFile* raises an *EOleException*.

Retrieve the data from file using the *LoadFromFile* method. *LoadFromFile* takes a single parameter, the name of the file to load. If the specified file does not exist, *LoadFromFile* raises an *EOleException* exception. On calling the *LoadFromFile* method, the dataset component is automatically activated.

In the example below, the first procedure saves the dataset retrieved by the *TADODataSet* component *ADODataSet1* to a file. The target file is an ADTG file named SaveFile, saved to a local drive. The second procedure loads this saved file into the *TADODataSet* component *ADODataSet2*.

```
procedure TForm1.SaveBtnClick(Sender: TObject);
begin
  if (FileExists('c:\SaveFile')) then
  begin
    DeleteFile('c:\SaveFile');
    StatusBar1.Panels[0].Text := 'Save file deleted!';
  end;
  ADODataSet1.SaveToFile('c:\SaveFile', pfADTG);
end;

procedure TForm1.LoadBtnClick(Sender: TObject);
begin
  if (FileExists('c:\SaveFile')) then
    ADODataSet2.LoadFromFile('c:\SaveFile')
  else
    StatusBar1.Panels[0].Text := 'Save file does not exist!';
end;
```

The datasets that save and load the data need not be on the same form as above, in the same application, or even on the same computer. This allows for the briefcase-style transfer of data from one computer to another.

Using TADODataSet

TADODataSet is a general-purpose dataset for working with data from an ADO data store. Unlike the other ADO dataset components, *TADODataSet* is not a table-type, query-type, or stored procedure-type dataset. Instead, it can function as any of these types:

- Like a table-type dataset, *TADODataSet* lets you represent all of the rows and columns of a single database table. To use it in this way, set the *CommandType* property to *cmdTable* and the *CommandText* property to the name of the table. *TADODataSet* supports table-type tasks such as

  - Assigning indexes to sort records or form the basis of record-based searches. In addition to the standard index properties and methods described in “Sorting records with indexes” on page 18-25, *TADODataSet* lets you sort using temporary indexes by setting the *Sort* property. Indexed-based searches performed using the *Seek* method use the current index.

  - Emptying the dataset. The *DeleteRecords* method provides greater control than related methods in other table-type datasets, because it lets you specify what records to delete.

  The table-type tasks supported by *TADODataSet* are available even when you are not using a *CommandType* of *cmdTable*.

- Like a query-type dataset, *TADODataSet* lets you specify a single SQL command that is executed when you open the dataset. To use it in this way, set the *CommandType* property to *cmdText* and the *CommandText* property to the SQL command you want to execute. At design time, you can double-click on the *CommandText* property in the Object Inspector to use the Command Text editor for help in constructing the SQL command. *TADODataSet* supports query-type tasks such as
    - Using parameters in the query text. See "Using parameters in queries" on page 18-43 for details on query parameters.
    - Setting up master/detail relationships using parameters. See "Establishing master/detail relationships using parameters" on page 18-46 for details on how to do this.
    - Preparing the query in advance to improve performance by setting the *Prepared* property to *True.*
- Like a stored procedure-type dataset, *TADODataSet* lets you specify a stored procedure that is executed when you open the dataset. To use it in this way, set the *CommandType* property to *cmdStoredProc* and the *CommandText* property to the name of the stored procedure. *TADODataSet* supports stored procedure-type tasks such as
    - Working with stored procedure parameters. See "Working with stored procedure parameters" on page 18-50 for details on stored procedure parameters.
    - Fetching multiple result sets. See "Fetching multiple result sets" on page 18-53 for details on how to do this.
    - Preparing the stored procedure in advance to improve performance by setting the *Prepared* property to *True*.

In addition, *TADODataSet* lets you work with data stored in files by setting the *CommandType* property to *cmdFile* and the *CommandText* property to the file name.

Before you set the *CommandText* and *CommandType* properties, you should link the *TADODataSet* to a data store by setting the *Connection* or *ConnectionString* property. This process is described in "Connecting an ADO dataset to a data store" on page 21-9. As an alternative, you can use an RDS DataSpace object to connect the *TADODataSet* to an ADO-based application server. To use an RDS DataSpace object, set the *RDSConnection* property to a *TRDSConnection* object.

Using Command objects

In the ADO environment, commands are textual representations of provider-specific action requests. Typically, they are Data Definition Language (DDL) and Data Manipulation Language (DML) SQL statements. The language used in commands is provider-specific, but usually compliant with the SQL-92 standard for the SQL language.

Although you can always execute commands using *TADOQuery*, you may not want the overhead of using a dataset component, especially if the command does not return a result set. As an alternative, you can use the *TADOCommand* component, which is a lighter-weight object designed to execute commands, one command at a time. *TADOCommand* is intended primarily for executing those commands that do not return result sets, such as Data Definition Language (DDL) SQL statements. Through an overloaded version of its *Execute* method, however, it is capable of returning a result set that can be assigned to the *RecordSet* property of an ADO dataset component.

In general, working with *TADOCommand* is very similar to working with *TADODataSet*, except that you can't use the standard dataset methods to fetch data, navigate records, edit data, and so on. *TADOCommand* objects connect to a data store in the same way as ADO datasets. See "Connecting an ADO dataset to a data store" on page 21-9 for details.

The following topics provide details on how to specify and execute commands using *TADOCommand*.

Specifying the command

Specify commands for a *TADOCommand* component using the *CommandText* property. Like *TADODataSet*, *TADOCommand* lets you specify the command in different ways, depending on the *CommandType* property. Possible values for *CommandType* include: *cmdText* (used if the command is an SQL statement), *cmdTable* (if it is a table name), and *cmdStoredProc* (if the command is the name of a stored procedure). At design-time, select the appropriate command type from the list in the Object Inspector. At runtime, assign a value of type *TCommandType* to the *CommandType* property.

```
with ADOCommand1 do begin
  CommandText := 'AddEmployee';
  CommandType := cmdStoredProc;
...
end;
```

If no specific type is specified, the server is left to decide as best it can based on the command in *CommandText*.

CommandText can contain the text of an SQL query that includes parameters or the name of a stored procedure that uses parameters. You must then supply parameter values, which are bound to the parameters before executing the command. See "Handling command parameters" on page 21-19 for details.

Using the Execute method

Before *TADOCommand* can execute its command, it must have a valid connection to a data store. This is established just as with an ADO dataset. See "Connecting an ADO dataset to a data store" on page 21-9 for details.

To execute the command, call the *Execute* method. *Execute* is an overloaded method that lets you choose the most appropriate way to execute the command.

For commands that do not require any parameters and for which you do not need to know how many records were affected, call *Execute* without any parameters:

```
with ADOCommand1 do begin
  CommandText := 'UpdateInventory';
  CommandType := cmdStoredProc;
  Execute;
end;
```

Other versions of *Execute* let you provide parameter values using a Variant array, and to obtain the number of records affected by the command.

For information on executing commands that return a result set, see "Retrieving result sets with commands" on page 21-18.

Canceling commands

If you are executing the command asynchronously, then after calling *Execute* you can abort the execution by calling the *Cancel* method:

```
procedure TDataForm.ExecuteButtonClick(Sender: TObject);
begin
  ADOCommand1.Execute;
end;

procedure TDataForm.CancelButtonClick(Sender: TObject);
begin
  ADOCommand1.Cancel;
end;
```

The *Cancel* method only has an effect if there is a command pending and it was executed asynchronously (*eoAsynchExecute* is in the *ExecuteOptions* parameter of the *Execute* method). A command is said to be pending if the *Execute* method has been called but the command has not yet been completed or timed out.

A command times out if it is not completed or canceled before the number of seconds specified in the *CommandTimeout* property expire. By default, commands time out after 30 seconds.

Retrieving result sets with commands

Unlike *TADOQuery* components, which use different methods to execute depending on whether they return a result set, *TADOCommand* always uses the *Execute* command to execute the command, regardless of whether it returns a result set. When the command returns a result set, *Execute* returns an interface to the ADO _RecordSet interface.

The most convenient way to work with this interface is to assign it to the *RecordSet* property of an ADO dataset.

For example, the following code uses *TADOCommand* (*ADOCommand1*) to execute a SELECT query, which returns a result set. This result set is then assigned to the *RecordSet* property of a *TADODataSet* component (*ADODataSet1*).

```
with ADOCommand1 do begin
  CommandText := 'SELECT Company, State ' +
    'FROM customer ' +
    'WHERE State = :StateParam';
  CommandType := cmdText;
  Parameters.ParamByName('StateParam').Value := 'HI';
  ADODataSet1.Recordset := Execute;
end;
```

As soon as the result set is assigned to the ADO dataset's *Recordset* property, the dataset is automatically activated and the data is available.

Handling command parameters

There are two ways in which a *TADOCommand* object may use parameters:

- The *CommandText* property can specify a query that includes parameters. Working with parameterized queries in *TADOCommand* works like using a parameterized query in an ADO dataset. See "Using parameters in queries" on page 18-43 for details on parameterized queries.
- The *CommandText* property can specify a stored procedure that uses parameters. Stored procedure parameters work much the same using *TADOCommand* as with an ADO dataset. See "Working with stored procedure parameters" on page 18-50 for details on stored procedure parameters.

There are two ways to supply parameter values when working with *TADOCommand*: you can supply them when you call the *Execute* method, or you can specify them ahead of time using the *Parameters* property.

The *Execute* method is overloaded to include versions that take a set of parameter values as a Variant array. This is useful when you want to supply parameter values quickly without the overhead of setting up the *Parameters* property:

```
ADOCommand1.Execute(VarArrayOf([Edit1.Text, Date]));
```

When working with stored procedures that return output parameters, you must use the *Parameters* property instead. Even if you do not need to read output parameters, you may prefer to use the *Parameters* property, which lets you supply parameters at design time and lets you work with *TADOCommand* properties in the same way you work with the parameters on datasets.

When you set the *CommandText* property, the *Parameters* property is automatically updated to reflect the parameters in the query or those used by the stored procedure. At design-time, you can use the Parameter Editor to access parameters, by clicking the ellipsis button for the *Parameters* property in the Object Inspector. At runtime, use properties and methods of *TParameter* to set (or get) the values of each parameter.

```
with ADOCommand1 do begin
  CommandText := 'INSERT INTO Talley ' +
    '(Counter) ' +
    'VALUES (:NewValueParam)';
  CommandType := cmdText;
  Parameters.ParamByName('NewValueParam').Value := 57;
  Execute
end;
```

Chapter

22

Using unidirectional datasets

dbExpress is a set of lightweight database drivers that provide fast access to SQL database servers. For each supported database, *dbExpress* provides a driver that adapts the server-specific software to a set of uniform *dbExpress* interfaces. When you deploy a database application that uses *dbExpress*, you need only include a dll (the server-specific driver) with the application files you build.

dbExpress lets you access databases using unidirectional datasets. Unidirectional datasets are designed for quick lightweight access to database information, with minimal overhead. Like other datasets, they can send an SQL command to the database server, and if the command returns a set of records, obtain a cursor for accessing those records. However, unidirectional datasets can only retrieve a unidirectional cursor. They do not buffer data in memory, which makes them faster and less resource-intensive than other types of dataset. However, because there are no buffered records, unidirectional datasets are also less flexible than other datasets. Many of the capabilities introduced by *TDataSet* are either unimplemented in unidirectional datasets, or cause them to raise exceptions. For example:

- The only supported navigation methods are the *First* and *Next* methods. Most others raise exceptions. Some, such as the methods involved in bookmark support, simply do nothing.
- There is no built-in support for editing because editing requires a buffer to hold the edits. The *CanModify* property is always *False*, so attempts to put the dataset into edit mode always fail. You can, however, use unidirectional datasets to update data using an SQL UPDATE command or provide conventional editing support by using a dbExpress-enabled client dataset or connecting the dataset to a client dataset (see “Connecting to another dataset” on page 14-10).
- There is no support for filters, because filters work with multiple records, which requires buffering. If you try to filter a unidirectional dataset, it raises an exception. Instead, all limits on what data appears must be imposed using the SQL command that defines the data for the dataset.

- There is no support for lookup fields, which require buffering to hold multiple records containing lookup values. If you define a lookup field on a unidirectional dataset, it does not work properly.

Despite these limitations, unidirectional datasets are a powerful way to access data. They are the fastest data access mechanism, and very simple to use and deploy.

Types of unidirectional datasets

The *dbExpress* page of the component palette contains four types of unidirectional dataset: *TSQLDataSet*, *TSQLQuery*, *TSQLTable*, and *TSQLStoredProc.*

TSQLDataSet is the most general of the four. You can use an SQL dataset to represent any data available through *dbExpress*, or to send commands to a database accessed through *dbExpress*. This is the recommended component to use for working with database tables in new database applications.

TSQLQuery is a query-type dataset that encapsulates an SQL statement and enables applications to access the resulting records, if any. See “Using query-type datasets” on page 18-41 for information on using query-type datasets.

TSQLTable is a table-type dataset that represents all of the rows and columns of a single database table. See “Using table-type datasets” on page 18-24 for information on using table-type datasets.

TSQLStoredProc is a stored procedure-type dataset that executes a stored procedure defined on a database server. See “Using stored procedure-type datasets” on page 18-48 for information on using stored procedure-type datasets.

Note The *dbExpress* page also includes *TSQLClientDataSet*, which is not a unidirectional dataset. Rather, it is a client dataset that uses a unidirectional dataset internally to access its data

Connecting to the database server

The first step when working with a unidirectional dataset is to connect it to a database server. At design time, once a dataset has an active connection to a database server, the Object Inspector can provide drop-down lists of values for other properties. For example, when representing a stored procedure, you must have an active connection before the Object Inspector can list what stored procedures are available on the server.

The connection to a database server is represented by a separate *TSQLConnection* component. You work with *TSQLConnection* like any other database connection component. For information about database connection components, see Chapter 17, “Connecting to databases”.

To use *TSQLConnection* to connect a unidirectional dataset to a database server, set the *SQLConnection* property. At design time, you can choose the SQL connection component from a drop-down list in the Object Inspector. If you make this assignment at runtime, be sure that the connection is active:

```
SQLDataSet1.SQLConnection := SQLConnection1;
SQLConnection1.Connected := True;
```

Typically, all unidirectional datasets in an application share the same connection component, unless you are working with data from multiple database servers. However, you may want to use a separate connection for each dataset if the server does not support multiple statements per connection. Check whether the database server requires a separate connection for each dataset by reading the *MaxStmtsPerConn* property. By default, *TSQLConnection* generates connections as needed when the server limits the number of statements that can be executed over a connection. If you want to keep stricter track of the connections you are using, set the *AutoClone* property to *False*.

Before you assign the *SQLConnection* property, you will need to set up the *TSQLConnection* component so that it identifies the database server and any required connection parameters (including which database to use on the server, the host name of the machine running the server, the username, password, and so on).

Setting up TSQLConnection

In order to describe a database connection in sufficient detail for *TSQLConnection* to open a connection, you must identify both the driver to use and a set of connection parameters the are passed to that driver.

Identifying the driver

The driver is identified by the *DriverName* property, which is the name of an installed *dbExpress* driver, such as INTERBASE, ORACLE, MYSQL, or DB2. The driver name is associated with two files

- The *dbExpress* driver. This can be either a dynamic-link library with a name like dbexpint.dll, dbexpora.dll, dbexpmys.dll, or dbexpdb2.dll, or a compiled unit that you can statically link into your application (dbexptint.dcu, dbexpora.dcu, dbexpmys.dcu, or dbexpdb2.dcu).
- The dynamic-link library provided by the database vendor for client-side support.

The relationship between these two files and the database name is stored in a file called dbxdrivers.ini, which is updated when you install a *dbExpress* driver. Typically, you do not need to worry about these files because the SQL connection component looks them up in dbxdrivers.ini when given the value of *DriverName*. When you set the *DriverName* property, *TSQLConnection* automatically sets the *LibraryName* and *VendorLib* properties to the names of the associated dlls. Once *LibraryName* and *VendorLib* have been set, your application does not need to rely on dbxdrivers.ini. (That is, you do not need to deploy dbxdrivers.ini with your application unless you set the *DriverName* property at runtime.)

Specifying connection parameters

The *Params* property is a string list that lists name/value pairs. Each pair has the form *Name=Value*, where *Name* is the name of the parameter, and *Value* is the value you want to assign.

The particular parameters you need depend on the database server you are using. However, one particular parameter, *Database*, is required for all servers. Its value depends on the server you are using. For example, with InterBase, *Database* is the name of the .gdb file, with ORACLE it is the entry in TNSNames.ora, while with DB2, it is the client-side node name.

Other typical parameters include the *User_Name* (the name to use when logging in), *Password* (the password for *User_Name*), *HostName* (the machine name or IP address of where the server is located), and *TransIsolation* (the degree to which transactions you introduce are aware of changes made by other transactions). When you specify a driver name, the *Params* property is preloaded with all the parameters you need for that driver type, initialized to default values.

Because *Params* is a string list, at design time you can double-click on the *Params* property in the Object Inspector to edit the parameters using the String List editor. At runtime, use the *Params.Values* property to assign values to individual parameters.

Naming a connection description

Although you can always specify a connection using only the *DatabaseName* and *Params* properties, it can be more convenient to name a specific combination and then just identify the connection by name. You can name *dbExpress* database and parameter combinations, which are then saved in a file called dbxconnections.ini. The name of each combination is called a connection name.

Once you have defined the connection name, you can identify a database connection by simply setting the *ConnectionName* property to a valid connection name. Setting *ConnectionName* automatically sets the *DriverName* and *Params* properties. Once *ConnectionName* is set, you can edit the *Params* property to create temporary differences from the saved set of parameter values, but changing the *DriverName* property clears both *Params* and *ConnectionName*.

One advantage of using connection names arises when you develop your application using one database (for example Local InterBase), but deploy it for use with another (such as ORACLE). In that case, *DriverName* and *Params* will likely differ on the system where you deploy your application from the values you use during development. You can switch between the two connection descriptions easily by using two versions of the dbxconnections.ini file. At design-time, your application loads the *DriverName* and *Params* from the design-time version of dbxconnections.ini. Then, when you deploy your application, it loads these values from a separate version of dbxconnections.ini that uses the “real” database. However, for this to work, you must instruct your connection component to reload the *DriverName* and *Params* properties at runtime. There are two ways to do this:

- Set the *LoadParamsOnConnect* property to *True*. This causes *TSQLConnection* to automatically set *DriverName* and *Params* to the values associated with *ConnectionName* in dbxconnections.ini when the connection is opened.

- Call the *LoadParamsFromIniFile* method. This method sets *DriverName* and *Params* to the values associated with *ConnectionName* in dbxconnections.ini (or in another file that you specify). You might choose to use this method if you want to then override certain parameter values before opening the connection.

Using the Connection Editor

The relationships between connection names and their associated driver and connection parameters is stored in the dbxconnections.ini file. You can create or modify these associations using the Connection Editor.

To display the Connection Editor, double-click on the *TSQLConnection* component. The Connection Editor appears, with a drop-down list containing all available drivers, a list of connection names for the currently selected driver, and a table listing the connection parameters for the currently selected connection name.

You can use this dialog to indicate the connection to use by selecting a driver and connection name. Once you have chosen the configuration you want, click the Test Connection button to check that you have chosen a valid configuration.

In addition, you can use this dialog to edit the named connections in dbxconnections.ini:

- Edit the parameter values in the parameter table to change the currently selected named connection. When you exit the dialog by clicking OK, the new parameter values are saved to dbxconnections.ini.
- Click the Add Connection button to define a new named connection. A dialog appears where you specify the driver to use and the name of the new connection. Once the connection is named, edit the parameters to specify the connection you want and click the OK button to save the new connection to dbxconnections.ini.
- Click the Delete Connection button to delete the currently selected named connection from dbxconnections.ini.
- Click the Rename Connection button to change the name of the currently selected named connection. Note that any edits you have made to the parameters are saved with the new name when you click the OK button.

Specifying what data to display

There are a number of ways to specify what data a unidirectional dataset represents. Which method you choose depends on the type of unidirectional dataset you are using and whether the information comes from a single database table, the results of a query, or from a stored procedure.

When you work with a *TSQLDataSet* component, use the *CommandType* property to indicate where the dataset gets its data. *CommandType* can take any of the following values:

- *ctQuery*: When *CommandType* is *ctQuery*, *TSQLDataSet* executes a query you specify. If the query is a SELECT command, the dataset contains the resulting set of records.

- *ctTable*: When *CommandType* is *ctTable*, *TSQLDataSet* retrieves all of the records from a specified table.
- *ctStoredProc*: When *CommandType* is *ctStoredProc*, *TSQLDataSet* executes a stored procedure. If the stored procedure returns a cursor, the dataset contains the returned records.

Note You can also populate the unidirectional dataset with metadata about what is available on the server. For information on how to do this, see “Fetching metadata into a unidirectional dataset” on page 22-12.

Representing the results of a query

Using a query is the most general way to specify a set of records. Queries are simply commands written in SQL. You can use either *TSQLDataSet* or *TSQLQuery* to represent the result of a query.

When using *TSQLDataSet*, set the *CommandType* property to *ctQuery* and assign the text of the query statement to the *CommandText* property. When using *TSQLQuery*, assign the query to the *SQL* property instead. These properties work the same way for all general-purpose or query-type datasets. “Specifying the query” on page 18-42 discusses them in greater detail.

When you specify the query, it can include parameters, or variables, the values of which can be varied at design time or runtime. Parameters can replace data values that appear in the SQL statement. Using parameters in queries and supplying values for those parameters is discussed in “Using parameters in queries” on page 18-43.

SQL defines queries such as UPDATE queries that perform actions on the server but do not return records. Such queries are discussed in “Executing commands that do not return records” on page 22-9.

Representing the records in a table

When you want to represent all of the fields and all of the records in a single underlying database table, you can use either *TSQLDataSet* or *TSQLTable* to generate the query for you rather than writing the SQL yourself.

Note If server performance is a concern, you may want to compose the query explicitly rather than relying on an automatically-generated query. Automatically-generated queries use wildcards rather than explicitly listing all of the fields in the table. This can result in slightly slower performance on the server. The wildcard (*) in automatically-generated queries is more robust to changes in the fields on the server.

Representing a table using TSQLDataSet

To make *TSQLDataSet* generate a query to fetch all fields and all records of a single database table, set the *CommandType* property to *ctTable*.

When *CommandType* is *ctTable*, *TSQLDataSet* generates a query based on the values of two properties:

- *CommandText* specifies the name of the database table that the *TSQLDataSet* object should represent.
- *SortFieldNames* lists the names of any fields to use to sort the data, in the order of significance.

For example, if you specify the following:

```
SQLDataSet1.CommandType := ctTable;
SQLDataSet1.CommandText := 'Employee';
SQLDataSet1.SortFieldNames := 'HireDate,Salary'
```

TSQLDataSet generates the following query, which lists all the records in the Employee table, sorted by HireDate and, within HireDate, by Salary:

```
select * from Employee order by HireDate, Salary
```

Representing a table using TSQLTable

When using *TSQLTable*, specify the table you want using the *TableName* property.

To specify the order of fields in the dataset, you must specify an index. There are two ways to do this:

- Set the *IndexName* property to the name of an index defined on the server that imposes the order you want.
- Set the *IndexFieldNames* property to a semicolon-delimited list of field names on which to sort. *IndexFieldNames* works like the *SortFieldNames* property of *TSQLDataSet*, except that it uses a semicolon instead of a comma as a delimiter.

Representing the results of a stored procedure

Stored procedures are sets of SQL statements that are named and stored on an SQL server. How you indicate the stored procedure you want to execute depends on the type of unidirectional dataset you are using.

When using *TSQLDataSet*, to specify a stored procedure:

- Set the *CommandType* property to *ctStoredProc*.
- Specify the name of the stored procedure as the value of the *CommandText* property:

```
SQLDataSet1.CommandType := ctStoredProc;
SQLDataSet1.CommandText := 'MyStoredProcName';
```

When using *TSQLStoredProc* , you need only specify the name of the stored procedure as the value of the *StoredProcName* property.

```
SQLStoredProc1.StoredProcName := 'MyStoredProcName';
```

After you have identified a stored procedure, your application may need to enter values for any input parameters of the stored procedure or retrieve the values of output parameters after you execute the stored procedure. See “Working with stored procedure parameters” on page 18-50 for information about working with stored procedure parameters.

Fetching the data

Once you have specified the source of the data, you must fetch the data before your application can access it. Once the dataset has fetched the data, data-aware controls linked to the dataset through a data source automatically display data values and client datasets linked to the dataset through a provider can be populated with records.

As with any dataset, there are two ways to fetch the data for a unidirectional dataset:

- Set the *Active* property to *True*, either at design time in the Object Inspector, or in code at runtime:

  ```
  CustQuery.Active := True;
  ```

- Call the *Open* method at runtime,

  ```
  CustQuery.Open;
  ```

Use the *Active* property or the *Open* method with any unidirectional dataset that obtains records from the server. It does not matter whether these records come from a SELECT query (including automatically-generated queries when the *CommandType* is *ctTable*) or a stored procedure.

Preparing the dataset

Before a query or stored procedure can execute on the server, it must first be “prepared”. Preparing the dataset means that *dbExpress* and the server allocate resources for the statement and its parameters. If *CommandType* is *ctTable*, this is when the dataset generates its SELECT query. Any parameters that are not bound by the server are folded into a query at this point.

Unidirectional datasets are automatically prepared when you set *Active* to *True* or call the *Open* method. When you close the dataset, the resources allocated for executing the statement are freed. If you intend to execute the query or stored procedure more than once, you can improve performance by explicitly preparing the dataset before you open it the first time. To explicitly prepare a dataset, set its *Prepared* property to *True*.

```
CustQuery.Prepared := True;
```

When you explicitly prepare the dataset, the resources allocated for executing the statement are not freed until you set *Prepared* to *False*.

Set the *Prepared* property to *False* if you want to ensure that the dataset is re-prepared before it executes (for example, if you change a parameter value or the *SortFieldNames* property).

Fetching multiple datasets

Some stored procedures return multiple sets of records. The dataset only fetches the first set when you open it. In order to access the other sets of records, call the *NextRecordSet* method:

```
var
  DataSet2: TSQLDataSet;
  nRows: Integer;
begin
  DataSet2 := SQLDataSet1.NextRecordSet(nRows);
  ...
```

NextRecordSet returns a newly created *TSQLDataSet* component that provides access to the next set of records. That is, the first time you call *NextRecordSet*, it returns a dataset for the second set of records. Calling *NextRecordSet* returns a third dataset, and so on, until there are no more sets of records. When there are no additional datasets, *NextRecordSet* returns **nil**.

Executing commands that do not return records

You can use a unidirectional dataset even if the query or stored procedure it represents does not return any records. Such commands include statements that use Data Definition Language (DDL) or Data Manipulation Language (DML) statements other than SELECT statements (For example, INSERT, DELETE, UPDATE, CREATE INDEX, and ALTER TABLE commands do not return any records). The language used in commands is server-specific, but usually compliant with the SQL-92 standard for the SQL language.

The SQL command you execute must be acceptable to the server you are using. Unidirectional datasets neither evaluate the SQL nor execute it. They merely pass the command to the server for execution.

Note If the command does not return any records, you do not need to use a unidirectional dataset at all, because there is no need for the dataset methods that provide access to a set of records. The SQL connection component that connects to the database server can be used directly to execute a command on the server. See “Sending commands to the server” on page 17-10 for details.

Specifying the command to execute

With unidirectional datasets, the way you specify the command to execute is the same whether the command results in a dataset or not. That is:

When using *TSQLDataSet*, use the *CommandType* and *CommandText* properties to specify the command:

- If *CommandType* is *ctQuery*, *CommandText* is the SQL statement to pass to the server.

- If *CommandType* is *ctStoredProc*, *CommandText* is the name of a stored procedure to execute.

When using *TSQLQuery*, use the *SQL* property to specify the SQL statement to pass to the server.

When using *TSQLStoredProc*, use the *StoredProcName* property to specify the name of the stored procedure to execute.

Just as you specify the command in the same way as when you are retrieving records, you work with query parameters or stored procedure parameters the same way as with queries and stored procedures that return records. See "Using parameters in queries" on page 18-43 and "Working with stored procedure parameters" on page 18-50 for details.

Executing the command

To execute a query or stored procedure that does not return any records, you do not use the *Active* property or the *Open* method. Instead, you must use

- The *ExecSQL* method if the dataset is an instance of *TSQLDataSet* or *TSQLQuery*.

```
FixTicket.CommandText := 'DELETE FROM TrafficViolations WHERE (TicketID = 1099)';
FixTicket.ExecSQL;
```

- The *ExecProc* method if the dataset is an instance of *TSQLStoredProc*.

```
SQLStoredProc1.StoredProcName := 'MyCommandWithNoResults';
SQLStoredProc1.ExecProc;
```

Tip If you are executing the query or stored procedure multiple times, it is a good idea to set the *Prepared* property to *True*.

Creating and modifying server metadata

Most of the commands that do not return data fall into two categories: those that you use to edit data (such as INSERT, DELETE, and UPDATE commands), and those that you use to create or modify entities on the server such as tables, indexes, and stored procedures.

If you don't want to use explicit SQL commands for editing, you can link your unidirectional dataset to a client dataset and let it handle all the generation of all SQL commands concerned with editing (see "Connecting a client dataset to another dataset in the same application" on page 14-11). In fact, this is the recommended approach because data-aware controls are designed to perform edits through a dataset such as *TClientDataSet*.

The only way your application can create or modify metadata on the server, however, is to send a command. Not all database drivers support the same SQL syntax. It is beyond the scope of this topic to describe the SQL syntax supported by each database type and the differences between the database types. For a comprehensive and up-to-date discussion of the SQL implementation for a given database system, see the documentation that comes with that system.

In general, use the CREATE TABLE statement to create tables in a database and CREATE INDEX to create new indexes for those tables. Where supported, use other CREATE statements for adding various metadata objects, such as CREATE DOMAIN, CREATE VIEW, CREATE SCHEMA, and CREATE PROCEDURE.

For each of the CREATE statements, there is a corresponding DROP statement to delete the metadata object. These statements include DROP TABLE, DROP VIEW, DROP DOMAIN, DROP SCHEMA, and DROP PROCEDURE.

To change the structure of a table, use the ALTER TABLE statement. ALTER TABLE has ADD and DROP clauses to create new elements in a table and to delete them. For example, use the ADD COLUMN clause to add a new column to the table and DROP CONSTRAINT to delete an existing constraint from the table.

For example, the following statement creates a stored procedure called GET_EMP_PROJ on an InterBase database:

```
CREATE PROCEDURE GET_EMP_PROJ (EMP_NO SMALLINT)
RETURNS (PROJ_ID CHAR(5))
AS
BEGIN
  FOR SELECT PROJ_ID
  FROM EMPLOYEE_PROJECT
  WHERE EMP_NO = :EMP_NO
  INTO :PROJ_ID
  DO
    SUSPEND;
END
```

The following code uses a *TSQLDataSet* to create this stored procedure. Note the use of the *ParamCheck* property to prevent the dataset from confusing the parameters in the stored procedure definition (:EMP_NO and :PROJ_ID) with a parameter of the query that creates the stored procedure.

```
with SQLDataSet1 do
begin
  ParamCheck := False;
  CommandType := ctQuery;
  CommandText := 'CREATE PROCEDURE GET_EMP_PROJ (EMP_NO SMALLINT) ' +
      'RETURNS (PROJ_ID CHAR(5)) AS ' +
      'BEGIN ' +
        'FOR SELECT PROJ_ID FROM EMPLOYEE_PROJECT ' +
        'WHERE EMP_NO = :EMP_NO ' +
        'INTO :PROJ_ID ' +
          'DO SUSPEND; ' +
       END';
  ExecSQL;
end;
```

Setting up master/detail linked cursors

There are two ways to use linked cursors to set up a master/detail relationship with a unidirectional dataset as the detail set. Which method you use depends on the type of unidirectional dataset you are using. Once you have set up such a relationship, the unidirectional dataset (the "many" in a one-to-many relationship) provides access only to those records that correspond to the current record on the master set (the "one" in the one-to-many relationship).

TSQLDataSet and *TSQLQuery* require you to use a parameterized query to establish a master/detail relationship. This is the technique for creating such relationships on all query-type datasets. For details on creating master/detail relationships with query-type datasets, see "Establishing master/detail relationships using parameters" on page 18-46.

To set up a master/detail relationship where the detail set is an instance of *TSQLTable*, use the *MasterSource* and *MasterFields* properties, just as you would with any other table-type dataset. For details on creating master/detail relationships with table-type datasets, see "Establishing master/detail relationships using parameters" on page 18-46.

Accessing schema information

There are two ways to obtain information about what is available on the server. This information, called schema information or metadata, includes information about what tables and stored procedures are available on the server and information about these tables and stored procedures (such as the fields a table contains, the indexes that are defined, and the parameters a stored procedure uses).

The simplest way to obtain this metadata is to use the methods of *TSQLConnection*. These methods fill an existing string list or list object with the names of tables, stored procedures, fields, or indexes, or with parameter descriptors. This technique is the same as the way you fill lists with metadata for any other database connection component. These methods are described in "Obtaining metadata" on page 17-12.

If you require more detailed schema information, you can populate a unidirectional dataset with metadata. Instead of a simple list, the unidirectional dataset is filled with schema information, where each record represents a single table, stored procedure, index, field, or parameter.

Fetching metadata into a unidirectional dataset

To populate a unidirectional datasets with metadata from the database server, you must first indicate what data you want to see, using the *SetSchemaInfo* method. *SetSchemaInfo* takes three parameters:

- The type of schema information (metadata) you want to fetch. This can be a list of tables (*stTables*), a list of system tables (*stSysTables*), a list of stored procedures (*stProcedures*), a list of fields in a table (*stColumns*), a list of indexes (*stIndexes*), or a list of parameters used by a stored procedure (*stProcedureParams*). Each type of information uses a different set of fields to describe the items in the list. For details on the structures of these datasets, see “The structure of metadata datasets” on page 22-13.

- If you are fetching information about fields, indexes, or stored procedure parameters, the name of the table or stored procedure to which they apply. If you are fetching any other type of schema information, this parameter is nil.
- A pattern that must be matched for every name returned. This pattern is an SQL pattern such as ‘Cust%’, which uses the wildcards ‘%’ (to match a string of arbitrary characters of any length) and ‘_’ (to match a single arbitrary character). To use a literal percent or underscore in a pattern, the character is doubled (%% or __). If you do not want to use a pattern, this parameter can be nil.

Note If you are fetching schema information about tables (*stTables*), the resulting schema information can describe ordinary tables, system tables, views, and/or synonyms, depending on the value of the SQL connection’s *TableScope* property.

The following call requests a table listing all system tables (server tables that contain metadata):

```
SQLDataSet1.SetSchemaInfo(stSysTable, '', '');
```

When you open the dataset after this call to *SetSchemaInfo*, the resulting dataset has a record for each table, with columns giving the table name, type, schema name, and so on. If the server does not use system tables to store metadata (for example MySQL), when you open the dataset it contains no records.

The previous example used only the first parameter. Suppose, Instead, you want to obtain a list of input parameters for a stored procedure named ‘MyProc’. Suppose, further, that the person who wrote that stored procedure named all parameters using a prefix to indicate whether they were input or output parameters (‘inName’, ‘outValue’ and so on). You could call *SetSchemaInfo* as follows:

```
SQLDataSet1.SetSchemaInfo(stProcedureParams, 'MyProc', 'in%');
```

The resulting dataset is a table of input parameters with columns to describe the properties of each parameter.

Fetching data after using the dataset for metadata

There are two ways to return to executing queries or stored procedures with the dataset after a call to *SetSchemaInfo*:

- Change the *CommandText* property, specifying the query, table, or stored procedure from which you want to fetch data.
- Call *SetSchemaInfo*, setting the first parameter to *stNoSchema*. In this case, the dataset reverts to fetching the data specified by the current value of *CommandText*.

The structure of metadata datasets

For each type of metadata you can access using *TSQLDataSet*, there is a predefined set of columns (fields) that are populated with information about the items of the requested type.

Information about tables

When you request information about tables (*stTables* or *stSysTables*), the resulting dataset includes a record for each table. It has the following columns:

Table 22.1 Columns in tables of metadata listing tables

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the table. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the table.
TABLE_NAME	ftString	The name of the table. This field determines the sort order of the dataset.
TABLE_TYPE	ftInteger	Identifies the type of table. It is a sum of one or more of the following values: 1: Table 2: View 4: System table 8: Synonym 16: Temporary table 32: Local table.

Information about stored procedures

When you request information about stored procedures (*stProcedures*), the resulting dataset includes a record for each stored procedure. It has following columns:

Table 22.2 Columns in tables of metadata listing stored procedures

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the stored procedure. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the stored procedure.
PROC_NAME	ftString	The name of the stored procedure. This field determines the sort order of the dataset.
PROC_TYPE	ftInteger	Identifies the type of stored procedure. It is a sum of one or more of the following values: 1: Procedure 2: Function 4: Package 8: System procedure
IN_PARAMS	ftSmallint	The number of input parameters
OUT_PARAMS	ftSmallint	The number of output parameters.

Information about fields

When you request information about the fields in a specified table (*stColumns*), the resulting dataset includes a record for each field. It includes the following columns:

Table 22.3 Columns in tables of metadata listing fields

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the table whose fields you listing. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the field.
TABLE_NAME	ftString	The name of the table that contains the fields.
COLUMN_NAME	ftString	The name of the field. This value determines the sort order of the dataset.
COLUMN_POSITION	ftSmallint	The position of the column in its table.
COLUMN_TYPE	ftInteger	Identifies the type of value in the field. It is a sum of one or more of the following: 1: Row ID 2: Row Version 4: Auto increment field 8: Field with a default value
COLUMN_DATATYPE	ftSmallint	The datatype of the column. This is one of the logical field type constants defined in sqllinks.pas.
COLUMN_TYPENAME	ftString	A string describing the datatype. This is the same information as contained in COLUMN_DATATYPE and COLUMN_SUBTYPE, but in a form used in some DDL statements.
COLUMN_SUBTYPE	ftSmallint	A subtype for the column's datatype. This is one of the logical subtype constants defined in sqllinks.pas.
COLUMN_PRECISION	ftInteger	The size of the field type (number of characters in a string, bytes in a bytes field, significant digits in a BCD value, members of an ADT field, and so on).
COLUMN_SCALE	ftSmallint	The number of digits to the right of the decimal on BCD values, or descendants on ADT and array fields.
COLUMN_LENGTH	ftInteger	The number of bytes required to store field values.
COLUMN_NULLABLE	ftSmallint	A Boolean that indicates whether the field can be left blank (0 means the field requires a value).

Information about indexes

When you request information about the indexes on a table (stIndexes), the resulting dataset includes a record for each field in each record. (Multi-record indexes are described using multiple records) The dataset has the following columns:

Table 22.4 Columns in tables of metadata listing indexes

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the index. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the index.
TABLE_NAME	ftString	The name of the table for which the index is defined.
INDEX_NAME	ftString	The name of the index. This field determines the sort order of the dataset.
PKEY_NAME	ftString	Indicates the name of the primary key.
COLUMN_NAME	ftString	The name of the field (column) in the index.
COLUMN_POSITION	ftSmallint	The position of this field in the index.
INDEX_TYPE	ftSmallint	Identifies the type of index. It is a sum of one or more of the following values: 1: Non-unique 2: Unique 4: Primary key
SORT_ORDER	ftString	Indicates that the index is ascending (a) or descending (d).
FILTER	ftString	Describes a filter condition that limits the indexed records.

Information about stored procedure parameters

When you request information about the parameters of a stored procedure (*stProcedureParams*), the resulting dataset includes a record for each parameter. It has the following columns:

Table 22.5 Columns in tables of metadata listing parameters

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the stored procedure. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the stored procedure.
PROC_NAME	ftString	The name of the stored procedure that contains the parameter.
PARAM_NAME	ftString	The name of the parameter. This field determines the sort order of the dataset.
PARAM_TYPE	ftSmallint	Identifies the type of parameter. This is the same as a *TParam* object's *ParamType* property.

Table 22.5 Columns in tables of metadata listing parameters (continued)

Column name	Field type	Contents
PARAM_DATATYPE	ftSmallint	The datatype of the parameter. This is one of the logical field type constants defined in sqllinks.pas.
PARAM_SUBTYPE	ftSmallint	A subtype for the parameter's datatype. This is one of the logical subtype constants defined in sqllinks.pas.
PARAM_TYPENAME	ftString	A string describing the datatype. This is the same information as contained in PARAM_DATATYPE and PARAM_SUBTYPE, but in a form used in some DDL statements.
PARAM_PRECISION	ftInteger	The maximum number of digits in floating-point values or bytes (for strings and Bytes fields).
PARAM_SCALE	ftSmallint	The number of digits to the right of the decimal on floating-point values.
PARAM_LENGTH	ftInteger	The number of bytes required to store parameter values.
PARAM_NULLABLE	ftSmallint	A Boolean that indicates whether the parameter can be left blank (0 means the parameter requires a value).

Debugging dbExpress applications

While you are debugging your database application, it may prove useful to monitor the SQL messages that are sent to and from the database server through your connection component, including those that are generated automatically for you (for example by a provider component or by the *dbExpress* driver).

Using TSQLMonitor to monitor SQL commands

TSQLConnection uses a companion component, *TSQLMonitor*, to intercept these messages and save them in a string list. *TSQLMonitor* works much like the SQL monitor utility that you can use with the BDE, except that it monitors only those commands involving a single *TSQLConnection* component rather than all commands managed by *dbExpress*.

To use *TSQLMonitor*,

1. Add a *TSQLMonitor* component to the form or data module containing the *TSQLConnection* component whose SQL commands you want to monitor.
2. Set its *SQLConnection* property to the *TSQLConnection* component.
3. Set the SQL monitor's *Active* property to *True*.

As SQL commands are sent to the server, the SQL monitor's *TraceList* property is automatically updated to list all the SQL commands that are intercepted.

You can save this list to a file by specifying a value for the *FileName* property and then setting the *AutoSave* property to *True*. *AutoSave* causes the SQL monitor to save the contents of the *TraceList* property to a file every time is logs a new message.

If you do not want the overhead of saving a file every time a message is logged, you can use the *OnLogTrace* event handler to only save files after a number of messages have been logged. For example, the following event handler saves the contents of *TraceList* every 10th message, clearing the log after saving it so that the list never gets too long:

```
procedure TForm1.SQLMonitor1LogTrace(Sender: TObject; CBInfo: Pointer);
var
  LogFileName: string;
begin
  with Sender as TSQLMonitor do
  begin
    if TraceCount = 10 then
    begin
      LogFileName := 'c:\log' + IntToStr(Tag) + '.txt';
      Tag := Tag + 1; {ensure next log file has a different name }
      SaveToFile(LogFileName);
      TraceList.Clear; { clear list }
    end;
  end;
end;
```

Note If you were to use the previous event handler, you would also want to save any partial list (fewer than 10 entries) when the application shuts down.

Using a callback to monitor SQL commands

Instead of using *TSQLMonitor*, you can customize the way your application traces SQL commands by using the SQL connection component's *SetTraceCallbackEvent* method. *SetTraceCallbackEvent* takes two parameters: a callback of type *TSQLCallbackEvent*, and a user-defined value that is passed to the callback function.

The callback function takes two parameters: *CallType* and *CBInfo*:

- *CallType* is reserved for future use.
- *CBInfo* is a pointer to a record that includes the category (the same as *CallType*), the text of the SQL command, and the user-defined value that is passed to the *SetTraceCallbackEvent* method.

The callback returns a value of type *CBRType*, typically *cbrUSEDEF*.

The *dbExpress* driver calls your callback every time the SQL connection component passes a command to the server or the server returns an error message.

Warning Do not call *SetTraceCallbackEvent* if the *TSQLConnection* object has an associated *TSQLMonitor* component. *TSQLMonitor* uses the callback mechanism to work, and *TSQLConnection* can only support one callback at a time.

Chapter

23

Using client datasets

Client datasets are specialized datasets that hold all their data in memory. The support for manipulating the data they store in memory is provided by midaslib.dcu or midas.dll. The format client datasets use for storing data is self-contained and easily transported, which allows client datasets to

- Read from and write to dedicated files on disk, acting as a file-based dataset. Properties and methods supporting this mechanism are described in "Using a client dataset with file-based data" on page 23-31.
- Cache updates for data from a database server. Client dataset features that support cached updates are described in "Using a client dataset to cache updates" on page 23-15.
- Represent the data in the client portion of a multi-tiered application. To function in this way, the client dataset must work with an external provider, as described in "Using a client dataset with a provider" on page 23-23. For information about multi-tiered database applications, see Chapter 25, "Creating multi-tiered applications."
- Represent the data from a source other than a dataset. Because a client dataset can use the data from an external provider, specialized providers can adapt a variety of information sources to work with client datasets. For example, you can use an XML provider to enable a client dataset to represent the information in an XML document.

Whether you use client datasets for file-based data, caching updates, data from an external provider (such as working with an XML document or in a multi-tiered application), or a combination of these approaches such as a "briefcase model" application, you can take advantage of broad range of features client datasets support for working with data.

Working with data using a client dataset

Like any dataset, you can use client datasets to supply the data for data-aware controls using a data source component. See Chapter 15, “Using data controls”for information on how to display database information in data-aware controls.

Client datasets implement all the properties an methods inherited from *TDataSet*. For a complete introduction to this generic dataset behavior, see Chapter 18, “Understanding datasets.”

In addition, client datasets implement many of the features common to table-type datasets such as

- Sorting records with indexes.
- Using Indexes to search for records.
- Limiting records with ranges.
- Creating master/detail relationships.
- Controlling read/write access
- Creating the underlying dataset
- Emptying the dataset
- Synchronizing client datasets

For details on these features, see “Using table-type datasets” on page 18-24.

Client datasets differ from other datasets in that they hold all their data in memory. Because of this, their support for some database functions can involve additional capabilities or considerations. This chapter describes some of these common functions and the differences introduced by client datasets.

Navigating data in client datasets

If an application uses standard data-aware controls, then a user can navigate through a client dataset’s records using the built-in behavior of those controls. You can also navigate programmatically through records using standard dataset methods such as *First*, *Last*, *Next*, and *Prior*. For more information about these methods, see “Navigating datasets” on page 18-5.

Unlike most datasets, client datasets can also position the cursor at a specific record in the dataset by using the *RecNo* property. Ordinarily an application uses *RecNo* to determine the record number of the current record. Client datasets can, however, set *RecNo* to a particular record number to make that record the current one.

Limiting what records appear

To restrict users to a subset of available data on a temporary basis, applications can use ranges and filters. When you apply a range or a filter, the client dataset does not display all the data in its in-memory cache. Instead, it only displays the data that meets the range or filter conditions. For more information about using filters, see “Displaying and editing a subset of data using filters” on page 18-12. For more information about ranges, see “Limiting records with ranges” on page 18-30.

With most datasets, filter strings are parsed into SQL commands that are then implemented on the database server. Because of this, the SQL dialect of the server limits what operations are used in filter strings. Client datasets implement their own filter support, which includes more operations than that of other datasets. For example, when using a client dataset, filter expressions can include string operators that return substrings, operators that parse date/time values, and much more. Client datasets also allow filters on BLOB fields or complex field types such as ADT fields and array fields.

The various operators and functions that client datasets can use in filters, along with a comparison to other datasets that support filters, is given below:

Table 23.1 Filter support in client datasets

Operator or function	Example	Supported by other datasets	Comment
Comparisons			
=	State = 'CA'	Yes	
<>	State <> 'CA'	Yes	
>=	DateEntered >= '1/1/1998'	Yes	
<=	Total <= 100,000	Yes	
>	Percentile > 50	Yes	
<	Field1 < Field2	Yes	
BLANK	State <> 'CA' or State = BLANK	Yes	Blank records do not appear unless explicitly included in the filter.
IS NULL	Field1 IS NULL	No	
IS NOT NULL	Field1 IS NOT NULL	No	
Logical operators			
and	State = 'CA' and Country = 'US'	Yes	
or	State = 'CA' or State = 'MA'	Yes	
not	not (State = 'CA')	Yes	
Arithmetic operators			
+	Total + 5 > 100	Depends on driver	Applies to numbers, strings, or date (time) + number.
-	Field1 - 7 <> 10	Depends on driver	Applies to numbers, dates, or date (time) - number.
*	Discount * 100 > 20	Depends on driver	Applies to numbers only.
/	Discount > Total / 5	Depends on driver	Applies to numbers only.

Table 23.1 Filter support in client datasets (continued)

Operator or function	Example	Supported by other datasets	Comment
String functions			
Upper	Upper(Field1) = 'ALWAYS'	No	
Lower	Lower(Field1 + Field2) = 'josp'	No	
Substring	Substring(DateFld,8) = '1998' Substring(DateFld,1,3) = 'JAN'	No	Value goes from position of second argument to end or number of chars in third argument. First char has position 1.

Trim	Trim(Field1 + Field2)
	Trim(Field1, '-')
		No	Removes third argument from front and back. If no third argument, trims spaces.

TrimLeft	TrimLeft(StringField) TrimLeft(Field1, '$') <> ''	No	See Trim.
TrimRight	TrimRight(StringField) TrimRight(Field1, '.') <> ''	No	See Trim.
DateTime functions			
Year	Year(DateField) = 2000	No	
Month	Month(DateField) <> 12	No	
Day	Day(DateField) = 1	No	
Hour	Hour(DateField) < 16	No	
Minute	Minute(DateField) = 0	No	
Second	Second(DateField) = 30	No	
GetDate	GetDate - DateField > 7	No	Represents current date and time.
Date	DateField = Date(GetDate)	No	Returns the date portion of a datetime value.
Time	TimeField > Time(GetDate)	No	Returns the time portion of a datetime value.
Miscellaneous			
Like	Memo LIKE '%filters%'	No	Works like SQL-92 without the ESC clause. When applied to BLOB fields, FilterOptions determines whether case is considered.
In	Day(DateField) in (1,7)	No	Works like SQL-92. Second argument is a list of values all with the same type.
*	State = 'M*'	Yes	Wildcard for partial comparisons.

When applying ranges or filters, the client dataset still stores all of its records in memory. The range or filter merely determines which records are available to controls that navigate or display data from the client dataset.

Note When fetching data from a provider, you can also limit the data that the client dataset stores by supplying parameters to the provider. For details, see "Limiting records with parameters" on page 23-28.

Editing data

Client datasets represent their data as an in-memory data packet. This packet is the value of the client dataset's *Data* property. By default, however, edits are not stored in the *Data* property. Instead the insertions, deletions, and modifications (made by users or programmatically) are stored in an internal change log, represented by the *Delta* property. Using a change log serves two purposes:

- The change log is required for applying updates to a database server or external provider component.
- The change log provides sophisticated support for undoing changes.

The *LogChanges* property lets you disable logging. When *LogChanges* is *True*, changes are recorded in the log. When *LogChanges* is *False*, changes are made directly to the *Data* property. You can disable the change log in file-based applications if you do not want the undo support.

Edits in the change log remain there until they are removed by the application. Applications remove edits when

- Undoing changes
- Saving changes

Note Saving the client dataset to a file does not remove edits from the change log. When you reload the dataset, the *Data* and *Delta* properties are the same as they were when the data was saved.

Undoing changes

Even though a record's original version remains unchanged in *Data*, each time a user edits a record, leaves it, and returns to it, the user sees the last changed version of the record. If a user or application edits a record a number of times, each changed version of the record is stored in the change log as a separate entry.

Storing each change to a record makes it possible to support multiple levels of undo operations should it be necessary to restore a record's previous state:

- To remove the last change to a record, call *UndoLastChange*. *UndoLastChange* takes a Boolean parameter, *FollowChange*, that indicates whether to reposition the cursor on the restored record (*True*), or to leave the cursor on the current record (*False*). If there are several changes to a record, each call to *UndoLastChange* removes another layer of edits. *UndoLastChange* returns a Boolean value indicating success or failure. If the removal occurs, *UndoLastChange* returns *True*. Use the *ChangeCount* property to check whether there are more changes to undo. *ChangeCount* indicates the number of changes stored in the change log.

- Instead of removing each layer of changes to a single record, you can remove them all at once. To remove all changes to a record, select the record, and call *RevertRecord*. *RevertRecord* removes any changes to the current record from the change log.
- To restore a deleted record, first set the *StatusFilter* property to [*usDeleted*], which makes the deleted records "visible." Next, navigate to the record you want to restore and call *RevertRecord*. Finally, restore the *StatusFilter* property to [*usModified*, *usInserted*, *usUnmodified*] so that the edited version of the dataset (now containing the restored record) is again visible.
- At any point during edits, you can save the current state of the change log using the *SavePoint* property. Reading *SavePoint* returns a marker into the current position in the change log. Later, if you want to undo all changes that occurred since you read the save point, set *SavePoint* to the value you read previously. Your application can obtain values for multiple save points. However, once you back up the change log to a save point, the values of all save points that your application read after that one are invalid.
- You can abandon all changes recorded in the change log by calling *CancelUpdates*. *CancelUpdates* clears the change log, effectively discarding all edits to all records. Be careful when you call *CancelUpdates*. After you call *CancelUpdates*, you cannot recover any changes that were in the log.

Saving changes

Client datasets use different mechanisms for incorporating changes from the change log, depending on whether the client datasets stores its data in a file or represents data obtained through a provider. Whichever mechanism is used, the change log is automatically emptied when all updates have been incorporated.

File-based applications can simply merge the changes into the local cache represented by the *Data* property. They do not need to worry about resolving local edits with changes made by other users. To merge the change log into the *Data* property, call the *MergeChangeLog* method. "Merging changes into data" on page 23-33 describes this process.

You can't use *MergeChangeLog* if you are using the client dataset to cache updates or to represent the data from an external provider component. The information in the change log is required fro resolving updated records with the data stored in the database (or source dataset). Instead, you call *ApplyUpdates*, which attempts to write the modifications to the database server or source dataset, and updates the *Data* property only when the modifications have been successfully committed. See "Applying updates" on page 23-19 for more information about this process.

Constraining data values

Client datasets can enforce constraints on the edits a user makes to data. These constraints are applied when the user tries to post changes to the change log. You can always supply custom constraints. These let you provide your own, application-defined limits on what values users post to a client dataset.

In addition, when client datasets represent server data that is accessed using the BDE, they also enforce data constraints imported from the database server. If the client dataset works with an external provider component, the provider can control whether those constraints are sent to the client dataset, and the client dataset can control whether it uses them. For details on how the provider controls whether constraints are included in data packets, see “Handling server constraints” on page 24-12. For details on how and why client dataset can turn off enforcement of server constraints, see “Handling constraints from the server” on page 23-28.

Specifying custom constraints

You can use the properties of the client dataset’s field components to impose your own constraints on what data users can enter. Each field component has two properties that you can use to specify constraints:

- The *DefaultExpression* property defines a default value that is assigned to the field if the user does not enter a value. Note that if the database server or source dataset also assigns a default expression for the field, the client dataset’s version takes precedence because it is assigned before the update is applied back to the database server or source dataset.
- The *CustomConstraint* property lets you assign a constraint condition that must be met before a field value can be posted. Custom constraints defined this way are applied in addition to any constraints imported from the server. For more information about working with custom constraints on field components, see “Creating a custom constraint” on page 19-21.

In addition, you can create record-level constraints using the client dataset’s *Constraints* property. *Constraints* is a collection of *TCheckConstraint* objects, where each object represents a separate condition. Use the *CustomConstraint* property of a *TCheckConstraint* object to add your own constraints that are checked when you post records.

Sorting and indexing

Using indexes provides several benefits to your applications:

- They allow client datasets to locate data quickly.
- They let you apply ranges to limit the available records.
- They let your application set up relationships with other datasets such as lookup tables or master/detail forms.
- They specify the order in which records appear.

If a client dataset represents server data or uses an external provider, it inherits a default index and sort order based on the data it receives. The default index is called DEFAULT_ORDER. You can use this ordering, but you cannot change or delete the index.

In addition to the default index, the client dataset maintains a second index, called CHANGEINDEX, on the changed records stored in the change log (*Delta* property). CHANGEINDEX orders all records in the client dataset as they would appear if the changes specified in *Delta* were applied. CHANGEINDEX is based on the ordering inherited from DEFAULT_ORDER. As with DEFAULT_ORDER, you cannot change or delete the CHANGEINDEX index.

You can use other existing indexes, and you can create your own indexes. The following sections describe how to create and use indexes with client datasets.

Note You may also want to review the material on indexes in table-type datasets, which also applies to client datasets. This material is in "Sorting records with indexes" on page 18-25 and "Limiting records with ranges" on page 18-30.

Adding a new index

There are three ways to add indexes to a client dataset:

- To create a temporary index at runtime that sorts the records in the client dataset, you can use the *IndexFieldNames* property. Specify field names, separated by semicolons. Ordering of field names in the list determines their order in the index.

  This is the least powerful method of adding indexes. You can't specify a descending or case-insensitive index, and the resulting indexes do not support grouping. These indexes do not persist when you close the dataset, and are not saved when you save the client dataset to a file.

- To create an index at runtime that can be used for grouping, call *AddIndex*. *AddIndex* lets you specify the properties of the index, including

  - The name of the index. This can be used for switching indexes at runtime.
  - The fields that make up the index. The index uses these fields to sort records and to locate records that have specific values on these fields.
  - How the index sorts records. By default, indexes impose an ascending sort order (based on the machine's locale). This default sort order is case-sensitive. You can set options to make the entire index case-insensitive or to sort in descending order. Alternately, you can provide a list of fields to be sorted case-insensitively and a list of fields to be sorted in descending order.
  - The default level of grouping support for the index.

  Indexes created with *AddIndex* do not persist when the client dataset is closed. (That is, they are lost when you reopen the client dataset). You can't call *AddIndex* when the dataset is closed. Indexes you add using *AddIndex* are not saved when you save the client dataset to a file.

- The third way to create an index is at the time the client dataset is created. Before creating the client dataset, specify the desired indexes using the *IndexDefs* property. The indexes are then created along with the underlying dataset when you call *CreateDataSet*. See "Creating and deleting tables" on page 18-37 for more information about creating client datasets.

  As with *AddIndex*, indexes you create with the dataset support grouping, can sort in ascending order on some fields and descending order on others, and can be case insensitive on some fields and case sensitive on others. Indexes created this way always persist and are saved when you save the client dataset to a file.

Tip You can index and sort on internally calculated fields with client datasets.

Deleting and switching indexes

To remove an index you created for a client dataset, call *DeleteIndex* and specify the name of the index to remove. You cannot remove the DEFAULT_ORDER and CHANGEINDEX indexes.

To use a different index when more than one index is available, use the *IndexName* property to select the index to use. At design time, you can select from available indexes in *IndexName* property drop-down box in the Object Inspector.

Using indexes to group data

When you use an index in your client dataset, it automatically imposes a sort order on the records. Because of this order, adjacent records usually contain duplicate values on the fields that make up the index. For example, consider the following fragment from an orders table that is indexed on the SalesRep and Customer fields:

SalesRep	Customer	OrderNo	Amount
1	1	5	100
1	1	2	50
1	2	3	200
1	2	6	75
2	1	1	10
2	3	4	200

Because of the sort order, adjacent values in the SalesRep column are duplicated. Within the records for SalesRep 1, adjacent values in the Customer column are duplicated. That is, the data is grouped by SalesRep, and within the SalesRep group it is grouped by Customer. Each grouping has an associated level. In this case, the SalesRep group has level 1 (because it is not nested in any other groups) and the Customer group has level 2 (because it is nested in the group with level 1). Grouping level corresponds to the order of fields in the index.

Client datasets let you determine where the current record lies within any given grouping level. This allows your application to display records differently, depending on whether they are the first record in the group, in the middle of a group, or the last record in a group. For example, you might want to display a field value only if it is on the first record of the group, eliminating the duplicate values. To do this with the previous table results in the following:

SalesRep	Customer	OrderNo	Amount
1	1	5	100
		2	50
	2	3	200
		6	75
2	1	1	10
	3	4	200

To determine where the current record falls within any group, use the *GetGroupState* method. *GetGroupState* takes an integer giving the level of the group and returns a value indicating where the current record falls the group (first record, last record, or neither).

When you create an index, you can specify the level of grouping it supports (up to the number of fields in the index). *GetGroupState* can't provide information about groups beyond that level, even if the index sorts records on additional fields.

Representing calculated values

As with any dataset, you can add calculated fields to your client dataset. These are fields whose values you calculate dynamically, usually based on the values of other fields in the same record. For more information about using calculated fields, see "Defining a calculated field" on page 19-7.

Client datasets, however, let you optimize when fields are calculated by using internally calculated fields. For more information on internally calculated fields, see "Using internally calculated fields in client datasets" below.

You can also tell client datasets to create calculated values that summarize the data in several records using maintained aggregates. For more information on maintained aggregates, see "Using maintained aggregates" on page 23-11.

Using internally calculated fields in client datasets

In other datasets, your application must compute the value of calculated fields every time the record changes or the user edits any fields in the current record. It does this in an *OnCalcFields* event handler.

While you can still do this, client datasets let you minimize the number of times calculated fields must be recomputed by saving calculated values in the client dataset's data. When calculated values are saved with the client dataset, they must still be recomputed when the user edits the current record, but your application need not recompute values every time the current record changes. To save calculated values in the client dataset's data, use internally calculated fields instead of calculated fields.

Internally calculated fields, just like calculated fields, are calculated in an *OnCalcFields* event handler. However, you can optimize your event handler by checking the *State* property of your client dataset. When *State* is *dsInternalCalc*, you must recompute internally calculated fields. When *State* is *dsCalcFields*, you need only recompute regular calculated fields.

To use internally calculated fields, you must define the fields as internally calculated before you create the client dataset. Depending on whether you use persistent fields or field definitions, you do this in one of the following ways:

- If you use persistent fields, define fields as internally calculated by selecting InternalCalc in the Fields editor.
- If you use field definitions, set the *InternalCalcField* property of the relevant field definition to *True*.

Note Other types of datasets use internally calculated fields. However, with other datasets, you do not calculate these values in an *OnCalcFields* event handler. Instead, they are computed automatically by the BDE or remote database server.

Using maintained aggregates

Client datasets provide support for summarizing data over groups of records. Because these summaries are automatically updated as you edit the data in the dataset, this summarized data is called a "maintained aggregate."

In their simplest form, maintained aggregates let you obtain information such as the sum of all values in a column of the client dataset. They are flexible enough, however, to support a variety of summary calculations and to provide subtotals over groups of records defined by a field in an index that supports grouping.

Specifying aggregates

To specify that you want to calculate summaries over the records in a client dataset, use the *Aggregates* property. *Aggregates* is a collection of aggregate specifications (*TAggregate*). You can add aggregate specifications to your client dataset using the Collection Editor at design time, or using the *Add* method of *Aggregates* at runtime. If you want to create field components for the aggregates, create persistent fields for the aggregated values in the Fields Editor.

Note When you create aggregated fields, the appropriate aggregate objects are added to the client dataset's *Aggregates* property automatically. Do not add them explicitly when creating aggregated persistent fields. For details on creating aggregated persistent fields, see "Defining an aggregate field" on page 19-10.

For each aggregate, the *Expression* property indicates the summary calculation it represents. *Expression* can contain a simple summary expression such as

```
Sum(Field1)
```

or a complex expression that combines information from several fields, such as

```
Sum(Qty * Price) - Sum(AmountPaid)
```

Aggregate expressions include one or more of the summary operators in Table 23.2

Table 23.2 Summary operators for maintained aggregates

Operator	Use
Sum	Totals the values for a numeric field or expression
Avg	Computes the average value for a numeric or date-time field or expression
Count	Specifies the number of non-blank values for a field or expression
Min	Indicates the minimum value for a string, numeric, or date-time field or expression
Max	Indicates the maximum value for a string, numeric, or date-time field or expression

The summary operators act on field values or on expressions built from field values using the same operators you use to create filters. (You can't nest summary operators, however.) You can create expressions by using operators on summarized values with other summarized values, or on summarized values and constants. However, you can't combine summarized values with field values, because such expressions are ambiguous (there is no indication of which record should supply the field value.) These rules are illustrated in the following expressions:

```
Sum(Qty * Price)             {legal -- summary of an expression on fields }
Max(Field1) - Max(Field2)    {legal -- expression on summaries }
Avg(DiscountRate) * 100      {legal -- expression of summary and constant }
Min(Sum(Field1))             {illegal -- nested summaries }
Count(Field1) - Field2       {illegal -- expression of summary and field }
```

Aggregating over groups of records

By default, maintained aggregates are calculated so that they summarize all the records in the client dataset. However, you can specify that you want to summarize over the records in a group instead. This lets you provide intermediate summaries such as subtotals for groups of records that share a common field value.

Before you can specify a maintained aggregate over a group of records, you must use an index that supports the appropriate grouping. See "Using indexes to group data" on page 23-9 for information on grouping support.

Once you have an index that groups the data in the way you want it summarized, specify the *IndexName* and *GroupingLevel* properties of the aggregate to indicate what index it uses, and which group or subgroup on that index defines the records it summarizes.

For example, consider the following fragment from an orders table that is grouped by SalesRep and, within SalesRep, by Customer:

SalesRep	Customer	OrderNo	Amount
1	1	5	100
1	1	2	50
1	2	3	200
1	2	6	75
2	1	1	10
2	3	4	200

The following code sets up a maintained aggregate that indicates the total amount for each sales representative:

```
Agg.Expression := 'Sum(Amount)';
Agg.IndexName := 'SalesCust';
Agg.GroupingLevel := 1;
Agg.AggregateName := 'Total for Rep';
```

To add an aggregate that summarizes for each customer within a given sales representative, create a maintained aggregate with level 2.

Maintained aggregates that summarize over a group of records are associated with a specific index. The *Aggregates* property can include aggregates that use different indexes. However, only the aggregates that summarize over the entire dataset and those that use the current index are valid. Changing the current index changes which aggregates are valid. To determine which aggregates are valid at any time, use the *ActiveAggs* property.

Obtaining aggregate values

To get the value of a maintained aggregate, call the *Value* method of the *TAggregate* object that represents the aggregate. *Value* returns the maintained aggregate for the group that contains the current record of the client dataset.

When you are summarizing over the entire client dataset, you can call *Value* at any time to obtain the maintained aggregate. However, when you are summarizing over grouped information, you must be careful to ensure that the current record is in the group whose summary you want. Because of this, it is a good idea to obtain aggregate values at clearly specified times, such as when you move to the first record of a group or when you move to the last record of a group. Use the *GetGroupState* method to determine where the current record falls within a group.

To display maintained aggregates in data-aware controls, use the Fields editor to create a persistent aggregate field component. When you specify an aggregate field in the Fields editor, the client dataset's *Aggregates* is automatically updated to include the appropriate aggregate specification. The *AggFields* property contains the new aggregated field component, and the *FindField* method returns it.

Copying data from another dataset

To copy the data from another dataset at design time, right click the client dataset and choose Assign Local Data. A dialog appears listing all the datasets available in your project. Select the one whose data and structure you want to copy and choose OK. When you copy the source dataset, your client dataset is automatically activated.

To copy from another dataset at runtime, you can assign its data directly or, if the source is another client dataset, you can clone the cursor.

Assigning data directly

You can use the client dataset's *Data* property to assign data to a client dataset from another dataset. *Data* is a data packet in the form of an OleVariant. A data packet can come from another client dataset or from any other dataset by using a provider. Once a data packet is assigned to *Data*, its contents are displayed automatically in data-aware controls connected to the client dataset by a data source component.

When you open a client dataset that represents server data or that uses an external provider component, data packets are automatically assigned to *Data*.

When your client dataset does not use a provider, you can copy the data from another client dataset as follows:

```
ClientDataSet1.Data := ClientDataSet2.Data;
```

Note When you copy the *Data* property of another client dataset, you copy the change log as well, but the copy does not reflect any filters or ranges that have been applied. To include filters or ranges, you must clone the source dataset's cursor instead.

If you are copying from a dataset other than a client dataset, you can create a dataset provider component, link it to the source dataset, and then copy its data:

```
TempProvider := TDataSetProvider.Create(Form1);
TempProvider.DataSet := SourceDataSet;
ClientDataSet1.Data := TempProvider.Data;
TempProvider.Free;
```

Note When you assign directly to the *Data* property, the new data packet is not merged into the existing data. Instead, all previous data is replaced.

If you want to merge changes from another dataset, rather than copying its data, you must use a provider component. Create a dataset provider as in the previous example, but attach it to the destination dataset and instead of copying the data property, use the *ApplyUpdates* method:

```
TempProvider := TDataSetProvider.Create(Form1);
TempProvider.DataSet := ClientDataSet1;
TempProvider.ApplyUpdates(SourceDataSet.Delta, -1, ErrCount);
TempProvider.Free;
```

Cloning a client dataset cursor

Client datasets use the *CloneCursor* method to let you work with a second view of the data at runtime. *CloneCursor* lets a second client dataset share the original client dataset's data. This is less expensive than copying all the original data, but, because the data is shared, the second client dataset can't modify the data without affecting the original client dataset.

CloneCursor takes three parameters: *Source* specifies the client dataset to clone. The last two parameters (*Reset* and *KeepSettings*) indicate whether to copy information other than the data. This information includes any filters, the current index, links to a master table (when the source dataset is a detail set), the *ReadOnly* property, and any links to a connection component or provider.

When *Reset* and *KeepSettings* are *False*, a cloned client dataset is opened, and the settings of the source client dataset are used to set the properties of the destination. When *Reset* is *True*, the destination dataset's properties are given the default values (no index or filters, no master table, *ReadOnly* is *False*, and no connection component or provider is specified). When *KeepSettings* is *True*, the destination dataset's properties are not changed.

Adding application-specific information to the data

Application developers can add custom information to the client dataset's *Data* property. Because this information is bundled with the data packet, it is included when you save the data to a file or stream. It is copied when you copy the data to another dataset. Optionally, it can be included with the *Delta* property so that a provider can read this information when it receives updates from the client dataset.

To save application-specific information with the *Data* property, use the *SetOptionalParam* method. This method lets you store an OleVariant that contains the data under a specific name.

To retrieve this application-specific information, use the *GetOptionalParam* method, passing in the name that was used when the information was stored.

Using a client dataset to cache updates

By default, when you edit data in most datasets, every time you delete or post a record, the dataset generates a transaction, deletes or writes that record to the database server, and commits the transaction. If there is a problem writing changes to the database, your application is notified immediately: the dataset raises an exception when you post the record.

If your dataset uses a remote database server, this approach can degrade performance due to network traffic between your application and the server every time you move to a new record after editing the current record. To minimize the network traffic, you may want to cache updates locally. When you cache updates, you application retrieves data from the database, caches and edits it locally, and then applies the cached updates to the database in a single transaction. When you cache updates, changes to a dataset (such as posting changes or deleting records) are stored locally instead of being written directly to the dataset's underlying table. When changes are complete, your application calls a method that writes the cached changes to the database and clears the cache.

Caching updates can minimize transaction times and reduce network traffic. However, cached data is local to your application and is not under transaction control. This means that while you are working on your local, in-memory, copy of the data, other applications can be changing the data in the underlying database table. They also can't see any changes you make until you apply the cached updates. Because of this, cached updates may not be appropriate for applications that work with volatile data, as you may create or encounter too many conflicts when trying to merge your changes into the database.

Although the BDE and ADO provide alternate mechanisms for caching updates, using a client dataset for caching updates has several advantages:

- Applying updates when datasets are linked in master/detail relationships is handled for you. This ensures that updates to multiple linked datasets are applied in the correct order.
- Client datasets give you the maximum of control over the update process. You can set properties to influence the SQL that is generated for updating records, specify the table to use when updating records from a multi-table join, or even apply updates manually from a *BeforeUpdateRecord* event handler.
- When errors occur applying cached updates to the database server, only client datasets (and dataset providers) provide you with information about the current record value on the database server in addition to the original (unedited) value from your dataset and the new (edited) value of the update that failed.
- Client datasets let you specify the number of update errors you want to tolerate before the entire update is rolled back.

Overview of using cached updates

To use cached updates, the following order of processes must occur in an application:

1. **Indicate the data you want to edit.** How you do this depends on the type of client dataset you are using:

   - If you are using *TClientDataSet*, Specify the provider component that represent the data you want to edit. This is described in "Specifying a provider" on page 23-24.
   - If you are using a client dataset associated with a particular data access mechanism, you must
     - Identify the database server by setting the *DBConnection* property to an appropriate connection component.
     - Indicate what data you want to see by specifying the *CommandText* and *CommandType* properties. *CommandType* indicates whether *CommandText* is an SQL statement to execute, the name of a stored procedure, or the name of a table. If *CommandText* is a query or stored procedure, use the *Params* property to provide any input parameters.
     - Optionally, use the *Options* property to indicate whether nested detail sets and BLOB data should be included in data packets or fetched separately, whether specific types of edits (insertions, modifications, or deletions) should be disabled, whether a single update can affect multiple server records, and whether the client dataset's records are refreshed when it applies updates. *Options* is identical to a provider's *Options* property. As a result, it allows you to set options that are not relevant or appropriate. For example, there is no reason to include *poIncFieldProps*, because the client dataset does not fetch its data from a dataset with persistent fields. Conversely, you do not want to exclude *poAllowCommandText*, which is included by default, because that would disable the *CommandText* property, which the client dataset uses to specify what data it wants. For information on the provider's *Options* property, see "Setting options that influence the data packets" on page 24-5.

2. **Display and edit the data,** permit insertion of new records, and support deletions of existing records. Both the original copy of each record and any edits to it are stored in memory. This process is described in "Editing data" on page 23-5.

3. **Fetch additional records as necessary.** By default, client datasets fetch all records and store them in memory. If a dataset contains many records or records with large BLOB fields, you may want to change this so that the client dataset fetches only enough records for display and re-fetches as needed. For details on how to control the record-fetching process, see "Requesting data from the source dataset or document" on page 23-25.

4. **Optionally, refresh the records.** As time passes, other users may modify the data on the database server. This can cause the client dataset's data to deviate more and more from the data on the server, increasing the chance of errors when you apply updates. To mitigate this problem, you can refresh records that have not already been edited. See "Refreshing records" on page 23-29 for details.

5 **Apply the locally cached records to the database** or cancel the updates. For each record written to the database, a *BeforeUpdateRecord* event is triggered. If an error occurs when writing an individual record to the database, an *OnUpdateError* event enables the application to correct the error, if possible, and continue updating. When updates are complete, all successfully applied updates are cleared from the local cache. For more information about applying updates to the database, see "Updating records" on page 23-19.

Instead of applying updates, an application can cancel the updates, emptying the change log without writing the changes to the database. You can cancel the updates by calling *CancelUpdates* method. All deleted records in the cache are undeleted, modified records revert to original values, and newly inserted record simply disappear.

Choosing the type of dataset for caching updates

Delphi includes some specialized client dataset components for caching updates. Each client dataset is associated with a particular data access mechanism. These are listed in Table 23.3:

Table 23.3 Specialized client datasets for caching updates

Client dataset	Data access mechanism
TBDEClientDataSet	Borland Database Engine
TSQLClientDataSet	dbExpress
TIBClientDataSet	InterBase Express

In addition, you can cache updates using the generic client dataset (*TClientDataSet*) with an external provider and source dataset. For information about using *TClientDataSet* with an external provider, see "Using a client dataset with a provider" on page 23-23.

Note The specialized client datasets associated with each data access mechanism actually use a provider and source dataset as well. However, both the provider and the source dataset are internal to the client dataset.

It is simplest to use one of the specialized client datasets to cache updates. However, there are times when it is preferable to use *TClientDataSet* with an external provider:

- If you are using a data access mechanism that does not have a specialized client dataset, you must use *TClientDataSet* with an external provider component. For example, if the data comes from an XML document or custom dataset.
- If you are working with tables that are related in a master/detail relationship, you should use *TClientDataSet* and connect it, using a provider, to the master table of two source datasets linked in a master/detail relationship. The client dataset sees the detail dataset as a nested dataset field. This approach is necessary so that updates to master and detail tables can be applied in the correct order.

- If you want to code event handlers that respond to the communication between the client dataset and the provider (for example, before and after the client dataset fetches records from the provider), you must use *TClientDataSet* with an external provider component. The specialized client datasets publish the most important events for applying updates (*OnReconcileError*, *BeforeUpdateRecord* and *OnGetTableName*), but do not publish the events surrounding communication between the client dataset and its provider, because they are intended primarily for multi-tiered applications.
- When using the BDE, you may want to use an external provider and source dataset if you need to use an update object. Although it is possible to code an update object from the *BeforeUpdateRecord* event handler of *TBDEClientDataSet*, it can be simpler just to assign the *UpdateObject* property of the source dataset. For information about using update objects, see "Using update objects to update a dataset" on page 20-39.

Indicating what records are modified

While the user edits a client dataset, you may find it useful to provide feedback about the edits that have been made. This is especially useful if you want to allow the user to undo specific edits, for example, by navigating to them and clicking an "Undo" button.

The *UpdateStatus* method and *StatusFilter* properties are useful when providing feedback on what updates have occurred:

- *UpdateStatus* indicates what type of update, if any, has occurred for the current record. It can be any of the following values:
  - *usUnmodified* indicates that the current record is unchanged.
  - *usModified* indicates that the current record has been edited.
  - *usInserted* indicates a record that was inserted by the user.
  - *usDeleted* indicates a record that was deleted by the user.
- *StatusFilter* controls what type of updates in the change log are visible. *StatusFilter* works on cached records in much the same way as filters work on regular data. *StatusFilter* is a set, so it can contain any combination of the following values:
  - *usUnmodified* indicates an unmodified record.
  - *usModified* indicates a modified record.
  - *usInserted* indicates an inserted record.
  - *usDeleted* indicates a deleted record.

  By default, *StatusFilter* is the set [*usModified*, *usInserted*, *usUnmodified*]. You can add *usDeleted* to this set to provide feedback about deleted records as well.

Note *UpdateStatus* and *StatusFilter* are also useful in *BeforeUpdateRecord* and *OnReconcileError* event handlers. For information about *BeforeUpdateRecord*, see "Intervening as updates are applied" on page 23-20. For information about *OnReconcileError*, see "Reconciling update errors" on page 23-22.

The following example shows how to provide feedback about the update status of records using the *UpdateStatus* method. It assumes that you have changed the

StatusFilter property to include *usDeleted*, allowing deleted records to remain visible in the dataset. It further assumes that you have added a calculated field to the dataset called "Status."

```
procedure TForm1.ClientDataSet1CalcFields(DataSet: TDataSet);
begin
  with ClientDataSet1 do begin
    case UpdateStatus of
      usUnmodified: FieldByName('Status').AsString := '';
      usModified: FieldByName('Status').AsString := 'M';
      usInserted: FieldByName('Status').AsString := 'I';
      usDeleted: FieldByName('Status').AsString := 'D';
    end;
  end;
end;
```

Updating records

The contents of the change log are stored as a data packet in the client dataset's *Delta* property. To make the changes in *Delta* permanent, the client dataset must apply them to the database (or source dataset or XML document).

When a client applies updates to the server, the following steps occur:

1. The client application calls the *ApplyUpdates* method of a client dataset object. This method passes the contents of the client dataset's *Delta* property to the (internal or external) provider. *Delta* is a data packet that contains a client dataset's updated, inserted, and deleted records.
2. The provider applies the updates, caching any problem records that it can't resolve itself. See "Responding to client update requests" on page 24-8 for details on how the provider applies updates.
3. The provider returns all unresolved records to the client dataset in a *Result* data packet. The *Result* data packet contains all records that were not updated. It also contains error information, such as error messages and error codes.
4. The client dataset attempts to reconcile update errors returned in the *Result* data packet on a record-by-record basis.

Applying updates

Changes made to the client dataset's local copy of data are not sent to the database server (or XML document) until the client application calls the *ApplyUpdates* method. *ApplyUpdates* takes the changes in the change log, and sends them as a data packet (called *Delta*) to the provider. (Note that, when using most client datasets, the provider is internal to the client dataset.)

ApplyUpdates takes a single parameter, *MaxErrors*, which indicates the maximum number of errors that the provider should tolerate before aborting the update process. If *MaxErrors* is *0*, then as soon as an update error occurs, the entire update process is terminated. No changes are written to the database, and the client dataset's change log remains intact. If *MaxErrors* is *-1*, any number of errors is tolerated, and the change log contains all records that could not be successfully applied. If *MaxErrors* is a positive value, and more errors occur than are permitted by *MaxErrors*, all updates are aborted. If fewer errors occur than specified by *MaxErrors*, all records successfully applied are automatically cleared from the client dataset's change log.

ApplyUpdates returns the number of actual errors encountered, which is always less than or equal to *MaxErrors* plus one. This return value indicates the number of records that could not be written to the database.

The client dataset's *ApplyUpdates* method does the following:

1 It indirectly calls the provider's *ApplyUpdates* method. The provider's *ApplyUpdates* method writes the updates to the database, source dataset, or XML document and attempts to correct any errors it encounters. Records that it cannot apply because of error conditions are sent back to the client dataset.

2 The client dataset 's *ApplyUpdates* method then attempts to reconcile these problem records by calling the *Reconcile* method. *Reconcile* is an error-handling routine that calls the *OnReconcileError* event handler. You must code the *OnReconcileError* event handler to correct errors. For details about using *OnReconcileError*, see "Reconciling update errors" on page 23-22.

3 Finally, *Reconcile* removes successfully applied changes from the change log and updates *Data* to reflect the newly updated records. When *Reconcile* completes, *ApplyUpdates* reports the number of errors that occurred.

Important In some cases, the provider can't determine how to apply updates (for example, when applying updates from a stored procedure or multi-table join). Client datasets and provider components generate events that let you handle these situations. See "Intervening as updates are applied" below for details.

Tip If the provider is on a stateless application server, you may want to communicate with it about persistent state information before or after you apply updates. *TClientDataSet* receives a *BeforeApplyUpdates* event before the updates are sent, which lets you send persistent state information to the server. After the updates are applied (but before the reconcile process), *TClientDataSet* receives an *AfterApplyUpdates* event where you can respond to any persistent state information returned by the application server.

Intervening as updates are applied

When a client dataset applies its updates, the provider determines how to handle writing the insertions, deletions, and modifications to the database server or source dataset. When you use *TClientDataSet* with an external provider component, you can use the properties and events of that provider to influence the way updates are applied. These are described in "Responding to client update requests" on page 24-8.

When the provider is internal, however, as it is for any client dataset associated with a data access mechanism, you can't set its properties or provide event handlers. As a result, the client dataset publishes one property and two events that let you influence how the internal provider applies updates.

- *UpdateMode* controls what fields are used to locate records in the SQL statements the provider generates for applying updates. *UpdateMode* is identical to the provider's *UpdateMode* property. For information on the provider's *UpdateMode* property, see "Influencing how updates are applied" on page 24-9.
- *OnGetTableName* lets you supply the provider with the name of the database table to which it should apply updates. This lets the provider generate the SQL statements for updates when it can't identify the database table from the stored procedure or query specified by *CommandText*. For example, if the query executes a multi-table join that only requires updates to a single table, supplying an *OnGetTableName* event handler allows the internal provider to correctly apply updates.

  An *OnGetTableName* event handler has three parameters: the internal provider component, the internal dataset that fetched the data from the server, and a parameter to return the table name to use in the generated SQL.
- *BeforeUpdateRecord* occurs for every record in the delta packet. This event lets you make any last-minute changes before the record is inserted, deleted, or modified. It also provides a way for you to execute your own SQL statements to apply the update in cases where the provider can't generate correct SQL (for example, for multi-table joins where multiple tables must be updated.)

  A *BeforeUpdateRecord* event handler has five parameters: the internal provider component, the internal dataset that fetched the data from the server, a delta packet that is positioned on the record that is about to be updated, an indication of whether the update is an insertion, deletion, or modification, and a parameter that returns whether the event handler performed the update.The use of these is illustrated in the following event handler. For simplicity, the example assumes the SQL statements are available as global variables that only need field values:

```
procedure TForm1.SQLClientDataSet1BeforeUpdateRecord(Sender: TObject;
   SourceDS: TDataSet; DeltaDS: TCustomClientDataSet; UpdateKind: TUpdateKind;
   var Applied Boolean);
var
  SQL: string;
  Connection: TSQLConnection;
begin
  Connection := (SourceDS as TCustomSQLDataSet).SQLConnection;
  case UpdateKind of
  ukModify:
    begin
     { 1st dataset: update Fields[1], use Fields[0] in where clause }
      SQL := Format(UpdateStmt1, [DeltaDS.Fields[1].NewValue, DeltaDS.Fields[0].OldValue]);
      Connection.Execute(SQL, nil, nil);
     { 2nd dataset: update Fields[2], use Fields[3] in where clause }
      SQL := Format(UpdateStmt2, [DeltaDS.Fields[2].NewValue, DeltaDS.Fields[3].OldValue]);
      Connection.Execute(SQL, nil, nil);
    end;
  ukDelete:
    begin
     { 1st dataset: use Fields[0] in where clause }
      SQL := Format(DeleteStmt1, [DeltaDS.Fields[0].OldValue]);
      Connection.Execute(SQL, nil, nil);
     { 2nd dataset: use Fields[3] in where clause }
      SQL := Format(DeleteStmt2, [DeltaDS.Fields[3].OldValue]);
      Connection.Execute(SQL, nil, nil);
    end;
  ukInsert:
    begin
     { 1st dataset: values in Fields[0] and Fields[1] }
       SQL := Format(InsertStmt1, [DeltaDS.Fields[0].NewValue, DeltaDS.Fields[1].NewValue]);
      Connection.Execute(SQL, nil, nil);
     { 2nd dataset: values in Fields[2] and Fields[3] }
      SQL := Format(InsertStmt2, [DeltaDS.Fields[2].NewValue, DeltaDS.Fields[3].NewValue]);
      Connection.Execute(SQL, nil, nil);
    end;
  end;
  Applied := True;
end;
```

Reconciling update errors

There are two events that let you handle errors that occur during the update process:

- During the update process, the internal provider generates an *OnUpdateError* event every time it encounters an update that it can't handle. If you correct the problem in an *OnUpdateError* event handler, then the error does not count toward the maximum number of errors passed to the *ApplyUpdates* method. This event only occurs for client datasets that use an internal provider. If you are using *TClientDataSet*, you can use the provider component's *OnUpdateError* event instead.
- After the entire update operation is finished, the client dataset generates an *OnReconcileError* event for every record that the provider could not apply to the database server.

You should always code an *OnReconcileError* or *OnUpdateError* event handler, even if only to discard the records returned that could not be applied. The event handlers for these two events work the same way. They include the following parameters:

- *DataSet:* A client dataset that contains the updated record which couldn't be applied. You can use this dataset's methods to get information about the problem record and to edit the record in order to correct any problems. In particular, you will want to use the *CurValue*, *OldValue*, and *NewValue* properties of the fields in the current record to determine the cause of the update problem. However, you must not call any client dataset methods that change the current record in your event handler.
- *E:* An object that represents the problem that occurred. You can use this exception to extract an error message or to determine the cause of the update error.
- *UpdateKind:* The type of update that generated the error. *UpdateKind* can be *ukModify* (the problem occurred updating an existing record that was modified), *ukInsert* (the problem occurred inserting a new record), or *ukDelete* (the problem occurred deleting an existing record).

- *Action:* A **var** parameter that indicates what action to take when the event handler exits. In your event handler, you set this parameter to
  - Skip this record, leaving it in the change log. (rrSkip or raSkip)
  - Stop the entire reconcile operation. (rrAbort or raAbort)
  - Merge the modification that failed into the corresponding record from the server. (rrMerge or raMerge) This only works if the server record does not include any changes to fields modified in the client dataset's record.
  - Replace the current update in the change log with the value of the record in the event handler, which has presumably been corrected. (rrApply or raCorrect)
  - Ignore the error completely. (rrIgnore) This possibility only exists in the *OnUpdateError* event handler, and is intended for the case where the event handler applies the update back to the database server. The updated record is removed from the change log and merged into *Data*, as if the provider had applied the update.
  - Back out the changes for this record on the client dataset, reverting to the originally provided values. (raCancel) This possibility only exists in the *OnReconcileError* event handler.
  - Update the current record value to match the record on the server. (raRefresh) This possibility only exists in the *OnReconcileError* event handler.

The following code shows an *OnReconcileError* event handler that uses the reconcile error dialog from the RecError unit which ships in the objrepos directory. (To use this dialog, add RecError to your uses clause.)

```
procedure TForm1.ClientDataSetReconcileError(DataSet: TCustomClientDataSet; E:
EReconcileError; UpdateKind: TUpdateKind, var Action TReconcileAction);
begin
  Action := HandleReconcileError(DataSet, UpdateKind, E);
end;
```

Using a client dataset with a provider

A client dataset uses a provider to supply it with data and apply updates when

- It caches updates from a database server or another dataset.
- It represents the data in an XML document.
- It stores the data in the client portion of a multi-tiered application.

For any client dataset other than *TClientDataSet*, this provider is internal, and so not directly accessible by the application. With *TClientDataSet*, the provider is an external component that links the client dataset to an external source of data.

An external provider component can reside in the same application as the client dataset, or it can be part of a separate application running on another system. For more information about provider components, see Chapter 24, "Using provider components." For more information about applications where the provider is in a separate application on another system, see Chapter 25, "Creating multi-tiered applications."

When using an (internal or external) provider, the client dataset always caches any updates. For information on how this works, see "Using a client dataset to cache updates" on page 23-15.

The following topics describe additional properties and methods of the client dataset that enable it to work with a provider.

Specifying a provider

Unlike the client datasets that are associated with a data access mechanism, *TClientDataSet* has no internal provider component to package data or apply updates. If you want it to represent data from a source dataset or XML document, therefore, you must associated the client dataset with an external provider component.

The way you associate *TClientDataSet* with a provider depends on whether the provider is in the same application as the client dataset or on a remote application server running on another system.

- If the provider is in the same application as the client dataset, you can associate it with a provider by choosing a provider from the drop-down list for the *ProviderName* property in the Object Inspector. This works as long as the provider has the same *Owner* as the client dataset. (The client dataset and the provider have the same *Owner* if they are placed in the same form or data module.) To use a local provider that has a different *Owner*, you must form the association at runtime using the client dataset's *SetProvider* method

  If you think you may eventually scale up to a remote provider, or if you want to make calls directly to the *IAppServer* interface, you can also set the *RemoteServer* property to a *TLocalConnection* component. If you use *TLocalConnection*, the *TLocalConnection* instance manages the list of all providers that are local to the application, and handles the client dataset's *IAppServer* calls. If you do not use *TLocalConnection*, Delphi creates a hidden object that handles the *IAppServer* calls from the client dataset.

- If the provider is on a remote application server, then, in addition to the *ProviderName* property, you need to specify a component that connects the client dataset to the application server. There are two properties that can handle this task: *RemoteServer*, which specifies the name of a connection component from which to get a list of providers, or *ConnectionBroker*, which specifies a centralized broker that provides an additional level of indirection between the client dataset and the connection component. The connection component and, if used, the connection broker, reside in the same data module as the client dataset. The connection component establishes and maintains a connection to an application server, sometimes called a "data broker". For more information, see "The structure of the client application" on page 25-4.

  At design time, after you specify *RemoteServer* or *ConnectionBroker,* you can select a provider from the drop-down list for the *ProviderName* property in the Object

Inspector. This list includes both local providers (in the same form or data module) and remote providers that can be accessed through the connection component.

Note If the connection component is an instance of *TDCOMConnection*, the application server must be registered on the client machine.

At runtime, you can switch among available providers (both local and remote) by setting *ProviderName* in code.

Requesting data from the source dataset or document

Client datasets can control how they fetch their data packets from a provider. By default, they retrieve all records from the source dataset. This is true whether the source dataset and provider are internal components (as with *TBDEClientDataSet, TSQLClientDataSet,* and *TIBClientDataSet*), or separate components that supply the data for *TClientDataSet*.

You can change how the client dataset fetches records using the *PacketRecords* and *FetchOnDemand* properties.

Incremental fetching

By changing the *PacketRecords* property, you can specify that the client dataset fetches data in smaller chunks. *PacketRecords* specifies either how many records to fetch at a time, or the type of records to return. By default, *PacketRecords* is set to *-1*, which means that all available records are fetched at once, either when the client dataset is first opened, or when the application explicitly calls *GetNextPacket*. When *PacketRecords* is *-1*, then after the client dataset first fetches data, it never needs to fetch more data because it already has all available records.

To fetch records in small batches, set *PacketRecords* to the number of records to fetch. For example, the following statement sets the size of each data packet to ten records:

```
ClientDataSet1.PacketRecords := 10;
```

This process of fetching records in batches is called “incremental fetching”. Client datasets use incremental fetching when *PacketRecords* is greater than zero.

To fetch each batch of records, the client dataset calls *GetNextPacket*. Newly fetched packets are appended to the end of the data already in the client dataset. *GetNextPacket* returns the number of records it fetches. If the return value is the same as *PacketRecords*, the end of available records was not encountered. If the return value is greater than *0* but less than *PacketRecords*, the last record was reached during the fetch operation. If *GetNextPacket* returns *0*, then there are no more records to fetch.

Warning Incremental fetching does not work if you are fetching data from a remote provider on a stateless application server. See “Supporting state information in remote data modules” on page 25-19 for information on how to use incremental fetching with stateless remote data modules.

Note You can also use *PacketRecords* to fetch metadata information about the source dataset. To retrieve metadata information, set *PacketRecords* to *0*.

Fetch-on-demand

Automatic fetching of records is controlled by the *FetchOnDemand* property. When *FetchOnDemand* is *True* (the default), the client dataset automatically fetches records as needed. To prevent automatic fetching of records, set *FetchOnDemand* to *False*. When *FetchOnDemand* is *False*, the application must explicitly call *GetNextPacket* to fetch records.

For example, Applications that need to represent extremely large read-only datasets can turn off *FetchOnDemand* to ensure that the client datasets do not try to load more data than can fit into memory. Between fetches, the client dataset frees its cache using the *EmptyDataSet* method. This approach, however, does not work well when the client must post updates to the server.

The provider controls whether the records in data packets include BLOB data and nested detail datasets. If the provider excludes this information from records, the *FetchOnDemand* property causes the client dataset to automatically fetch BLOB data and detail datasets on an as-needed basis. If *FetchOnDemand* is *False,* and the provider does not include BLOB data and detail datasets with records, you must explicitly call the *FetchBlobs* or *FetchDetails* method to retrieve this information.

Getting parameters from the source dataset

There are two circumstances when the client dataset needs to fetch parameter values:

- The application needs the value of output parameters on a stored procedure.
- The application wants to initialize the input parameters of a query or stored procedure to the current values on the source dataset.

Client datasets store parameter values in their *Params* property. These values are refreshed with any output parameters when the client dataset fetches data from the source dataset. However, there may be times a *TClientDataSet* component in a client application needs output parameters when it is not fetching data.

To fetch output parameters when not fetching records, or to initialize input parameters, the client dataset can request parameter values from the source dataset by calling the *FetchParams* method. The parameters are returned in a data packet from the provider and assigned to the client dataset's *Params* property.

At design time, the *Params* property can be initialized by right-clicking the client dataset and choosing Fetch Params.

Note There is never a need to call *FetchParams* when the client dataset uses an internal provider and source dataset, because the *Params* property always reflects the parameters of the internal source dataset. With *TClientDataSet*, the *FetchParams* method (or the Fetch Params command) only works if the client dataset is connected to a provider whose associated dataset can supply parameters. For example, if the source dataset is a table-type dataset, there are no parameters to fetch.

If the provider is on a separate system as part of a stateless application server, you can't use *FetchParams* to retrieve output parameters. In a stateless application server, other clients can change and rerun the query or stored procedure, changing output parameters before the call to *FetchParams*. To retrieve output parameters from a stateless application server, use the *Execute* method. If the provider is associated with a query or stored procedure, *Execute* tells the provider to execute the query or stored procedure and return any output parameters. These returned parameters are then used to automatically update the *Params* property.

Passing parameters to the source dataset

Client datasets can pass parameters to the source dataset to specify what data they want provided in the data packets it sends. These parameters can specify

- Input parameter values for a query or stored procedure that is run on the application server
- Field values that limit the records sent in data packets

You can specify parameter values that your client dataset sends to the source dataset at design time or at runtime. At design time, select the client dataset and double-click the *Params* property in the Object Inspector. This brings up the collection editor, where you can add, delete, or rearrange parameters. By selecting a parameter in the collection editor, you can use the Object Inspector to edit the properties of that parameter.

At runtime, use the *CreateParam* method of the *Params* property to add parameters to your client dataset. *CreateParam* returns a parameter object, given a specified name, parameter type, and datatype. You can then use the properties of that parameter object to assign a value to the parameter.

For example, the following code adds an input parameter named CustNo with a value of 605:

```
with ClientDataSet1.Params.CreateParam(ftInteger, 'CustNo', ptInput) do
  AsInteger := 605;
```

If the client dataset is not active, you can send the parameters to the application server and retrieve a data packet that reflects those parameter values simply by setting the *Active* property to *True*.

Sending query or stored procedure parameters

When the client dataset's *CommandType* property is *ctQuery* or *ctStoredProc*, or, if the client dataset is a *TClientDataSet* instance, when the associated provider represents the results of a query or stored procedure, you can use the *Params* property to specify parameter values. When the client dataset requests data from the source dataset or uses its *Execute* method to run a query or stored procedure that does not return a dataset, it passes these parameter values along with the request for data or the execute command. When the provider receives these parameter values, it assigns them to its associated dataset. It then instructs the dataset to execute its query or stored procedure using these parameter values, and, if the client dataset requested data, begins providing data, starting with the first record in the result set.

Note Parameter names should match the names of the corresponding parameters on the source dataset.

Limiting records with parameters

If the client dataset is

- a *TClientDataSet* instance whose associated provider represents a *TTable* or *TSQLTable* component
- a *TSQLClientDataSet* or *TBDEClientDataSet* instance whose *CommandType* property is *ctTable*

then it can use the *Params* property to limit the records that it caches in memory. Each parameter represents a field value that must be matched before a record can be included in the client dataset's data. This works much like a filter, except that with a filter, the records are still cached in memory, but unavailable.

Each parameter name must match the name of a field. When using *TClientDataSet*, these are the names of fields in the *TTable* or *TSQLTable* component associated with the provider. When using *TSQLClientDataSet* or *TBDEClientDataSet*, these are the names of fields in the table on the database server. The data in the client dataset then includes only those records whose values on the corresponding fields match the values assigned to the parameters.

For example, consider an application that displays the orders for a single customer. When the user identifies the customer, the client dataset sets its *Params* property to include a single parameter named CustID (or whatever field in the source table is called) whose value identifies the customer whose orders should be displayed. When the client dataset requests data from the source dataset, it passes this parameter value. The provider then sends only the records for the identified customer. This is more efficient than letting the provider send all the orders records to the client application and then filtering the records using the client dataset.

Handling constraints from the server

When a database server defines constraints on what data is valid, it is useful if the client dataset knows about them. That way, the client dataset can ensure that user edits never violate those server constraints. As a result, such violations are never passed to the database server where they would be rejected. This means fewer updates generate error conditions during the updating process.

Regardless of the source of data, you can duplicate such server constraints by explicitly adding them to the client dataset. This process is described in “Specifying custom constraints” on page 23-7.

It is more convenient, however, if the server constraints are automatically included in data packets. Then you need not explicitly specify default expressions and constraints, and the client dataset changes the values it enforces when the server constraints change. By default, this is exactly what happens: if the source dataset is aware of server constraints, the provider automatically includes them in data packets and the client dataset enforces them when the user posts edits to the change log.

Note Only datasets that use the BDE can import constraints from the server. This means that server constraints are only included in data packets when using *TBDEClientDataSet* or *TClientDataSet* with a provider that represents a BDE-based dataset. For more information on how to import server constraints and how to prevent a provider from including them in data packets, see “Handling server constraints” on page 24-12.

Note For more information on working with the constraints once they have been imported, see “Using server constraints” on page 19-21.

While importing server constraints and expressions is an extremely valuable feature that helps an application preserve data integrity, there may be times when it needs to disable constraints on a temporary basis. For example, if a server constraint is based on the current maximum value of a field, but the client dataset uses incremental fetching, the current maximum value for a field in the client dataset may differ from the maximum value on the database server, and constraints may be invoked differently. In another case, if a client dataset applies a filter to records when constraints are enabled, the filter may interfere in unintended ways with constraint conditions. In each of these cases, an application may disable constraint-checking.

To disable constraints temporarily, call the *DisableConstraints* method. Each time *DisableConstraints* is called, a reference count is incremented. While the reference count is greater than zero, constraints are not enforced on the client dataset.

To reenable constraints for the client dataset, call the dataset’s *EnableConstraints* method. Each call to *EnableConstraints* decrements the reference count. When the reference count is zero, constraints are enabled again.

Tip Always call *DisableConstraints* and *EnableConstraints* in paired blocks to ensure that constraints are enabled when you intend them to be.

Refreshing records

Client datasets work with an in-memory snapshot of the data from the source dataset. If the source dataset represents server data, then as time elapses other users may modify that data. The data in the client dataset becomes a less accurate picture of the underlying data.

Like any other dataset, client datasets have a *Refresh* method that updates its records to match the current values on the server. However, calling *Refresh* only works if there are no edits in the change log. Calling *Refresh* when there are unapplied edits results in an exception.

Client datasets can also update the data while leaving the change log intact. To do this, call the *RefreshRecord* method. Unlike the *Refresh* method, *RefreshRecord* updates only the current record in the client dataset. *RefreshRecord* changes the record value originally obtained from the provider but leaves any changes in the change log.

Warning It is not always appropriate to call *RefreshRecord*. If the user’s edits conflict with changes made to the underlying dataset by other users, calling *RefreshRecord* masks this conflict. When the client dataset applies its updates, no reconcile error occurs and the application can’t resolve the conflict.

In order to avoid masking update errors, you may want to check that there are no pending updates before calling *RefreshRecord*. For example, the following *AfterScroll* refreshes the current record every time the user moves to a new record (ensuring the most up-to-date value), but only when it is safe to do so.:

```
procedure TForm1.ClientDataSet1AfterScroll(DataSet: TDataSet);
begin
  if ClientDataSet1.UpdateStatus = usUnModified then
    ClientDataSet1.RefreshRecord;
end;
```

Communicating with providers using custom events

Client datasets communicate with a provider component through a special interface called *IAppServer*. If the provider is local, *IAppServer* is the interface to an automatically-generated object that handles all communication between the client dataset and its provider. If the provider is remote, *IAppServer* is the interface to a remote data module on the application server

TClientDataSet provides many opportunities for customizing the communication that uses the *IAppServer* interface. Before and after every *IAppServer* method call that is directed at the client dataset's provider, *TClientDataSet* receives special events that allow it to communicate arbitrary information with its provider. These events are matched with similar events on the provider. Thus for example, when the client dataset calls its *ApplyUpdates* method, the following events occur:

1. The client dataset receives a *BeforeApplyUpdates* event, where it specifies arbitrary custom information in an OleVariant called *OwnerData*.
2. The provider receives a *BeforeApplyUpdates* event, where it can respond to the *OwnerData* from the client dataset and update the value of *OwnerData* to new information.
3. The provider goes through its normal process of assembling a data packet (including all the accompanying events).
4. The provider receives an *AfterApplyUpdates* event, where it can respond to the current value of *OwnerData* and update it to a value for the client dataset.
5. The client dataset receives an *AfterApplyUpdates* event, where it can respond to the returned value of *OwnerData*.

Every other *IAppServer* method call is accompanied by a similar set of *BeforeXXX* and *AfterXXX* events that let you customize the communication between client dataset and provider.

In addition, the client dataset has a special method, *DataRequest*, whose only purpose is to allow application-specific communication with the provider. When the client dataset calls *DataRequest*, it passes an OleVariant as a parameter that can contain any information you want. This, in turn, generates an is the *OnDataRequest* event on the provider, where you can respond in any application-defined way and return a value to the client dataset.

Overriding the source dataset

The client datasets that are associated with a particular data access mechanism use the *CommandText* and *CommandType* properties to specify the data they represent. When using *TClientDataSet*, however, the data is specified by the source dataset, not the client dataset. Typically, this source dataset has a property that specifies an SQL statement to generate the data or the name of a database table or stored procedure.

If the provider allows, *TClientDataSet* can override the property on the source dataset that indicates what data it represents. That is, if the provider permits, the client dataset's *CommandText* property replaces the property on the provider's dataset that specifies what data it represents. This allows *TClientDataSet* to specify dynamically what data it wants to see.

By default, external provider components do not let client datasets use the *CommandText* value in this way. To allow *TClientDataSet* to use its *CommandText* property, you must add *poAllowCommandText* to the *Options* property of the provider. Otherwise, the value of *CommandText* is ignored.

Note Never remove *poAllowCommandText* from the *Options* property of *TSQLClientDataSet*, *TBDEClientDataSet*, or *TIBClientDataSet*. The client dataset's *Options* property is forwarded to the internal provider, so removing *poAllowCommandText* prevents the client dataset from specifying what data to access.

The client dataset sends its *CommandText* string to the provider at two times:

- When the client dataset first opens. After it has retrieved the first data packet from the provider, the client dataset does not send *CommandText* when fetching subsequent data packets.
- When the client dataset sends an *Execute* command to provider.

To send an SQL command or to change a table or stored procedure name at any other time, you must explicitly use the *IAppServer* interface that is available as the *AppServer* property. This property represents the interface through which the client dataset communicates with its provider.

Using a client dataset with file-based data

Client datasets can work with dedicated files on disk as well as server data. This allows them to be used in file-based database applications and "briefcase model" applications. The special files that client datasets use for their data are called MyBase.

Tip All client datasets are appropriate for a briefcase model application, but for a pure MyBase application (one that does not use a provider), it is preferable to use *TClientDataSet*, because it involves less overhead.

In a pure MyBase application, the client application cannot get table definitions and data from the server, and there is no server to which it can apply updates. Instead, the client dataset must independently

- Define and create tables

- Load saved data
- Merge edits into its data
- Save data

Creating a new dataset

There are three ways to define and create client datasets that do not represent server data:

- You can define and create a new client dataset using persistent fields or field and index definitions. This follows the same scheme as creating any table-type dataset. See "Creating and deleting tables" on page 18-37 for details.
- You can copy an existing dataset (at design or runtime). See "Copying data from another dataset" on page 23-13 for more information about copying existing datasets.
- You can create a client dataset from an arbitrary XML document. See "Converting XML documents into data packets" on page 26-6 for details.

Once the dataset is created, you can save it to a file. From then on, you do not need to recreate the table, only load it from the file you saved. When beginning a file-based database application, you may want to first create and save empty files for your datasets before writing the application itself. This way, you start with the metadata for your client dataset already defined, making it easier to set up the user interface.

Loading data from a file or stream

To load data from a file, call a client dataset's *LoadFromFile* method. *LoadFromFile* takes one parameter, a string that specifies the file from which to read data. The file name can be a fully qualified path name, if appropriate. If you always load the client dataset's data from the same file, you can use the *FileName* property instead. If *FileName* names an existing file, the data is automatically loaded when the client dataset is opened.

To load data from a stream, call the client dataset's *LoadFromStream* method. *LoadFromStream* takes one parameter, a stream object that supplies the data.

The data loaded by *LoadFromFile* (*LoadFromStream)* must have previously been saved in a client dataset's data format by this or another client dataset using the *SaveToFile (SaveToStream)* method, or generated from an XML document. For more information about saving data to a file or stream, see "Saving data to a file or stream" on page 23-33. For information about creating client dataset data from an XML document, see Chapter 26, "Using XML in database applications."

When you call *LoadFromFile* or *LoadFromStream*, all data in the file is read into the *Data* property. Any edits that were in the change log when the data was saved are read into the *Delta* property. However, the only indexes that are read from the file are those that were created with the dataset.

Merging changes into data

When you edit the data in a client dataset, all edits to the data exist only in an in-memory change log. This log can be maintained separately from the data itself, although it is completely transparent to objects that use the client dataset. That is, controls that navigate the client dataset or display its data see a view of the data that includes the changes. If you do not want to back out of changes, however, you should merge the change log into the data of the client dataset by calling the *MergeChangeLog* method. *MergeChangeLog* overwrites records in *Data* with any changed field values in the change log.

After *MergeChangeLog* executes, *Data* contains a mix of existing data and any changes that were in the change log. This mix becomes the new *Data* baseline against which further changes can be made. *MergeChangeLog* clears the change log of all records and resets the *ChangeCount* property to *0*.

Warning Do not call *MergeChangeLog* for client datasets that use a provider. In this case, call *ApplyUpdates* to write changes to the database. For more information, see “Applying updates” on page 23-19.

Note It is also possible to merge changes into the data of a separate client dataset if that dataset originally provided the data in the *Data* property. To do this, you must use a dataset provider. For an example of how to do this, see “Assigning data directly” on page 23-13.

If you do not want to use the extended undo capabilities of the change log, you can set the client dataset’s *LogChanges* property to *False*. When *LogChanges* is *False*, edits are automatically merged when you post records and there is no need to call *MergeChangeLog*.

Saving data to a file or stream

Even when you have merged changes into the data of a client dataset, this data still exists only in memory. While it persists if you close the client dataset and reopen it in your application, it will disappear when your application shuts down. To make the data permanent, it must be written to disk. Write changes to disk using the *SaveToFile* method.

SaveToFile takes one parameter, a string that specifies the file into which to write data. The file name can be a fully qualified path name, if appropriate. If the file already exists, its current contents are completely overwritten.

Note *SaveToFile* does not preserve any indexes you added to the client dataset at runtime, only indexes that were added when you created the client dataset.

If you always save the data to the same file, you can use the *FileName* property instead. If *FileName* is set, the data is automatically saved to the named file when the client dataset is closed.

You can also save data to a stream, using the *SaveToStream* method. *SaveToStream* takes one parameter, a stream object that receives the data.

Note If you save a client dataset while there are still edits in the change log, these are not merged with the data. When you reload the data, using the *LoadFromFile* or *LoadFromStream* method, the change log will still contain the unmerged edits. This is important for applications that support the briefcase model, where those changes will eventually have to be applied to a provider component on the application server.

Chapter

24

Using provider components

Provider components (*TDataSetProvider* and *TXMLTransformProvider*) supply the most common mechanism by which client datasets obtain their data. Providers

- Receive data requests from a client dataset (or XML broker), fetch the requested data, package the data into a transportable data packet, and return the data to the client dataset (or XML broker). This activity is called “providing.”
- Receive updated data from a client dataset (or XML broker), apply updates to the database server, source dataset, or source XML document, and log any updates that cannot be applied, returning unresolved updates to the client dataset for further reconciliation. This activity is called “resolving.”

Most of the work of a provider component happens automatically. You need not write any code on the provider to create data packets from the data in a dataset or XML document or to apply updates. However, provider components include a number of events and properties that allow your application more direct control over what information is packaged for clients and how your application responds to client requests.

When using *TBDEClientDataSet*, *TSQLClientDataSet*, or *TIBClientDataSet*, the provider is internal to the client dataset, and the application has no direct access to it. When using *TClientDataSet* or *TXMLBroker*, however, the provider is a separate component that you can use to control what information is packaged for clients and for responding to events that occur around the process of providing and resolving. The client datasets that have internal providers surface some of the internal provider’s properties and events as their own properties and events, but for the greatest amount of control, you may want to use *TClientDataSet* with a separate provider component.

When using a separate provider component, it can reside in the same application as the client dataset (or XML broker), or it can reside on an application server as part of a multi-tiered application.

This chapter describes how to use a provider component to control the interaction with client datasets or XML brokers.

Determining the source of data

When you use a provider component, you must specify the source it uses to get the data it assembles into data packets. Depending on your version of Delphi, you can specify the source as one of the following:

- To provide the data from a dataset, use *TDataSetProvider*.
- To provide the data from an XML document, use *TXMLTransformProvider*.

Using a dataset as the source of the data

If the provider is a dataset provider (*TDataSetProvider*), set the *DataSet* property of the provider to indicate the source dataset. At design time, select from available datasets in the *DataSet* property drop-down list in the Object Inspector.

TDataSetProvider interacts with the source dataset using the *IProviderSupport* interface. This interface is introduced by *TDataSet*, so it is available for all datasets. However, the *IProviderSupport* methods implemented in *TDataSet* are mostly stubs that don’t do anything or that raise exceptions.

The dataset classes that ship with Delphi (BDE-enabled datasets, ADO-enabled datasets, *dbExpress* datasets, and InterBase Express datasets) override these methods to implement the *IProviderSupport* interface in a more useful fashion. Client datasets don’t add anything to the inherited *IProviderSupport* implementation, but can still be used as a source dataset as long as the *ResolveToDataSet* property of the provider is *True*.

Component writers that create their own custom descendants from *TDataSet* must override all appropriate *IProviderSupport* methods if their datasets are to supply data to a provider. If the provider only provides data packets on a read-only basis (that is, if it does not apply updates), the *IProviderSupport* methods implemented in *TDataSet* may be sufficient.

Using an XML document as the source of the data

If the provider is an XML provider, set the *XMLDataFile* property of the provider indicate the source document.

XML providers must transform the source document into data packets, so in addition to indicating the source document, you must also specify how to transform that document into data packets. This transformation is handled by the provider’s *TransformRead* property. *TransformRead* represents a *TXMLTransform* object. You can set its properties to specify what transformation to use, and use its events to provide your own input to the transformation. For more information on using XML providers, see “Using an XML document as the source for a provider” on page 26-8.

Communicating with the client dataset

All communication between a provider and a client dataset or XML broker takes place through an *IAppServer* interface. If the provider is in the same application as the client, this interface is implemented by a hidden object generated automatically for you, or by a *TLocalConnection* component. If the provider is part of a multi-tiered application, this is the interface for the application server's remote data module.

Most applications do not use *IAppServer* directly, but invoke it indirectly through the properties and methods of the client dataset or XML broker. However, when necessary, you can make direct calls to the *IAppServer* interface by using the *AppServer* property of a client dataset.

Table 24.1 lists the methods of the *IAppServer* interface, as well as the corresponding methods and events on the provider component and the client dataset. These *IAppServer* methods include a *Provider* parameter. In multi-tiered applications, this parameter indicates the provider on the application server with which the client dataset communicates. Most methods also include an OleVariant parameter called *OwnerData* that allows a client dataset and a provider to pass custom information back and forth. *OwnerData* is not used by default, but is passed to all event handlers so that you can write code that allows your provider to adjust to application-defined information before and after each call from a client dataset.

Table 24.1 AppServer interface members

IAppServer	provider component	TClientDataSet
AS_ApplyUpdates method	ApplyUpdates method, BeforeApplyUpdates event, AfterApplyUpdates event	ApplyUpdates method, BeforeApplyUpdates event, AfterApplyUpdates event.
AS_DataRequest method	DataRequest method, OnDataRequest event	DataRequest method.
AS_Execute method	Execute method, BeforeExecute event, AfterExecute event	Execute method, BeforeExecute event, AfterExecute event.
AS_GetParams method	GetParams method, BeforeGetParams event, AfterGetParams event	FetchParams method, BeforeGetParams event, AfterGetParams event.
AS_GetProviderNames method	Used to identify all available providers.	Used to create a design-time list for ProviderName property.
AS_GetRecords method	GetRecords method, BeforeGetRecords event, AfterGetRecords event	GetNextPacket method, Data property, BeforeGetRecords event, AfterGetRecords event
AS_RowRequest method	RowRequest method, BeforeRowRequest event, AfterRowRequest event	FetchBlobs method, FetchDetails method, RefreshRecord method, BeforeRowRequest event, AfterRowRequest event

Choosing how to apply updates using a dataset provider

TXMLTransformProvider components always apply updates to the associated XML document. When using *TDataSetProvider*, however, you can choose how updates are applied. By default, when *TDataSetProvider* components apply updates and resolve update errors, they communicate directly with the database server using dynamically generated SQL statements. This approach has the advantage that your server application does not need to merge updates twice (first to the dataset, and then to the remote server).

However, you may not always want to take this approach. For example, you may want to use some of the events on the dataset component. Alternately, the dataset you use may not support the use of SQL statements (for example if you are providing from a *TClientDataSet* component).

TDataSetProvider lets you decide whether to apply updates to the database server using SQL or to the source dataset by setting the *ResolveToDataSet* property. When this property is *True*, updates are applied to the dataset. When it is *False*, updates are applied directly to the underlying database server.

Controlling what information is included in data packets

When working with a dataset provider, there are a number of ways to control what information is included in data packets that are sent to and from the client. These include

- Specifying what fields appear in data packets
- Setting options that influence the data packets
- Adding custom information to data packets

Note These techniques for controlling the content of data packets are only available for dataset providers. When using *TXMLTransformProvider*, you can only control the content of data packets by controlling the transformation file the provider uses.

Specifying what fields appear in data packets

When using a dataset provider, you can control what fields are included in data packets by creating persistent fields on the dataset that the provider uses to build data packets. The provider then includes only these fields. Fields whose values are generated dynamically by the source dataset (such as calculated fields or lookup fields) can be included, but appear to client datasets on the receiving end as static read-only fields. For information about persistent fields, see “Persistent field components” on page 19-3.

If the client dataset will be editing the data and applying updates, you must include enough fields so that there are no duplicate records in the data packet. Otherwise, when the updates are applied, it is impossible to determine which record to update. If you do not want the client dataset to be able to see or use extra fields provided only to ensure uniqueness, set the *ProviderFlags* property for those fields to include *pfHidden*.

Note Including enough fields to avoid duplicate records is also a consideration when the provider's source dataset represents a query. You must specify the query so that it includes enough fields to ensure all records are unique, even if your application does not use all the fields.

Setting options that influence the data packets

The *Options* property of a dataset provider lets you specify when BLOBs or nested detail tables are sent, whether field display properties are included, what type of updates are allowed, and so on. The following table lists the possible values that can be included in *Options*.

Table 24.2 Provider options

Value	Meaning
poAutoRefresh	The provider refreshes the client dataset with current record values whenever it applies updates.
poReadOnly	The client dataset can't apply updates to the provider.
poDisableEdits	Client datasets can't modify existing data values. If the user tries to edit a field, the client dataset raises exception. (This does not affect the client dataset's ability to insert or delete records).
poDisableInserts	Client datasets can't insert new records. If the user tries to insert a new record, the client dataset raises an exception. (This does not affect the client dataset's ability to delete records or modify existing data)
poDisableDeletes	Client datasets can't delete records. If the user tries to delete a record, the client dataset raises an exception. (This does not affect the client dataset's ability to insert or modify records)
poFetchBlobsOnDemand	BLOB field values are not included in data packets. Instead, client datasets must request these values on an as-needed basis. If the client dataset's *FetchOnDemand* property is *True*, it requests these values automatically. Otherwise, the application must call the client dataset's *FetchBlobs* method to retrieve BLOB data.
poFetchDetailsOnDemand	When the provider's dataset represents the master of a master/detail relationship, nested detail values are not included in data packets. Instead, client datasets request these on an as-needed basis. If the client dataset's *FetchOnDemand* property is *True*, it requests these values automatically. Otherwise, the application must call the client dataset's *FetchDetails* method to retrieve nested details.
poIncFieldProps	The data packet includes the following field properties (where applicable): *Alignment*, *DisplayLabel*, *DisplayWidth*, *Visible*, *DisplayFormat*, *EditFormat*, *MaxValue*, *MinValue*, *Currency*, *EditMask*, *DisplayValues.*

Table 24.2 Provider options (continued)

Value	Meaning
poCascadeDeletes	When the provider's dataset represents the master of a master/ detail relationship, the server automatically deletes detail records when master records are deleted. To use this option, the database server must be set up to perform cascaded deletes as part of its referential integrity.
poCascadeUpdates	When the provider's dataset represents the master of a master/ detail relationship, key values on detail tables are updated automatically when the corresponding values are changed in master records. To use this option, the database server must be set up to perform cascaded updates as part of its referential integrity.
poAllowMultiRecordUpdates	A single update can cause more than one record of the underlying database table to change. This can be the result of triggers, referential integrity, SQL statements on the source dataset, and so on. Note that if an error occurs, the event handlers provide access to the record that was updated, not the other records that change in consequence.
poNoReset	Client datasets can't specify that the provider should reposition the cursor on the first record before providing data.
poPropogateChanges	Changes made by the server to updated records as part of the update process are sent back to the client and merged into the client dataset.
poAllowCommandText	The client can override the associated dataset's SQL text or the name of the table or stored procedure it represents.
poRetainServerOrder	The client dataset should not re-sort the records in the dataset to enforce a default order.

Adding custom information to data packets

Dataset providers can add application-defined information to data packets using the *OnGetDataSetProperties* event. This information is encoded as an OleVariant, and stored under a name you specify. Client datasets can then retrieve the information using their *GetOptionalParam* method. You can also specify that the information be included in delta packets that the client dataset sends when updating records. In this case, the client dataset may never be aware of the information, but the provider can send a round-trip message to itself.

When adding custom information in the *OnGetDataSetProperties* event, each individual attribute (sometimes called an "optional parameter") is specified using a Variant array that contains three elements: the name (a string), the value (a Variant), and a boolean flag indicating whether the information should be included in delta packets when the client applies updates. Add multiple attributes by creating a Variant array of Variant arrays. For example, the following *OnGetDataSetProperties* event handler sends two values, the time the data was provided and the total number of records in the source dataset. Only the time the data was provided is returned when client datasets apply updates:

```
procedure TMyDataModule1.Provider1GetDataSetProperties(Sender: TObject; DataSet: TDataSet;
out Properties: OleVariant);
begin
  Properties := VarArrayCreate([0,1], varVariant);
  Properties[0] := VarArrayOf(['TimeProvided', Now, True]);
  Properties[1] := VarArrayOf(['TableSize', DataSet.RecordCount, False]);
end;
```

When the client dataset applies updates, the time the original records were provided can be read in the provider's *OnUpdateData* event:

```
procedure TMyDataModule1.Provider1UpdateData(Sender: TObject; DataSet:
TCustomClientDataSet);
var
  WhenProvided: TDateTime;
begin
  WhenProvided := DataSet.GetOptionalParam('TimeProvided');
  ...
end;
```

Responding to client data requests

Usually client requests for data are handled automatically. A client dataset or XML broker requests a data packet by calling *GetRecords* (indirectly, through the *IAppServer* interface). The provider responds automatically by fetching data from the associated dataset or XML document, creating a data packet, and sending the packet to the client.

The provider has the option of editing data after it has been assembled into a data packet but before the packet is sent to the client. For example, you might want to remove records from the packet based on some criterion (such as the user's level of access), or, in a multi-tiered application, you might want to encrypt sensitive data before it is sent on to the client.

To edit the data packet before sending it on to the client, write an *OnGetData* event handler. *OnGetData* event handlers provide the data packet as a parameter in the form of a client dataset. Using the methods of this client dataset, you can edit data before it is sent to the client.

As with all method calls made through the *IAppServer* interface, the provider can communicate persistent state information with a client dataset before and after the call to *GetRecords*. This communication takes place using the *BeforeGetRecords* and *AfterGetRecords* event handlers. For a discussion of persistent state information in application servers, see "Supporting state information in remote data modules" on page 25-19.

Responding to client update requests

A provider applies updates to database records based on a *Delta* data packet received from a client dataset or XML broker. The client requests updates by calling the *ApplyUpdates* method (indirectly, through the *IAppServer* interface).

As with all method calls made through the *IAppServer* interface, the provider can communicate persistent state information with a client dataset before and after the call to *ApplyUpdates*. This communication takes place using the *BeforeApplyUpdates* and *AfterApplyUpdates* event handlers. For a discussion of persistent state information in application servers, see "Supporting state information in remote data modules" on page 25-19.

If you are using a dataset provider, a number of additional events allow you more control:

When a dataset provider receives an update request, it generates an *OnUpdateData* event, where you can edit the Delta packet before it is written to the dataset or influence how updates are applied. After the *OnUpdateData* event, the provider writes the changes to the database or source dataset.

The provider performs the update on a record-by-record basis. Before the dataset provider applies each record, it generates a *BeforeUpdateRecord* event, which you can use to screen updates before they are applied. If an error occurs when updating a record, the provider receives an *OnUpdateError* event where it can resolve the error. Usually errors occur because the change violates a server constraint or a database record was changed by a different application subsequent to its retrieval by the provider, but prior to the client dataset's request to apply updates.

Update errors can be processed by either the dataset provider or the client dataset. When the provider is part of a multi-tiered application, it should handle all update errors that do not require user interaction to resolve. When the provider can't resolve an error condition, it temporarily stores a copy of the offending record. When record processing is complete, the provider returns a count of the errors it encountered to the client dataset, and copies the unresolved records into a results data packet that it returns to the client dataset for further reconciliation.

The event handlers for all provider events are passed the set of updates as a client dataset. If your event handler is only dealing with certain types of updates, you can filter the dataset based on the update status of records. By filtering the records, your event handler does not need to sort through records it won't be using. To filter the client dataset on the update status of its records, set its *StatusFilter* property.

Note Applications must supply extra support when the updates are directed at a dataset that does not represent a single table. For details on how to do this, see "Applying updates to datasets that do not represent a single table" on page 24-11.

Editing delta packets before updating the database

Before a dataset provider applies updates to the database, it generates an *OnUpdateData* event. The *OnUpdateData* event handler receives a copy of the *Delta* packet as a parameter. This is a client dataset.

In the *OnUpdateData* event handler, you can use any of the properties and methods of the client dataset to edit the *Delta* packet before it is written to the dataset. One particularly useful property is the *UpdateStatus* property. *UpdateStatus* indicates what type of modification the current record in the delta packet represents. It can have any of the values in Table 24.3.

Table 24.3 UpdateStatus values

Value	Description
usUnmodified	Record contents have not been changed
usModified	Record contents have been changed
usInserted	Record has been inserted
usDeleted	Record has been deleted

For example, the following *OnUpdateData* event handler inserts the current date into every new record that is inserted into the database:

```
procedure TMyDataModule1.Provider1UpdateData(Sender: TObject; DataSet:
TCustomClientDataSet);
begin
  with DataSet do
  begin
    First;
    while not Eof do
    begin
      if UpdateStatus = usInserted then
      begin
        Edit;
        FieldByName('DateCreated').AsDateTime := Date;
        Post;
      end;
      Next;
    end;
end;
```

Influencing how updates are applied

The *OnUpdateData* event also gives your dataset provider a chance to indicate how records in the delta packet are applied to the database.

By default, changes in the delta packet are written to the database using automatically generated SQL UPDATE, INSERT, or DELETE statements such as

```
UPDATE EMPLOYEES
  set EMPNO = 748, NAME = 'Smith', TITLE = 'Programmer 1', DEPT = 52
WHERE
  EMPNO = 748 and NAME = 'Smith' and TITLE = 'Programmer 1' and DEPT = 47
```

Unless you specify otherwise, all fields in the delta packet records are included in the UPDATE clause and in the WHERE clause. However, you may want to exclude some of these fields. One way to do this is to set the *UpdateMode* property of the provider. *UpdateMode* can be assigned any of the following values:

Table 24.4 UpdateMode values

Value	Meaning
upWhereAll	All fields are used to locate fields (the WHERE clause).
upWhereChanged	Only key fields and fields that are changed are used to locate records.
upWhereKeyOnly	Only key fields are used to locate records.

You might, however, want even more control. For example, with the previous statement, you might want to prevent the EMPNO field from being modified by leaving it out of the UPDATE clause and leave the TITLE and DEPT fields out of the WHERE clause to avoid update conflicts when other applications have modified the data. To specify the clauses where a specific field appears, use the *ProviderFlags* property. *ProviderFlags* is a set that can include any of the values in Table 24.5

Table 24.5 ProviderFlags values

Value	Description
pfInWhere	The field appears in the WHERE clause of generated INSERT, DELETE, and UPDATE statements when *UpdateMode* is *upWhereAll* or *upWhereChanged*.
pfInUpdate	The field appears in the UPDATE clause of generated UPDATE statements.
pfInKey	The field is used in the WHERE clause of generated statements when *UpdateMode* is *upWhereKeyOnly*.
pfHidden	The field is included in records to ensure uniqueness, but can't be seen or used on the client side.

Thus, the following *OnUpdateData* event handler allows the TITLE field to be updated and uses the EMPNO and DEPT fields to locate the desired record. If an error occurs, and a second attempt is made to locate the record based only on the key, the generated SQL looks for the EMPNO field only:

```
procedure TMyDataModule1.Provider1UpdateData(Sender: TObject; DataSet:
TCustomClientDataSet);
begin
  with DataSet do
  begin
    FieldByName('TITLE').ProviderFlags := [pfInUpdate];
    FieldByName('EMPNO').ProviderFlags := [pfInWhere, pfInKey];
    FieldByName('DEPT').ProviderFlags := [pfInWhere];
  end;
end;
```

Note You can use the *UpdateFlags* property to influence how updates are applied even if you are updating to a dataset and not using dynamically generated SQL. These flags still determine which fields are used to locate records and which fields get updated.

Screening individual updates

Immediately before each update is applied, a dataset provider receives a *BeforeUpdateRecord* event. You can use this event to edit records before they are applied, similar to the way you can use the *OnUpdateData* event to edit entire delta packets. For example, the provider does not compare BLOB fields (such as memos) when checking for update conflicts. If you want to check for update errors involving BLOB fields, you can use the *BeforeUpdateRecord* event.

In addition, you can use this event to apply updates yourself or to screen and reject updates. The *BeforeUpdateRecord* event handler lets you signal that an update has been handled already and should not be applied. The provider then skips that record, but does not count it as an update error. For example, this event provides a mechanism for applying updates to a stored procedure (which can't be updated automatically), allowing the provider to skip any automatic processing once the record is updated from within the event handler.

Resolving update errors on the provider

When an error condition arises as the dataset provider tries to post a record in the delta packet, an *OnUpdateError* event occurs. If the provider can't resolve an update error, it temporarily stores a copy of the offending record. When record processing is complete, the provider returns a count of the errors it encountered, and copies the unresolved records into a results data packet that it passes back to the client for further reconciliation.

In multi-tiered applications, this mechanism lets you handle any update errors you can resolve mechanically on the application server, while still allowing user interaction on the client application to correct error conditions.

The *OnUpdateError* handler gets a copy of the record that could not be changed, an error code from the database, and an indication of whether the resolver was trying to insert, delete, or update the record. The problem record is passed back in a client dataset. You should never use the data navigation methods on this dataset. However, for each field in the dataset, you can use the *NewValue*, *OldValue*, and *CurValue* properties to determine the cause of the problem and make any modifications to resolve the update error. If the *OnUpdateError* event handler can correct the problem, it sets the *Response* parameter so that the corrected record is applied.

Applying updates to datasets that do not represent a single table

When a dataset provider generates SQL statements that apply updates directly to a database server, it needs the name of the database table that contains the records. This can be handled automatically for many datasets such as table-type datasets or “live” *TQuery* components. Automatic updates are a problem however, if the provider must apply updates to the data underlying a stored procedure with a result set or a multi-table query. There is no easy way to obtain the name of the table to which updates should be applied.

If the query or stored procedure is a BDE-enabled dataset (*TQuery* or *TStoredProc*) and it has an associated update object, the provider uses the update object. However, if there is no update object, you can supply the table name programmatically in an *OnGetTableName* event handler. Once an event handler supplies the table name, the provider can generate appropriate SQL statements to apply updates.

Supplying a table name only works if the target of the updates is a single database table (that is, only the records in one table need to be updated). If the update requires making changes to multiple underlying database tables, you must explicitly apply the updates in code using the *BeforeUpdateRecord* event of the provider. Once this event handler has applied an update, you can set the event handler's *Applied* parameter to *True* so that the provider does not generate an error.

Note If the provider is associated with a BDE-enabled dataset, you can use an update object in the *BeforeUpdateRecord* event handler to apply updates using customized SQL statements. See "Using update objects to update a dataset" on page 20-39 for details.

Responding to client-generated events

Provider components implement a general-purpose event that lets you create your own calls from client datasets directly to the provider. This is the *OnDataRequest* event.

OnDataRequest is not part of the normal functioning of the provider. It is simply a hook to allow your client datasets to communicate directly with providers. The event handler takes an OleVariant as an input parameter and returns an OleVariant. By using OleVariants, the interface is sufficiently general to accommodate almost any information you want to pass to or from the provider.

To generate an *OnDataRequest* event, the client application calls the *DataRequest* method of the client dataset.

Handling server constraints

Most relational database management systems implement constraints on their tables to enforce data integrity. A constraint is a rule that governs data values in tables and columns, or that governs data relationships across columns in different tables. For example, most SQL-92 compliant relational databases support the following constraints:

- NOT NULL, to guarantee that a value supplied to a column has a value.
- NOT NULL UNIQUE, to guarantee that column value has a value and does not duplicate any other value already in that column for another record.
- CHECK, to guarantee that a value supplied to a column falls within a certain range, or is one of a limited number of possible values.
- CONSTRAINT, a table-wide check constraint that applies to multiple columns.

- PRIMARY KEY, to designate one or more columns as the table's primary key for indexing purposes.
- FOREIGN KEY, to designate one or more columns in a table that reference another table.

Note This list is not exclusive. Your database server may support some or all of these constraints in part or in whole, and may support additional constraints. For more information about supported constraints, see your server documentation.

Database server constraints obviously duplicate many kinds of data checks that traditional desktop database applications manage. You can take advantage of server constraints in multi-tiered database applications without having to duplicate the constraints in application server or client application code.

If the provider is working with a BDE-enabled dataset, the *Constraints* property lets you replicate and apply server constraints to data passed to and received from client datasets. When *Constraints* is *True* (the default), server constraints stored in the source dataset are included in data packets and affect client attempts to update data.

Important Before the provider can pass constraint information on to client datasets, it must retrieve the constraints from the database server. To import database constraints from the server, use SQL Explorer to import the database server's constraints and default expressions into the Data Dictionary. Constraints and default expressions in the Data Dictionary are automatically made available to BDE-enabled datasets.

There may be times when you do not want to apply server constraints to data sent to a client dataset. For example, a client dataset that receives data in packets and permits local updating of records prior to fetching more records may need to disable some server constraints that might be triggered because of the temporarily incomplete set of data. To prevent constraint replication from the provider to a client dataset, set *Constraints* to *False*. Note that client datasets can disable and enable constraints using the *DisableConstraints* and *EnableConstraints* methods. For more information about enabling and disabling constraints from the client dataset, see "Handling constraints from the server" on page 23-28.

Chapter

25

Creating multi-tiered applications

This chapter describes how to create a multi-tiered, client/server database application. A multi-tiered client/server application is partitioned into logical units, called tiers, which run in conjunction on separate machines. Multi-tiered applications share data and communicate with one another over a local-area network or even over the Internet. They provide many benefits, such as centralized business logic and thin client applications.

In its simplest form, sometimes called the “three-tiered model,” a multi-tiered application is partitioned into thirds:

- **Client application**: provides a user interface on the user’s machine.
- **Application server**: resides in a central networking location accessible to all clients and provides common data services.
- **Remote database server**: provides the relational database management system (RDBMS).

In this three-tiered model, the application server manages the flow of data between clients and the remote database server, so it is sometimes called a “data broker.” With Delphi you usually only create the application server and its clients, although, if you are really ambitious, you could create your own database back end as well.

In more complex multi-tiered applications, additional services reside between a client and a remote database server. For example, there might be a security services broker to handle secure Internet transactions, or bridge services to handle sharing of data with databases on other platforms.

Delphi’s support for developing multi-tiered applications is an extension of the way client datasets communicate with a provider component using transportable data packets. This chapter focuses on creating a three-tiered database application. Once you understand how to create and manage a three-tiered application, you can create and add additional service layers based on your needs.

Advantages of the multi-tiered database model

The multi-tiered database model breaks a database application into logical pieces. The client application can focus on data display and user interactions. Ideally, it knows nothing about how the data is stored or maintained. The application server (middle tier) coordinates and processes requests and updates from multiple clients. It handles all the details of defining datasets and interacting with the database server.

The advantages of this multi-tiered model include the following:

- **Encapsulation of business logic in a shared middle tier**. Different client applications all access the same middle tier. This allows you to avoid the redundancy (and maintenance cost) of duplicating your business rules for each separate client application.
- **Thin client applications**. Your client applications can be written to make a small footprint by delegating more of the processing to middle tiers. Not only are client applications smaller, but they are easier to deploy because they don't need to worry about installing, configuring, and maintaining the database connectivity software (such as the Borland Database Engine and the database server's client-side software). Thin client applications can be distributed over the Internet for additional flexibility.
- **Distributed data processing**. Distributing the work of an application over several machines can improve performance because of load balancing, and allow redundant systems to take over when a server goes down.
- **Increased opportunity for security**. You can isolate sensitive functionality into tiers that have different access restrictions. This provides flexible and configurable levels of security. Middle tiers can limit the entry points to sensitive material, allowing you to control access more easily. If you are using HTTP, CORBA, or COM+, you can take advantage of the security models they support.

Understanding provider-based multi-tiered applications

Delphi's support for multi-tiered applications use the components on the DataSnap page and the Data Access page of the component palette, plus a remote data module that is created by a wizard on the Multitier page of the New Items dialog. They are based on the ability of provider components to package data into transportable data packets and handle updates received as transportable delta packets.

The components needed for a multi-tiered application are described in Table 25.1:

Table 25.1 Components used in multi-tiered applications

Component	Description
Remote data modules	Specialized data modules that can act as a COM Automation server, SOAP server, or CORBA server to give client applications access to any providers they contain. Used on the application server.
Provider component	A data broker that provides data by creating data packets and resolves client updates. Used on the application server.
Client dataset component	A specialized dataset that uses midas.dll or midaslib.dcu to manage data stored in data packets. The client dataset is used in the client application. It caches updates locally, and applies them in delta packets to the application server.
Connection components	A family of components that locate the server, form connections, and make the *IAppServer* interface available to client datasets. Each connection component is specialized to use a particular communications protocol.

The provider and client dataset components require midas.dll or midaslib.dcu, which manages datasets stored as data packets. (Note that, because the provider is used on the application server and the client dataset is used on the client application, if you are using midas.dll, you must deploy it on both application server and client application.)

If you are using BDE-enabled datasets, the application server may also require SQL Explorer to help in database administration and to import server constraints into the Data Dictionary so that they can be checked at any level of the multi-tiered application.

Note You must purchase server licenses for deploying your application server.

An overview of the architecture into which these components fit is described in “Using a multi-tiered architecture” on page 14-12.

Overview of a three-tiered application

The following numbered steps illustrate a normal sequence of events for a provider-based three-tiered application:

1. A user starts the client application. The client connects to the application server (which can be specified at design time or runtime). If the application server is not already running, it starts. The client receives an *IAppServer* interface from the application server.
2. The client requests data from the application server. A client may request all data at once, or may request chunks of data throughout the session (fetch on demand).
3. The application server retrieves the data (first establishing a database connection, if necessary), packages it for the client, and returns a data packet to the client. Additional information, (for example, field display characteristics) can be included in the metadata of the data packet. This process of packaging data into data packets is called “providing.”

4 The client decodes the data packet and displays the data to the user.

5 As the user interacts with the client application, the data is updated (records are added, deleted, or modified). These modifications are stored in a change log by the client.

6 Eventually the client applies its updates to the application server, usually in response to a user action. To apply updates, the client packages its change log and sends it as a data packet to the server.

7 The application server decodes the package and posts updates (in the context of a transaction if appropriate). If a record can't be posted (for example, because another application changed the record after the client requested it and before the client applied its updates), the application server either attempts to reconcile the client's changes with the current data, or saves the records that could not be posted. This process of posting records and caching problem records is called "resolving."

8 When the application server finishes the resolving process, it returns any unposted records to the client for further resolution.

9 The client reconciles unresolved records. There are many ways a client can reconcile unresolved records. Typically the client attempts to correct the situation that prevented records from being posted or discards the changes. If the error situation can be rectified, the client applies updates again.

10 The client refreshes its data from the server.

The structure of the client application

To the end user, the client application of a multi-tiered application looks and behaves no differently than a traditional two-tiered application that uses cached updates. User interaction takes place through standard data-aware controls that display data from a *TClientDataSet* component. For detailed information about using the properties, events, and methods of client datasets, see Chapter 23, "Using client datasets."

TClientDataSet fetches data from and applies updates to a provider component, just as in two-tiered applications that use a client dataset with an external provider. For details about providers, see Chapter 24, "Using provider components". For details about client dataset features that facilitate its communication with a provider, see "Using a client dataset with a provider" on page 23-23

The client dataset communicates with the provider through the *IAppServer* interface. It gets this interface from a connection component. The connection component establishes the connection to the application server. Different connection components are available for using different communications protocols. These connection components are summarized in the following table:

Table 25.2 Connection components

Component	Protocol
TDCOMConnection	DCOM
TSocketConnection	Windows sockets (TCP/IP)
TWebConnection	HTTP
TSOAPConnection	SOAP (HTTP and XML)
TCorbaConnection	CORBA (IIOP)

Note Delphi also includes a connection component that does not connect to an application server at all, but instead supplies an *IAppServer* interface for client datasets to use when communicating with providers in the same application. This component, *TLocalConnection*, is not required, but makes it easier to later scale up to a multi-tiered application.

For more information about using connection components, see “Connecting to the application server” on page 25-23.

The structure of the application server

When you set up and run an application server, it does not establish any connection with client applications. Instead, connection is initiated and maintained by client applications. The client application uses its connection component to establish a connection to the application server, which it uses to communicate with its selected provider. All of this happens automatically, without your having to write code to manage incoming requests or supply interfaces.

The basis of an application server is a remote data module, which is a specialized data module that supports the *IAppServer* interface. Client applications use the *IAppServer* interface to communicate with providers on the application server.

There are four types of remote data modules:

- **TRemoteDataModule**: This is a dual-interface Automation server. Use this type of remote data module if clients use DCOM, HTTP, sockets, or OLE to connect to the application server, unless you want to install the application server with MTS.
- **TMTSDataModule**: This is a dual-interface Automation server. Use this type of remote data module if you are creating the application server as an Active Library (.DLL) that is installed with MTS or COM+. You can use MTS remote data modules with DCOM, HTTP, sockets, or OLE.
- **TCorbaDataModule**: This is a CORBA server. Use this type of remote data module to provide data to CORBA clients.
- **TSoapDataModule**: This is a data module that implements an *IAppServer* descendant as an invokable interface in a Web Service application. Use this type of remote data module to provide data to clients that access data as a Web Service.

If the application server is to be deployed under MTS or COM+, the remote data module includes events for when the application server is activated or deactivated. This allows it to acquire database connections when activated and release them when deactivated.

The contents of the remote data module

As with any data module, you can include any nonvisual component in the remote data module. There are certain components, however, that you must include:

- If the remote data module is exposing information from a database server, it must include a dataset component to represent the records from that database server. Other components, such as a database connection component of some type, may be required to allow the dataset to interact with a database server. For information about datasets, see Chapter 18, “Understanding datasets.” For information about database connection components, see Chapter 17, “Connecting to databases.”

  For every dataset that the remote data module exposes to clients, it must include a dataset provider. A dataset provider packages data into data packets that are sent to client datasets and applies updates received from client datasets back to a source dataset or a database server. For more information about dataset providers, see Chapter 24, “Using provider components.”
- For every XML document that the remote data module exposes to clients, it must include an XML provider. An XML provider acts like a dataset provider, except that it fetches data from and applies updates to an XML document rather than a database server. For more information about XML providers, see “Using an XML document as the source for a provider” on page 26-8.

Note Do not confuse database connection components, which connect datasets to a database server, with the connection components used by client applications in a multi-tiered application. The connection components in multi-tiered applications can be found on the DataSnap page of the Component palette.

Using transactional data modules

You can write an application server that takes advantage of special services for distributed applications that are supplied by MTS (before Windows 2000) or COM+ (under Windows 2000 and later). To do so, you create a transactional data module instead of an ordinary remote data module.

When you use a transactional data module, your application can take advantage of the following special services:

- **Security.** MTS and COM+ provide role-based security for your application server. Clients are assigned roles, which determine how they can access the MTS data module’s interface. The MTS data module implements the *IsCallerInRole* method, which you lets you check the role of the currently connected client and conditionally allow certain functions based on that role. For more information about MTS and COM+ security, see “Role-based security” on page 39-14.
- **Database handle pooling.** Transactional data modules automatically pool database connections that are made via ADO or (if you are using MTS and turn on MTS POOLING) the BDE. When one client is finished with a database connection,

another client can reuse it. This cuts down on network traffic, because your middle tier does not need to log off of the remote database server and then log on again. When pooling database handles, your database connection component should set its *KeepConnection* property to *False*, so that your application maximizes the sharing of connections. For more information about pooling database handles, see "Database resource dispensers" on page 39-5.

- **Transactions**. When using a transactional data module, you can provide enhanced transaction support beyond that available with a single database connection. Transactional data modules can participate in transactions that span multiple databases, or include functions that do not involve databases at all. For more information about the transaction support provided by transactional objects such as transactional data modules, see "Managing transactions in multi-tiered applications" on page 25-18.
- **Just-in-time activation and as-soon-as-possible deactivation.** You can write your server so that remote data module instances are activated and deactivated on an as-needed basis. When using just-in-time activation and as-soon-as-possible deactivation, your remote data module is instantiated only when it is needed to handle client requests. This prevents it from tying up resources such as database handles when they are not in use.

  Using just-in-time activation and as-soon-as-possible deactivation provides a middle ground between routing all clients through a single remote data module instance, and creating a separate instance for every client connection. With a single remote data module instance, the application server must handle all database calls through a single database connection. This acts as a bottleneck, and can impact performance when there are many clients. With multiple instances of the remote data module, each instance can maintain a separate database connection, thereby avoiding the need to serialize database access. However, this monopolizes resources because other clients can't use the database connection while it is associated with another client's remote data module.

To take advantage of transactions, just-in-time activation, and as-soon-as-possible deactivation, remote data module instances must be stateless. This means you must provide additional support if your client relies on state information. For example, the client must pass information about the current record when performing incremental fetches. For more information about state information and remote data modules in multi-tiered applications, see "Supporting state information in remote data modules" on page 25-19.

By default, all automatically generated calls to a transactional data module are transactional (that is, they assume that when the call exits, the data module can be deactivated and any current transactions committed or rolled back). You can write a transactional data module that depends on persistent state information by setting the *AutoComplete* property to *False*, but it will not support transactions, just-in-time activation, or as-soon-as-possible deactivation unless you use a custom interface.

Warning Application servers containing transactional data modules should not open database connections until the data module is activated. While developing your application, be sure that all datasets are not active and the database is not connected before running your application. In the application itself, add code to open database connections when the data module is activated and close them when it is deactivated.

Pooling remote data modules

Object pooling allows you to create a cache of remote data modules that are shared by their clients, thereby conserving resources. How this works depends on the type of remote data module and on the connection protocol.

If you are creating a transactional data module that will be installed to COM+, you can use the COM+ Component Manager to install the application server as a pooled object. See "Object pooling" on page 39-8 for details.

Even if you are not using a transactional data module, you can take advantage of object pooling if the connection is formed using HTTP (*TWebConnection*). Under this second type of object pooling, you limit the number of instances of your remote data module that are created. This limits the number of database connections that you must hold, as well as any other resources used by the remote data module.

When the Web Server application (which passes calls to your remote data module) receives client requests, it passes them on to the first available remote data module in the pool. If there is no available remote data module, it creates a new one (up to a maximum number that you specify). This provides a middle ground between routing all clients through a single remote data module instance (which can act as a bottleneck), and creating a separate instance for every client connection (which can consume many resources).

If a remote data module instance in the pool does not receive any client requests for a while, it is automatically freed. This prevents the pool from monopolizing resources unless they are used.

To set up object pooling when using a Web connection (HTTP), your remote data module must override the *UpdateRegistry* method. In the overridden method, call *RegisterPooled* when the remote data module registers and *UnregisterPooled* when the remote data module unregisters. When using either method of object pooling, your remote data module must be stateless. This is because a single instance potentially handles requests from several clients. If it relied on persistent state information, clients could interfere with each other. See "Supporting state information in remote data modules" on page 25-19 for more information on how to ensure that your remote data module is stateless.

Choosing a connection protocol

Each communications protocol you can use to connect your client applications to the application server provides its own unique benefits. Before choosing a protocol, consider how many clients you expect, how you are deploying your application, and future development plans.

Using DCOM connections

DCOM provides the most direct approach to communication, requiring no additional runtime applications on the server. However, because DCOM is not included with Windows 95, some older client machines may not have DCOM installed.

DCOM provides the only approach that lets you use security services when writing a transactional data module. These security services are based on assigning roles to the callers of transactional objects. When using DCOM, DCOM identifies the caller to the system that calls your application server (MTS or COM+). Therefore, it is possible to accurately determine the role of the caller. When using other protocols, however, there is a runtime executable, separate from the application server, that receives client calls. This runtime executable makes COM calls into the application server on behalf of the client. Because of this, it is impossible to assign roles to separate clients: The runtime executable is, effectively, the only client. For more information about security and transactional objects, see “Role-based security” on page 39-14.

Using Socket connections

TCP/IP Sockets let you create lightweight clients. For example, if you are writing a Web-based client application, you can’t be sure that client systems support DCOM. Sockets provide a lowest common denominator that you know will be available for connecting to the application server. For more information about sockets, see Chapter 32, “Working with sockets.”

Instead of instantiating the remote data module directly from the client (as happens with DCOM), sockets use a separate application on the server (ScktSrvr.exe), which accepts client requests and instantiates the remote data module using COM. The connection component on the client and ScktSrvr.exe on the server are responsible for marshaling *IAppServer* calls.

Note ScktSrvr.exe can run as an NT service application. Register it with the Service manager by starting it using the -install command line option. You can unregister it using the -uninstall command line option.

Before you can use a socket connection, the application server must register its availability to clients using a socket connection. By default, all new remote data modules automatically register themselves by adding a call to *EnableSocketTransport* in the *UpdateRegistry* method. You can remove this call to prevent socket connections to your application server.

Note Because older servers did not add this registration, you can disable the check for whether an application server is registered by unchecking the Connections | Registered Objects Only menu item on ScktSrvr.exe.

When using sockets, there is no protection on the server against client systems failing before they release a reference to interfaces on the application server. While this results in less message traffic than when using DCOM (which sends periodic keep-alive messages), this can result in an application server that can’t release its resources because it is unaware that the client has gone away.

Using Web connections

HTTP lets you create clients that can communicate with an application server that is protected by a firewall. HTTP messages provide controlled access to internal applications so that you can distribute your client applications safely and widely. Like socket connections, HTTP messages provide a lowest common denominator that you know will be available for connecting to the application server. For more information about HTTP messages, see Chapter 27, “Creating Internet applications.”

Instead of instantiating the remote data module directly from the client (as happens with DCOM), HTTP-based connections use a Web server application on the server (httpsrvr.dll) that accepts client requests and instantiates the remote data module using COM. Because of this, they are also called Web connections. The connection component on the client and httpsrvr.dll on the server are responsible for marshaling *IAppServer* calls.

Web connections can take advantage of the SSL security provided by wininet.dll (a library of Internet utilities that runs on the client system). Once you have configured the Web server on the server system to require authentication, you can specify the user name and password using the properties of the Web connection component.

As an additional security measure, the application server must register its availability to clients using a Web connection. By default, all new remote data modules automatically register themselves by adding a call to *EnableWebTransport* in the *UpdateRegistry* method. You can remove this call to prevent Web connections to your application server.

Web connections can take advantage of object pooling. This allows your server to create a limited pool of remote data module instances that are available for client requests. By pooling the remote data modules, your server does not consume the resources for the data module and its database connection except when they are needed. For more information on object pooling, see “Pooling remote data modules” on page 25-8.

Unlike most other connection components, you can’t use callbacks when the connection is formed via HTTP.

Using SOAP connections

SOAP is the protocol that underlies Delphi’s support for Web Service applications. SOAP marshals method calls using an XML encoding. SOAP connections use HTTP as a transport protocol.

SOAP connections have the advantage that they work in cross-platform applications because they are supported on both the Windows and Linux. Because SOAP connections use HTTP, they have the same advantages as Web connections: HTTP provides a lowest common denominator that you know is available on all clients, and clients can communicate with an application server that is protected by a “firewall”. For more information about using SOAP to distribute applications in Delphi, see Chapter 31, “Using Web Services.”

As with HTTP connections, you can’t use callbacks when the connection is formed via SOAP. SOAP connections also limit you to a single remote data module in the application server.

Using CORBA connections

CORBA lets you integrate your multi-tiered database applications into an environment that is standardized on CORBA. For example, when working with a client application written in Java, only the CORBA connection is available. Because CORBA (and Java) is available on multiple platforms, this allows you to write cross-platform multi-tiered applications.

By using CORBA, your application automatically gets the benefits of load-balancing, location transparency, and fail-over from the ORB runtime software. In addition, you can add hooks to take advantage of other CORBA services.

Building a multi-tiered application

The general steps for creating a multi-tiered database application are

1. Create the application server.
2. Register or install the application server.
3. Create a client application.

The order of creation is important. You should create and run the application server before you create a client. At design time, you can then connect to the application server to test your client. You can, of course, create a client without specifying the application server at design time, and only supply the server name at runtime. However, doing so prevents you from seeing if your application works as expected when you code at design time, and you will not be able to choose servers and providers using the Object Inspector.

Note If you are not creating the client application on the same system as the server, and you are using a DCOM connection, you may want to register the application server on the client system. This makes the connection component aware of the application server at design time so that you can choose server names and provider names from a drop-down list in the Object Inspector. (If you are using a Web connection, SOAP connection, or socket connection, the connection component fetches the names of registered servers from the server machine.)

Creating the application server

You create an application server very much as you create most database applications. The major difference is that the application server uses a remote data module.

To create an application server, follow these steps:

1. Start a new project:
   - If you are using SOAP as a transport protocol, this should be a new Web Service application. Choose File | New | Other, and on the Web Services page of the new items dialog, choose Web Service application.
   - For any other transport protocol, you need only choose File | New | Application.

   Save the new project.
2. Add a new remote data module to the project. From the main menu, choose File | New | Other, and on the Multitier page of the new items dialog, select
   - **Remote Data Module** if you are creating a COM Automation server that clients access using DCOM, HTTP, or sockets.

- **Transactional Data Module** if you are creating a remote data module that runs under MTS or COM+. Connections can be formed using DCOM, HTTP, or sockets. However, only DCOM supports the security services.
- **CORBA Data Module** if you are creating a CORBA server.
- **SOAP Data Module** if you are creating a SOAP server in a Web Service application.

For more detailed information about setting up a remote data module, see "Setting up the remote data module" on page 25-13.

Note Remote data modules are more than simple data modules. The CORBA data module acts as a CORBA server. The SOAP data module implements an invokable interface in a Web Service application. Other data modules are COM Automation objects.

3 Place the appropriate dataset components on the data module and set them up to access the database server.

4 Place a *TDataSetProvider* component on the data module for each dataset. This provider is required for brokering client requests and packaging data. Set the *DataSet* property for each provider component to the name of the dataset to access. You can set additional properties for the provider. See Chapter 24, "Using provider components" for more detailed information about setting up a provider.

If you are working with data from XML documents, you can use a *TXMLTransformProvider* component instead of a dataset and *TDataSetProvider* component. When using *TXMLTransformProvider*, set the *XMLDataFile* property to specify the XML document from which data is provided and to which updates are applied.

5 Write application server code to implement events, shared business rules, shared data validation, and shared security. When writing this code, you may want to

- Extend the application server's interface to provide additional ways for the client application to call the server. Extending the application server's interface is described in "Extending the application server's interface" on page 25-16.
- Provide transaction support beyond the transactions automatically created when applying updates. Transaction support in multi-tiered database applications is described in "Managing transactions in multi-tiered applications" on page 25-18.
- Create master/detail relationships between the datasets in your application server. Master/detail relationships are described in "Supporting master/detail relationships" on page 25-19.
- Ensure your application server is stateless. Handling state information is described in "Supporting state information in remote data modules" on page 25-19.
- Divide your application server into multiple remote data modules. Using multiple remote data modules is described in "Using multiple remote data modules" on page 25-21.

6 Save, compile, and register or install the application server. Registering an application server is described in “Registering the application server” on page 25-22.

7 If your server application does not use DCOM or SOAP, you must install the runtime software that receives client messages, instantiates the remote data module, and marshals interface calls.

   - For TCP/IP sockets this is a socket dispatcher application, Scktsrvr.exe.
   - For HTTP connections this is httpsrvr.dll, an ISAPI/NSAPI DLL that must be installed with your Web server.
   - For CORBA, this is the VisiBroker ORB.

Setting up the remote data module

When you create the remote data module, you must provide certain information that indicates how it responds to client requests. This information varies, depending on the type of remote data module. See “The structure of the application server” on page 25-5 for information on what type of remote data module you need.

Configuring TRemoteDataModule

To add a *TRemoteDataModule* component to your application, choose File | New | Other and select Remote Data Module from the Multitier page of the new items dialog. You will see the Remote Data Module wizard.

You must supply a class name for your remote data module. This is the base name of a descendant of *TRemoteDataModule* that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name *MyDataServer*, the wizard creates a new unit declaring *TMyDataServer*, a descendant of *TRemoteDataModule*, which implements *IMyDataServer*, a descendant of *IAppServer*.

Note You can add your own properties and methods to the new interface. For more information, see “Extending the application server’s interface” on page 25-16.

You must specify the threading model in the Remote Data Module wizard. You can choose Single-threaded, Apartment-threaded, Free-threaded, or Both.

- If you choose Single-threaded, COM ensures that only one client request is serviced at a time. You do not need to worry about client requests interfering with each other.
- If you choose Apartment-threaded, COM ensures that any instance of your remote data module services one request at a time. When writing code in an Apartment-threaded library, you must guard against thread conflicts if you use global variables or objects not contained in the remote data module. This is the recommended model if you are using BDE-enabled datasets. (Note that you will need a session component with its *AutoSessionName* property set to *True* to handle threading issues on BDE-enabled datasets).

- If you choose Free-threaded, your application can receive simultaneous client requests on several threads. You are responsible for ensuring your application is thread-safe. Because multiple clients can access your remote data module simultaneously, you must guard your instance data (properties, contained objects, and so on) as well as global variables. This is the recommended model if you are using ADO datasets.
- If you choose Both, your library works the same as when you choose Free-threaded, with one exception: all callbacks (calls to client interfaces) are serialized for you.
- If you choose Neutral, the remote data module can receive simultaneous calls on separate threads, as in the Free-threaded model, but COM guarantees that no two threads access the same method at the same time.

If you are creating an EXE, you must also specify what type of instancing to use. You can choose Single instance or Multiple instance (Internal instancing applies only if the client code is part of the same process space.)

- If you choose Single instance, each client connection launches its own instance of the executable. That process instantiates a single instance of the remote data module, which is dedicated to the client connection.
- If you choose Multiple instance, a single instance of the application (process) instantiates all remote data modules created for clients. Each remote data module is dedicated to a single client connection, but they all share the same process space.

Configuring TMTSDataModule

To add a *TMTSDataModule* component to your application, choose File | New | Other and select Transactional Data Module from the Multitier page of the new items dialog. You will see the Transactional Data Module wizard.

You must supply a class name for your remote data module. This is the base name of a descendant of *TMTSDataModule* that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name *MyDataServer*, the wizard creates a new unit declaring *TMyDataServer*, a descendant of *TMTSDataModule*, which implements *IMyDataServer*, a descendant of *IAppServer*.

Note You can add your own properties and methods to your new interface. For more information, see “Extending the application server’s interface” on page 25-16.

You must specify the threading model in the Transactional Data Module wizard. Choose Single, Apartment, or Both.

- If you choose Single, client requests are serialized so that your application services only one at a time. You do not need to worry about client requests interfering with each other.
- If you choose Apartment, the system ensures that any instance of your remote data module services one request at a time, and calls always use the same thread. You must guard against thread conflicts if you use global variables or objects not contained in the remote data module. Instead of using global variables, you can use the shared property manager. For more information on the shared property manager, see “Shared property manager” on page 39-6.

- If you choose Both, MTS calls into the remote data module's interface in the same way as when you choose Apartment. However, any callbacks you make to client applications are serialized, so that you don't need to worry about them interfering with each other.

Note The Apartment model under MTS or COM+ is different from the corresponding model under DCOM.

You must also specify the transaction attributes of your remote data module. You can choose from the following options:

- Requires a transaction. When you select this option, every time a client uses your remote data module's interface, that call is executed in the context of a transaction. If the caller supplies a transaction, a new transaction need not be created.
- Requires a new transaction. When you select this option, every time a client uses your remote data module's interface, a new transaction is automatically created for that call.
- Supports transactions. When you select this option, your remote data module can be used in the context of a transaction, but the caller must supply the transaction when it invokes the interface.
- Does not support transactions. When you select this option, your remote data module can't be used in the context of transactions.

Configuring TSoapDataModule

To add a *TSoapDataModule* component to your application, choose File | New | Other and select SOAP Data Module from the Multitier page of the new items dialog. The SOAP data module wizard appears.

You must supply a class name for your SOAP data module. This is the base name of a *TSoapDataModule* descendant that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name *MyDataServer*, the wizard creates a new unit declaring *TMyDataServer*, a descendant of *TSoapDataModule*, which implements *IMyDataServer*, a descendant of *IAppServer*.

You may want to edit the definitions of the generated interface and *TSoapDataModule* descendant, adding your own properties and methods. These properties and methods are not called automatically, but client applications that request your new interface by name can use any of the properties and methods that you add.

Note To use *TSoapDataModule*, the new data module should be added to a Web Service application. The *IAppServer* interface is an invokable interface, which is registered in the initialization section of the new unit. This allows the invoker component in the main Web module to forward all incoming calls to your data module.

Configuring TCorbaDataModule

To add a *TCorbaDataModule* component to your application, choose File | New and select CORBA Data Module from the Multitier page of the new items dialog. You will see the CORBA Data Module wizard.

You must supply a class name for your remote data module. This is the base name of a descendant of *TCorbaDataModule* that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name *MyDataServer*, the wizard creates a new unit declaring *TMyDataServer*, a descendant of *TCorbaDataModule*, which implements *IMyDataServer*, a descendant of *IAppServer*.

Note You can add your own properties and methods to your new interface. For more information on adding to your data module's interface, see "Extending the application server's interface" on page 25-16.

The CORBA Data Module wizard lets you specify how you want your server application to create instances of the remote data module. You can choose either shared or instance-per-client.

- When you choose shared, your application creates a single instance of the remote data module that handles all client requests. This is the model used in traditional CORBA development.
- When you choose instance-per-client, a new remote data module instance is created for each client connection. This instance persists until its timeout period elapses with no messages from the client. This allows the server to free instances when they are no longer used by clients, but holds the risk that the server may be freed prematurely if the client does not use the server's interface for a long time.

Note Unlike instancing for COM servers, where the model determines the number of instances of the process that run, with CORBA, instancing determines the number of instances created of your object. They are all created within a single instance of the server executable.

In addition to the instancing model, you must specify the threading model in the CORBA Data Module wizard. You can choose Single- or Multi-threaded.

- If you choose Single-threaded, each remote data module instance is guaranteed to receive only one client request at a time. You can safely access the objects contained in your remote data module. However, you must guard against thread conflicts when you use global variables or objects not contained in the remote data module.
- If you choose Multi-threaded, each client connection has its own dedicated thread. However, your application may be called by multiple clients simultaneously, each on a separate thread. You must guard against simultaneous access of instance data as well as global memory. Writing Multi-threaded servers is tricky when you are using a shared remote data module instance, because you must protect all use of objects contained in your remote data module.

Extending the application server's interface

Client applications interact with the application server by creating or connecting to an instance of the remote data module. They use its interface as the basis of all communication with the application server.

You can add to your remote data module's interface to provide additional support for your client applications. This interface is a descendant of *IAppServer* and is created for you automatically by the wizard when you create the remote data module.

To add to the remote data module's interface, you can

- Choose the Add to Interface command from the Edit menu in the IDE. Indicate whether you are adding a procedure, function, or property, and enter its syntax. When you click OK, you will be positioned in the code editor on the implementation of your new interface member.
- Use the type library editor. Select the interface for your application server in the type library editor, and click the tool button for the type of interface member (method or property) that you are adding. Give your interface member a name in the Attributes page, specify parameters and type in the Parameters page, and then refresh the type library. See Chapter 34, "Working with type libraries" for more information about using the type library editor, Note that many of the features you can specify in the type library editor (such as help context, version, and so on) do not apply to CORBA interfaces. Any values you specify for these in the type library editor are ignored.

Note Neither of these approaches works if you are implementing *TSoapDataModule*. For *TSoapDataModule* descendants, you must edit the server interface directly.

What Delphi does when you add new entries to the interface using the type library editor or the Add To Interface command depends on whether you are creating a COM-based (*TRemoteDataModule* or *TMTSDataModule*) or CORBA (*TCorbaDataModule*) server.

- When you add to a COM interface, your changes are added to your unit source code and the type library file (.TLB).
- When you add to a CORBA interface, your changes are reflected in your unit source code and the automatically generated _TLB unit. The _TLB unit is added to the **uses** clause of your unit. You must add this unit to the **uses** clause in your client application if you want to take advantage of early binding. In addition, you can save an .IDL file from the type library editor using the Export to IDL button. The .IDL file is needed for registering the interface with the Interface Repository and Object Activation Daemon.

Note You must explicitly save the TLB file by choosing Refresh in the type library editor and then saving the changes from the IDE.

Once you have added to your remote data module's interface, locate the properties and methods that were added to your remote data module's implementation. Add code to finish this implementation by filling in the bodies of the new methods.

Client applications call your interface extensions using the *AppServer* property of their connection component. For more information on how to do this, see "Calling server interfaces" on page 25-29.

Adding callbacks to the application server's interface

You can allow the application server to call your client application by introducing a callback. To do this, the client application passes an interface to one of the application server's methods, and the application server later calls this method as needed.

However, if your extensions to the remote data module's interface include callbacks, you can't use an HTTP or SOAP-based connection. *TWebConnection* does not support callbacks. If you are using a socket-based connection, client applications must indicate whether they are using callbacks by setting the *SupportCallbacks* property. All other types of connection automatically support callbacks.

Extending a transactional application server's interface

When using transactions or just-in-time activation, you must be sure all new methods call *SetComplete* to indicate when they are finished. This allows transactions to complete and permits the remote data module to be deactivated.

Furthermore, you can't return any values from your new methods that allow the client to communicate directly with objects or interfaces on the application server unless they provide a safe reference. If you are using a stateless MTS data module, neglecting to use a safe reference can lead to crashes because you can't guarantee that the remote data module is active. For more information on safe references, see "Passing object references" on page 39-20.

Managing transactions in multi-tiered applications

When client applications apply updates to the application server, the provider component automatically wraps the process of applying updates and resolving errors in a transaction. This transaction is committed if the number of problem records does not exceed the *MaxErrors* value specified as an argument to the *ApplyUpdates* method. Otherwise, it is rolled back.

In addition, you can add transaction support to your server application by adding a database connection component or managing the transaction directly by sending SQL to the database server. This works the same way that you would manage transactions in a two-tiered application. For more information about this sort of transaction control, see "Managing transactions" on page 17-5.

If you have a transactional data module, you can broaden your transaction support by using MTS or COM+ transactions. These transactions can include any of the business logic on your application server, not just the database access. In addition, because they support two-phase commits, they can span multiple databases.

Only the BDE- and ADO-based data access components support two-phase commit. Do not use InterbaseExpress or dbExpress components if you want to have transactions that span multiple databases.

Warning When using the BDE, two-phase commit is fully implemented only on Oracle7 and MS-SQL databases. If your transaction involves multiple databases, and some of them are remote servers other than Oracle7 or MS-SQL, your transaction runs a small risk of only partially succeeding. Within any one database, however, you will always have transaction support.

By default, all *IAppServer* calls on a transactional data module are transactional. You need only set the transaction attribute of your data module to indicate that it must participate in transactions. In addition, you can extend the application server's interface to include method calls that encapsulate transactions that you define.

If your transaction attribute indicates that the remote data module requires a transaction, then every time a client calls a method on its interface, it is automatically wrapped in a transaction. All client calls to your application server are then enlisted in that transaction until you indicate that the transaction is complete. These calls either succeed as a whole or are rolled back.

Note Do not combine MTS or COM+ transactions with explicit transactions created by a database connection component or using explicit SQL commands. When your transactional data module is enlisted in a transaction, it automatically enlists all of your database calls in the transaction as well.

For more information about using MTS and COM+ transactions, see "MTS and COM+ transaction support" on page 39-8.

Supporting master/detail relationships

You can create master/detail relationships between client datasets in your client application in the same way you set them up using any table-type dataset. For more information about setting up master/detail relationships in this way, see "Creating master/detail relationships" on page 18-34.

However, this approach has two major drawbacks:

- The detail table must fetch and store all of its records from the application server even though it only uses one detail set at a time. (This problem can be mitigated by using parameters. For more information, see "Limiting records with parameters" on page 23-28.)
- It is very difficult to apply updates, because client datasets apply updates at the dataset level and master/detail updates span multiple datasets. Even in a two-tiered environment, where you can use the database connection component to apply updates for multiple tables in a single transaction, applying updates in master/detail forms is tricky.

In multi-tiered applications, you can avoid these problems by using nested tables to represent the master/detail relationship. To do this when providing from datasets, set up a master/detail relationship between the datasets on the application server. Then set the *DataSet* property of your provider component to the master table. To use nested tables to represent master/detail relationships when providing from XML documents, use a transformation file that defines the nested detail sets.

When clients call the *GetRecords* method of the provider, it automatically includes the detail dataset as a DataSet field in the records of the data packet. When clients call the *ApplyUpdates* method of the provider, it automatically handles applying updates in the proper order.

Supporting state information in remote data modules

The *IAppServer* interface, which controls all communication between client datasets and providers on the application server, is mostly stateless. When an application is stateless, it does not "remember" anything that happened in previous calls by the client. This stateless quality is useful if you are pooling database connections in a transactional data module, because your application server does not need to distinguish between database connections for persistent information such as record currency. Similarly, this stateless quality is important when you are sharing remote data module instances between many clients, as occurs with just-in-time activation, object pooling, or typical CORBA servers. SOAP data modules must be stateless.

However, there are times when you want to maintain state information between calls to the application server. For example, when requesting data using incremental fetching, the provider on the application server must "remember" information from previous calls (the current record).

Before and after any calls to the *IAppServer* interface that the client dataset makes (AS_*ApplyUpdates*, AS_*Execute*, AS_*GetParams*, AS_*GetRecords*, or AS_*RowRequest*), it receives an event where it can send or retrieve custom state information. Similarly, before and after providers respond to these client-generated calls, they receive events where they can retrieve or send custom state information. Using this mechanism, you can communicate persistent state information between client applications and the application server, even if the application server is stateless.

For example, consider a dataset that represents the following parameterized query:

```
SELECT * from CUSTOMER WHERE CUST_NO > :MinVal ORDER BY CUST_NO
```

To enable incremental fetching in a stateless application server, you can do the following:

- When the provider packages a set of records in a data packet, it notes the value of CUST_NO on the last record in the packet:

```
TRemoteDataModule1.DataSetProvider1GetData(Sender: TObject; DataSet: TCustomClientDataSet);
begin
  DataSet.Last; { move to the last record }
  with Sender as TDataSetProvider do
    Tag := DataSet.FieldValues['CUST_NO']; {save the value of CUST_NO }
end;
```

- The provider sends this last CUST_NO value to the client after sending the data packet:

```
TRemoteDataModule1.DataSetProvider1AfterGetRecords(Sender: TObject;
                   var OwnerData: OleVariant);
begin
  with Sender as TDataSetProvider do
    OwnerData := Tag; {send the last value of CUST_NO }
end;
```

- On the client, the client dataset saves this last value of CUST_NO:

```
TDataModule1.ClientDataSet1AfterGetRecords(Sender: TObject; var OwnerData: OleVariant);
begin
  with Sender as TClientDataSet do
    Tag := OwnerData; {save the last value of CUST_NO }
end;
```

- Before fetching a data packet, the client sends the last value of CUST_NO it received:

```
TDataModule1.ClientDataSet1BeforeGetRecords(Sender: TObject; var OwnerData: OleVariant);
begin
  with Sender as TClientDataSet do
  begin
    if not Active then Exit;
    OwnerData := Tag; { Send last value of CUST_NO to application server }
  end;
end;
```

- Finally, on the server, the provider uses the last CUST_NO sent as a minimum value in the query:

```
TRemoteDataModule1.DataSetProvider1BeforeGetRecords(Sender: TObject;
                    var OwnerData: OleVariant);
begin
  if not VarIsEmpty(OwnerData) then
    with Sender as TDataSetProvider do
      with DataSet as TSQLDataSet do
      begin
        Params.ParamValues['MinVal'] := OwnerData;
        Refresh; { force the query to reexecute }
    end;
end;
```

Using multiple remote data modules

You may want to structure your application server so that it uses multiple remote data modules. Using multiple remote data modules lets you partition your code, organizing a large application server into multiple self-contained units, where each unit is relatively self-contained.

Although you can always create multiple remote data modules on the application server that function independently, Delphi provides support for a model where you have one main “parent” remote data module that dispatches connections from clients to other “child” remote data modules.

To create the parent remote data module, you must extend its *IAppServer* interface, adding properties that expose the interfaces of the child remote data modules. That is, for each child remote data module, add a property to the parent data module’s interface whose value is the *IAppServer* interface for the child data module. The property getter should look something like the following:

```
function ParentRDM.Get_ChildRDM: IChildRDM;
begin
  {note the parent RDM uses a factory component defined in the child RDM’s unit.
  This is more efficient if it must create several children for different clients }
  Result := ChildRDMFactory.CreateCOMObject(nil) as IChildRDM;
  Result.ParentRDM := Self;
end;
```

For information about extending the parent remote data module's interface, see "Extending the application server's interface" on page 25-16.

Tip You may also want to extend the interface for each child data module, exposing the parent data module's interface, or the interfaces of the other child data modules. This lets the various data modules in your application server communicate more freely with each other.

Once you have added properties that represent the child remote data modules to the main remote data module, client applications do not need to form separate connections to each remote data module on the application server. Instead, they share a single connection to the parent remote data module, which then dispatches messages to the "child" data modules. Because each client application uses the same connection for every remote data module, the remote data modules can share a single database connection, conserving resources. For information on how child applications share a single connection, see "Connecting to an application server that uses multiple data modules" on page 25-30.

Registering the application server

Before client applications can locate and use an application server, it must be registered or installed. (This is not strictly true for CORBA application servers, although registration is still recommended.)

- If the application server uses DCOM, HTTP, or sockets as a communication protocol, it acts as an Automation server and must be registered like any other COM server. For information about registering a COM server, see "Registering a COM object" on page 36-16.
- If you are using a transactional data module, you do not register the application server. Instead, you install it with MTS or COM+. For information about installing transactional objects, see "Installing transactional objects" on page 39-22.
- When the application server uses SOAP, the application must be a Web Service application. As such, it must be registered with your Web Server, so that it receives incoming HTTP messages. In addition, if you want clients that are not written using Delphi to access any of the interfaces in your application, you can publish a WSDL document that describes the invokable interfaces in your application. For information about exporting a WSDL document for a Web Service application, see "Generating WSDL documents for a Web Service application" on page 31-7.
- When the application server uses CORBA, registration is optional. If you want to allow client applications to use dynamic binding to your interface, you must install the server's interface in the Interface Repository. In addition, if you want to allow client applications to launch the application server when it is not already running, it must be registered with the OAD (Object Activation Daemon).

Creating the client application

In most regards, creating a multi-tiered client application is similar to creating a two-tiered client that uses a client dataset to cache updates. The major difference is that a multi-tiered client uses a connection component to establish a conduit to the application server.

To create a multi-tiered client application, start a new project and follow these steps:

1. Add a new data module to the project.
2. Place a connection component on the data module. The type of connection component you add depends on the communication protocol you want to use. See "The structure of the client application" on page 25-4 for details.
3. Set properties on your connection component to specify the application server with which it should establish a connection. To learn more about setting up the connection component, see "Connecting to the application server" on page 25-23.
4. Set the other connection component properties as needed for your application. For example, you might set the *ObjectBroker* property to allow the connection component to choose dynamically from several servers. For more information about using the connection components, see "Managing server connections" on page 25-28
5. Place as many *TClientDataSet* components as needed on the data module, and set the *RemoteServer* property for each component to the name of the connection component you placed in Step 2. For a full introduction to client datasets, see Chapter 23, "Using client datasets."
6. Set the *ProviderName* property for each *TClientDataSet* component. If your connection component is connected to the application server at design time, you can choose available application server providers from the *ProviderName* property's drop-down list.
7. Continue in the same way you would create any other database application. There are a few additional features available to clients of multi-tiered applications:
   - Your application may want to make direct calls to the application server. "Calling server interfaces" on page 25-29 describes how to do this.
   - You may want to use the special features of client datasets that support their interaction with the provider components. These are described in "Using a client dataset with a provider" on page 23-23.

Connecting to the application server

To establish and maintain a connection to an application server, a client application uses one or more connection components. You can find these components on the DataSnap page of the Component palette.

Use a connection component to

- Identify the protocol for communicating with the application server. Each type of connection component represents a different communication protocol. See “Choosing a connection protocol” on page 25-8 for details on the benefits and limitations of the available protocols.
- Indicate how to locate the server machine. The details of identifying the server machine vary depending on the protocol.
- Identify the application server on the server machine.

  If you are not using CORBA, identify the server using the *ServerName* or *ServerGUID* property. *ServerName* identifies the base name of the class you specify when creating the remote data module on the application server. See “Setting up the remote data module” on page 25-13 for details on how this value is specified on the server. If the server is registered or installed on the client machine, or if the connection component is connected to the server machine, you can set the *ServerName* property at design time by choosing from a drop-down list in the Object Inspector. *ServerGUID* specifies the GUID of the remote data module’s interface. You can look up this value using the type library editor.

  If you are using CORBA, identify the server using the *RepositoryID* property. *RepositoryID* specifies the Repository ID of the application server’s factory interface, which appears as the third argument in the call to *TCorbaVCLComponentFactory.Create* that is automatically added to the initialization section of the CORBA server’s implementation unit. You can also set this property to the base name of the CORBA data module’s interface (the same string as the *ServerName* property for other connection components), and it is automatically converted into the appropriate Repository ID for you.
- Manage server connections. Connection components can be used to create or drop connections and to call application server interfaces.

Usually the application server is on a different machine from the client application, but even if the server resides on the same machine as the client application (for example, during the building and testing of the entire multi-tier application), you can still use the connection component to identify the application server by name, specify a server machine, and use the application server interface.

Specifying a connection using DCOM

When using DCOM to communicate with the application server, client applications include a *TDCOMConnection* component for connecting to the application server. *TDCOMConnection* uses the *ComputerName* property to identify the machine on which the server resides.

When *ComputerName* is blank, the DCOM connection component assumes that the application server resides on the client machine or that the application server has a system registry entry. If you do not provide a system registry entry for the application server on the client when using DCOM, and the server resides on a different machine from the client, you must supply *ComputerName*.

Note Even when there is a system registry entry for the application server, you can specify *ComputerName* to override this entry. This can be especially useful during development, testing, and debugging.

If you have multiple servers that your client application can choose from, you can use the *ObjectBroker* property instead of specifying a value for *ComputerName*. For more information, see "Brokering connections" on page 25-27.

If you supply the name of a host computer or server that cannot be found, the DCOM connection component raises an exception when you try to open the connection.

Specifying a connection using sockets

You can establish a connection to the application server using sockets from any machine that has a TCP/IP address. This method has the advantage of being applicable to more machines, but does not provide for using any security protocols. When using sockets, include a *TSocketConnection* component for connecting to the application server.

TSocketConnection identifies the server machine using the IP Address or host name of the server system, and the port number of the socket dispatcher program (Scktsrvr.exe) that is running on the server machine. For more information about IP addresses and port values, see "Describing sockets" on page 32-3.

Three properties of *TSocketConnection* specify this information:

- *Address* specifies the IP Address of the server.
- *Host* specifies the host name of the server.
- *Port* specifies the port number of the socket dispatcher program on the application server.

Address and *Host* are mutually exclusive. Setting one unsets the value of the other. For information on which one to use, see "Describing the host" on page 32-4.

If you have multiple servers that your client application can choose from, you can use the *ObjectBroker* property instead of specifying a value for *Address* or *Host*. For more information, see "Brokering connections" on page 25-27.

By default, the value of *Port* is 211, which is the default port number of the socket dispatcher programs supplied with Delphi. If the socket dispatcher has been configured to use a different port, set the *Port* property to match that value.

Note You can configure the port of the socket dispatcher while it is running by right-clicking the Borland Socket Server tray icon and choosing Properties.

Although socket connections do not provide for using security protocols, you can customize the socket connection to add your own encryption. To do this

1. Create a COM object that supports the *IDataIntercept* interface. This is an interface for encrypting and decrypting data.
2. Use *TPacketInterceptFactory* as the class factory for this object. If you are using a wizard to create the COM object in step 1, replace the line in the initialization section that says `TComponentFactory.Create(...)` with `TPacketInterceptFactory.Create(...)`.
3. Register your new COM server on the client machine.

4 Set the *InterceptName* or *InterceptGUID* property of the socket connection component to specify this COM object. If you used *TPacketInterceptFactory* in step 2, your COM server appears in the drop-down list of the Object Inspector for the *InterceptName* property.

5 Finally, right click the Borland Socket Server tray icon, choose Properties, and on the properties tab set the Intercept Name or Intercept GUID to the ProgId or GUID for the interceptor.

This mechanism can also be used for data compression and decompression.

Specifying a connection using HTTP

You can establish a connection to the application server using HTTP from any machine that has a TCP/IP address. Unlike sockets, however, HTTP allows you to take advantage of SSL security and to communicate with a server that is protected behind a firewall. When using HTTP, include a *TWebConnection* component for connecting to the application server.

The Web connection component establishes a connection to the Web server application (httpsrvr.dll), which in turn communicates with the application server. *TWebConnection* locates httpsrvr.dll using a Uniform Resource Locator (URL). The URL specifies the protocol (http or, if you are using SSL security, https), the host name for the machine that runs the Web server and httpsrvr.dll, and the path to the Web server application (httpsrvr.dll). Specify this value using the *URL* property.

Note When using *TWebConnection*, wininet.dll must be installed on the client machine. If you have IE3 or higher installed, wininet.dll can be found in the Windows system directory.

If the Web server requires authentication, or if you are using a proxy server that requires authentication, you must set the values of the *UserName* and *Password* properties so that the connection component can log on.

If you have multiple servers that your client application can choose from, you can use the *ObjectBroker* property instead of specifying a value for *URL*. For more information, see “Brokering connections” on page 25-27.

Specifying a connection using SOAP

You can establish a connection to a SOAP application server using the *TSoapConnection* component. *TSoapConnection* is very similar to *TWebConnection*, because it also uses HTTP as a transport protocol. Thus, you can use *TSoapConnection* from any machine that has a TCP/IP address, and it can take advantage of SSL security to communicate with a server that is protected by a firewall.

The SOAP connection component establishes a connection to a Web server application that implements the *IAppServer* interface as a Web Service. *TSoapConnection* locates this Web Server application using a Uniform Resource Locator (URL). The URL specifies the protocol (http or, if you are using SSL security, https), the host name for the machine that runs the Web server, the name of the Web Service application, and a path that matches the path name of the *THTTPSoapDispatcher* on the application server. Specify this value using the *URL* property.

Note When using *TSoapConnection*, wininet.dll must be installed on the client machine. If you have IE3 or higher installed, wininet.dll can be found in the Windows system directory.

If the Web server requires authentication, or if you are using a proxy server that requires authentication, you must set the values of the *UserName* and *Password* properties so that the connection component can log on.

Specifying a connection using CORBA

Only the *RepositoryID* property is necessary in order to specify a CORBA connection. This is because a Smart Agent on the local network automatically locates an available server for your CORBA client.

However, you can limit the possible servers to which your client application connects by the other properties of the CORBA connection component. If you want to specify a particular server machine, rather than letting the CORBA Smart Agent locate any available server, use the *HostName* property. If there is more than one object instance that implements your server interface, you can specify which object you want to use by setting the *ObjectName* property.

The *TCorbaConnection* component obtains an interface to the CORBA data module on the application server in one of two ways:

- If you are using early (static) binding, you must add the _TLB.pas file (generated by the type library editor) to your client application. Early binding is highly recommended, both for compile-time type checking and because it is much faster than late (dynamic) binding.
- If you are using late (dynamic) binding, the interface must be registered with the Interface Repository.

For more information on early vs. late binding, see “Calling server interfaces” on page 25-29.

Brokering connections

If you have multiple servers that your client application can choose from, you can use an Object Broker to locate an available server system. The object broker maintains a list of servers from which the connection component can choose. When the connection component needs to connect to an application server, it asks the Object Broker for a computer name (or IP address, host name, or URL). The broker supplies a name, and the connection component forms a connection. If the supplied name does not work (for example, if the server is down), the broker supplies another name, and so on, until a connection is formed.

Once the connection component has formed a connection with a name supplied by the broker, it saves that name as the value of the appropriate property (*ComputerName*, *Address*, *Host*, *RemoteHost*, or *URL*). If the connection component closes the connection later, and then needs to reopen the connection, it tries using this property value, and only requests a new name from the broker if the connection fails.

Use an Object Broker by specifying the *ObjectBroker* property of your connection component. When the *ObjectBroker* property is set, the connection component does not save the value of *ComputerName*, *Address*, *Host*, *RemoteHost*, or *URL* to disk.

Note Do not use the *ObjectBroker* property with CORBA connections. CORBA has its own brokering mechanism.

Managing server connections

The main purpose of connection components is to locate and connect to the application server. Because they manage server connections, you can also use connection components to call the methods of the application server's interface.

Connecting to the server

To locate and connect to the application server, you must first set the properties of the connection component to identify the application server. This process is described in "Connecting to the application server" on page 25-23. Before opening the connection, any client datasets that use the connection component to communicate with the application server should indicate this by setting their *RemoteServer* property to specify the connection component.

The connection is opened automatically when client datasets try to access the application server. For example, setting the *Active* property of the client dataset to *True* opens the connection, as long as the *RemoteServer* property has been set.

If you do not link any client datasets to the connection component, you can open the connection by setting the *Connected* property of the connection component to *True*.

Before a connection component establishes a connection to an application server, it generates a *BeforeConnect* event. You can perform any special actions prior to connecting in a *BeforeConnect* handler that you code. After establishing a connection, the connection component generates an *AfterConnect* event for any special actions.

Dropping or changing a server connection

A connection component drops a connection to the application server when you

- set the *Connected* property to *False*.
- free the connection component. A connection object is automatically freed when a user closes the client application.
- change any of the properties that identify the application server (*ServerName*, *ServerGUID*, *ComputerName*, and so on). Changing these properties allows you to switch among available application servers at runtime. The connection component drops the current connection and establishes a new one.

Note Instead of using a single connection component to switch among available application servers, a client application can instead have more than one connection component, each of which is connected to a different application server.

Before a connection component drops a connection, it automatically calls its *BeforeDisconnect* event handler, if one is provided. To perform any special actions prior to disconnecting, write a *BeforeDisconnect* handler. Similarly, after dropping the connection, the *AfterDisconnect* event handler is called. If you want to perform any special actions after disconnecting, write an *AfterDisconnect* handler.

Calling server interfaces

Applications do not need to call the *IAppServer* interface directly because the appropriate calls are made automatically when you use the properties and methods of the client dataset. However, while it is not necessary to work directly with the *IAppServer* interface, you may have added your own extensions to the remote data module's interface. When you extend the application server's interface, you need a way to call those extensions using the connection created by your connection component. Unless you are using SOAP, you can do this using the *AppServer* property of the connection component. For information about extending the application server's interface, see "Extending the application server's interface" on page 25-16.

AppServer is a Variant that represents the application server's interface. You can call an interface method using *AppServer* by writing a statement such as

```
MyConnection.AppServer.SpecialMethod(x,y);
```

However, this technique provides late (dynamic) binding of the interface call. That is, the *SpecialMethod* procedure call is not bound until runtime when the call is executed. Late binding is very flexible, but by using it you lose many benefits such as code insight and type checking. In addition, late binding is slower than early binding, because the compiler generates additional calls to the server to set up interface calls before they are invoked.

When you are using DCOM or CORBA as a communications protocol, you can use early binding of *AppServer* calls. Use the **as** operator to cast the *AppServer* variable to the *IAppServer* descendant you created when you created the remote data module. For example:

```
with MyConnection.AppServer as IMyAppServer do
  SpecialMethod(x,y);
```

To use early binding under DCOM, the server's type library must be registered on the client machine. You can use TRegsvr.exe, which ships with Delphi to register the type library.

Note See the TRegSvr demo (which provides the source for TRegsvr.exe) for an example of how to register the type library programmatically.

To use early binding with CORBA, you must add the _TLB unit that is generated by the type library editor to your project. To do this, add this unit to the **uses** clause of your unit.

When you are using TCP/IP or HTTP, you can't use true early binding, but because the remote data module uses a dual interface, you can use the application server's dispinterface to improve performance over simple late-binding. The dispinterface has the same name as the remote data module's interface, with the string 'Disp' appended. You can assign the *AppServer* property to a variable of this type to obtain the dispinterface. Thus:

```
var
  TempInterface: IMyAppServerDisp;
begin
  TempInterface :=IMyAppServerDisp(IDispatch(MyConnection.AppServer));
...
  TempInterface.SpecialMethod(x,y);
...
end;
```

Note To use the dispinterface, you must add the _TLB unit that is generated when you save the type library to the **uses** clause of your client module.

If you are using SOAP, you can't use the *AppServer* property. Instead, you must use a remote interfaced object (*THTTPRio*) and make early-bound calls. As with all early-bound calls, the client application must know the application server's interface declaration at compile time. You can add this to your client application either by adding the same unit the server uses to declare and register the interface to the client's uses clause, or you can reference a WSDL document that describes the interface. For information on importing a WSDL document that describes the server interface, see "Importing WSDL documents" on page 31-8.

Note The unit that declares the server interface must also register it with the invocation registry. For details on how to register invokable interfaces, see "Defining invokable interfaces" on page 31-3.

Once your application uses the server unit that declares and registers the interface, or you have imported a WSDL document to generate such a unit, create an instance of *THTTPRio* for the desired interface:

```
X := THTTPRio.Create(nil);
```

Next, assign the URL that your connection component uses to the remote interfaced object:

```
X.URL := SoapConnection1.URL;
```

You can then use the **as** operator to cast the instance of *THTTPRio* to the application server's interface:

```
InterfaceVariable := X as IMyAppServer;
InterfaceVariable.SpecialMethod(x,y);
```

Connecting to an application server that uses multiple data modules

If the application server uses a main "parent" remote data module and several child remote data modules, as described in "Using multiple remote data modules" on page 25-21, then you need a separate connection component for every remote data module on the application server. Each connection component represents the connection to a single remote data module.

While it is possible to have your client application form independent connections to each remote data module on the application server, it is more efficient to use a single connection to the application server that is shared by all the connection components. That is, you add a single connection component that connects to the "main" remote data module on the application server, and then, for each "child" remote data module, add an additional component that shares the connection to the main remote data module.

1 For the connection to the main remote data module, add and set up a connection component as described in "Connecting to the application server" on page 25-23. The only limitation is that you can't use a CORBA or SOAP connection.

2 For each child remote data module, use a *TSharedConnection* component.

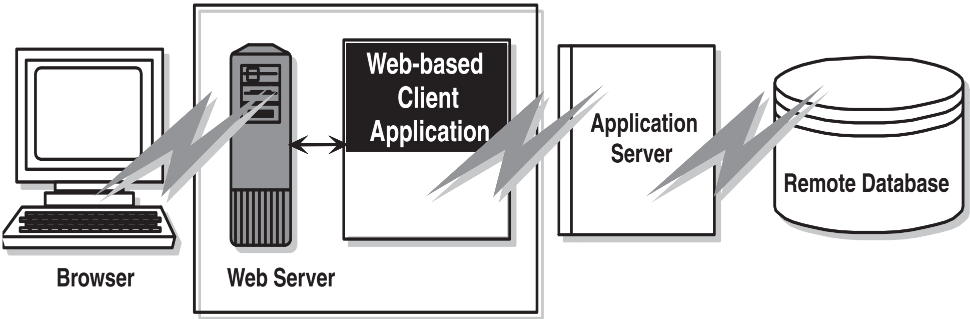
  - Set its *ParentConnection* property to the connection component you added in step 1. The *TSharedConnection* component shares the connection that this main connection establishes.
  - Set its *ChildName* property to the name of the property on the main remote data module's interface that exposes the interface of the desired child remote data module.

When you assign the *TSharedConnection* component placed in step 2 as the value of a client dataset's *RemoteServer* property, it works as if you were using an entirely independent connection to the child remote data module. However, the *TSharedConnection* component uses the connection established by the component you placed in step 1.

Writing Web-based client applications

If you want to create Web-based clients for your multi-tiered database application, you must replace the client tier with a special Web application that acts simultaneously as a client to an application server and as a Web server application that is installed with a Web server on the same machine. This architecture is illustrated in Figure 25.1.

Figure 25.1 Web-based multi-tiered database application



There are two approaches that you can take to build the Web application:

- You can combine the multi-tiered database architecture with Delphi's ActiveX support to distribute the client application as an ActiveX control. This allows any browser that supports ActiveX to run your client application as an in-process server.

- You can use XML data packets to build an InternetExpress application. This allows browsers that supports javascript to interact with your client application through html pages.

These two approaches are very different. Which one you choose depends on the following considerations:

- Each approach relies on a different technology (ActiveX vs. javascript and XML). Consider what systems your end users will use. The first approach requires a browser to support ActiveX (which limits clients to a Windows platform). The second approach requires a browser to support javascript and the DHTML capabilities introduced by Netscape 4 and Internet Explorer 4.
- ActiveX controls must be downloaded to the browser to act as an in-process server. As a result, the clients using an ActiveX approach require much more memory than the clients of an HTML-based application.
- The InternetExpress approach can be integrated with other HTML pages. An ActiveX client must run in a separate window.
- The InternetExpress approach uses standard HTTP, thereby avoiding any firewall issues that confront an ActiveX application.
- The ActiveX approach provides greater flexibility in how you program your application. You are not limited by the capabilities of the javascript libraries. The client datasets used in the ActiveX approach surface more features (such as filters, ranges, aggregation, optional parameters, delayed fetching of BLOBs or nested details, and so on) than the XML brokers used in the InternetExpress approach.

Caution Your Web client application may look and act differently when viewed from different browsers. Test your application with the browsers you expect your end-users to use.

Distributing a client application as an ActiveX control

The multi-tiered database architecture can be combined with Delphi's ActiveX features to distribute a client application as an ActiveX control.

When you distribute your client application as an ActiveX control, create the application server as you would for any other multi-tiered application. The only limitation is that you will want to use DCOM, HTTP, SOAP, or sockets as a communications protocol, because you can't count on client machines having installed the CORBA runtime software. For details on creating the application server, see "Creating the application server" on page 25-11.

When creating the client application, you must use an Active Form as the basis instead of an ordinary form. See "Creating an Active Form for the client application" for details.

Once you have built and deployed your client application, it can be accessed from any ActiveX-enabled Web browser on another machine. For a Web browser to successfully launch your client application, the Web server must be running on the machine that has the client application.

If the client application uses DCOM to communicate between the client application and the application server, the machine with the Web browser must be enabled to work with DCOM. If the machine with the Web browser is a Windows 95 machine, it must have installed DCOM95, which is available from Microsoft.

Creating an Active Form for the client application

1. Because the client application will be deployed as an ActiveX control, you must have a Web server that runs on the same system as the client application. You can use a ready-made server such as Microsoft's Personal Web server or you can write your own using the socket components described in Chapter 32, "Working with sockets."
2. Create the client application following the steps described in "Creating the client application" on page 25-23, except start by choosing File | New | Active Form, rather than beginning the client project as an ordinary Delphi project.
3. If your client application uses a data module, add a call to explicitly create the data module in the active form initialization.
4. When your client application is finished, compile the project, and select Project | Web Deployment Options. In the Web Deployment Options dialog, you must do the following:
   1. On the Project page, specify the Target directory, the URL for the target directory, and the HTML directory. Typically, the Target directory and the HTML directory will be the same as the projects directory for your Web Server. The target URL is typically the name of the server machine that is specified in the Windows Network | DNS settings.
   2. On the Additional Files page, include midas.dll with your client application.
5. Finally, select Project | WebDeploy to deploy the client application as an active form.

Any Web browser that can run Active forms can run your client application by specifying the .HTM file that was created when you deployed the client application. This .HTM file has the same name as your client application project, and appears in the directory specified as the Target directory.

Building Web applications using InternetExpress

A client application can request that the application server provide data packets that are coded in XML instead of OleVariants. By combining XML-coded data packets, special javascript libraries of database functions, and Delphi's Web server application support, you can create thin client applications that can be accessed using a Web browser that supports javascript. These applications make up Delphi's InternetExpress support.

Before building an InternetExpress application, you should understand Delphi's Web server application architecture. This is described in Chapter 27, "Creating Internet applications."

An InternetExpress application extends the basic Web server application architecture to act as the client of an application server. InternetExpress applications generate HTML pages that contain a mixture of HTML, XML, and javascript. The HTML governs the layout and appearance of the pages seen by end users in their browsers. The XML encodes the data packets and delta packets that represent database information. The javascript allows the HTML controls to interpret and manipulate the data in these XML data packets on the client machine.

If the InternetExpress application uses DCOM to connect to the application server, you must take additional steps to ensure that the application server grants access and launch permissions to its clients. See "Granting permission to access and launch the application server" on page 25-36 for details.

Tip You can create an InternetExpress application to provide Web browsers with "live" data even if you do not have an application server. Simply add the provider and its dataset to the Web module.

Building an InternetExpress application

The following steps describe one way to build a Web application using InternetExpress. The result is an application that creates HTML pages that let users interact with the data from an application server via a javascript-enabled Web browser. You can also build an InternetExpress application using the Site Express architecture by using the InternetExpress page producer (*TInetXPageProducer*).

1. Choose File | New to display the New Items dialog box, and on the New page select Web Server application. This process is described in "Creating Web server applications with Web Broker" on page 28-1.
2. From the DataSnap page of the component palette, add a connection component to the Web Module that appears when you create a new Web server application. The type of connection component you add depends on the communication protocol you want to use. See "Choosing a connection protocol" on page 25-8 for details.
3. Set properties on your connection component to specify the application server with which it should establish a connection. To learn more about setting up the connection component, see "Connecting to the application server" on page 25-23.
4. Instead of a client dataset, add an XML broker from the InternetExpress page of the component palette to the Web module. Like *TClientDataSet*, *TXMLBroker* represents the data from a provider on the application server and interacts with the application server through its *IAppServer* interface. However, unlike client datasets, XML brokers request data packets as XML instead of as OleVariants and interact with InternetExpress components instead of data controls.
5. Set the *RemoteServer* property of the XML broker to point to the connection component you added in step 2. Set the *ProviderName* property to indicate the provider on the application server that provides data and applies updates. For more information about setting up the XML broker, see "Using an XML broker" on page 25-36.

6 Add an InternetExpress page producer (*TInetXPageProducer*) to the Web module for each separate page that users will see in their browsers. For each page producer, you must set the *IncludePathURL* property to indicate where it can find the javascript libraries that augment its generated HTML controls with data management capabilities.

7 Right-click a Web page and choose Action Editor to display the Action editor. Add action items for every message you want to handle from browsers. Associate the page producers you added in step 6 with these actions by setting their *Producer* property or writing code in an *OnAction* event handler. For more information on adding action items using the Action editor, see “Adding actions to the dispatcher” on page 28-4.

8 Double-click each Web page to display the Web Page editor. (You can also display this editor by clicking the ellipsis button in the Object Inspector next to the *WebPageItems* property.) In this editor you can add Web Items to design the pages that users see in their browsers. For more information about designing Web pages for your InternetExpress application, see “Creating Web pages with an InternetExpress page producer” on page 25-38.

9 Build your Web application. Once you install this application with your Web server, browsers can call it by specifying the name of the application as the scriptname portion of the URL and the name of the Web Page component as the pathinfo portion.

Using the javascript libraries

The HTML pages generated by the InternetExpress components and the Web items they contain make use of several javascript libraries that ship with Delphi:

Table 25.3 Javascript libraries

Library	Description
xmldom.js	This library is a DOM-compatible XML parser written in javascript. It allows parsers that do not support XML to use XML data packets. Note that this does not include support for XML Islands, which are supported by IE5 and later.
xmldb.js	This library defines data access classes that manage XML data packets and XML delta packets.
xmldisp.js	This library defines classes that associate the data access classes in xmldb with HTML controls in the HTML page.
xmlerrdisp.js	This library defines classes that can be used when reconciling update errors. These classes are not used by any of the built-in InternetExpress components, but are useful when writing a Reconcile producer.
xmlshow.js	This library includes functions to display formatted XML data packets and XML delta packets. This library is not used by any of the InternetExpress components, but is useful when debugging.

These libraries can be found in the Source/Webmidas directory. Once you have installed these libraries, you must set the *IncludePathURL* property of all InternetExpress page producers to indicate where they can be found.

It is possible to write your own HTML pages using the javascript classes provided in these libraries instead of using Web items to generate your Web pages. However, you must ensure that your code does not do anything illegal, as these classes include minimal error checking (so as to minimize the size of the generated Web pages).

The classes in the javascript libraries are an evolving standard, and are updated regularly. If you want to use them directly rather than relying on Web items to generate the javascript code, you can get the latest versions and documentation of how to use them from CodeCentral available through community.borland.com.

Granting permission to access and launch the application server

Requests from the InternetExpress application appear to the application server as originating from a guest account with the name IUSR_computername, where computername is the name of the system running the Web application. By default, this account does not have access or launch permission for the application server. If you try to use the Web application without granting these permissions, when the Web browser tries to load the requested page it times out with `EOLE_ACCESS_ERROR`.

Note Because the application server runs under this guest account, it can't be shut down by other accounts.

To grant the Web application access and launch permissions, run DCOMCnfg.exe, which is located in the System32 directory of the machine that runs the application server. The following steps describe how to configure your application server:

1. When you run DCOMCnfg, select your application server in the list of applications on the Applications page.
2. Click the Properties button. When the dialog changes, select the Security page.
3. Select Use Custom Access Permissions, and press the Edit button. Add the name IUSR_computername to the list of accounts with access permission, where computername is the name of the machine that runs the Web application.
4. Select Use Custom Launch Permissions, and press the Edit button. Add IUSR_computername to this list as well.
5. Click the Apply button.

Using an XML broker

The XML broker serves two major functions:

- It fetches XML data packets from the application server and makes them available to the Web Items that generate HTML for the InternetExpress application.
- It receives updates in the form of XML delta packets from browsers and applies them to the application server.

Fetching XML data packets

Before the XML broker can supply XML data packets to the components that generate HTML pages, it must fetch them from the application server. To do this, it uses the *IAppServer* interface of the application server, which it acquires through a connection component. You must set the following properties so that the XML producer can use the application server's *IAppServer* interface:

- Set the *RemoteServer* property to the connection component that establishes the connection to the application server and gets its *IAppServer* interface. At design time, you can select this value from a drop-down list in the object inspector.
- Set the *ProviderName* property to the name of the provider component on the application server that represents the dataset for which you want XML data packets. This provider both supplies XML data packets and applies updates from XML delta packets. At design time, if the *RemoteServer* property is set and the connection component has an active connection, the Object Inspector displays a list of available providers. (If you are using a DCOM connection the application server must also be registered on the client machine).

Two properties let you indicate what you want to include in data packets:

- You can limit the number of records that are added to the data packet by setting the *MaxRecords* property. This is especially important for large datasets because InternetExpress applications send the entire data packet to client Web browsers. If the data packet is too large, the download time can become prohibitively long.
- If the provider on the application server represents a query or stored procedure, you may want to provide parameter values before obtaining an XML data packet. You can supply these parameter values using the *Params* property.

The components that generate HTML and javascript for the InternetExpress application automatically use the XML broker's XML data packet once you set their *XMLBroker* property. To obtain the XML data packet directly in code, use the *RequestRecords* method.

Note When the XML broker supplies a data packet to another component (or when you call *RequestRecords*), it receives an *OnRequestRecords* event. You can use this event to supply your own XML string instead of the data packet from the application server. For example, you could fetch the XML data packet from the application server using *GetXMLRecords* and then edit it before supplying it to the emerging Web page.

Applying updates from XML delta packets

When you add the XML broker to the Web module (or data module containing a *TWebDispatcher*), it automatically registers itself with the Web dispatcher as an auto-dispatching object. This means that, unlike other components, you do not need to create an action item for the XML broker in order for it to respond to update messages from a Web browser. These messages contain XML delta packets that should be applied to the application server. Typically, they originate from a button that you create on one of the HTML pages produced by the Web client application.

So that the dispatcher can recognize messages for the XML broker, you must describe them using the *WebDispatch* property. Set the *PathInfo* property to the path portion of the URL to which messages for the XML broker are sent. Set *MethodType* to the value of the method header of update messages addressed to that URL (typically *mtPost*). If you want to respond to all messages with the specified path, set *MethodType* to *mtAny*. If you don't want the XML broker to respond directly to update messages (for example, if you want to handle them explicitly using an action item), set the *Enabled* property to *False*. For more information on how the Web dispatcher determines which component handles messages from the Web browser, see “Dispatching request messages” on page 28-5.

When the dispatcher passes an update message on to the XML broker, it passes the updates on to the application server and, if there are update errors, receives an XML delta packet describing all update errors. Finally, it sends a response message back to the browser, which either redirects the browser to the same page that generated the XML delta packet or sends it some new content.

A number of events allow you to insert custom processing at all steps of this update process:

1. When the dispatcher first passes the update message to the XML broker, it receives a *BeforeDispatch* event, where you can preprocess the request or even handle it entirely. This event allows the XML broker to handle messages other than update messages.
2. If the *BeforeDispatch* event handler does not handle the message, the XML broker receives an *OnRequestUpdate* event, where you can apply the updates yourself rather than using the default processing.
3. If the *OnRequestUpdate* event handler does not handle the request, the XML broker applies the updates and receives a delta packet containing any update errors.
4. If there are no update errors, the XML broker receives an *OnGetResponse* event, where you can create a response message that indicates the updates were successfully applied or sends refreshed data to the browser. If the *OnGetResponse* event handler does not complete the response (does not set the *Handled* parameter to *True*), the XML broker sends a response that redirects the browser back to the document that generated the delta packet.
5. If there are update errors, the XML broker receives an *OnGetErrorResponse* event instead. You can use this event to try to resolve update errors or to generate a Web page that describes them to the end user. If the *OnGetErrorResponse* event handler does not complete the response (does not set the *Handled* parameter to *True*), the XML broker calls on a special content producer called the *ReconcileProducer* to generate the content of the response message.
6. Finally, the XML broker receives an *AfterDispatch* event, where you can perform any final actions before sending a response back to the Web browser.

Creating Web pages with an InternetExpress page producer

Each InternetExpress page producer generates an HTML document that appears in the browsers of your application’s clients. If your application includes several separate Web documents, use a separate page producer for each of them.

The InternetExpress page producer (*TInetXPageProducer*) is a special page producer component. As with other page producers, you can assign it as the *Producer* property of an action item or call it explicitly from an *OnAction* event handler. For more information about using content producers with action items, see “Responding to request messages with action items" on page 28-7. For more information about page producers, see "Using page producer components" on page 28-13.

Unlike most page producers, the InternetExpress page producer has a default template as the value of its *HTMLDoc* property. This template contains a set of HTML-transparent tags that the InternetExpress page producer uses to assemble an HTML document (with embedded javascript and XML) including content produced by other components. Before it can translate all of the HTML-transparent tags and assemble this document, you must indicate the location of the javascript libraries used for the embedded javascript on the page. This location is specified by setting the *IncludePathURL* property.

You can specify the components that generate parts of the Web page using the Web page editor. Display the Web page editor by double-clicking the Web page component or clicking the ellipsis button next to the *WebPageItems* property in the Object Inspector.

The components you add in the Web page editor generate the HTML that replaces one of the HTML-transparent tags in the InternetExpress page producer's default template. These components become the value of the *WebPageItems* property. After adding the components in the order you want them, you can customize the template to add your own HTML or change the default tags.

Using the Web page editor

The Web page editor lets you add Web items to your InternetExpress page producer and view the resulting HTML page. Display the Web page editor by double-clicking on a InternetExpress page producer component.

Note You must have Internet Explorer 4 or better installed to use the Web page editor.

The top of the Web page editor displays the Web items that generate the HTML document. These Web items are nested, where each type of Web item assembles the HTML generated by its subitems. Different types of items can contain different subitems. On the left, a tree view displays all of the Web items, indicating how they are nested. On the right, you can see the Web items included by the currently selected item. When you select a component in the top of the Web page editor, you can set its properties using the Object Inspector.

Click the New Item button to add a subitem to the currently selected item. The Add Web Component dialog lists only those items that can be added to the currently selected item.

The InternetExpress page producer can contain one of two types of item, each of which generates an HTML form:

- *TDataForm*, which generates an HTML form for displaying data and the controls that manipulate that data or submit updates.

  Items you add to *TDataForm* display data in a multi-record grid (*TDataGrid*) or in a set of controls each of which represents a single field from a single record (*TFieldGroup*). In addition, you can add a set of buttons to navigate through data or post updates (*TDataNavigator*), or a button to apply updates back to the Web client (*TApplyUpdatesButton*). Each of these items contains subitems to represent individual fields or buttons. Finally, as with most Web items, you can add a layout grid (*TLayoutGroup*), that lets you customize the layout of any items it contains.

- *TQueryForm*, which generates an HTML form for displaying or reading application-defined values. For example, you can use this form for displaying and submitting parameter values.

  Items you add to *TQueryForm* display application-defined values(*TQueryFieldGroup*) or a set of buttons to submit or reset those values (*TQueryButtons*). Each of these items contains subitems to represent individual values or buttons. You can also add a layout grid to a query form, just as you can to a data form.

The bottom of the Web page editor displays the generated HTML code and lets you see what it looks like in a browser (IE4).

Setting Web item properties

The Web items that you add using the Web page editor are specialized components that generate HTML. Each Web item class is designed to produce a specific control or section of the final HTML document, but a common set of properties influences the appearance of the final HTML.

When a Web item represents information from the XML data packet (for example, when it generates a set of field or parameter display controls or a button that manipulates the data), the *XMLBroker* property associates the Web item with the XML broker that manages the data packet. You can further specify a dataset that is contained in a dataset field of that data packet using the *XMLDataSetField* property. If the Web item represents a specific field or parameter value, the Web item has a *FieldName* or *ParamName* property.

You can apply a style attribute to any Web item, thereby influencing the overall appearance of all the HTML it generates. Styles and style sheets are part of the HTML 4 standard. They allow an HTML document to define a set of display attributes that apply to a tag and everything in its scope. Web items offer a flexible selection of ways to use them:

- The simplest way to use styles is to define a style attribute directly on the Web item. To do this, use the *Style* property. The value of *Style* is simply the attribute definition portion of a standard HTML style definition, such as
  `color: red.`
- You can also define a style sheet that defines a set of style definitions. Each definition includes a style selector (the name of a tag to which the style always applies or a user-defined style name) and the attribute definition in curly braces:

  ```
  H2 B  {color: red}
  .MyStyle  {font-family: arial; font-weight: bold; font-size: 18px }
  ```

  The entire set of definitions is maintained by the InternetExpress page producer as its *Styles* property. Each Web item can then reference the styles with user-defined names by setting its *StyleRule* property.

- If you are sharing a style sheet with other applications, you can supply the style definitions as the value of the InternetExpress page producer's *StylesFile* property instead of the *Styles* property. Individual Web items still reference styles using the *StyleRule* property.

Another common property of Web items is the *Custom* property. *Custom* includes a set of options that you add to the generated HTML tag. HTML defines a different set of options for each type of tag. The VCL reference for the *Custom* property of most Web items gives an example of possible options. For more information on possible options, use an HTML reference.

Customizing the InternetExpress page producer template

The template of an InternetExpress page producer is an HTML document with extra embedded tags that your application translates dynamically. Initially, the page producer generates a default template as the value of the *HTMLDoc* property. This default template has the form

```
<HTML>
<HEAD>
</HEAD>
<BODY>
<#INCLUDES> <#STYLES> <#WARNINGS> <#FORMS> <#SCRIPT>
</BODY>
</HTML>
```

The HTML-transparent tags in the default template are translated as follows:

<#INCLUDES> generates the statements that include the javascript libraries. These statements have the form

```
<SCRIPT language=Javascript type="text/javascript" SRC="IncludePathURL/xmldom.js"> </SCRIPT>
<SCRIPT language=Javascript type="text/javascript" SRC="IncludePathURL/xmldb.js"> </SCRIPT>
<SCRIPT language=Javascript type="text/javascript" SRC="IncludePathURL/xmlbind.js"> </SCRIPT>
```

<#STYLES> generates the statements that defines a style sheet from definitions listed in the *Styles* or *StylesFile* property of the InternetExpress page producer.

<#WARNINGS> generates nothing at runtime. At design time, it adds warning messages for problems detected while generating the HTML document. You can see these messages in the Web page editor.

<#FORMS> generates the HTML produced by the components that you add in the Web page editor. The HTML from each component is generated in the order it appears in *WebPageItems*.

<#SCRIPT> generates a block of javascript declarations that are used in the HTML generated by the components added in the Web page editor.

You can replace the default template by changing the value of *HTMLDoc* or setting the *HTMLFile* property. The customized HTML template can include any of the HTML-transparent tags that make up the default template. The InternetExpress page producer automatically translates these tags when you call the *Content* method. In addition, The InternetExpress page producer automatically translates three additional tags:

`<#BODYELEMENTS>` is replaced by the same HTML as results from the 5 tags in the default template. It is useful when generating a template in an HTML editor when you want to use the default layout but add additional elements using the editor.

`<#COMPONENT Name=WebComponentName>` is replaced by the HTML that the component named *WebComponentName* generates. This component can be one of the components added in the Web page editor, or it can be any component that supports the *IWebContent* interface and has the same Owner as the InternetExpress page producer.

`<#DATAPACKET XMLBroker=BrokerName>` is replaced with the XML data packet obtained from the XML broker specified by *BrokerName*. When, in the Web page editor, you see the HTML that the InternetExpress page producer generates, you see this tag instead of the actual XML data packet.

In addition, the customized template can include any other HTML-transparent tags that you define. When the InternetExpress page producer encounters a tag that is not one of the seven types it translates automatically, it generates an *OnHTMLTag* event, where you can write code to perform your own translations. For more information about HTML templates in general, see “HTML templates” on page 28-13.

Tip The components that appear in the Web page editor generate static code. That is, unless the application server changes the metadata that appears in data packets, the HTML is always the same, no matter when it is generated. You can avoid the overhead of generating this code dynamically at runtime in response to every request message by copying the generated HTML in the Web page editor and using it as a template. Because the Web page editor displays a <#DATAPACKET> tag instead of the actual XML, using this as a template still allows your application to fetch data packets from the application server dynamically.

Chapter

26

Using XML in database applications

In addition to the support for connecting to database servers, Delphi lets you work with XML documents as if they were database servers. XML (Extensible Markup Language) is a markup language for describing structured data. XML documents provide a standard, transportable format for data that is used in Web applications, business-to-business communication, and so on. For information on Delphi's support for working directly with XML documents, see Chapter 30, "Working with XML documents."

Delphi's support for working with XML documents in database applications is based on a set of components that can convert data packets (the *Data* property of a client dataset) into XML documents and convert XML documents into data packets. In order to use these components, you must first define the transformation between the XML document and the data packet. Once you have defined the transformation, you can use special components to

- convert XML documents into data packets.
- provide data from and resolve updates to an XML document.
- use an XML document as the client of a provider.

Defining transformations

Before you can convert between data packets and XML documents, you must define the relationship between the metadata in a data packet and the nodes of the corresponding XML document. A description of this relationship is stored in a special XML document called a transformation.

Each transformation file contains two things: the mapping between the nodes in an XML schema and the fields in a data packet, and a skeletal XML document that represents the structure for the results of the transformation. A transformation is a one-way mapping: from an XML schema or document to a data packet or from the metadata in a data packet to an XML schema. Often, you create transformation files in pairs: one that maps from XML to data packet, and one that maps from data packet to XML.

In order to create the transformation files for a mapping, use the XMLMapper utility that ships in the bin directory.

Mapping between XML nodes and data packet fields

XML provides a text-based way to store or describe structured data. Datasets provide another way to store and describe structured data. To convert an XML document into a dataset, therefore, you must identify the correspondences between the nodes in an XML document and the fields in a dataset.

Consider, for example, an XML document that represents a set of email messages. It might look like the following (containing a single message):

```
<?xml version="1.0" standalone='yes' ?>
<email>
   <head>
      <from>
         <name>Dave Boss</name>
         <address>dboss@MyCo.com</address>
      </from>
      <to>
         <name>Joe Engineer</name>
         <address>jengineer@MyCo.com</address>
      </to>
      <cc>
         <name>Robin Smith/name>
         <address>rsmith@MyCo.com</address>
      </cc>
      <cc>
         <name>Leonard Devon</name>
         <address>ldevon@MyCo.com</address>
      </cc>
   </head>
   <body>
      <subject>XML components</subject>
      <content>
        Joe,
        Attached is the specification for the new XML component support in Delphi.
        This looks like a good solution to our buisness-to-buisness application!
        Also attached, please find the project schedule. Do you think its reasonable?
           Dave.
      </content>
      <attachment attachfile="XMLSpec.txt"/>
      <attachment attachfile="Schedule.txt"/>
   </body>
</email>
```

One natural mapping between this document and a dataset would map each email message to a single record. The record would have fields for the sender's name and address. Because an email message can have multiple recipients, the recipient (<to> would map to a nested dataset. Similarly, the cc list maps to a nested dataset. The subject line would map to a string field while the message itself (<content>) would probably be a memo field. The names of attachment files would map to a nested dataset because one message can have several attachments. Thus, the email above would map to a dataset something like the following:

SenderName	SenderAddress	To	CC	Subject	Content	Attach
Dave Boss	dboss@MyCo.Com	(DataSet)	(DataSet)	XML components	(MEMO)	(DataSet)

where the nested dataset in the "To" field is

Name	Address
Joe Engineer	jengineer@MyCo.Com

the nested dataset in the "CC" field is

Name	Address
Robin Smith	rsmith@MyCo.Com
Leonard Devon	ldevon@MyCo.Com

and the nested dataset in the "Attach" field is

Attachfile
XMLSpec.txt
Schedule.txt

Defining such a mapping involves identifying those nodes of the XML document that can be repeated and mapping them to nested datasets. Tagged elements that have values and appear only once (such as <content>...</content>) map to fields whose datatype reflects the type of data that can appear as the value. Attributes of a tag (such as the AttachFile attribute of the attachment tag) also map to fields.

Note that not all tags in the XML document appear in the corresponding dataset. For example, the <head>...<head/> element has no corresponding element in the resulting dataset. Typically, only elements that have values, elements that can be repeated, or the attributes of a tag map to the fields (including nested dataset fields) of a dataset. The exception to this rule is when a parent node in the XML document maps to a field whose value is built up from the values of the child nodes. For example, an XML document might contain a set of tags such as

```
<FullName>
   <Title> Mr. </Title>
   <FirstName> John </FirstName>
   <LastName> Smith </LastName>
</FullName>
```

which could map to a single dataset field with the value

```
Mr. John Smith
```

Using XMLMapper

The XML mapper utility, xmlmapper.exe, lets you define mappings in three ways:

- From an existing XML schema (or document) to a client dataset that you define. This is useful when you want to create a database application to work with data for which you already have an XML schema.
- From an existing data packet to a new XML schema you define. This is useful when you want to expose existing database information in XML, for example to create a new business-to-business communication system.
- Between an existing XML schema and an existing data packet. This is useful when you have an XML schema and a database that both describe the same information and you want to make them work together.

Once you define the mapping, you can generate the transformation files that are used to convert XML documents to data packets and to convert data packets to XML documents. Note that only the transformation file is directional: a single mapping can be used to generate both the transformation from XML to data packet and from data packet to XML.

Note XML mapper relies on two .DLLs (midas.dll and msxml.dll) to work correctly. Be sure that you have both of these .DLLs installed before you try to use xmlmapper.exe. In addition, msxml.dll must be registered as a COM server. You can register it using Regsvr32.exe.

Loading an XML schema or data packet

Before you can define a mapping and generate a transformation file, you must first load descriptions of the XML document and the data packet between which you are mapping.

You can load an XML document or schema by choosing File|Open and selecting the document or schema in the resulting dialog.

You can load a data packet by choosing File|Open and selecting a data packet file in the resulting dialog. (The data packet is simply the file generated when you call a client dataset's *SaveToFile* method.) If you have not saved the data packet to disk, you can fetch the data packet directly from the application server of a multi-tiered application by right-clicking in the Datapacket pane and choosing Connect To Remote Server.

You can load only an XML document or schema, only a data packet, or you can load both. If you load only one side of the mapping, XML mapper can generate a natural mapping for the other side.

Defining mappings

The mapping between an XML document and a data packet need not include all of the fields in the data packet or all of the tagged elements in the XML document. Therefore, you must first specify those elements that are mapped. To specify these elements, first select the Mapping page in the central pane of the dialog.

To specify the elements of an XML document or schema that are mapped to fields in a data packet, select the Sample or Structure tab of the XML document pane and double-click on the nodes for elements that map to data packet fields.

To specify the fields of the data packet that are mapped to tagged elements or attributes in the XML document and double-click on the nodes for those fields in the Datapacket pane.

If you have only loaded one side of the mapping (the XML document or the data packet), you can generate the other side after you have selected the nodes that are mapped.

- If you are generating a data packet from an XML document, you first define attributes for the selected nodes that determine the types of fields to which they correspond in the data packet. In the center pane, select the Node Repository page. Select each node that participates in the mapping and indicate the attributes of the corresponding field. If the mapping is not straightforward (for example, a node with subnodes that corresponds to a field whose value is built from those subnodes), check the User Defined Translation check box. You will need to write an event handler later to perform the transformation on user defined nodes.

  Once you have specified the way nodes are to be mapped, choose Create | Datapacket from XML. The corresponding data packet is automatically generated and displayed in the Datapacket pane.

- If you are generating an XML document from a data packet, choose Create | XML from Datapacket. A dialog appears where you can specify the names of the tags and attributes in the XML document that correspond to fields, records, and datasets in the data packet. For field values, you specify whether they map to a tagged element with a value or to an attribute by the way you name them. Names that begin with an @ symbol map to attributes of the tag that corresponds to the record, while names that do not begin with an @ symbol map to tagged elements that have values and that are nested within the element for the record.
- If you have loaded both an XML document and a data packet (client dataset file), be sure you select corresponding nodes in the same order. The corresponding nodes should appear next to each other in the table at the top of the Mapping page.

Once you have loaded or generated both the XML document and the data packet and selected the nodes that appear in the mapping, the table at the top of the Mapping page should reflect the mapping you have defined.

Generating transformation files

To generate a transformation file, use the following steps:

1. First select the radio button that indicates what the transformation creates:
   - Choose the Datapacket to XML button if the mapping goes from data packet to XML document.
   - Choose the XML to Datapacket button if the mapping goes from XML document to data packet.

2 If you are generating a data packet, you will also want to use the radio buttons in the Create Datapacket As section. These buttons let you specify how the data packet will be used: as a dataset, as a delta packet for applying updates, or as the parameters to supply to a provider before fetching data.

3 Click Create and Test Transformation to generate an in-memory version of the transformation. XML mapper displays the XML document that would be generated for the data packet in the Datapacket pane or the data packet that would be generated for the XML document in the XML Document pane.

4 Finally, choose File | Save | Transformation to save the transformation file. The transformation file is a special XML file (with the .xtr extension) that describes the transformation you have defined.

Converting XML documents into data packets

Once you have created a transformation file that indicates how to transform an XML document into a data packet, you can create data packets for any XML document that conforms to the schema used in the transformation. These data packets can then be assigned to a client dataset and saved to a file so that they form the basis of a file-based database application.

The *TXMLTransform* component transforms an XML document into a data packet according to the mapping in a transformation file.

Note You can also use *TXMLTransform* to convert a data packet that appears in XML format into an arbitrary XML document.

Specifying the source XML document

There are three ways to specify the source XML document:

- If the source document is a .xml file on disk, you can use the *SourceXmlFile* property.
- If the source document is an in-memory string of XML, you can use the *SourceXml* property.
- If you have an IDOMDocument interface for the source document, you can use the *SourceXmlDocument* property.

TXMLTransform checks these properties in the order listed above. That is, it first checks for a file name in the *SourceXmlFile* property. Only if *SourceXmlFile* is an empty string does it check the *SourceXml* property. Only if *SourceXml* is an empty string does it then check the *SourceXmlDocument* property.

Specifying the transformation

There are two ways to specify the transformation that converts the XML document into a data packet:

- Set the *TransformationFile* property to indicate a transformation file that was created using xmlmapper.exe.
- Set the *TransformationDocument* property if you have an *IDOMDocument* interface for the transformation.

TXMLTransform checks these properties in the order listed above. That is, it first checks for a file name in the *TransformationFile* property. Only if *TransformationFile* is an empty string does it check the *TransformationDocument* property.

Obtaining the resulting data packet

To cause *TXMLTranform* to perform its transformation and generate a data packet, you need only read the *Data* property. For example, the following code uses an XML document and transformation file to generate a data packet, which is then assigned to a client dataset:

```
XMLTransform1.SourceXMLFile := 'CustomerDocument.xml';
XMLTransform1.TransformationFile := 'CustXMLToCustTable.xtr';
ClientDataSet1.XMLData := XMLTransform1.Data;
```

Converting user-defined nodes

When you define a transformation using xmlmapper.exe, you can specify that some of the nodes in the XML document are “user-defined”. User-defined nodes are nodes for which you want to provide the transformation in code rather than relying on a straightforward node-value-to-field-value translation.

You can provide the code to translate user-defined nodes using the *OnTranslate* event. *OnTranslate* is called every time the *TXMLTransform* component encounters a user-defined node in the XML document. In the OnTranslate event handler, you can read the source document and specify the resulting value for the field in the data packet.

For example, the following *OnTranslate* event handler converts a node in the XML document with the following form

```
<FullName>
   <Title> </Title>
   <FirstName> </FirstName>
   <LastName> </LastName>
</FullName>
```

into a single field value:

```
procedure TForm1.XMLTransform1Translate(Sender: TObject; Id: String; SrcNode: IDOMNode;
  var Value: String; DestNode: IDOMNode);
var
```

```
    CurNode: IDOMNode;
  begin
    if Id = 'FullName' then
    begin
      Value = '';
      if SrcNode.hasChildNodes then
      begin
        CurNode := SrcNode.firstChild;
        Value := Value + CurNode.nodeValue;
        while CurNode <> SrcNode.lastChild do
        begin
          CurNode := CurNode.nextSibling;
          Value := Value + ' ';
          Value := Value + CurNode.nodeValue;
        end;
      end;
    end;
  end;
```

Using an XML document as the source for a provider

The *TXMLTransformProvider* component lets you use an XML document as if it were a database table. *TXMLTransformProvider* packages the data from an XML document and applies updates from clients back to that XML document. It appears to clients such as client datasets or XML brokers like any other provider component. For information on provider components, see Chapter 24, “Using provider components.” For information on using provider components with client datasets, see “Using a client dataset with a provider” on page 23-23.

You can specify the XML document from which the XML provider provides data and to which it applies updates using the *XMLDataFile* property.

TXMLTransformProvider components use internal *TXMLTransform* components to translate between data packets and the source XML document: one to translate the XML document into data packets, and one to translate data packets back into the XML format of the source document after applying updates. These two *TXMLTransform* components can be accessed using the *TransformRead* and *TransformWrite* properties, respectively.

When using *TXMLTransformProvider*, you must specify the transformations that these two *TXMLTransform* components use to translate between data packets and the source XML document. You do this by setting the *TXMLTransform* component’s *TransformationFile* or *TransformationDocument* property, just as when using a stand-alone *TXMLTransform* component.

In addition, if the transformation includes any user-defined nodes, you must supply an *OnTranslate* event handler to the internal *TXMLTransform* components.

You do not need to specify the source document on the *TXMLTransform* components that are the values of *TransformRead* and *TransformWrite*. For *TransformRead*, the source is the file specified by the provider’s *XMLDataFile* property (although, if you set *XMLDataFile* to an empty string, you can supply the source document using *TransformRead.XmlSource* or *TransformRead.XmlSourceDocument*). For *TransformWrite*, the source is generated internally by the provider when it applies updates.

Using an XML document as the client of a provider

The *TXMLTransformClient* component acts as an adapter to let you use an XML document (or set of documents) as the client for an application server (or simply as the client of a dataset to which it connects via a *TDataSetProvider* component). That is, *TXMLTransform* client lets you publish database data as an XML document and to make use of update requests (insertions or deletions) from an external application that supplies them in the form of XML documents.

To specify the provider from which the *TXMLTransformClient* object fetches data and to which it applies updates, set the *ProviderName* property. As with the *ProviderName* property of a client dataset, *ProviderName* can be the name of a provider on a remote application server or it can be a local provider in the same form or data module as the *TXMLTransformClient* object. For information about providers, see Chapter 24, "Using provider components."

If the provider is on a remote application server, you must use a DataSnap connection component to connect to that application server. Specify the connection component using the *RemoteServer* property. For information on DataSnap connection components, see "Connecting to the application server" on page 25-23.

Fetching an XML document from a provider

TXMLTransformClient uses an internal *TXMLTransform* component to translate data packets from the provider into an XML document. You can access this TXMLTransform component as the value of the *TransformGetData* property.

Before you can create an XML document that represents the data from a provider, you must specify the transformation file that *TransformGetData* uses to translate the data packet into the appropriate XML format. You do this by setting the *TXMLTransform* component's *TransformationFile* or *TransformationDocument* property, just as when using a stand-alone *TXMLTransform* component. If that transformation includes any user-defined nodes, you will want to supply *TransformGetData* with an *OnTranslate* event handler as well.

There is no need to specify the source document for *TransformGetData*, *TXMLTransformClient* fetches that from the provider. However, if the provider expects any input parameters, you may want to set them before fetching the data. Use the *SetParams* method to supply these input parameters before you fetch data from the provider. *SetParams* takes two arguments: a string of XML from which to extract parameter values, and the name of a transformation file to translate that XML into a data packet. *SetParams* uses the transformation file to convert the string of XML into a data packet, and then extracts the parameter values from that data packet.

Note You can override either of these arguments if you want to specify the parameter document or transformation in another way. Simply set one of the properties on *TransformSetParams* property to indicate the document that contains the parameters or the transformation to use when converting them, and then set the argument you want to override to an empty string when you call *SetParams*. For details on the properties you can use, see “Converting XML documents into data packets” on page 26-6.

Once you have configured *TransformGetData* and supplied any input parameters, you can call the *GetDataAsXml* method to fetch the XML. *GetDataAsXml* sends the current parameter values to the provider, fetches a data packet, converts it into an XML document, and returns that document as a string. You can save this string to a file:

```
var
  XMLDoc: TFileStream;
  XML: string;
begin
  XMLTransformClient1.ProviderName := 'Provider1';
  XMLTransformClient1.TransformGetData.TransformationFile := 'CustTableToCustXML.xtr';
  XMLTransformClient1.TransFormSetParams.SourceXmlFile := 'InputParams.xml';
  XMLTransformClient1.SetParams('', 'InputParamsToDP.xtr');
  XML := XMLTransformClient1.GetDataAsXml;
  XMLDoc := TFileStream.Create('Customers.xml', fmCreate or fmOpenWrite);
  try
    XMLDoc.Write(XML, Length(XML));
  finally
    XMLDoc.Free;
  end;
end;
```

Applying updates from an XML document to a provider

TXMLTransformClient also lets you insert all of the data from an XML document into the provider’s dataset or to delete all of the records in an XML document from the provider’s dataset. To perform these updates, call the *ApplyUpdates* method, passing in

- A string whose value is the contents of the XML document with the data to insert or delete.
- The name of a transformation file that can convert that XML data into an insert or delete delta packet. (When you define the transformation file using the XML mapper utility, you specify whether the transformation is for an insert or delete delta packet.)
- The number of update errors that can be tolerated before the update operation is aborted. If fewer than the specified number of records can’t be inserted or deleted, *ApplyUpdates* returns the number of actual failures. If more than the specified number of records can’t be inserted or deleted, the entire update operation is rolled back, and no update is performed.

The following call transforms the XML document Customers.xml into a delta packet and applies all updates regardless of the number of errors:

```
StringList1.LoadFromFile('Customers.xml');
nErrors := ApplyUpdates(StringList1.Text, 'CustXMLToInsert.xtr', -1);
```

Part

III

Writing Internet applications

The chapters in “Writing Internet applications” present concepts and skills necessary for building applications that are distributed over the Internet.

Note The components described in this section are not available in all editions of Delphi.

Chapter 27

Creating Internet applications

Web server applications extend the functionality and capability of existing Web servers. A Web server application receives HTTP request messages from the Web server, performs any actions requested in those messages, and formulates responses that it passes back to the Web server. Any operation that you can perform with a Delphi application can be incorporated into a Web server application.

Delphi provides two different architectures for developing Web server applications: Web Broker and WebSnap. Although these two architectures are different, WebSnap and Web Broker have many common elements. The WebSnap architecture acts as a superset of Web Broker. It provides additional components, and new features such as the WebSnap Surface Designer—which allows the content of a page to be displayed without the developer having to run the application. Applications developed with WebSnap can include Web Broker components, whereas applications developed with Web Broker cannot include WebSnap components.

This chapter describes the features of the Web Broker and WebSnap technologies and provides general information on Internet-based client/server applications.

About Web Broker and WebSnap

The first step in building a Web server application is choosing which architecture you want to use. Both approaches provide many of the same features, including

- Support for many types of Web server applications, including ISAPI, NSAPI, CGI, Win CGI, and Apache. These are described in "Types of Web server applications" on page 27-6.
- Multithreading support so that incoming client requests are handled on separate threads.
- Caching of Web modules for quicker responses.

However, each approach has certain advantages and disadvantages. The major differences between these two approaches are outlined in the following table:

Table 27.1 Web Broker versus WebSnap

Web Broker	WebSnap
Backward compatible	Although WebSnap applications can use any Web Broker components that produce content, the Web modules and dispatcher that contain these are new.
Available in cross-platform (CLX) applications.	At present, WebSnap is only available on Windows.
Only one Web module allowed in an application.	Multiple Web modules can partition the application into units, allowing multiple developers to work on the same project with fewer conflicts.
Only one Web dispatcher allowed in the application.	Multiple, special-purpose dispatchers handle different types of requests.
Specialized components for creating content include page producers, InternetExpress components, and Web Services components.	Supports all the content producers that can appear in Web broker applications, plus many others designed to let you quickly build complex data-driven Web pages.
No scripting support.	Support for server-side scripting (JScript or VBscript) allows HTML generation logic to be separated from the business logic.
No built-in support for named pages.	Named pages can be automatically retrieved by a page dispatcher and addressed from server-side scripts.
No session support.	Sessions store information about an end user that is needed for a short period of time. This can be used for such tasks as login/logout support.
Every request must be explicitly handled, using either an action item or an auto-dispatching component.	Dispatch components automatically respond to a variety of requests.
Only a few specialized components provide previews of the content they produce. Most development is not visual.	The WebSnap surface designer lets you build Web pages visually, and view the results at design time. Previews are available for all components.

For more information on Web Broker, see Chapter 28, “Using Web Broker.” For more information on WebSnap, see Chapter 29, “Using WebSnap.”

Terminology and standards

Many of the protocols that control activity on the Internet are defined in Request for Comment (RFC) documents that are created, updated, and maintained by the Internet Engineering Task Force (IETF), the protocol engineering and development arm of the Internet. There are several important RFCs that you will find useful when writing Internet applications:

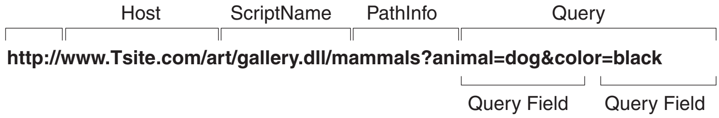
- RFC822, “Standard for the format of ARPA Internet text messages,” describes the structure and content of message headers.
- RFC1521, “MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies,” describes the method used to encapsulate and transport multipart and multiformat messages.
- RFC1945, “Hypertext Transfer Protocol — HTTP/1.0,” describes a transfer mechanism used to distribute collaborative hypermedia documents.

The IETF maintains a library of the RFCs on their Web site, `www.ietf.cnri.reston.va.us`

Parts of a Uniform Resource Locator

The Uniform Resource Locator (URL) is a complete description of the location of a resource that is available over the net. It is composed of several parts that may be accessed by an application. These parts are illustrated in Figure 27.1:

Figure 27.1 Parts of a Uniform Resource Locator



Host
ScriptName
PathInfo
Query
http://www.Tsite.com/art/gallery.dll/mammals?animal=dog&color=black
Query Field
Query Field

The first portion (not technically part of the URL) identifies the protocol (http). This portion can specify other protocols such as https (secure http), ftp, and so on.

The Host portion identifies the machine that runs the Web server and Web server application. Although it is not shown in the preceding picture, this portion can override the port that receives messages. Usually, there is no need to specify a port, because the port number is implied by the protocol.

The ScriptName portion specifies the name of the Web server application. This is the application to which the Web server passes messages.

Following the script name is the pathinfo. This identifies the destination of the message within the Web server application. Path info values may refer to directories on the host machine, the names of components that respond to specific messages, or any other mechanism the Web server application uses to divide the processing of incoming messages.

The Query portion contains a set a named values. These values and their names are defined by the Web server application.

URI vs. URL

The URL is a subset of the Uniform Resource Identifier (URI) defined in the HTTP standard, RFC1945. Web server applications frequently produce content from many sources where the final result does not reside in a particular location, but is created as necessary. URIs can describe resources that are not location-specific.

HTTP request header information

HTTP request messages contain many headers that describe information about the client, the target of the request, the way the request should be handled, and any content sent with the request. Each header is identified by a name, such as “Host” followed by a string value. For example, consider the following HTTP request:

```
GET /art/gallery.dll/animals?animal=dog&color=black HTTP/1.0
Connection: Keep-Alive
User-Agent: Mozilla/3.0b4Gold (WinNT; I)
Host: www.TSite.com:1024
Accept: image/gif, image/x-xbitmap, image/jpeg, image/pjpeg, */*
```

The first line identifies the request as a GET. A GET request message asks the Web server application to return the content associated with the URI that follows the word GET (in this case /art/gallery.dll/animals?animal=doc&color=black). The last part of the first line indicates that the client is using the HTTP 1.0 standard.

The second line is the Connection header, and indicates that the connection should not be closed once the request is serviced. The third line is the User-Agent header, and provides information about the program generating the request. The next line is the Host header, and provides the Host name and port on the server that is contacted to form the connection. The final line is the Accept header, which lists the media types the client can accept as valid responses.

HTTP server activity

The client/server nature of Web browsers is deceptively simple. To most users, retrieving information on the World Wide Web is a simple procedure: click on a link, and the information appears on the screen. More knowledgeable users have some understanding of the nature of HTML syntax and the client/server nature of the protocols used. This is usually sufficient for the production of simple, page-oriented Web site content. Authors of more complex Web pages have a wide variety of options to automate the collection and presentation of information using HTML.

Before building a Web server application, it is useful to understand how the client issues a request and how the server responds to client requests.

Composing client requests

When an HTML hypertext link is selected (or the user otherwise specifies a URL), the browser collects information about the protocol, the specified domain, the path to the information, the date and time, the operating environment, the browser itself, and other content information. It then composes a request.

For example, to display a page of images based on criteria selected by clicking buttons on a form, the client might construct this URL:

```
http://www.TSite.com/art/gallery.dll/animals?animal=dog&color=black
```

which specifies an HTTP server in the www.TSite.com domain. The client contacts www.TSite.com, connects to the HTTP server, and passes it a request. The request might look something like this:

```
GET /art/gallery.dll/animals?animal=dog&color=black HTTP/1.0
Connection: Keep-Alive
User-Agent: Mozilla/3.0b4Gold (WinNT; I)
Host: www.TSite.com:1024
Accept: image/gif, image/x-xbitmap, image/jpeg, image/pjpeg, */*
```

Serving client requests

The Web server receives a client request and can perform any number of actions, based on its configuration. If the server is configured to recognize the /gallery.dll portion of the request as a program, it passes information about the request to that program. The way information about the request is passed to the program depends on the type of Web server application:

- If the program is a Common Gateway Interface (CGI) program, the server passes the information contained in the request directly to the CGI program. The server waits while the program executes. When the CGI program exits, it passes the content directly back to the server.
- If the program is WinCGI, the server opens a file and writes out the request information. It then executes the Win-CGI program, passing the location of the file containing the client information and the location of a file that the Win-CGI program should use to create content. The server waits while the program executes. When the program exits, the server reads the data from the content file written by the Win-CGI program.
- If the program is a dynamic-link library (DLL), the server loads the DLL (if necessary) and passes the information contained in the request to the DLL as a structure. The server waits while the program executes. When the DLL exits, it passes the content directly back to the server.

In all cases, the program acts on the request of and performs actions specified by the programmer: accessing databases, doing simple table lookups or calculations, constructing or selecting HTML documents, and so on.

Responding to client requests

When a Web server application finishes with a client request, it constructs a page of HTML code or other MIME content, and passes it back (via the server) to the client for display. The way the response is sent also differs based on the type of program:

- When a Win-CGI script finishes it constructs a page of HTML, writes it to a file, writes any response information to another file, and passes the locations of both files back to the server. The server opens both files and passes the HTML page back to the client.

- When a DLL finishes, it passes the HTML page and any response information directly back to the server, which passes them back to the client.

Creating a Web server application as a DLL reduces system load and resource use by reducing the number of processes and disk accesses necessary to service an individual request.

Types of Web server applications

Whether you use Web Broker or WebSnap, you can create five types of Web server applications. In addition, you can create a Web Application Debugger executable, which integrates the Web server into your application so that you can debug your application logic. The Web Application Debugger executable is intended only for debugging. When you deploy your application, you should migrate to one of the other five types.

Each of the five types of Web server application uses a type-specific descendant of *TWebApplication*, *TWebRequest*, and *TWebResponse*:

Table 27.2 Web server application components

Application Type	Application Object	Request Object	Response Object
Microsoft Server DLL (ISAPI)	*TISAPIApplication*	*TISAPIRequest*	*TISAPIResponse*
Netscape Server DLL (NSAPI)	*TISAPIApplication*	*TISAPIRequest*	*TISAPIResponse*
Apache Server DLL	*TApacheApplication*	*TApacheRequest*	*TApacheResponse*
Console CGI application	*TCGIApplication*	*TCGIRequest*	*TCGIResponse*
Windows CGI application	*TCGIApplication*	*TWinCGIRequest*	*TWinCGIResponse*

ISAPI and NSAPI

An ISAPI or NSAPI Web server application is a DLL that is loaded by the Web server. Client request information is passed to the DLL as a structure and evaluated by *TISAPIApplication*, which creates *TISAPIRequest* and *TISAPIResponse* objects. Each request message is automatically handled in a separate execution thread.

Apache

An Apache Web server application is a DLL that is loaded by the Web server. Client request information is passed to the DLL as a structure and evaluated by *TApacheApplication*, which creates *TApacheRequest* and *TApacheResponse* objects. Each request message is automatically handled in a separate execution thread.

CGI stand-alone

A CGI stand-alone Web server application is a console application that receives client request information on standard input and passes the results back to the server on standard output. This data is evaluated by *TCGIApplication*, which creates

TCGIRequest and *TCGIResponse* objects. Each request message is handled by a separate instance of the application.

Win-CGI stand-alone

A Win-CGI stand-alone Web server application is a Windows application that receives client request information from a configuration settings (INI) file written by the server and writes the results to a file that the server passes back to the client. The INI file is evaluated by *TCGIApplication*, which creates *TWinCGIRequest* and *TWinCGIResponse* objects. Each request message is handled by a separate instance of the application.

Debugging server applications

Debugging Web server applications presents some unique problems, because they run in response to messages from a Web server. You can not simply launch your application from the IDE, because that leaves the Web server out of the loop, and your application will not find the request message it is expecting.

The following topics describe techniques you can use to debug Web server applications.

Using the Web Application Debugger

The Web Application Debugger provides an easy way to monitor HTTP requests, responses, and response times. The Web Application Debugger takes the place of the Web server. Once you have debugged your application, you can convert it to one of the supported types of Web application and install it with a commercial Web server.

To use the Web Application Debugger, you must first create your Web application as a Web Application Debugger executable. Whether you are using Web Broker or WebSnap, the wizard that creates your Web server application includes this as an option when you first begin the application. This creates a Web server application that is also a COM server.

For information on how to write this Web server application using Web Broker, see Chapter 28, “Using Web Broker”. For more information on using WebSnap, see Chapter 29, “Using WebSnap”.

Launching your application with the Web Application Debugger

Once you have developed your Web server application, you can run and debug it as follows:

1. With your project loaded in the IDE, set any breakpoints so that you can debug your application just like any other executable.
2. Choose Run | Run. This displays the console window of the COM server that is your Web server application. The first time you run your application, it registers your COM server so that the Web App debugger can access it.

3 Select Tools | Web App Debugger.

4 Click the Start button. This displays the ServerInfo page in your default Browser.

5 The ServerInfo page provides a drop-down list of all registered Web Application Debugger executables. Select your application from the drop-down list. If you do not find your application in this drop-down list, try running your application as an executable. Your application must be run once so that it can register itself. If you still do not find your application in the drop-down list, try refreshing the Web page. (Sometimes the Web browser caches this page, preventing you from seeing the most recent changes.)

6 Once you have selected your application in the drop-down list, press the Go button. This launches your application in the Web Application Debugger, which provides you with details on request and response messages that pass between your application and the Web Application Debugger.

Converting your application to another type of Web server application

When you have finished debugging your Web server application, you will need to convert it to another type of Web application before you install it with a commercial Web server. The following steps describe how to make these changes:

1 In the IDE, choose Project | Add New Project. This opens a new project without closing down the current one (you Web server application).

2 Launch the wizard to start a Web Broker or WebSnap application and choose the type of application you want to create.

3 Choose View | Project Manager to display the project manager.

4 In the project manager, drag all the units that make up your Web Server application from the old project to the one you just added. Omit the unit that implements the console window.

You now have a Web server application of the appropriate type.

Debugging Web applications that are DLLs

ISAPI , NSAPI, and Apache applications are actually DLLs that contain predefined entry points. The Web server passes request messages to the application by making calls to these entry points. Because these applications are DLLs, you can debug them by setting your application's run parameters to launch the server.

To set up your application's run parameters, choose Run | Parameters and set the Host Application and Run Parameters to specify the executable for the Web server and any parameters it requires when you launch it. For details about these values on your Web server, see the documentation provided by you Web server vendor.

Note Some Web Servers require additional changes before you have the rights to launch the Host Application in this way. See your Web server vendor for details.

Tip If you are using Windows 2000 with IIS 5, details on all of the changes you need to make to set up your rights properly are described at the following Web site:

http://community.borland.com/article/0,1410,23024,00.html

Once you have set the Host Application and Run Parameters, you can set up your breakpoints so that when the server passes a request message to your DLL, you hit one of your breakpoints, and can debug normally.

Note Before launching the Web server using your application's run parameters, make sure that the server is not already running.

Debugging under Windows NT

Under Windows NT, you must have the correct user rights to debug a DLL. In the User Manager, add your name to the lists granting rights for

- Log on as Service
- Act as part of the operation system
- Generate security audits

Tip Insert a hard-coded _asm int 3 into your code where you wish to begin debugging. Recreate your DLL and use Just-In-Time Debugging (Tools | Options | Debug).

Debugging under Windows 2000

Under Windows 2000, you grant the same rights as follows:

1. In the Administrative Tools portion of the Control Panel, click on Local Security Policy. Expand Local Policies and click on User Rights Assignment. Double-click on Act as part of the operating system in the right-hand panel.
2. Select Add to add a user to the list. Add your current user.
3. Reboot so the changes take effect.

Chapter

28

Using Web Broker

Web Broker components (located on the Internet tab of the component palette) enable you to create event handlers that are associated with a specific Uniform Resource Identifier (URI). When processing is complete, You can programmatically construct HTML or XML documents and transfer them to the client. You can use Web Broker components for cross-platform application development.

Frequently, the content of Web pages is drawn from databases. You can use Internet components to automatically manage connections to databases, allowing a single DLL to handle numerous simultaneous, thread-safe database connections.

The following sections of this chapter explain how you use the Web Broker components to create a Web server application.

Creating Web server applications with Web Broker

To create a new Web server application using the Web Broker architecture:

1 Select File | New | Other.

2 In the New Items dialog box, select the New tab and choose Web Server Application.

3 A dialog box appears, where you can select one of the Web server application types:

- ISAPI and NSAPI: Selecting this type of application sets up your project as a DLL, with the exported methods expected by the Web server. It adds the library header to the project file and the required entries to the uses list and exports clause of the project file.
- Apache: Selecting this type of application sets up your project as a DLL, with the exported methods expected by the Apache Web server. It adds the library header to the project file and the required entries to the uses list and exports clause of the project file.

- CGI stand-alone: Selecting this type of application sets up your project as a console application, and adds the required entries to the uses clause of the project file.
- Win-CGI stand-alone: Selecting this type of application sets up your project as a Windows application, and adds the required entries to the uses clause of the project file.
- Web Application Debugger stand-alone executable: Selecting this type of application sets up an environment for developing and testing Web server applications. This type of application is not intended for deployment.

Choose the type of Web Server Application that communicates with the type of Web Server your application will use. This creates a new project configured to use Internet components and containing an empty Web Module.

The Web module

The Web module (*TWebModule*) is a descendant of *TDataModule* and may be used in the same way: to provide centralized control for business rules and non-visual components in the Web application.

Add any content producers that your application uses to generate response messages. These can be the built-in content producers such as *TPageProducer*, *TDataSetPageProducer*, *TDataSetTableProducer*, *TQueryTableProducer* and *TInetXPageProducer*, or descendants of *TCustomContentProducer* that you have written yourself. If your application generates response messages that include material drawn from databases, you can add data access components or special components for writing a Web server that acts as a client in a multi-tiered database application.

In addition to storing non-visual components and business rules, the Web module also acts as a dispatcher, matching incoming HTTP request messages to action items that generate the responses to those requests.

You may have a data module already that is set up with many of the non-visual components and business rules that you want to use in your Web application. You can replace the Web module with your pre-existing data module. Simply delete the automatically generated Web module and replace it with your data module. Then, add a *TWebDispatcher* component to your data module, so that it can dispatch request messages to action items, the way a Web module can. If you want to change the way action items are chosen to respond to incoming HTTP request messages, derive a new dispatcher component from *TCustomWebDispatcher*, and add that to the data module instead.

Your project can contain only one dispatcher. This can either be the Web module that is automatically generated when you create the project, or the *TWebDispatcher* component that you add to a data module that replaces the Web module. If a second data module containing a dispatcher is created during execution, the Web server application generates a runtime error.

Note The Web module that you set up at design time is actually a template. In ISAPI and NSAPI applications, each request message spawns a separate thread, and separate instances of the Web module and its contents are created dynamically for each thread.

Warning The Web module in a DLL-based Web server application is cached for later reuse to increase response time. The state of the dispatcher and its action list is not reinitialized between requests. Enabling or disabling action items during execution may cause unexpected results when that module is used for subsequent client requests.

The Web Application object

The project that is set up for your Web application contains a global variable named *Application*. *Application* is a descendant of *TWebApplication* (either *TISAPIApplication* or *TCGIApplication*) that is appropriate to the type of application you are creating. It runs in response to HTTP request messages received by the Web server.

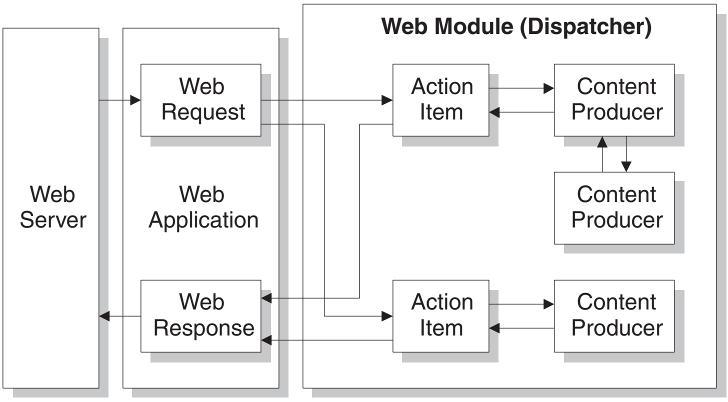
Warning Do not include the forms unit in the project **uses** clause after the CGIApp or ISAPIApp unit. Forms also declares a global variable named *Application*, and if it appears after the CGIApp or ISAPIApp unit, *Application* will be initialized to an object of the wrong type.

The structure of a Web Broker application

When the Web application receives an HTTP request message, it creates a *TWebRequest* object to represent the HTTP request message, and a *TWebResponse* object to represent the response that should be returned. The application then passes these objects to the Web dispatcher (either the Web module or a *TWebDispatcher* component).

The Web dispatcher controls the flow of the Web server application. The dispatcher maintains a collection of action items (*TWebActionItem*) that know how to handle certain types of HTTP request messages. The dispatcher identifies the appropriate action items or auto-dispatching components to handle the HTTP request message, and passes the request and response objects to the identified handler so that it can perform any requested actions or formulate a response message. It is described more fully in the section “The Web dispatcher” on page 28-4.

Figure 28.1 Structure of a Server Application



The action items are responsible for reading the request and assembling a response message. Specialized content producer components aid the action items in dynamically generating the content of response messages, which can include custom HTML code or other MIME content. The content producers can make use of other content producers or descendants of *THTMLTagAttributes*, to help them create the content of the response message. For more information on content producers, see "Generating the content of response messages" on page 28-13.

If you are creating the Web Client in a multi-tiered database application, your Web server application may include additional, auto-dispatching components that represent database information encoded in XML and database manipulation classes encoded in javascript. If you are creating a server that implements a Web Service, your Web server application may include an auto-dispatching component that passes SOAP-based messages on to an invoker that interprets and executes them. The dispatcher calls on these auto-dispatching components to handle the request message after it has tried all of its action items.

When all action items (or auto-dispatching components) have finished creating the response by filling out the *TWebResponse* object, the dispatcher passes the result back to the Web application. The application sends the response on to the client via the Web server.

The Web dispatcher

If you are using a Web module, it acts as a Web dispatcher. If you are using a pre-existing data module, you must add a single dispatcher component (*TWebDispatcher*) to that data module. The dispatcher maintains a collection of action items that know how to handle certain kinds of request messages. When the Web application passes a request object and a response object to the dispatcher, it chooses one or more action items to respond to the request.

Adding actions to the dispatcher

Open the action editor from the Object Inspector by clicking the ellipsis on the *Actions* property of the dispatcher. Action items can be added to the dispatcher by clicking the Add button in the action editor.

Add actions to the dispatcher to respond to different request methods or target URIs. You can set up your action items in a variety of ways. You can start with action items that preprocess requests, and end with a default action that checks whether the response is complete and either sends the response or returns an error code. Or, you can add a separate action item for every type of request, where each action item completely handles the request.

Action items are discussed in further detail in "Action items" on page 28-5.

Dispatching request messages

When the dispatcher receives the client request, it generates a *BeforeDispatch* event. This provides your application with a chance to preprocess the request message before it is seen by any of the action items.

Next, the dispatcher looks through its list of action items for one that matches the pathinfo portion of the request message's target URL and that can provide the service specified as the method of the request message. It does this by comparing the *PathInfo* and *MethodType* properties of the *TWebRequest* object with the properties of the same name on the action item.

When the dispatcher finds an appropriate action item, it causes that action item to fire. When the action item fires, it does one of the following:

- Fills in the response content and sends the response or signals that the request is completely handled.
- Adds to the response and then allows other action items to complete the job.
- Defers the request to other action items.

After checking all its action items, if the message is not handled the dispatcher checks any specially registered auto-dispatching components that do not use action items. These components are specific to multi-tiered database applications, which are described in "Building Web applications using InternetExpress" on page 25-33

If, after checking all the action items and any specially registered auto-dispatching components, the request message has still not been fully handled, the dispatcher calls the default action item. The default action item does not need to match either the target URL or the method of the request.

If the dispatcher reaches the end of the action list (including the default action, if any) and no actions have been triggered, nothing is passed back to the server. The server simply drops the connection to the client.

If the request is handled by the action items, the dispatcher generates an *AfterDispatch* event. This provides a final opportunity for your application to check the response that was generated, and make any last minute changes.

Action items

Each action item (*TWebActionItem*) performs a specific task in response to a given type of request message.

Action items can completely respond to a request or perform part of the response and allow other action items to complete the job. Action items can send the HTTP response message for the request, or simply set up part of the response for other action items to complete. If a response is completed by the action items but not sent, the Web server application sends the response message.

Determining when action items fire

Most properties of the action item determine when the dispatcher selects it to handle an HTTP request message. To set the properties of an action item, you must first bring up the action editor: select the *Actions* property of the dispatcher in the Object Inspector and click on the ellipsis. When an action is selected in the action editor, its properties can be modified in the Object Inspector.

The target URL

The dispatcher compares the *PathInfo* property of an action item to the *PathInfo* of the request message. The value of this property should be the path information portion of the URL for all requests that the action item is prepared to handle. For example, given this URL,

```
http://www.TSite.com/art/gallery.dll/mammals?animal=dog&color=black
```

and assuming that the `/gallery.dll` part indicates the Web server application, the path information portion is

```
/mammals
```

Use path information to indicate where your Web application should look for information when servicing requests, or to divide you Web application into logical subservices.

The request method type

The *MethodType* property of an action item indicates what type of request messages it can process. The dispatcher compares the *MethodType* property of an action item to the *MethodType* of the request message. *MethodType* can take one of the following values:

Table 28.1 MethodType values

Value	Meaning
mtGet	The request is asking for the information associated with the target URI to be returned in a response message.
mtHead	The request is asking for the header properties of a response, as if servicing an *mtGet* request, but omitting the content of the response.
mtPost	The request is providing information to be posted to the Web application.
mtPut	The request asks that the resource associated with the target URI be replaced by the content of the request message.
mtAny	Matches any request method type, including *mtGet*, *mtHead*, *mtPut*, and *mtPost*.

Enabling and disabling action items

Each action item has an *Enabled* property that can be used to enable or disable that action item. By setting *Enabled* to *False*, you disable the action item so that it is not considered by the dispatcher when it looks for an action item to handle a request.

A *BeforeDispatch* event handler can control which action items should process a request by changing the *Enabled* property of the action items before the dispatcher begins matching them to the request message.

Caution Changing the *Enabled* property of an action during execution may cause unexpected results for subsequent requests. If the Web server application is a DLL that caches Web modules, the initial state will not be reinitialized for the next request. Use the *BeforeDispatch* event to ensure that all action items are correctly initialized to their appropriate starting states.

Choosing a default action item

Only one of the action items can be the default action item. The default action item is selected by setting its *Default* property to *True*. When the *Default* property of an action item is set to *True*, the *Default* property for the previous default action item (if any) is set to *False*.

When the dispatcher searches its list of action items to choose one to handle a request, it stores the name of the default action item. If the request has not been fully handled when the dispatcher reaches the end of its list of action items, it executes the default action item.

The dispatcher does not check the *PathInfo* or *MethodType* of the default action item. The dispatcher does not even check the *Enabled* property of the default action item. Thus, you can make sure the default action item is only called at the very end by setting its *Enabled* property to *False*.

The default action item should be prepared to handle any request that is encountered, even if it is only to return an error code indicating an invalid URI or *MethodType*. If the default action item does not handle the request, no response is sent to the Web client.

Caution Changing the *Default* property of an action during execution may cause unexpected results for the current request. If the *Default* property of an action that has already been triggered is set to *True*, that action will not be re-evaluated and the dispatcher will not trigger that action when it reaches the end of the action list.

Responding to request messages with action items

The real work of the Web server application is performed by action items when they execute. When the Web dispatcher fires an action item, that action item can respond to the current request message in two ways:

- If the action item has an associated producer component as the value of its *Producer* property, that producer automatically assigns the *Content* of the response message using its *Content* method. The Internet page of the component palette includes a number of content producer components that can help construct an HTML page for the content of the response message.
- After the producer has assigned any response content (if there is an associated producer), the action item receives an *OnAction* event. The *OnAction* event handler is passed the *TWebRequest* object that represents the HTTP request message and a *TWebResponse* object to fill with any response information.

If the action item's content can be generated by a single content producer, it is simplest to assign the content producer as the action item's *Producer* property. However, you can always access any content producer from the *OnAction* event handler as well. The *OnAction* event handler allows more flexibility, so that you can use multiple content producers, assign response message properties, and so on.

Both the content-producer component and the *OnAction* event handler can use any objects or runtime library methods to respond to request messages. They can access databases, perform calculations, construct or select HTML documents, and so on. For more information about generating response content using content-producer components, see "Generating the content of response messages" on page 28-13.

Sending the response

An *OnAction* event handler can send the response back to the Web client by using the methods of the *TWebResponse* object. However, if no action item sends the response to the client, it will still get sent by the Web server application as long as the last action item to look at the request indicates that the request was handled.

Using multiple action items

You can respond to a request from a single action item, or divide the work up among several action items. If the action item does not completely finish setting up the response message, it must signal this state in the *OnAction* event handler by setting the *Handled* parameter to *False*.

If many action items divide up the work of responding to request messages, each setting *Handled* to *False* so that others can continue, make sure the default action item leaves the *Handled* parameter set to *True*. Otherwise, no response will be sent to the Web client.

When dividing the work among several action items, either the *OnAction* event handler of the default action item or the *AfterDispatch* event handler of the dispatcher should check whether all the work was done and set an appropriate error code if it is not.

Accessing client request information

When an HTTP request message is received by the Web server application, the headers of the client request are loaded into the properties of a *TWebRequest* object. In NSAPI and ISAPI applications, the request message is encapsulated by a *TISAPIRequest* object. Console CGI applications use *TCGIRequest* objects, and Windows CGI applications use *TWinCGIRequest* objects.

The properties of the request object are read-only. You can use them to gather all of the information available in the client request.

Properties that contain request header information

Most properties in a request object contain information about the request that comes from the HTTP request header. Not every request supplies a value for every one of these properties. Also, some requests may include header fields that are not surfaced in a property of the request object, especially as the HTTP standard continues to evolve. To obtain the value of a request header field that is not surfaced as one of the properties of the request object, use the *GetFieldByName* method.

Properties that identify the target

The full target of the request message is given by the *URL* property. Usually, this is a URL that can be broken down into the protocol (HTTP), *Host* (server system), *ScriptName* (server application), *PathInfo* (location on the host), and *Query*.

Each of these pieces is surfaced in its own property. The protocol is always HTTP, and the *Host* and *ScriptName* identify the Web server application. The dispatcher uses the *PathInfo* portion when matching action items to request messages. The *Query* is used by some requests to specify the details of the requested information. Its value is also parsed for you as the *QueryFields* property.

Properties that describe the Web client

The request also includes several properties that provide information about where the request originated. These include everything from the e-mail address of the sender (the *From* property), to the URI where the message originated (the *Referer* or *RemoteHost* property). If the request contains any content, and that content does not arise from the same URI as the request, the source of the content is given by the *DerivedFrom* property. You can also determine the IP address of the client (the *RemoteAddr* property), and the name and version of the application that sent the request (the *UserAgent* property).

Properties that identify the purpose of the request

The *Method* property is a string describing what the request message is asking the server application to do. The HTTP 1.1 standard defines the following methods:

Value	What the message requests
OPTIONS	Information about available communication options.
GET	Information identified by the *URL* property.
HEAD	Header information from an equivalent GET message, without the content of the response.
POST	The server application to post the data included in the *Content* property, as appropriate.
PUT	The server application to replace the resource indicated by the *URL* property with the data included in the *Content* property.
DELETE	The server application to delete or hide the resource identified by the *URL* property.
TRACE	The server application to send a loop-back to confirm receipt of the request.

The *Method* property may indicate any other method that the Web client requests of the server.

The Web server application does not need to provide a response for every possible value of *Method*. The HTTP standard does require that it service both GET and HEAD requests, however.

The *MethodType* property indicates whether the value of *Method* is GET (mtGet), HEAD (mtHead), POST (mtPost), PUT (mtPut) or some other string (mtAny). The dispatcher matches the value of the *MethodType* property with the *MethodType* of each action item.

Properties that describe the expected response

The *Accept* property indicates the media types the Web client will accept as the content of the response message. The *IfModifiedSince* property specifies whether the client only wants information that has changed recently. The *Cookie* property includes state information (usually added previously by your application) that can modify the response.

Properties that describe the content

Most requests do not include any content, as they are requests for information. However, some requests, such as POST requests, provide content that the Web server application is expected to use. The media type of the content is given in the *ContentType* property, and its length in the *ContentLength* property. If the content of the message was encoded (for example, for data compression), this information is in the *ContentEncoding* property. The name and version number of the application that produced the content is specified by the *ContentVersion* property. The *Title* property may also provide information about the content.

The content of HTTP request messages

In addition to the header fields, some request messages include a content portion that the Web server application should process in some way. For example, a POST request might include information that should be added to a database maintained by the Web server application.

The unprocessed value of the content is given by the *Content* property. If the content can be parsed into fields separated by ampersands (&), a parsed version is available in the *ContentFields* property.

Creating HTTP response messages

When the Web server application creates a *TWebRequest* object for an incoming HTTP request message, it also creates a corresponding *TWebResponse* object to represent the response message that will be sent in return. In NSAPI and ISAPI applications, the response message is encapsulated by a *TISAPIResponse* object. Console CGI applications use *TCGIResponse* objects, and Windows CGI applications use *TWinCGIResponse* objects.

The action items that generate the response to a Web client request fill in the properties of the response object. In some cases, this may be as simple as returning an error code or redirecting the request to another URI. In other cases, this may involve complicated calculations that require the action item to fetch information from other sources and assemble it into a finished form. Most request messages require some response, even if it is only the acknowledgment that a requested action was carried out.

Filling in the response header

Most of the properties of the *TWebResponse* object represent the header information of the HTTP response message that is sent back to the Web client. An action item sets these properties from its *OnAction* event handler.

Not every response message needs to specify a value for every one of the header properties. The properties that should be set depend on the nature of the request and the status of the response.

Indicating the response status

Every response message must include a status code that indicates the status of the response. You can specify the status code by setting the *StatusCode* property. The HTTP standard defines a number of standard status codes with predefined meanings. In addition, you can define your own status codes using any of the unused possible values.

Each status code is a three-digit number where the most significant digit indicates the class of the response, as follows:

- 1xx: Informational (The request was received but has not been fully processed).
- 2xx: Success (The request was received, understood, and accepted).
- 3xx: Redirection (Further action by the client is needed to complete the request).
- 4xx: Client Error (The request cannot be understood or cannot be serviced).
- 5xx: Server Error (The request was valid but the server could not handle it).

Associated with each status code is a string that explains the meaning of the status code. This is given by the *ReasonString* property. For predefined status codes, you do not need to set the *ReasonString* property. If you define your own status codes, you should also set the *ReasonString* property.

Indicating the need for client action

When the status code is in the 300-399 range, the client must perform further action before the Web server application can complete its request. If you need to redirect the client to another URI, or indicate that a new URI was created to handle the request, set the *Location* property. If the client must provide a password before you can proceed, set the *WWWAuthenticate* property.

Describing the server application

Some of the response header properties describe the capabilities of the Web server application. The *Allow* property indicates the methods to which the application can respond. The *Server* property gives the name and version number of the application used to generate the response. The *Cookies* property can hold state information about the client's use of the server application which is included in subsequent request messages.

Describing the content

Several properties describe the content of the response. *ContentType* gives the media type of the response, and *ContentVersion* is the version number for that media type. *ContentLength* gives the length of the response. If the content is encoded (such as for data compression), indicate this with the *ContentEncoding* property. If the content came from another URI, this should be indicated in the *DerivedFrom* property. If the value of the content is time-sensitive, the *LastModified* property and the *Expires* property indicate whether the value is still valid. The *Title* property can provide descriptive information about the content.

Setting the response content

For some requests, the response to the request message is entirely contained in the header properties of the response. In most cases, however, action item assigns some content to the response message. This content may be static information stored in a file, or information that was dynamically produced by the action item or its content producer.

You can set the content of the response message by using either the *Content* property or the *ContentStream* property.

The *Content* property is a string. Delphi strings are not limited to text values, so the value of the *Content* property can be a string of HTML commands, graphics content such as a bit-stream, or any other MIME content type.

Use the *ContentStream* property if the content for the response message can be read from a stream. For example, if the response message should send the contents of a file, use a *TFileStream* object for the *ContentStream* property. As with the *Content* property, *ContentStream* can provide a string of HTML commands or other MIME content type. If you use the *ContentStream* property, do not free the stream yourself. The Web response object automatically frees it for you.

Note If the value of the *ContentStream* property is not **nil**, the *Content* property is ignored.

Sending the response

If you are sure there is no more work to be done in response to a request message, you can send a response directly from an *OnAction* event handler. The response object provides two methods for sending a response: *SendResponse* and *SendRedirect*. Call *SendResponse* to send the response using the specified content and all the header properties of the *TWebResponse* object. If you only need to redirect the Web client to another URI, the *SendRedirect* method is more efficient.

If none of the event handlers send the response, the Web application object sends it after the dispatcher finishes. However, if none of the action items indicate that they have handled the response, the application will close the connection to the Web client without sending any response.

Generating the content of response messages

Delphi provides a number of objects to assist your action items in producing content for HTTP response messages. You can use these objects to generate strings of HTML commands that are saved in a file or sent directly back to the Web client. You can write your own content producers, deriving them from *TCustomContentProducer* or one of its descendants.

TCustomContentProducer provides a generic interface for creating any MIME type as the content of an HTTP response message. Its descendants include page producers and table producers:

- Page producers scan HTML documents for special tags that they replace with customized HTML code. They are described in the following section.
- Table producers create HTML commands based on the information in a dataset. They are described in “Using database information in responses” on page 28-17.

Using page producer components

Page producers (*TPageProducer* and its descendants) take an HTML template and convert it by replacing special HTML-transparent tags with customized HTML code. You can store a set of standard response templates that are filled in by page producers when you need to generate the response to an HTTP request message. You can chain page producers together to iteratively build up an HTML document by successive refinement of the HTML-transparent tags.

HTML templates

An HTML template is a sequence of HTML commands and HTML-transparent tags. An HTML-transparent tag has the form

```
<#TagName Param1=Value1 Param2=Value2 ...>
```

The angle brackets (< and >) define the entire scope of the tag. A pound sign (#) immediately follows the opening angle bracket (<) with no spaces separating it from the angle bracket. The pound sign identifies the string to the page producer as an HTML-transparent tag. The tag name immediately follows the pound sign with no spaces separating it from the pound sign. The tag name can be any valid identifier and identifies the type of conversion the tag represents.

Following the tag name, the HTML-transparent tag can optionally include parameters that specify details of the conversion to be performed. Each parameter is of the form *ParamName=Value*, where there is no space between the parameter name, the equals symbol (=) and the value. The parameters are separated by whitespace.

The angle brackets (< and >) make the tag transparent to HTML browsers that do not recognize the #TagName construct.

While you can create your own HTML-transparent tags to represent any kind of information processed by your page producer, there are several predefined tag names associated with values of the *TTag* data type. These predefined tag names correspond to HTML commands that are likely to vary over response messages. They are listed in the following table:

Tag Name	TTag value	What the tag should be converted to
Link	*tgLink*	A hypertext link. The result is an HTML sequence beginning with an <A> tag and ending with an </A> tag.
Image	*tgImage*	A graphic image. The result is an HTML <IMG> tag.
Table	*tgTable*	An HTML table. The result is an HTML sequence beginning with a <TABLE> tag and ending with a </TABLE> tag.
ImageMap	*tgImageMap*	A graphic image with associated hot zones. The result is an HTML sequence beginning with a <MAP> tag and ending with a </MAP> tag.
Object	*tgObject*	An embedded ActiveX object. The result is an HTML sequence beginning with an <OBJECT> tag and ending with an </OBJECT> tag.
Embed	*tgEmbed*	A Netscape-compliant add-in DLL. The result is an HTML sequence beginning with an <EMBED> tag and ending with an </EMBED> tag.

Any other tag name is associated with *tgCustom*. The page producer supplies no built-in processing of the predefined tag names. They are simply provided to help applications organize the conversion process into many of the more common tasks.

Note The predefined tag names are case insensitive.

Specifying the HTML template

Page producers provide you with many choices in how to specify the HTML template. You can set the *HTMLFile* property to the name of a file that contains the HTML template. You can set the *HTMLDoc* property to a *TStrings* object that contains the HTML template. If you use either the *HTMLFile* property or the *HTMLDoc* property to specify the template, you can generate the converted HTML commands by calling the *Content* method.

In addition, you can call the *ContentFromString* method to directly convert an HTML template that is a single string which is passed in as a parameter. You can also call the *ContentFromStream* method to read the HTML template from a stream. Thus, for example, you could store all your HTML templates in a memo field in a database, and use the *ContentFromStream* method to obtain the converted HTML commands, reading the template directly from a *TBlobStream* object.

Converting HTML-transparent tags

The page producer converts the HTML template when you call one of its *Content* methods. When the *Content* method encounters an HTML-transparent tag, it triggers the *OnHTMLTag* event. You must write an event handler to determine the type of tag encountered, and to replace it with customized content.

If you do not create an *OnHTMLTag* event handler for the page producer, HTML-transparent tags are replaced with an empty string.

Using page producers from an action item

A typical use of a page producer component uses the *HTMLFile* property to specify a file containing an HTML template. The *OnAction* event handler calls the *Content* method to convert the template into a final HTML sequence:

```
procedure WebModule1.MyActionEventHandler(Sender: TObject; Request: TWebRequest;
   Response: TWebResponse; var Handled: Boolean);
begin
  PageProducer1.HTMLFile := 'Greeting.html';
  Response.Content := PageProducer1.Content;
end;
```

Greeting.html is a file that contains this HTML template:

```
<HTML>
<HEAD><TITLE>Our brand new web site</TITLE></HEAD>
<BODY>
Hello <#UserName>!  Welcome to our web site.
</BODY>
</HTML>
```

The *OnHTMLTag* event handler replaces the custom tag (`<#UserName>`) in the HTML during execution:

```
procedure WebModule1.PageProducer1HTMLTag(Sender : TObject;Tag: TTag;
   const TagString: string; TagParams: TStrings; var ReplaceText: string);
begin
  if CompareText(TagString,'UserName') = 0 then
    ReplaceText := TPageProducer(Sender).Dispatcher.Request.Content;
end;
```

If the content of the request message was the string *Mr. Ed*, the value of *Response.Content* would be

```
<HTML>
<HEAD><TITLE>Our brand new web site</TITLE></HEAD>
<BODY>
Hello Mr. Ed!  Welcome to our web site.
</BODY>
</HTML>
```

Note This example uses an *OnAction* event handler to call the content producer and assign the content of the response message. You do not need to write an *OnAction* event handler if you assign the page producer’s *HTMLFile* property at design time. In that case, you can simply assign *PageProducer1* as the value of the action item’s *Producer* property to accomplish the same effect as the *OnAction* event handler above.

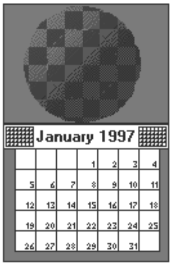
Chaining page producers together

The replacement text from an *OnHTMLTag* event handler need not be the final HTML sequence you want to use in the HTTP response message. You may want to use several page producers, where the output from one page producer is the input for the next.

The simplest way is to chain the page producers together is to associate each page producer with a separate action item, where all action items have the same *PathInfo* and *MethodType*. The first action item sets the content of the Web response message from its content producer, but its *OnAction* event handler makes sure the message is not considered handled. The next action item uses the *ContentFromString* method of its associated producer to manipulate the content of the Web response message, and so on. Action items after the first one use an *OnAction* event handler such as the following:

```
procedure WebModule1.Action2Action(Sender: TObject; Request: TWebRequest;
   Response: TWebResponse; var Handled: Boolean);
begin
  Response.Content := PageProducer2.ContentFromString(Response.Content);
end;
```

For example, consider an application that returns calendar pages in response to request messages that specify the month and year of the desired page. Each calendar page contains a picture, followed by the name and year of the month between small images of the previous month and next months, followed by the actual calendar. The resulting image looks something like this:



January 1997

			1	2	3	4
5	6	7	8	9	10	11
12	13	14	15	16	17	18
19	20	21	22	23	24	25
26	27	28	29	30	31	

The general form of the calendar is stored in a template file. It looks like this:

```
<HTML>
<Head></HEAD>
<BODY>
<#MonthlyImage> <#TitleLine><#MainBody>
</BODY>
</HTML>
```

The *OnHTMLTag* event handler of the first page producer looks up the month and year from the request message. Using that information and the template file, it does the following:

- Replaces <#MonthlyImage> with <#Image Month=January Year=1997>.
- Replaces <#TitleLine> with <#Calendar Month=December Year=1996 Size=Small> January 1997 <#Calendar Month=February Year=1997 Size=Small>.
- Replaces <#MainBody> with <#Calendar Month=January Year=1997 Size=Large>.

The *OnHTMLTag* event handler of the next page producer uses the content produced by the first page producer, and replaces the <#Image Month=January Year=1997> tag with the appropriate HTML <IMG> tag. Yet another page producer resolves the #Calendar tags with appropriate HTML tables.

Using database information in responses

The response to an HTTP request message may include information taken from a database. Specialized content producers on the Internet palette page can generate the HTML to represent the records from a database in an HTML table.

As an alternate approach, special components on the InternetExpress page of the component palette let you build Web servers that are part of a multi-tiered database application. See "Building Web applications using InternetExpress" on page 25-33 for details.

Adding a session to the Web module

Both console CGI applications and Win-CGI applications are launched in response to HTTP request messages. When working with databases in these types of applications, you can use the default session to manage your database connections, because each request message has its own instance of the application. Each instance of the application has its own distinct, default session.

When writing an ISAPI application or an NSAPI application, however, each request message is handled in a separate thread of a single application instance. To prevent the database connections from different threads from interfering with each other, you must give each thread its own session.

Each request message in an ISAPI or NSAPI application spawns a new thread. The Web module for that thread is generated dynamically at runtime. Add a *TSession* object to the Web module to handle the database connections for the thread that contains the Web module.

Separate instances of the Web module are generated for each thread at runtime. Each of those modules contains the session object. Each of those sessions must have a separate name, so that the threads that handle separate request messages do not interfere with each other's database connections. To cause the session objects in each module to dynamically generate unique names for themselves, set the *AutoSessionName* property of the session object. Each session object will dynamically generate a unique name for itself and set the *SessionName* property of all datasets in the module to refer to that unique name. This allows all interaction with the database for each request thread to proceed without interfering with any of the other request messages. For more information on sessions, see "Managing database sessions" on page 20-16.

Representing database information in HTML

Specialized Content producer components on the Internet palette page supply HTML commands based on the records of a dataset. There are two types of data-aware content producers:

- The dataset page producer, which formats the fields of a dataset into the text of an HTML document.
- Table producers, which format the records of a dataset as an HTML table.

Using dataset page producers

Dataset page producers work like other page producer components: they convert a template that includes HTML-transparent tags into a final HTML representation. They include the special ability, however, of converting tags that have a tagname which matches the name of a field in a dataset into the current value of that field. For more information about using page producers in general, see “Using page producer components” on page 28-13.

To use a dataset page producer, add a *TDataSetPageProducer* component to your web module and set its *DataSet* property to the dataset whose field values should be displayed in the HTML content. Create an HTML template that describes the output of your dataset page producer. For every field value you want to display, include a tag of the form

```
<#FieldName>
```

in the HTML template, where *FieldName* specifies the name of the field in the dataset whose value should be displayed.

When your application calls the *Content*, *ContentFromString*, or *ContentFromStream* method, the dataset page producer substitutes the current field values for the tags that represent fields.

Using table producers

The Internet palette page includes two components that create an HTML table to represent the records of a dataset:

- Dataset table producers, which format the fields of a dataset into the text of an HTML document.
- Query table producers, which runs a query after setting parameters supplied by the request message and formats the resulting dataset as an HTML table.

Using either of the two table producers, you can customize the appearance of a resulting HTML table by specifying properties for the table’s color, border, separator thickness, and so on. To set the properties of a table producer at design time, double-click the table producer component to display the Response Editor dialog.

Specifying the table attributes

Table producers use the *THTMLTableAttributes* object to describe the visual appearance of the HTML table that displays the records from the dataset. The

THTMLTableAttributes object includes properties for the table's width and spacing within the HTML document, and for its background color, border thickness, cell padding, and cell spacing. These properties are all turned into options on the HTML <TABLE> tag created by the table producer.

At design time, specify these properties using the Object Inspector. Select the table producer object in the Object Inspector and expand the *TableAttributes* property to access the display properties of the *THTMLTableAttributes* object.

You can also specify these properties programmatically at runtime.

Specifying the row attributes

Similar to the table attributes, you can specify the alignment and background color of cells in the rows of the table that display data. The *RowAttributes* property is a *THTMLTableRowAttributes* object.

At design time, specify these properties using the Object Inspector by expanding the *RowAttributes* property. You can also specify these properties programmatically at runtime.

You can also adjust the number of rows shown in the HTML table by setting the *MaxRows* property.

Specifying the columns

If you know the dataset for the table at design time, you can use the Columns editor to customize the columns' field bindings and display attributes. Select the table producer component, and right-click. From the context menu, choose the Columns editor. This lets you add, delete, or rearrange the columns in the table. You can set the field bindings and display properties of individual columns in the Object Inspector after selecting them in the Columns editor.

If you are getting the name of the dataset from the HTTP request message, you can't bind the fields in the Columns editor at design time. However, you can still customize the columns programmatically at runtime, by setting up the appropriate *THTMLTableColumn* objects and using the methods of the *Columns* property to add them to the table. If you do not set up the *Columns* property, the table producer creates a default set of columns that match the fields of the dataset and specify no special display characteristics.

Embedding tables in HTML documents

You can embed the HTML table that represents your dataset in a larger document by using the *Header* and *Footer* properties of the table producer. Use *Header* to specify everything that comes before the table, and *Footer* to specify everything that comes after the table.

You may want to use another content producer (such as a page producer) to create the values for the *Header* and *Footer* properties.

If you embed your table in a larger document, you may want to add a caption to the table. Use the *Caption* and *CaptionAlignment* properties to give your table a caption.

Setting up a dataset table producer

TDataSetTableProducer is a table producer that creates an HTML table for a dataset. Set the *DataSet* property of *TDataSetTableProducer* to specify the dataset that contains the records you want to display. You do not set the *DataSource* property, as you would for most data-aware objects in a conventional database application. This is because *TDataSetTableProducer* generates its own data source internally.

You can set the value of *DataSet* at design time if your Web application always displays records from the same dataset. You must set the *DataSet* property at runtime if you are basing the dataset on the information in the HTTP request message.

Setting up a query table producer

You can produce an HTML table to display the results of a query, where the parameters of the query come from the HTTP request message. Specify the *TQuery* object that uses those parameters as the *Query* property of a *TQueryTableProducer* component.

If the request message is a GET request, the parameters of the query come from the *Query* fields of the URL that was given as the target of the HTTP request message. If the request message is a POST request, the parameters of the query come from the content of the request message.

When you call the *Content* method of *TQueryTableProducer*, it runs the query, using the parameters it finds in the request object. It then formats an HTML table to display the records in the resulting dataset.

As with any table producer, you can customize the display properties or column bindings of the HTML table, or embed the table in a larger HTML document.

Chapter

Using WebSnap

WebSnap augments WebBroker with new components, wizards, and views—making it easier to build Web applications that contain complex, data-driven Web pages. WebSnap's support for multiple modules and for server-side scripts makes team development easier.

The dispatcher components automatically handle requests for page content, HTML form submissions, and requests for dynamic images. New components called adapters provide a means to define a scriptable interface to the business rules of your application. For example, the *TDataSetAdapter* object is used to make data-set components scriptable. You can use new producer components to quickly build complex, data-driven forms and tables, or to use XSL to generate a page. You can use the session component to keep track of end-users. You can use the user list component to provide access to user names, passwords, and access rights.

The Web application wizard allows you to quickly build an application that is customized with the components that you will need. The Web page module wizard allows you to create a module that defines a new page in your application. Or use the Web data module wizard to create a container for components that are shared across your Web application.

The page module views make it possible to see the result of server-side script without running the application. The Preview tab shows the page in an embedded browser. The HTML Result view shows the generated HTML. The XSL Tree and XML Tree views make it easier to work with XML and XSL.

To support a team of developers, you can use WebSnap's multiple-module support to partition the application into units that can be worked on independently. When creating a new page module, you can have the page module wizard create an external template file. You can edit the template file outside of the IDE and test it without recompiling the application.

The following sections of this chapter explain how you use the WebSnap components to create a Web server application.

Creating Web server applications with WebSnap

To create a new Web server application using the WebSnap architecture:

1 Select File | New | Other.

2 In the New Items dialog box, select the WebSnap tab and choose WebSnap Application.

3 A dialog box appears which requires the following types of information:

   - Server type
   - Web application module types
   - Web application module options
   - Application components

Server type

Select one of the following types of Web server application, depending on your application's type of Web server:

- ISAPI and NSAPI: Selecting this type of application sets up your project as a DLL with the exported methods expected by the Web server. It adds the library header to the project file, and adds the required entries to the uses list and to the exports clause of the project file.
- Apache: Selecting this type of application sets up your project as a DLL with the exported methods expected by the Apache Web server. It adds the library header to the project file and the required entries to the uses list and exports clause of the project file.
- CGI stand-alone: Selecting this type of application sets up your project as a console application, and adds the required entries to the uses clause of the project file.
- Win-CGI stand-alone: Selecting this type of application sets up your project as a Windows application and adds the required entries to the uses clause of the project file.
- Web Application Debugger executable: Selecting this type of application sets up an environment for developing and testing Web server applications. This type of application is not intended for deployment.

Choose the type of Web server application that communicates with the type of Web server your application will use.

Web application module types

The Web application module provides centralized control for business rules and non-visual components in the Web application. There are two types of Web application modules:

- Page Module: Selecting this type of module creates a content page. The page module contains a page producer which is responsible for generating the content of a page. The page producer displays its associated page when the HTTP request pathinfo matches the page name. The page can act as the default page when the pathinfo is blank.
- Data Module: Selecting this type of module does not create a content page. This module is used as a container for components shared by other modules—for example, database components used by two Web Page modules.

Web application module options

If the selected application module type is page module, you can associate a name with the page by entering a name in the Page Name field in the dialog box. At runtime, the instance of this module can be either kept in cache, or removed from memory when the request has been serviced. Select either of the options from the Caching field. You can select more page module options through the Page Options button. You can set the following categories:

- Producer: The producer type for the page can be set to one of *AdapterPageProducer*, *DataSetPageProducer*, *InetXPageProducer*, *PageProducer*, or *XSLPageProducer*. If the selected page producer supports scripting, then use the Script Engine drop-down list to select the language used to script the page.

Note The *AdapterPageProducer* supports only JScript.

- HTML: When the selected producer uses an HTML template this group will be visible.
- XSL: When the selected producer uses an XSL template, such as *TXSLPageProducer*, this group will be visible.
- New File: Check New File if you want a template file to be created and managed as part of the unit. A managed template file will appear in the project manager and have the same file name and location as the unit source file. Uncheck New File if you want to use the properties of the producer component (typically the *HTMLDoc* or *HTMLFile* property).
- Template: When New File is checked, choose the default content for the template file from the Template drop-down. The “Default” template displays the title of the application, the title of the page, and hyperlinks to published pages.
- Page: Enter a page name and title for the page module. The page name is used to reference the page in an HTTP request or within the application's logic, whereas the title is the name that the end user will see when the page is displayed in a browser.

- Published: Check Published to allow the page to automatically respond to HTTP requests where the page name matches the pathinfo in the request message.
- Login Required: Check Login Required to require the user to log on before the page can be accessed.

Application components

Application components provide the Web application's functionality. For example, including an adapter dispatcher component automatically handles HTML form submissions and the return of dynamically generated images. Including a page dispatcher automatically displays the content of a page when the HTTP request pathinfo contains the name of the page.

Selecting the Components button displays a dialog box where you can select one or more of the Application components:

- Application Adapter: Contains information about the application, such as the title. The default type is *TApplicationAdapter*.
- End User Adapter: Contains information about the user, such as their name, access rights, and whether they are logged in. The default type is *TEndUserAdapter*. *TEndUserSessionAdapter* may also be selected.
- Page Dispatcher: Examines the HTTP request's pathinfo, and calls the appropriate page module to return the content of a page. The default type is *TPageDispatcher*.
- Adapter Dispatcher: Automatically handles HTML form submissions, and requests for dynamic images, by calling adapter action and field components. The default type is *TAdapterDispatcher*.
- Dispatch Actions: Allows you to define a collection of action items to handle requests based on pathinfo and method type. Action items call user-defined events, or request the content of page-producer components. The default type is *TWebDispatcher*.
- Locate File Service: Provides control over the loading of template files, and script include files, when the Web application is running. The default type is *TLocateFileService*.
- Sessions Service: Used to store information about an end-users that is needed for a short period of time. For example, you can use sessions to keep track of logged-in users, and to automatically log a user out after a period of inactivity. The default type is *TSessionService*.
- User List Service: Keeps track of authorized users, and their passwords and access rights. The default type is *TWebUserList*.

For each of the above components, the component types listed are the default types shipped with the Delphi software product. Users can create their own component types or use third-party component types.

Web modules

There are four Web module types:

- *TWebAppPageModule*
- *TWebAppDataModule*
- *TWebPageModule*
- *TWebDataModule*

The Web application module (*TWebAppPageModule* or *TWebAppDataModule*) is a container for the application components that perform functions for the application as a whole—such as dispatching requests, managing sessions, and maintaining user lists. Your project can contain only one of these types of application modules.

The Web page module (*TWebPageModule)* provides content to a page and the Web data module (*TWebDataModule*) acts as a container for components shared across your application. You can optionally include one or more Web page and Web data modules in the Web application module.

Web data modules

Like standard data modules, a Web data module is a container for components from the palette. Data modules provide a design surface for adding, removing, and selecting components. When the application is running, a data module does not create a window.

The Web data module differs from a standard data module in the structure of the unit and the interfaces that the Web data module implements.

Use the Web data module as a container for components that are shared across your application. For example, you can put a dataset component in a data module and access the dataset from both:

- a page module that displays a grid, and
- a page module that displays an input form.

Structure of a Web data module unit

Standard data modules have a variable called the form variable, which is used to access the data module object. Web data modules replace this with a function. The purpose is the same. However, because WebSnap applications may be multi-threaded and may have multiple instances of a particular module that service multiple requests concurrently, this function is implemented to return the correct instance.

The unit also registers a factory. The factory specifies how the module should be managed by the WebSnap application. For example, flags indicate whether to cache the module and reuse it for other requests, or to destroy the module after a request has been serviced.

Interfaces implemented by a Web data module

A Web data module implements the following interfaces:

INotifyWebActivate: This interface is called when the module is activated to service a Web request, and before the module is deactivated after a Web request is serviced.

IWebVariablesContainer: This interface is called during script execution to resolve variable references. The adapter dispatcher also calls this interface to locate adapter actions and fields that are referenced in an HTTP request.

IGetScriptObject: This interface is called to retrieve the module's IDispatch implementation. The returned object is the interface between the module and the active scripting engine.

IIteratorObjectSupport: This interface is used to iterate through all of the objects within the module that can be accessed by active scripting.

Web page modules

The page module has a page producer component associated with it. When a request is received, the page dispatcher analyses the request and calls the appropriate page module to process the request and return the content of the page.

Like Web data modules, Web page modules are containers for components. The difference between a Web data module and a Web page module is that a Web page module is used to produce a Web page.

Page producer component

Web page modules have a property that identifies the page producer component responsible for generating content for the page. The WebSnap wizards automatically adds a producer when creating a Web page module. You can change the page producer component later by dropping in a different producer from the WebSnap palette. However, if the page module has a template file, be sure that the content of this file is compatible with the producer component.

Page name

Web page modules have a page name that can be used to reference the page in an HTTP request or within the application's logic. A factory in the Web page module's unit specifies the page name for the Web page module.

Producer template

Most page producers use a template. HTML templates typically contain some static HTML mixed in with transparent tags or server-side script. When page producers create their content, they replace the transparent tags with appropriate values and execute the server-side script to produce the HTML that is displayed by a client browser. The XSLPageProducer is an exception to this. It uses XSL templates, which contain XSL rather than HTML. The XSL templates do not support transparent tags or server-side script.

Web page modules may have an associated template file that is managed as part of the unit. A managed template file appears in the project manager and has the same base file name and location as the unit service file. If the Web page module does not have an associated template file then the properties of the page producer component specify the template.

Interfaces that the Web page module implements

A Web page module implements all of the interfaces of a Web data module, in addition to the following:

IDefaultPageFileName: The WebSnap surface designer uses this interface to ensure that a page module uses the proper template file.

ISetWebContentOptions: The WebSnap surface designer uses this interface to control the content that the page module generates. For example, an option can be used to retrieve the content before the Active Script executes.

IGetProducerComponent: The WebSnap surface designer uses this interface to retrieve the producer component associated with the page module.

IProducerEditorViewSupport: The WebSnap surface designer uses this interface to retrieve information about the editor views that it should display when the page module is active. The available editor views include HTML Script, Preview, HTML Result, XSL Tree, and XML Tree.

IPageResult: This interface provides access to the result that a page module produces. This interface supports three types of results: HTTP Content, HTTP Redirection, and Page Include.

IGetDefaultAction: This interface retrieves the default adapter action (if any) that is associated with the page module.

Web application modules

The Web application module implements interfaces that are not implemented by *TWebPageModule* or *TWebDataModule*.

Interfaces implemented by a Web application data module

A Web application data module implements all the interfaces of a Web data module, in addition to the following:

IGetWebAppServices: Retrieves the interface to the application's Web request handler.

IGetWebAppComponents: Retrieves the interface to the application-level components, including the AdapterDispatcher, PageDispatcher, SessionsService, and EndUserAdapter.

Interfaces implemented by a Web application page module

A Web application page module implements all the interfaces of a Web Application data module and a Web page module.

Adapters

Adapters provide a way to create an interface to the application data. They allow you to insert scripting languages into a page, and to retrieve information by making calls from your script code to the adapters.

For example, you can use an adapter to define data fields to be displayed on an HTML page. A scripted HTML page can then contain HTML content and script statements that retrieve the values of those data fields.

Fields

Fields are components that the page producer uses to retrieve data from your application and to display the content on a Web page. Fields can also be used to retrieve an image. In this case, the field returns the address of the image written to the Web page. When a page displays its content, a request sent to the Web application, invokes the adapter dispatcher to retrieve the actual image from the field component.

Actions

Actions are components that execute commands on behalf of the adapter. When a page producer generates its page, the scripting language calls adapter action components to return the name of the action along with any parameters necessary to execute the command. For example, consider clicking a button on an HTML form to delete a row from a table. This returns, in the HTTP request, the action name associated with the button and a parameter indicating the row number. The adapter dispatcher locates the named action component and passes the row number as a parameter to the action.

Errors

Adapters keep a list of errors that occur while executing an action. Page producers can access this list of errors and display them in the Web page that the application returns to the end user.

Records

Some adapter components, such as *TDataSetAdapter*, represent multiple rows. The adapter provides a scripting interface which allows iteration through the rows. Some adapters support paging, and iterate over only the rows on the current page.

Page producers

You use page producers to generate content on behalf of a Web page module. You can also use producers in the same way as they are used in WebBroker applications, by associating the producer with a Web dispatcher action item. The advantages of using the Web page module are:

- the ability to preview the page’s layout without running the application, and
- the ability to associate a page name with the module, so that the page dispatcher can call the page producer automatically.

Templates

Producers provide the following functionality:

- They generate HTML content.
- They can reference an external file using the HTMLfile property, or the internal string using the HTMLDoc property.
- When the producers are used in conjunction with a Web page module, the template can be a file associated with a unit.
- Producers dynamically generate HTML which can be inserted into the template using transparent tags or active scripting. Transparent tags can be used in the same way as WebBroker applications. For more details, see “Converting HTML-transparent tags” on page 28-14. Active scripting support allows you to embed JavaScript or VBscript inside the HTML page.

Server-side scripting in WebSnap

Page producer templates can include scripting languages such as JScript or VBScript. The page producer executes the script in response to a request for the producer's content. Because the Web application evaluates the script, it is called server-side script, as opposed to client-side script (which is evaluated by the browser).

Active scripting

WebSnap relies on *active scripting* to implement server-side script. Active scripting is a technology created by Microsoft to allow a scripting language to be used with application objects through COM interfaces. Microsoft ships two active scripting languages, VBScript and JScript. Support for other languages is available through third parties.

Script engine

The page producer's *ScriptEngine* property identifies the active scripting engine that evaluates the script within a template.

Script blocks

Script blocks are delimited by <% and %>. The script engine evaluates any text inside script blocks. The result becomes part of the page producer's content. The page producer writes text outside of a script block after translating any embedded transparent tags. Script blocks can also enclose text, allowing conditional logic and loops to dictate the output of text. For example, the following JScript block generates a list of five numbered lines:

```
<ul>
<% for (i=0;i<5;i++) { %>
    <li>Item <% Response.Write(i) %></li>
<% } %>
</ul>
```

The following script block is equivalent:

```
<ul>
<% for (i=0;i<5;i++) { %>
    <li>Item <%=i %></li>
<% } %>
</ul>
```

The <%= delimiter is short for *Response.Write*.

Creating script

Developers can take advantage of WebSnap features to automatically generate script.

Wizard templates

When they create a new WebSnap application or page module, WebSnap wizards provide a template field that is used to select the initial content for the page module template. For example, the template called "Default" generates JScript to display the application title, page name, and links to published pages.

TAdapterPageProducer

The *TAdapterPageProducer* builds forms and tables by generating HTML and JScript. The generated JScript calls adapter objects to retrieve field values, field image parameters, and action parameters.

Editing and viewing script

The WebSnap surface designer provides a view of your Web Page modules which lets you preview a scripted page. Use the HTML Result tab to view the HTML resulting from the executed script. Use the Preview tab to view the result in a browser. The HTML Script tab is available when the Web Page module uses *TAdapterPageProducer*. The HTML Script tab displays the HTML and JScript generated by the *TAdapterPageProducer* object. Consult this view to see how to write script that builds HTML forms to display adapter fields and execute adapter actions.

Including script in a page

A template can include script from a file or from another page. To include script from a file, use the following code statement:

```
<!-- #include file="filename.html" -->
```

When the template includes script from another page, the script is evaluated by the including page, use the following code statement to include the unevaluated content of page1.

```
<!-- #include page="page1" -- >
```

Script objects

Script objects are either VCL or CLX objects that can be referenced by script. You make VCL or CLX objects available for scripting by registering an *IDispatch* interface to the object with the active scripting engine. The following objects are available for scripting:

- **Application—**The application object (which may be null) provides access to the application adapter of the Web Application module. The following JScript block writes the application title:

  ```
  <%= Application.Title %>
  ```

- **EndUser—**The EndUser object provides access to the end-user adapter of the Web Application module. The following JScript block writes the end-user name:

  ```
  <%= EndUser.DisplayName %>
  ```

- **Session—**The session object provides access to the session object of the Web Application module. The following JScript block writes the session ID:

  ```
  <%= Session.SessionID %>
  ```

- **Pages—**The pages object (*Pages*) provides access to the application pages. The following JScript block writes links to all published pages:

  ```
  <%  e = new Enumerator(Pages)
       for (; !e.atEnd(); e.moveNext())
       {
         if (e.item().Published)
         {
             Response.Write('<A HREF="' + e.item().HREF +'">' + e.item().Title + '</A>')
         }
       }
  %>
  ```

Note that the editor's Preview tab will not display the proper result of this script block. The pages object is always empty at design time because the Web page module factories have not been registered.

- **Modules—**The modules object provides access to the application modules. The following JScript block writes the content of an adapter field in a module called DM.

```
<%= Modules.DM.Adapter1.Field1.DisplayText %>
```

- **Page—**The Page object provides access to the current page. The following JScript block writes the title of the current page:

```
<%= Page.Title %>
```

- **Producer—**The Producer object provides access to the page producer of the Web Page module. The following JScript block evaluates a transparent tag before writing the content:

```
<% Producer.Write('Here is a tag <#TAG>') %>
```

Note that the editor's Preview tab will probably not display the proper result of this script block. The event handlers that usually replace transparent tags do not execute unless the application is running.

- **Response—**The Response object provides access to the WebResponse. Use this object when tag replacement is not desired.

```
<% Response.Write('Hello World!') %>
```

- **Request—**The Request object provides access to the WebRequest. The following JScript block displays the pathinfo.

```
<%= Request.PathInfo %>
```

- **Adapter Objects—**All of the adapter's components on the current page can be referenced without qualification. Adapter's in other modules must be qualified using the Modules objects. The following JScript block displays the text value of the *FirstName* field from of all rows of Adapter1:

```
<% e = new Enumerator(Adapter1.Records) %>
  <% for (; !e.atEnd(); e.moveNext()) %>
  <% { %>
      <p><%= Adapter1.FirstName.DisplayText %>
  <% } %>
```

Dispatching requests

When the WebSnap application receives an HTTP request message, it creates a *TWebRequest* object to represent the HTTP request message, and a *TWebResponse* object to represent the response that should be returned.

WebContext

Before handling the request, the Web application module initializes the WebContext object (of type *TWebContext*). The WebContext is a thread variable that provides global access to variables used by components servicing the request. For example, the WebContext contains the *TWebResponse* and *TWebRequest* objects, as well as the adapter request and adapter response objects discussed later in this section.

Dispatcher components

The dispatcher components within the Web Application module control the flow of the application. The dispatchers determine how to handle certain types of HTTP request messages by examining the HTTP request.

The adapter dispatcher component (*TAdapterDispatcher)* looks for a content field, or a query field, that identifies an adapter action component or an adapter image field component. If the adapter dispatcher finds a component, it will pass control to that component.

The Web Dispatcher component (*TWebDispatcher*) maintains a collection of action items (*TWebActionItem*) that know how to handle certain types of HTTP request messages. The Web dispatcher looks for an action item that matches the request. If it finds one, it passes control to that action item. The Web dispatcher also looks for auto-dispatching components that can handle the request.

The page dispatcher component (*TPageDispatcher*) examines the pathInfo property of the *TWebRequest* object, looking for the name of a registered Web page module. If the dispatcher finds a Web page module name, then it will pass control to that Web page module.

Adapter dispatcher operation

The adapter dispatcher component automatically handles HTML form submissions, and requests for dynamic images, by calling adapter action and field components.

Using adapter components to generate content

In order for WebSnap applications to automatically execute adapter actions and retrieve dynamic images from adapter fields, the HTML content must be properly constructed. If the HTML content is not properly constructed, then the resulting HTTP request will not contain the information that the adapter dispatcher needs to call adapter action and field components.

To reduce errors in constructing the HTML page, adapter components indicate what the names and values of HTML elements must be. Adapter components have methods that retrieve the names and values of hidden fields that must appear on an HTML form used to update adapter fields. Typically, page producers use server-side scripts to retrieve names and values from adapter components and generates HTML using these names and values. For example, the following script constructs an <IMG> element that references the field called Graphic from Adapter1:

```
<img src="<%=Adapter1.Graphic.Image.AsHREF%>" alt="<%=Adapter1.Graphic.DisplayText%>">
```

When the Web application evaluates the script, the HTML src attribute will contain the information necessary to identify the field and any parameters that the field component needs to retrieve the image. The resulting HTML might look like this:

```
<img src="?_lSpecies No=90090&__id=DM.Adapter1.Graphic" alt="(GRAPHIC)">
```

When the browser sends an HTTP request to retrieve this image to the Web application, the adapter dispatcher will be able to determine that the Graphic field of Adapter1, in the module DM, should be called with the parameter "Species No=90090". The adapter dispatcher will call the Graphic field to write an appropriate HTTP response.

The following script constructs an <A> element referencing the EditRow action of Adapter1 and the page called "Details":

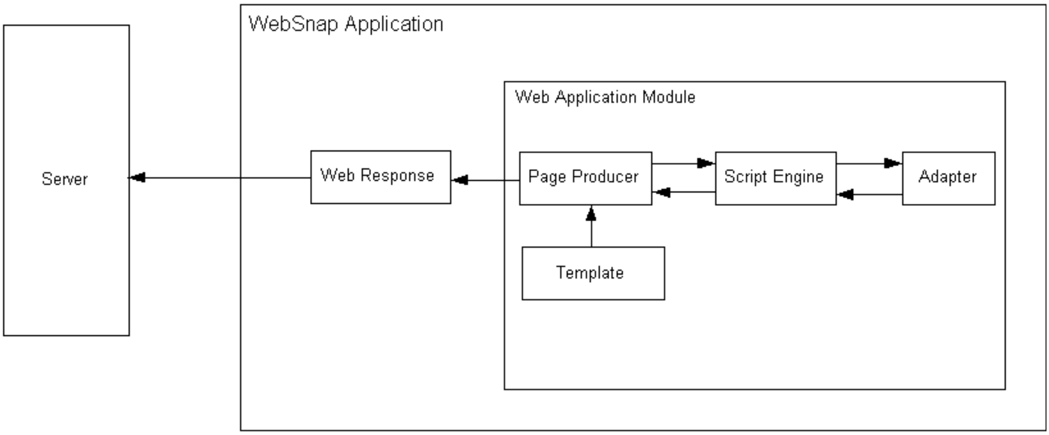
```
<a href="<%=Adapter1.EditRow.LinkToPage("Details", Page.Name).AsHREF%>">Edit...</a>
```

The resulting HTML might look like this:

```
<a href="?&_lSpecies No=90310&__sp=Edit&__fp=Grid&__id=DM.Adapter1.EditRow">Edit...</a>
```

When the end-user clicks this hyperlink and the browser sends an HTTP request, the adapter dispatcher will be able to determine that the EditRow action of Adapter1, in the module DM, should be called with the parameter "Species No=903010". The adapter dispatcher will also indicate that the Edit page is to be displayed if the action executes successfully, and that the Grid page is to be displayed if action execution fails. It will then call the EditRow action to locate the row to be edited, and the page named Edit will be called to generate an HTTP response. Figure 29.1 shows how adapter components are used to generate content.

Figure 29.1 Generating Content Flow



Adapter requests and responses

When the adapter dispatcher receives the client request, the adapter dispatcher creates adapter request and adapter response objects to hold information about the HTTP request. The adapter request and adapter response objects are stored in the WebContext to allow access during the processing of the request.

The adapter dispatcher creates two types of adapter request objects: action and image. It creates the action request object when executing an adapter action. It creates the image request object when retrieving an image from an adapter field.

The adapter response object is used by the adapter component to indicate the response to an adapter action or adapter image request. There are two types of adapter response objects, action and image.

Action request

The action request object is responsible for breaking the HTTP request down into information needed to execute an adapter action. The types of information needed for executing an adapter action may include:

- **Component Name—**Identifies the adapter action component.
- **Adapter Mode—**Adapters can define a mode. For example, *TDataSetAdapter* supports Edit, Insert, and Browse modes. An adapter action may execute differently depending on the mode. For example, the *TDataSetAdapter* Apply action adds a new record when in Insert mode, and updates a record when in Edit mode.
- **Success Page—**The success page identifies the page displayed after successful execution of the action.
- **Failure Page—**The failure page identifies the page displayed if an error occurs during execution of the action.
- **Action Request Parameters—**This identifies the parameters need by the adapter action. For example, the *TDataSetAdapter* Apply action will include the key values identifying the record to be updated.
- **Adapter Field Values—**These are the values for the adapter fields passed in the HTTP request when an HTML form is submitted. A field value can include new values entered by the end-user, the original values of the adapter field, and uploaded files.
- **Record Keys—**If an HTML form submits changes to multiple records, keys used by the adapter action component are required to uniquely identify each record so that the adapter action can be performed on each record. For example, when the *TDataSetAdapter* Apply action is performed on multiple records, the record keys are used to locate each record in the dataset before updating the dataset fields.

Action response

The Action Response object generates an HTTP response on behalf of an adapter action component. The adapter action indicates the type of response by setting properties within the object, or by calling methods in the Action Response object. The properties include:

- *Redirect Options*—The redirect options indicate whether to perform an HTTP redirect instead of returning HTML content.
- *Execution Status*—Setting the status to success causes the default action response to be the content of the success page identified in the Action Request.

The Action response methods include:

- *RespondWithPag* —The adapter action calls this method when a particular Web page module should generate the response.
- *RespondWithComponent*—The adapter action calls this method when the response should come from the Web page module containing this component.
- *RespondWithURL*—The adapter action calls this method when the response is a redirect to a specified URL.

When responding with a page, the Action response object attempts to use the page dispatcher to generate page content. If it does not find the page dispatcher, it calls the Web Page module directly.

Figure 29.4 illustrates how action request and action response objects handle a request.

Figure 29.2 Action request and response

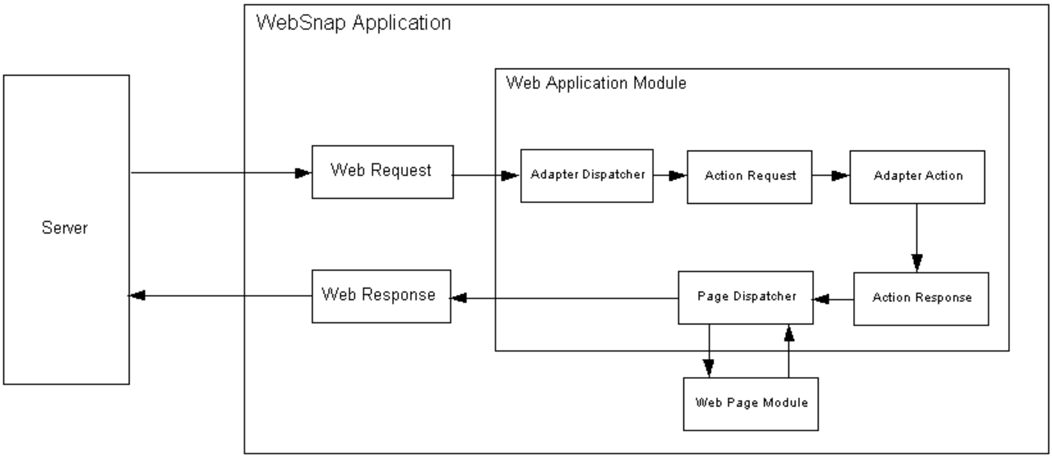


Image request

The Image Request object is responsible for breaking the HTTP request down into the information required by the adapter image field to generate an image. The types of information represented by the Image Request include:

- Component Name - Identifies the adapter field component.

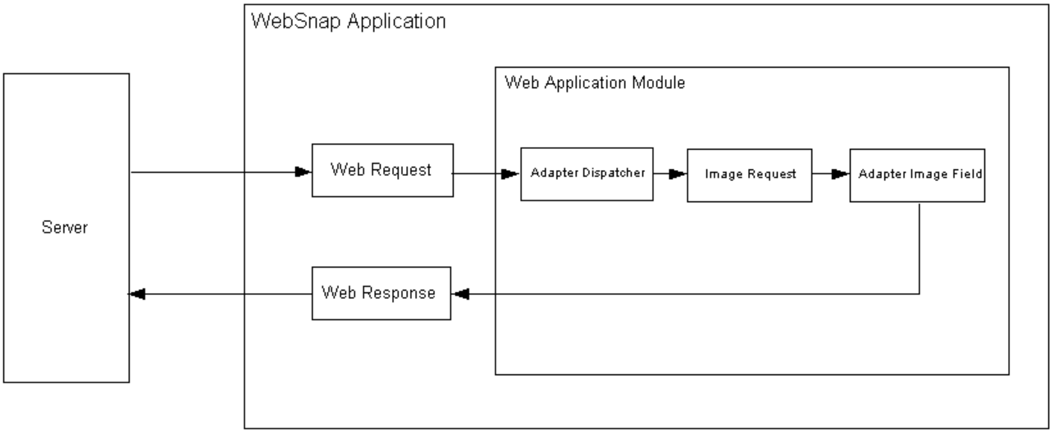
- Image Request Parameters - Identifies the parameters needed by the adapter image. For example, the *TDataSetAdapterImageField* object needs key values to identify the record that contains the image.

Image response

The Image response object contains the *TWebResponse* object. Adapter fields respond to an adapter request by writing an image to the Web response object.

Figure 29.3 illustrates how adapter image fields respond to a request.

Figure 29.3 Image response to a request



Dispatching action items

The Web dispatcher (*TWebDispatcher*) searches through its list of action items for one that:

- matches the Pathinfo portion of the target URL's request message, and
- can provide the service specified as the method of the request message.

It accomplishes this by comparing the *PathInfo* and *MethodType* properties of the *TWebRequest* object with the properties of the same name on the action item.

When the dispatcher finds the appropriate action item, it causes that action item to fire. When the action item fires, it does one of the following:

- Fills in the response content and sends the response, or signals that the request has been completely handled.
- Adds to the response, and then allows other action items to complete the job.
- Defers the request to other action items.

After the dispatcher has checked all of its action items, if the message has not been handled correctly, the dispatcher checks for specially registered auto-dispatching components that do not use action items. These components are specific to multi-tiered database applications. If the request message has still not been fully handled, the dispatcher calls the default action item. The default action item does not need to match either the target URL or the method of the request.

Page dispatcher operation

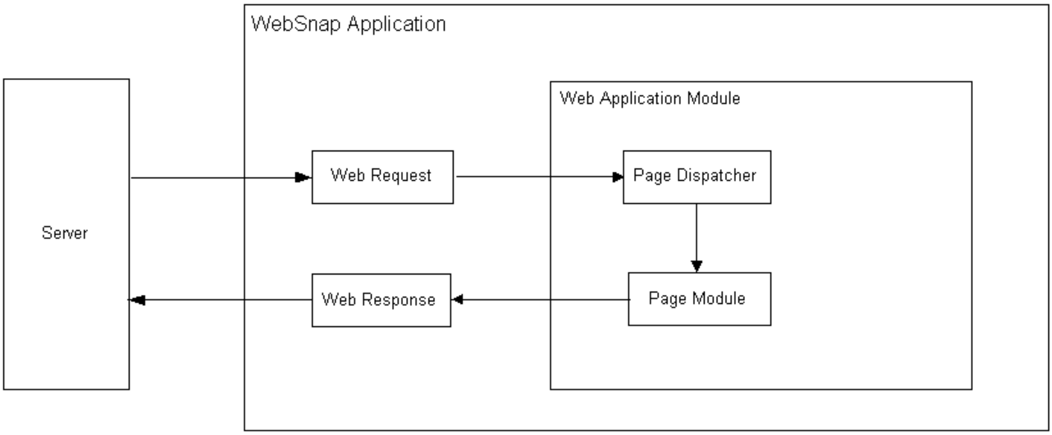
When the page dispatcher receives a client request, it determines the page name by checking the Pathinfo portion of the target URL's request message. If the pathinfo portion is not blank, the page dispatcher uses the ending word of pathinfo as the page name. If the pathinfo portion is blank, the page dispatcher tries to determine a default page name.

If the page dispatcher's *DefaultPage* property contains a page name, then the page dispatcher uses this name as the default page name. If the *DefaultPage* property is blank, and the Web application module is a page module, then the page dispatcher uses the name of the Web application module as the default page name.

If the page name is not blank, the page dispatcher searches for a Web page module with a matching name. If it finds a Web page module, then it calls that module to generated a response. If the page name is blank, or if the page dispatcher does not find a Web page module, the page dispatcher raises an exception.

Figure 29.4 shows how the page dispatcher responds to a request.

Figure 29.4 Dispatching a page



WebSnap tutorial

The following section describes the steps to build a WebSnap application. Completing the tutorial will familiarize users with the WebSnap architecture and new concepts, by incorporating the new dispatcher and adapter components into the new Web Page module. The WebSnap application demonstrates how to use WebSnap HTML components to build an application that edits the content of a table.

Create a new application

To create a new WebSnap application:

Step 1. Start the WebSnap application wizard

1 Run the Delphi application and select File | New | Other.

2 In the New Items dialog box, select the WebSnap tab and choose WebSnap Application.

3 In the New WebSnap Application dialog box:

- Select the Web App Debugger Executable.
- In the CoClass field type **CountryTutorial.**
- Select Page Module as the component type.
- In the Page Name field type **Home.**

4 Click OK.

Step 2. Save the generated files and project

To save the pascal unit file and project:

1 Select File | Save All.

2 In the File name field enter **HomeU.pas** and Click OK.

3 In the File name field enter **CountryU.pas** and Click OK.

4 In the File name field enter **CountryTutorial.dpr** and Click OK.

5 Click OK.

Note Save the unit and the project to the same directory since the application will look for the HomeU.html file in the same directory as the executable.

Step 3. Specify the application title

The application title is the name displayed to the end user. To specify the application title:

1 Select View | Project Manager.

2 In the Project Manager window expand CountryTutorial.exe and double click the HomeU entry.

3 In the Object Inspector window (bottom left), select ApplicationAdapter from the pull down list.

4 In the Properties tab, enter **Country Tutorial** in the ApplicationTitle field.

5 Click on the Preview tab in the editor window. The application title is displayed at the top of the page.

Create a CountryTable page

A Web page module is used to define a published page, and as a container for data components.

Step 1. Add a new module

To add a new module:

1 Select File | New | Other.

2 In the New Items dialog box, select the WebSnap tab and choose WebSnap Page Module.

3 In the dialog box, set the Producer Type to AdapterPageProducer from the list.

4 In the Page Name field enter **CountryTable.**

5 Leave the rest of the fields and selection at their default values.

6 Click OK.

Step 2. Save the new module

Save the unit to the directory of the project file. When the application runs, it searches for the CountryTableU.html file in the same directory as the executable.

1 Select File | Save.

2 In the File name field, enter **CountryTableU.pas** and Click OK.

Add data components to the CountryTable module

A *TTable* component provides the data for the HTML table. The *TDataSetAdapter* component allows server side script to access the *TTable* component.

Step 1. Add data-aware components

1 Select View | Project Manager.

2 In the Project Manager window expand CountryTutorial.exe and double click the CountryTableU entry.

3 Select View | Object TreeView. The Object TreeView window (left hand side) becomes active.

4 Select the Data Access tab in the tool palette.

5 Select a Table component (left-click and hold) and drag the component to the Object TreeView window.

6 Select a Session component (left-click and hold) and drag the component to the Object TreeView window.

7 Select the Session component in the Object TreeView window. This displays the Session component values in the Object Inspector window.

8 In the Object Inspector window, set the AutoSessionName property to *True*.

9 Select the Table component in the Object TreeView window. This displays the Table component values in the Object Inspector window.

10 In the Object Inspector window, change the following properties:

- Set the *Active* property to *True*.
- Set the *DatabaseName* property to DBDEMOS .
- In the *Name* property, type **Country**.
- Set the *TableName* property to country.db.

Note The Session component is required because we are using the BDE component (*TTable*) in a multi threaded application.

Step 2. Specify a key field

The key field is used to identify records within a table. This becomes important when we add an edit page to the application. To specify a key field:

1 In the Object Tree View window, expand the Session and DBDemos node, and select the country.db node. This node is the Country Table component.

2 Right-click on the country.db node and select Fields Editor.

3 Right-click in the CountryTable.Country editor window and select the Add All Fields command.

4 Select the Name field from the list of added fields.

5 In the Object Inspector window, expand the *ProviderFlags* property.

6 Set the pfInKey property value to *True*.

Step 3. Add an adapter component

To expose the data in the *TTable* server-side scripting, you must include a DataSetAdapter (*TDataSetAdapter*) component. To add such a component:

1 Select the WebSnap tab in the tool palette.

2 Select the DataSetAdapter component (left-click and hold) and drag the component to the Object TreeView window.

3 In the Object Inspector window, change the following properties:

- Set the DataSet field to Country.
- In the Name field type **Adapter**.

Create a grid to display the data

The *AdapterPageProducer* leverages server-side script to quickly build an HTML table.

Step 1. Add a grid

To add a grid to display the data from the Country table:

1 Select View | Project Manager.

2 In the Project Manager window, expand CountryTutorial.exe and double-click the CountryTableU entry.

3 Select View | Object TreeView. The Object TreeView window (left-hand side) becomes active.

4 Expand the *AdapterPageProducer* component.

5 Right-click on WebPageItems entry and select New Component.

6 In the Add Web Component window, select AdapterForm, then Click OK. An AdapterForm1 component appears in the Object TreeView window.

7 Right-click on AdapterForm1 and select New Component.

8 In the Add Web Component window, select AdapterGrid then click OK. An AdapterGrid1 component appears in the Object TreeView window.

9 In the Object Inspector window, set the Adapter property to Adapter.

10 To preview the Page, select the CountryTableU.pas tab in the code editor window, and select the Preview tab at the bottom. If the Preview tab is not shown, use the right arrow at the bottom to scroll through the tabs.

11 Select the HTML Script tab to view the JScript generated by the WebSnap components.

Step 2. Add editing commands to the grid

Users may need to update the content of the table. To allow users to make such updates, such as deleting or inserting a row, add command components.

To add command components:

1 In the Object TreeView window for the CountryTable, expand the *AdapterPageProducer* component and all its branches.

2 Right-click on the AdapterGrid1 component and select Add All Columns.

3 Right-click on the AdapterGrid1 component and select New Component. An AdapterCommandColumn1 entry is added to the AdapterGrid1 component.

4 Right-click on AdapterCommandColumn1 and choose Add Commands.

5 Multi-select the DeleteRow, EditRow, and NewRow commands; then click OK.

6 To preview the Page, click on the Preview tab at the bottom of the code editor.

Add an edit form

Create a Web page module to be the Edit form for the country table.

Step 1. Add a new module

To add a new WebSnap page module:

1 Select File | New | Other.

2 In the New Items dialog box, select the WebSnap tab and choose WebSnap Page Module.

3 In the dialog box, set the Producer Type to AdapterPageProducer from the list.

4 In the Page Name field, enter **CountryForm**.

5 Uncheck the Published box.

6 Leave the rest of the fields and selections at their default values.

7 Click OK.

Step 2. Save the new module

Save the unit to the directory as the project file. When the application runs, it will look for the CountryFormU.html file in the same directory as the executable.

1 Select File | Save.

2 In the File name field enter **CountryFormU.pas** and Click OK.

Step 3. Use the CountryTableU unit

Add CountryTableU unit to the **uses** clause to allow the module access to the Adapter component.

1 Select File | Use Unit.

2 Select CountryTableU from the list then click OK.

Step 4. Add input fields

Add components to the *AdapterPageProducer* component to generate data entry fields in the HTML form.

To add input fields:

1 Select View | Project Manager.

2 In the Project Manager window, expand CountryTutorial.exe and double-click the CountryFormU entry.

3 Select View | Object TreeView. The Object TreeView window (left-hand side) becomes active.

4 In the Object TreeView window, expand the *AdapterPageProducer* component, right-click on WebPageItems, and select New Component.

5 Select AdapterForm, then click OK. An AdapterForm1 entry appears in the Object TreeView window.

6 Right-click on AdapterForm1 and select New Component.

7 Select AdapterFieldGroup then click OK. An AdapterFieldGroup1 entry appears in the Object TreeView window.

8 In the Object Inspector window, set the Adapter property to CountryTable.Adapter.

9 To preview the Page, click the Preview tab at the bottom of the code editor.

Step 5. Add buttons

Add components to the *AdapterPageProducer* component to generate the submit buttons in the HTML form. To add components:

1 In the Object TreeView, expand the *AdapterPageProducer* component and all its branches.

2 Right-click on AdapterForm1 entry and select New Component.

3 Select AdapterCommandGroup then click OK. An AdapterCommandGroup1 entry appears in the Object TreeView window.

4 In the Object Inspector window, set the DisplayComponent property to AdapterFieldGroup1.

5 Right-click on AdapterCommandGroup1 entry and select Add Commands.

6 Multi-select the Cancel, Apply, and Refresh Row commands; then click OK.

7 To preview the Page, click the Preview tab at the bottom of the code editor window. If the preview does not show the country form, click on the Code tab and then re-click the Preview tab.

Step 6. Link form actions to the grid page

When the user clicks a button, an adapter action is executed. To specify which page to display after an adapter action is executed:

1 In the Object TreeView, expand AdapterCommandGroup1 to show the CmdCancel, CmdApply, and CmdRefreshRow entries.

2 Select CmdCancel. In the Object Inspector window, type **CountryTable** in the PageName property.

3 Select CmdApply. In the Object Inspector window, type **CountryTable** in the PageName property.

Step 7. Link grid actions to the form page

To specify which page to display after an adapter action is executed by pushing a button in the grid:

1 Select View | Project Manager.

2 In the Project Manager window, expand CountryTutorial.exe and double-click the CountryTableU entry.

3 In the Object TreeView window, expand the *AdapterPageProducer* component and all its branches, to show the CmdNewRow, CmdEditRow, and CmdDeleteRow entries. These entries appear under the AdapterCommandColumn1 entry.

4 Select CmdNewRow. In the Object Inspector window, type **CountryForm** in the PageName property.

5 Select CmdEditRow. In the Object Inspector window, type **CountryForm** in the PageName property.

6 To verify that the application is working and that all buttons perform some action, run the application.

Note There will be no indication of database errors, such as an invalid type. For example, try adding a new country with an invalid value (for example, 'abc') in the Area field.

Add error reporting

To report errors to the end user, an AdapterErrorList component is used to display errors that occur while executing adapter actions that edit the country table.

Step 1. Add error support to the grid

1 In the Object TreeView for CountryTable, expand the *AdapterPageProducer* component and all its branches to show AdapterForm1.

2 Right-click on AdapterForm1 and select New Component.

3 Select AdapterErrorList from the list, then click OK. An AdapterErrorList1 entry appears in the Object TreeView window.

4 Move AdapterErrorList1 above AdapterGrid1 (either by dragging it or by using the upward-pointing arrow in the Object TreeView toolbar).

5 In the Object Inspector window, set the Adapter property to Adapter.

Step 2. Add error support to the form

1 In the Object TreeView for CountryForm, expand the *AdapterPageProducer* component and all its branches to show AdapterForm1.

2 Right-click on AdapterForm1 and select New Component.

3 Select AdapterErrorList from the list, then click OK. An AdapterErrorList1 entry appears in the Object TreeView window.

4 Move AdapterErrorList1 above AdapterGrid1 (either by dragging it or by using the upward-pointing arrow in the Object TreeView toolbar).

5 In the Object Inspector window, set the Adapter property to CountryTable.Adapter.

Step 3. Test the error-reporting mechanism

To test Grid Errors:

1 Run the application, and browse to the CountryTable page.

2 Start up another instance of your browser and browse to the CountryTable page.

3 Click the DeleteRow button on the first row in the grid.

4 Without refreshing the second browser, click the DeleteRow button on the first row in the grid.

5 An error message will be displayed above the grid.

To test Form Errors:

1 Run the application, and browse to the CountryTable page.

2 Click on the EditRow Button.

3 The CountryForm page is displayed.

4 Change the area field to 'abc', and click the Apply Button.

5 An error message will be displayed above the first field.

Run the completed application

To run the completed application:

1 Select Run | Run. You will see a form displayed. Web App Debugger executable Web applications are COM servers, and the form you see is the console window for the COM server. The first time that you run the project, it registers the COM object that can be accessed directly by Web App Debugger.

2 Select Tools | Web App Debugger.

3 Click on the default URL link to display the ServerInfo page. The ServerInfo page displays the names of all registered Web Application Debugger executables.

4 Select CountryTutorial in the drop-down list and click on the Go button.

Chapter

30

Working with XML documents

XML (Extensible Markup Language) is a markup language for describing structured data. It is similar to HTML, except that the tags describe the structure of information rather than its display characteristics. XML documents provide a simple, text-based way to store information so that it is easily searched or edited. They are often used as a standard, transportable format for data in Web applications, business-to-business communication, and so on.

XML documents provide a hierarchical view of a body of data. Tags in the XML document describe the role or meaning of each data element, as illustrated in the following document, which describes a collection of stock holdings:

```
<?xml version="1.0" standalone='yes' ?>
<!DOCTYPE stockholdings SYSTEM “sth.dtd”>
<StockList>
   <Stock exchange=NASDAQ>
      <name>Inprise (Borland)</name>
      <price>15.375</price>
      <symbol>INPR</symbol>
      <shares>100</shares>
   </Stock>
   <Stock exchange=NYSE>
      <name>Pfizer</name>
      <price>42.75</price>
      <symbol>PFE</symbol>
      <shares type=preferred>25</shares>
   </Stock>
</StockList>
```

This example illustrates a number of typical elements in an XML document. The first line is a processing instruction. It provides information on how to interpret the file, but does not include any data.

The second line, which begins with the <!DOCType> tag, is a document type declaration. It names the structure of the document and references another file (sth.dtd) that describes that structure. In this case, the structure is described by a

Document Type Definition (DTD) file. Other types of files that describe the structure of an XML document include Reduced XML Data (XDR) and XML schemas (XSD).

The remaining lines are organized into a hierarchy with a single root node (the <StockList> tag). Each node in this hierarchy contains either a set of child nodes, or a text value. Some of the tags (the <Stock> and <shares> tags) include attributes, which are Name=Value pairs that provide details on how to interpret the tag.

Although it is possible to work directly with the text in an XML document, typically applications use some sort of additional tools for parsing and editing the data. W3C defines a set of standard interfaces for representing a parsed XML document called the Document Object Model (DOM). A number of vendors provide XML parsers that implement the DOM interfaces to let you interpret and edit XML documents more easily.

Delphi provides a number of additional tools for working with XML documents. These tools use a DOM parser that is provided by another vendor, and make it even easier to work with XML documents. This chapter describes those tools.

Note In addition to the tools described in this chapter, Delphi comes with tools and components for converting XML documents to data packets that integrate into the Delphi database architecture. For details on tools for integrating XML documents into database applications, see Chapter 26, "Using XML in database applications."

Using the Document Object Model

The Document Object Model (DOM) is a set of standard interfaces for representing a parsed XML document. Delphi ships with two DOM implementations (from Microsoft and from IBM). In addition, it includes a registration mechanism that lets you integrate additional DOM implementations by other vendors into the Delphi XML framework.

The XMLDOM unit includes declarations for all the DOM interfaces defined in the W3C XML DOM level 2 specification. Each DOM vendor provides an implementation for these interfaces.

- To use the Microsoft implementation, include the MSXMLDOM unit in your uses clause. Because the Microsoft implementation is COM-based, you must also register the msxml.dll library as a COM server. You can use Regsvr32.exe to register this DLL.
- To use the IBM implementation, include the IBMXMLDOM unit in your uses clause.
- To use another DOM implementation, you must create a unit that includes a function to return the top-level interface (*IDOMImplementation*). Your unit should register this function by calling the global *RegisterDOMImplementation* procedure.

Some vendors supply extensions to the standard DOM interfaces. To allow you to uses these extensions, the XMLDOM unit also defines an *IDOMNodeEx* interface. *IDOMNodeEx* is a descendant of the standard *IDOMNode* that includes the most useful of these extensions.

You can work directly with the DOM interfaces to parse and edit XML documents. Simply call the *GetDOM* function to obtain an *IDOMImplementation* interface, which you can use as a starting point.

Note For detailed descriptions of the DOM interfaces, see the declarations in the XMLDOM unit, the documentation supplied by your DOM Vendor, or the specifications provided on the W3C web site (www.w3.org).

You may find it more convenient to use Delphi's XML classes rather than working directly with the DOM interfaces. These are described below.

Working with XML components

Delphi defines a number of classes and interfaces for working with XML documents. These simplify the process of loading, editing, and saving XML documents.

Using TXMLDocument

The starting point for working with an XML document is the *TXMLDocument* component. The following steps describe how to use *TXMLDocument* to work directly with an XML document:

1. Add a *TXMLDocument* component into your form or data module. *TXMLDocument* appears on the Internet page of the Component palette.
2. Set the *DOMVendor* property to specify the DOM implementation you want the component to use for parsing and editing an XML document. The Object Inspector lists all the currently registered DOM vendors. For information on DOM implementations, see "Using the Document Object Model" on page 30-2.
3. Depending on your implementation, you may want to set the *ParseOptions* property to configure how the underlying DOM implementation parses the XML document.
4. If you are working with an existing XML document, specify the document:
   - If the XML document is stored in a file, set the *FileName* property to the name of that file.
   - You can specify the XML document as a string instead by using the *XML* property.
5. Set the *Active* property to *True*.

Once you have an active *TXMLDocument* object, you can traverse the hierarchy of its nodes, reading or setting their values. The root node of this hierarchy is available as the *DocumentElement* property.

Working with XML nodes

Once an XML document has been parsed by a DOM implementation, the data it represents is available as a hierarchy of nodes. Each node corresponds to a tagged element in the document. For example, given the following XML:

```
Component palette<?xml version="1.0" standalone='yes' ?>
<!DOCTYPE stockholdings SYSTEM “sth.dtd”>
<StockList>
   <Stock exchange=NASDAQ>
      <name>Inprise (Borland)</name>
      <price>15.375</price>
      <symbol>INPR</symbol>
      <shares>100</shares>
   </Stock>
   <Stock exchange=NYSE>
      <name>Pfizer</name>
      <price>42.75</price>
      <symbol>PFE</symbol>
      <shares type=preferred>25</shares>
   </Stock>
</StockList>
```

TXMLDocument would generate a hierarchy of nodes as follows: The root of the hierarchy would be the *StockList* node. *StockList* would have two child nodes, which correspond to the two *Stock* tags. Each of these two child nodes would have four child nodes of its own (*name*, *price*, *symbol*, and *shares*). Those four child nodes would act as leaf nodes. The text they contain would appear as the value of each of the leaf nodes.

Note This division into nodes differs slightly from the way a DOM implementation generates nodes for an XML document. In particular, a DOM parser treats all tagged elements as internal nodes. Additional nodes (of type text node) would be created for the values of the *name*, *price*, *symbol*, and *shares* nodes. These text nodes would then appear as the children of the *name*, *price*, *symbol*, and *shares* nodes.

Each node is accessed through an *IXMLNode* interface, starting with the root node, which is the value of the XML document component’s *DocumentElement* property.

Working with a node’s value

Given an *IXMLNode* interface, you can check whether it represents an internal node or a leaf node by checking the *IsTextElement* property.

- If it represents a leaf node, you can read or set its value using the *Text* property.
- If it represents an internal node, you can access its child nodes using the *ChildNodes* property.

Thus, for example, using the XML document above, you can read the price of Inprise’s stock as follows:

```
InpriseStock := XMLDocument1.DocumentElement.ChildNodes[0];
Price := InpriseStock.ChildNodes['price'].Text;
```

Working with a node's attributes

If the node includes any attributes, you can work with them using the *Attributes* property. You can read or change an attribute value by specifying an existing attribute name. You can add new attributes by specifying a new attribute name when you set the *Attributes* property:

```
InpriseStock := XMLDocument1.DocumentElement.ChildNodes[0];
InpriseStock.ChildNodes['shares'].Attributes['type'] := 'common';
```

Adding and deleting child nodes

You can add child nodes using the *AddChild* method. *AddChild* creates new nodes that correspond to tagged elements in the XML document. Such nodes are called element nodes.

To create a new element node, specify the name that appears in the new tag and, optionally, the position where the new node should appear. For example, the following code adds a new stock listing to the document above:

```
var
  NewStock: IXMLNode;
  ValueNode: IXMLNode;
begin
  NewStock := XMLDocument1.DocumentElement.AddChild('stock');
  NewStock.Attributes['exchange'] := 'NASDAQ';
  ValueNode := NewStock.AddChild('name');
  ValueNode.Text := 'Cisco Systems'
  ValueNode := NewStock.AddChild('price');
  ValueNode.Text := '62.375';
  ValueNode := NewStock.AddChild('symbol');
  ValueNode.Text := 'CSCO';
  ValueNode := NewStock.AddChild('shares');
  ValueNode.Text := '25';
end;
```

An overloaded version of *AddChild* lets you specify the namespace in which the tag name is defined.

You can delete child nodes using the methods of the *ChildNodes* property. *ChildNodes* is an *IXMLNodeList* interface, which manages the children of a node. You can use its *Delete* method to delete a single child node that is identified by position or by name. For example, the following code deletes the last stock listed in the document above:

```
StockList := XMLDocument1.DocumentElement;
StockList.ChildNodes.Delete(StockList.ChildNodes.Count - 1);
```

Abstracting XML documents with the Data Binding wizard

Although it is possible to work with an XML document using only the *TXMLDocument* component and the *IXMLNode* interface it surfaces for the nodes in that document, or even to work exclusively with the DOM interfaces (avoiding even *TXMLDocument*), you can write code that is much simpler and more readable by using the XML Data Binding wizard.

The Data Binding wizard takes an XML schema or data file and generates a set of interfaces that map on top of it. For example, given XML data that looks like the following:

```
<customer id=1>
  <name>Mark</name>
  <phone>(831) 431-1000</phone>
</customer>
```

The Data Binding wizard generates the following interface (along with a class to implement it):

```
ICustomer = interface(IXMLNode)
  property id: Integer read Getid write Setid;
  property name: DOMString read Getname write Setname;
  property phone: DOMString read Getphone write Setphone;
  function Getid: Integer;
  function Getname: DOMString;
  function Getphone: DOMString;
  procedure Setid(Value: Integer);
  procedure Setname(Value: DOMString);
  procedure Setphone(Value: DOMString);
end;
```

Every child node is mapped to a property whose name matches the tag name of the child node and whose value is the interface of the child node (if the child is an internal node) or the value of the child node (for leaf nodes). Every node attribute is also mapped to a property, where the property name is the attribute name and the property value is the attribute value.

In addition to creating interfaces (and implementation classes) for each tagged element in the XML document, the wizard creates a global function for obtaining the interface to the root node. For example, if the XML above came from a document whose root node had the tag <Customers>, the Data Binding wizard would create the following global routine:

```
function GetCustomers(XMLDoc: TXMLDocument): ICustomers;
```

Using the generated interfaces simplifies your code, because they reflect the structure of the XML document more directly. For example, instead of writing code such as the following:

```
CustName := XMLDocument1.DocumentElement.ChildNodes[0].ChildNodes['name'].Value;
```

Your code would look as follows:

```
CustName := GetCustomers(XMLDocument1)[0].Name;
```

Note that the interfaces generated by the Data Binding wizard all descend from *IXMLNode*. This means you can still add and delete child nodes in the same way as when you do not use the Data Binding wizard. (See “Adding and deleting child nodes” on page 30-5.) In addition, when child nodes represent repeating elements (when all of the children of a node are of the same type), the parent node is given two methods, *Add*, and *Insert*, for adding additional repeats. These methods are simpler than using *AddChild*, because you do not need to specify the type of node to create.

Using the XML Data Binding wizard

To use the Data Binding wizard,

1 Choose File | New | Other and select the icon labeled XML Data Binding from the bottom of the New page.

2 The XML Data Binding wizard appears.

3 On the first page of the wizard

- specify the XML document or schema for which you want to generate interfaces. This can be a sample XML document, a Document Type Definition (.dtd) file, a Reduced XML Data (.xdr) file, or an XML schema (.xsd) file.

4 Click the Options button to specify the naming strategies you want the wizard to use when generating interfaces and implementation classes and the default mapping of types defined in the schema to Pascal data types.

5 Move to the second page of the wizard. This page lets you provide detailed information about every node type in the document or schema. At the left is a tree view that shows all of the node types in the document. For complex nodes (nodes that have children), the tree view can be expanded to display the child elements. When you select a node in this tree view, the right-hand side of the dialog displays information about that node and lets you specify how you want the wizard to treat that node.

- The Source Name control displays the name of the node type in the XML schema.
- The Source Type control displays the type of the node's value, as specified in the XML schema.
- The Documentation control lets you add comments to the schema describing the use or purpose of the node.
- If the wizard generates code for the selected node (that is, if it is a complex type for which the wizard generates an interface and implementation class, or if it is one of the child elements of a complex type for which the wizard generates a property on the complex type's interface), you can use the Generate Binding check box to specify whether you want the wizard to generate code for the node. If you uncheck Generate Binding, the wizard does not generate the interface or implementation class for a complex type, or does not create a property in the parent interface for a child element or attribute.
- The Binding Options section lets you influence the code that the wizard generates for the selected element. For any node, you can specify the Identifier Name (the name of the generated interface or property). In addition, for interfaces, you must indicate which one represents the root node of the document. For nodes that represent properties, you can specify the type of the property and, if the property is not an interface, whether it is a read-only property.

6 Once you have specified what code you want the wizard to generate for each node, move to the third page. This page lets you choose some global options about how the wizard generates its code and lets you preview the code that will be generated, and lets you tell the wizard how to save your choices for future use.

- To preview the code the wizard generates, select an interface in the Binding Summary list and view the resulting interface definition in the Code Preview control.
- Use the Data Binding Settings to indicate how the wizard should save your choices. You can store the settings as annotations in a schema file that is associated with the document (the schema file specified on the first page of the dialog), or you can name an independent schema file that is used only by the wizard.

7 When you click Finish, the Data Binding wizard generates a new unit that defines interfaces and implementation classes for all of the node types in your XML document. In addition, it creates a global function that takes a *TXMLDocument* object and returns the interface for the root node of the data hierarchy.

Using code that the XML Data Binding wizard generates

Once the wizard has generated a set of interfaces and implementation classes, you can use them to work with XML documents that match the structure of the document or schema you supplied to the wizard. Just as when you are using only the built-in XML components that ship with Delphi, your starting point is the *TXMLDocument* component that appears on the Internet page of the Component palette.

To work with an XML document, use the following steps:

1 Place a *TXMLDocument* component in your form or data module.

2 Bind the *TXMLDocument* to an XML document by setting the *FileName* property. (As an alternative approach, you can use a string of XML by setting the *XML* property at runtime.)

3 In your code, call the global function that the wizard created to obtain an interface for the root node of the XML document. For example, if the root element of the XML document was the tag <StockList>, by default, the wizard generates a function *GetStockListType*, which returns an *IStockListType* interface:

```
var
  StockList: IStockListType;
begin
  StockList := GetStockListType(XMLDocument1);
```

4 This interface has properties that correspond to the subnodes of the document's root element, as well as properties that correspond to that root element's attributes. You can use these to traverse the hierarchy of the XML document, modify the data in the document, and so on.

5 To save any changes you make using the interfaces generated by the wizard, call the *TXMLDocument* component's *SaveToFile* method or read its *XML* property.

Chapter 31

Using Web Services

Web Services are self-contained modular applications that can be published and invoked over a network (such as the World Wide Web). Web Services provide well-defined interfaces that describe the services provided.

Web Services are designed to allow a loose coupling between client and server. That is, server implementations do not require clients to use a specific platform or programming language. In addition to defining interfaces in a language-neutral fashion, they are designed to allow multiple communications mechanisms as well.

Delphi's support for Web Services is designed to work using SOAP (Simple Object Access Protocol). SOAP is a standard lightweight protocol for exchanging information in a decentralized, distributed environment. It uses XML to encode remote procedure calls and typically uses HTTP as a communications protocol. For more information about SOAP, see the SOAP specification available at

```
http://www.w3.org/TR/SOAP/
```

Note Although Delphi's support for Web Services is based on SOAP and HTTP, the framework is sufficiently general that it can be expanded to use other encoding and communications protocols.

Delphi's SOAP-based technology is available on Windows and will later be implemented on Linux, so that it can form the basis of cross-platform distributed applications. There is no special client runtime software to install, as you must have when distributing applications using CORBA. Because this technology is based on HTTP messages, it has the advantage that it is widely available on a variety of machines. Support for Web Services is built on top of Delphi's cross-platform Web server application architecture.

You can use Delphi to build both servers that implement Web Services and clients that call on those services. If you use Delphi to create both the server and client applications, you can share a single unit that defines the interfaces for the Web Services. In addition, you can write Delphi clients for arbitrary servers that implement Web Services that respond to SOAP messages, and Delphi servers that publish Web Services that can be used by arbitrary clients.

When either the client or server is not written using Delphi, you can publish or import information on what interfaces are available and how to call them using a WSDL (Web Service Definition Language) document. On the server side, your application can publish a WSDL document that describes your Web Service. On the client side, a wizard can import a published WSDL document, providing you with the interface definitions and connection information you need.

Writing Servers that support Web Services

In Delphi, servers that support Web Services are built using invokable interfaces. Invokable interfaces are interfaces that are compiled to include runtime type information (RTTI). This RTTI is used when interpreting incoming method calls from clients so that they can be correctly marshaled.

In addition to the invokable interfaces, and the classes that implement them, your server requires two components: a dispatcher and an invoker. The dispatcher (*THTTPSoapDispatcher*) is an auto-dispatching component that receives incoming SOAP messages and passes them on to the invoker. The invoker (*THTTPSoapPascalInvoker*) interprets the SOAP message, identifies the invokable interface it calls, executes the call and assembles the response message.

Note *THTTPSoapDispatcher* and *THTTPSoapPascalInvoker* are designed to respond to HTTP messages containing a SOAP request. The underlying architecture is sufficiently general, however, that it can support other protocols with the substitution of different dispatcher and invoker components.

Once you register your invokable interfaces and their implementation classes, the dispatcher and invoker automatically handle any messages that identify those interfaces in the SOAP Action header of the HTTP request message.

Building a Web Service server

Use the following steps to build a server application that implements a Web Service:

1. Define the interfaces that make up your Web Service. These interface definitions must be invokable interfaces. It is a good idea to create your interface definitions in their own units, separate from the unit that contains the implementation classes. In this way, the unit that defines the interfaces can be included in both the server and client applications. In the initialization section of this unit, add code to register the interfaces. For details on writing and registering invokable interfaces, see “Defining invokable interfaces” on page 31-3.
2. If your interface uses any complex (non-scalar) types, you must make sure these can be marshalled correctly. The Web Service application can only handle these using special objects that contain runtime type information (RTTI) that describes their structure. For details on creating and registering objects to represent complex types, see “Using complex types in invokable interfaces” on page 31-5.

3 Define and implement classes that implement the invokable interfaces you defined in step 1. For each implementation class, you may also need to create a factory procedure that instantiates the class. In the initialization section of this unit, add code to register the implementation class. This process is described in “Creating and registering the implementation” on page 31-6.

4 If your application raises an exception when attempting to execute a SOAP request, the exception will be automatically encoded in a SOAP fault packet, which is returned instead of the results of the method call. If you want to convey more information than a simple error message, you can create your own exception classes that are encoded and passed to the client. This is described in “Creating custom exception classes for Web Services” on page 31-7.

5 Choose File | New | Other, and on the Web Services page, double-click the Web Service application icon. Choose the type of Web server application you want to have implement your Web Service. For information about different types of Web Server applications, see “Types of Web server applications” on page 27-6.

6 The wizard generates a new Web Service application that includes an invoker component (*THTTPSOAPPascalInvoker*) and a dispatcher component (*THTTPSoapDispatcher*). The invoker converts between SOAP messages and the methods of any interfaces you registered in step 1. The dispatcher automatically responds to incoming SOAP messages and forwards them to the invoker. You can use its *WebDispatch* property to identify the HTTP request messages to which your application responds. This involves setting the *PathInfo* property to indicate the path portion of any URL directed to your application, and the *MethodType* property to indicate the method header for request messages.

7 Choose Project | Add To Project, and add the units you created in steps 1 through 4 to your Web server application.

8 If you want your application to work with clients that are not written using Delphi, publish a WSDL document that defines your interfaces and how to call them. For details on how to generate a WSDL document that describes your Web Service application, see “Generating WSDL documents for a Web Service application” on page 31-7.

Defining invokable interfaces

To create an invokable interface, you need only compile an interface with the {$M+} compiler option. The descendant of any invokable interface is also invokable. However, if an invokable interface descends from another interface that is not invokable, clients of your Web Service server can only call the methods defined in the invokable interface and its descendants. Methods inherited from the non-invokable ancestors are not compiled with type information and so can’t be called by clients.

Delphi defines a base invokable interface, *IInvokable*, that can be used as the basis of any interface exposed to clients by a Web Service server. *IInvokable* is the same as the base interface (*IInterface*), except that it is compiled using the {$M+} compiler option so that it and all its descendants are compiled to include RTTI.

For example, the following code defines an invokable interface that contains two methods for encoding and decoding numeric values:

```
IEncodeDecode = interface(IInvokable)
  ['{C527B88F-3F8E-1134-80e0-01A04F57B270}']
    function EncodeValue(Value: Integer): Double; stdcall;
    function DecodeValue(Value: Double): Integer; stdcall;
end;
```

Before a Web Service application can use this invokable interface, it must be registered with the invocation registry. On the server, the invocation registry entry allows the invoker component (*THTTPSOAPPascalInvoker*) to identify an implementation class to use for executing interface calls. On client applications, an invocation registry entry allows components to look up information that identifies the invokable interface and supplies information on how to call it.

In the initialization section of the unit that defines the interface, add code to register the interface with the invocation registry. To access the invocation registry, add the InvokeRegistry unit to the uses clause of your unit. The InvokeRegistry unit declares a global variable, *InvRegistry*, which maintains in memory a catalog of all registered invokable interfaces, their implementation classes, and the factories that create instances of the implementation classes.

When you are finished, the unit that defines the interface should look something like the following:

```
unit EncodeDecode;

interface
type

IEncodeDecode = interface(IInvokable)
  ['{C527B88F-3F8E-1134-80e0-01A04F57B270}']
    function EncodeValue(Value: Integer): Double; stdcall;
    function DecodeValue(Value: Double): Integer; stdcall;
end;

implementation
uses  InvokeRegistry;

initialization
InvRegistry.RegisterInterface(TypeInfo(IEncodeDecode));
end.
```

Because the interfaces of Web Services must have a namespace to identify them among all the interfaces in all possible Web Services, when you register an interface the invocation registry automatically generates a namespace for the interface. The default namespace is built from a string that uniquely identifies the application (the *AppNamespacePrefix* variable), the interface name, and the name of the unit in which it is defined.

Tip It is a good idea to keep the unit that defines your invokable interfaces separate from the unit in which you write the classes that implement them. This unit can then be included in both the client and the server application. Because the generated namespace includes the name of the unit in which the interface is defined, sharing the same unit in both client and server applications enables them to automatically use the same namespace.

Using complex types in invokable interfaces

The invoker component (*THTTPSOAPPascalInvoker*) automatically knows how to marshal scalar types on invokable interfaces. It can also handle dynamic arrays, as long as they are registered with the remotable class registry (see below). However, you must provide additional support if you want to transmit data in more complex types such as static arrays, interfaces, records, sets, or classes. This support must take the form of a class that includes runtime type information (RTTI), which the invoker can use to convert between data in the SOAP stream and type values.

Use *TRemotable* as a base class when defining a class to represent a complex data type on an invokable interface. For example, in the case where you would ordinarily pass a record as a parameter, you would instead define a *TRemotable* descendant where every member of the record is a published property on your new class.

If the value of your new *TRemotable* descendant represents to a scalar type in a WSDL document that does not correspond to an Object Pascal scalar type, you should use *TRemotableXS* as a base class instead. *TRemotableXS* is a *TRemotable* descendant that introduces two methods for converting between your new class and its string representation. Provide these methods by overriding the *XSToNative* and *NativeToXS* methods.

In the initialization section of the unit that defines the *TRemotable* descendant, you must register this class with the remotable class registry. Access the remotable class registry by adding the InvokeRegistry unit to the uses clause. This unit declares a global variable, *RemClassRegistry*, which maintains a catalog of all registered remotable classes, and an indication of whether their values can be transmitted as strings. For example, the following line comes from the XSBuiltIns unit. It registers *TXSDateTime*, a *TRemotable* descendant that represents *TDateTime* values:

```
RemClassRegistry.RegisterXSClass(TXSDateTime, XMLSchemaNameSpace, 'dateTime', True);
```

The first parameter is the name of the *TRemotable* descendant. The second is a uniform resource identifier (URI) that uniquely identifies the namespace of the new class. If you supply an empty string, the registry can generate a URI for you. The third parameter is the name of the data type your class represents. If you supply an empty string, the registry simply uses the class name. The last parameter indicates whether the value of class instances can be transmitted as a string (whether you implemented the *XSToNative* and *NativeToXS* methods).

Tip It is a good idea to implement and register *TRemotable* descendants in a separate unit from the rest of your server application, including from the units that declare and register invokable interfaces. In this way, you can use the unit that defines your type in both the client and server, and you can use the type for more than one interface.

If you are using dynamic arrays for parameters, you do not need to create a remotable class to represent them, but you do have to register them with the remotable class registry. Thus, for example, if your interface uses a type such as the following:

```
type
  TDateTimeArray = array of TXSDateTime;
```

You must add the following registration to the initialization section of the unit where you declare this dynamic array:

```
RemClassRegistry.RegisterXSInfo(TypeInfo(TDateTimeArray), MyNameSpace, ‘DTarray’, False);
```

The parameters are the same as those used by *RegisterXSClass*, except for the first which takes a pointer to the type information of the dynamic array rather than a class reference.

Creating and registering the implementation

The simplest way to write an implementation for an invokable interface is to create a class that descends from *TInvokableClass*. Add the class declaration, including the invokable interfaces you are supporting, and then type *Ctrl+Shift+C* to invoke class completion. The interface members appear in your class declaration, and empty methods appear in the implementation section of the unit.

For example, the declaration for an implementation class implement the interface declared in "Defining invokable interfaces" above might look like the following:

```
TEncodeDecode = class(TInvokableClass, IEncodeDecode)
protected
  function EncodeValue(Value: Integer): Double; stdcall;
  function DecodeValue(Value: Double): Integer; stdcall;
end;
```

In the implementation section of the unit that declares this class, fill in the *EncodeValue* and *DecodeValue* methods.

Once you have created an implementation class, you must register this class with the invocation registry. The invocation registry uses this to identify the class that implements a registered interface and to make it available to the invoker component when the invoker needs to call the interface. To register the implementation class, add a call the *RegisterInvokableClass* method of the global *InvRegistry* variable to the initialization section of your implementation unit:

```
InvRegistry.RegisterInvokableClass(TEncodeDecode);
```

You can also create implementation classes that do not descend from *TInvokableClass*. In this case, however, you must provide a factory procedure that the invocation registry can call to create instances of your class.

The factory procedure must be of type *TCreateInstanceProc*. It returns an instance of your implementation class. If the procedure creates a new instance, the object should free itself when the reference count on its interface drops to zero, as the invocation registry does not explicitly free object instances. As an alternative, the factory procedure can return a reference to a global instance that is shared by all callers. The following code illustrates this latter approach:

```
procedure CreateEncodeDecode(out obj: TObject);
begin
  if FEncodeDecode = nil then
  begin
    FEncodeDecode := TEncodeDecode.Create;
    {save a reference to the interface so that the global instance doesn't free itself }
    FEncodeDecodeInterface := FEncodeDecode as IEncodeDecode;
  end;
  obj := FEncodeDecode; { return global instance }
end;
```

When using a factory procedure, supply the factory procedure as a second parameter to the *RegisterInvokableClass* method:

```
InvRegistry.RegisterInvokableClass(TEncodeDecode, CreateEncodeDecode);
```

Creating custom exception classes for Web Services

When your Web Service application raises an exception in the course of trying to execute a SOAP request, it automatically encodes information about that exception in a SOAP fault packet, which it returns instead of the results of the method call. The client application then raises the exception.

By default, the client application merely raises a generic exception (*Exception*) with the error message in the SOAP fault packet. However, you can transmit additional exception information by using an exception class that descends from *ERemotableException*. The values of any published properties you add to your exception class are included in the SOAP fault packet so that the client can raise an equivalent exception.

To use an *ERemotableException* descendant, you must register it with the remotable class registry. Thus, in the unit that defines your *ERemotableException* descendant, you must add the InvokeRegistry unit to the uses clause and add a call to the *RegisterXSClass* method of the global *RemClassRegistry* variable.

If the client uses the same unit that defines and registers your *ERemotableException* descendant, then when it receives the SOAP fault packet, it automatically raises an instance of the appropriate exception class, with all properties set to the values in the SOAP fault packet.

Generating WSDL documents for a Web Service application

If you include the same units that define and register your invokable interfaces, the classes that represent complex type information, and your remotable exceptions in a Delphi client application, it can generate calls to use your Web Service. All you need to do is supply the URL where you install your Web Service application.

However, you may want to make your Web Service available to a wider range of clients. For example, you may have clients that are not written in Delphi. If you are deploying several versions of your server application, you may not want to use a single hard-coded URL for the server, but rather let the client look up the server location dynamically. For these cases, you may want to publish a WSDL document that describes the types and interfaces in your Web Service, with information on how to call them.

To publish a WSDL document that describes your Web Service, simply add a *TWSDLHTMLPublish* component to your Web Module. *TWSDLHTMLPublish* is an auto-dispatching component, which means it automatically responds to incoming messages that request a list of WSDL documents for your Web Service. Use the *WebDispatch* property to specify the path information of the URL clients must use to access the list of WSDL documents. The Web browser can then request the list of WSDL documents by specifying an URL that is made up of the location of the server application followed by the path in the WebDispatch property. This URL looks something like the following:

```
http://www.myco.com/MyService.dll/WSDL
```

Tip If you want a physical WSDL file instead, you can display the WSDL document in your Web browser and then save it to generate a WSDL document file.

It is not necessary to publish the WSDL document from the same application that implements your Web Service. To create an application that simply publishes the WSDL document, omit the units that contain the implementation objects, and only include the units that define and register invokable interfaces, remotable classes that represent complex types, and any remotable exceptions.

By default, when you publish a WSDL document, it indicates that the services are available at the same URL as the one where you published the WSDL document (but with a different path). If you are deploying multiple versions of your Web Service application, or if you are publishing the WSDL document from a different application than the one that implements the Web Service, you will need to change the WSDL document so that includes updated information on where to locate the Web Service.

To change the URL, use the WSDL administrator. The first step is to enable the administrator. You do this by setting the *AdminEnabled* property of the *TWSDLHTMLPublish* component to *True*. Then, when you use your browser to display the list of WSDL documents, it includes a button to administer them as well. Use the WSDL administrator to specify the locations (URLs) where you have deployed your Web Service application.

Writing clients for Web Services

Delphi provides client-side support for calling Web Services that use a SOAP-based binding. These Web Services can be supplied by a server written in Delphi, or by any other server that defines its Web Service in a WSDL document.

If the server is not written in Delphi, you can first import the WSDL document that describes the server. This process is described below. If the server was written using Delphi, you do not need to use a WSDL document: you can simply add any units that define the invokable interfaces you want to use to your project, as well as any units that define remotable classes that represent complex types and that define remotable exceptions that the Web Service application can raise.

Note For information about creating the unit that defines an invokable interface in a Delphi Web Service server, see “Defining invokable interfaces” on page 31-3. For information about creating a unit that defines a remotable class for a complex type, see “Using complex types in invokable interfaces” on page 31-5. For information about creating a unit that defines a remotable exception, see “Creating custom exception classes for Web Services” on page 31-7.

Importing WSDL documents

Before you can use a Web Service that was not written using Delphi, you must import a WSDL document (or XML schema file) that defines the service. The Web Services importer creates a unit that defines and registers the interfaces and types you need to use.

To use the Web Services importer, choose File | New | Other, and on the WebServices page double-click the icon labelled Web Services importer. In the dialog that appears, specify the file name of a WSDL document (or XML schema file) or provide the URL where that document is published. When you click Generate, the importer creates new units that define and register invokable interfaces for the operations defined in the document, and that define and register remotable classes for the types that the document defines.

If the WSDL document or XML schema file uses identifiers that are also Object Pascal keywords, the importer automatically adjusts their names so that the generated code can compile. When complex types are declared inline, the importer adds code to define and register the corresponding remotable class in the same unit as the invokable interface that uses them. Otherwise, types are defined and registered in a separate unit.

Calling invokable interfaces

To call an invokable interface, your client application must include any units that define the invokable interfaces and any remotable classes that implement complex types. If the server is written in Delphi, these should be the same units that the server application uses to define and register these interfaces and classes. It is best to use the same unit, because when you register an invokable interface or remotable class, it is given a uniform resource identifier (URI) that uniquely identifies it. That URI is derived from the name of the interface (or class) and the name of the unit in which it is defined. If the client and server do not register the interface (or class) using the same URI, they can’t communicate. If you do not use the same unit, the code that registers the interface and implementation class must explicitly specify a namespace URI to ensure that client and server use the same namespace.

If the server is not written in Delphi, or if you do not want to use the same unit in the client that you used in the server, these units can be created by the Web Services importer.

Once the client application has the declaration of an invokable interface, create an instance of *THTTPRio* for the desired interface:

```
X := THTTPRio.Create(nil);
```

Next, provide the *THTTPRio* object with the information it needs to identify the server interface and locate the server. There are two ways to supply this information:

- If the server is written in Delphi, the identification of the interface on the server is handled automatically, based on the URI that is generated for it when the interface is registered. You need only set the *URL* property to indicate the location of the server. The path portion of this URL should match the path of the dispatcher component in the server’s Web Module:

  ```
  X.URL := 'http://www.myco.com/MyService.dll/SOAP/';
  ```

- If the server is not written in Delphi, *THTTPRio* must look up the URI for the interface, the information that must be included in the Soap Action header, and the location of the server from a WSDL document. You tell it how to do this using the *WSDLLocation*, *Service*, and *Port* properties:

  ```
  X.WSDLLocation := 'Cryptography.wsdl';
  X.Service := 'Cryptography';
  X.Port := 'SoapEncodeDecode';
  ```

You can then use the **as** operator to cast the instance of *THTTPRio* to the invokable interface. When you do this, it creates a vtable for the associated interface dynamically in memory, enabling you to make interface calls:

```
InterfaceVariable := X as IEncodeDecode;
Code := InterfaceVariable.EncodeValue(5);
```

THTTPRio relies on the invocation registry to obtain information about the invokable interface. If the client application does not have an invocation registry, or if the invokable interface is not registered, *THTTPRio* can’t build its in-memory vtable.

Chapter

32

Working with sockets

This chapter describes the socket components that let you create an application that can communicate with other systems using TCP/IP and related protocols. Using sockets, you can read and write over connections to other machines without worrying about the details of the underlying networking software. Sockets provide connections based on the TCP/IP protocol, but are sufficiently general to work with related protocols such as User Datagram Protocol (UDP), Xerox Network System (XNS), Digital's DECnet, or Novell's IPX/SPX family.

Using sockets, you can write network servers or client applications that read from and write to other systems. A server or client application is usually dedicated to a single service such as Hypertext Transfer Protocol (HTTP) or File Transfer Protocol (FTP). Using server sockets, an application that provides one of these services can link to client applications that want to use that service. Client sockets allow an application that uses one of these services to link to server applications that provide the service.

Implementing services

Sockets provide one of the pieces you need to write network servers or client applications. For many services, such as HTTP or FTP, third party servers are readily available. Some are even bundled with the operating system, so that there is no need to write one yourself. However, when you want more control over the way the service is implemented, a tighter integration between your application and the network communication, or when no server is available for the particular service you need, then you may want to create your own server or client application. For example, when working with distributed data sets, you may want to write a layer to communicate with databases on other systems.

Understanding service protocols

Before you can write a network server or client, you must understand the service that your application is providing or using. Many services have standard protocols that your network application must support. If you are writing a network application for a standard service such as HTTP, FTP, or even finger or time, you must first understand the protocols used to communicate with other systems. See the documentation on the particular service you are providing or using.

If you are providing a new service for an application that communicates with other systems, the first step is designing the communication protocol for the servers and clients of this service. What messages are sent? How are these messages coordinated? How is the information encoded?

Communicating with applications

Often, your network server or client application provides a layer between the networking software and an application that uses the service. For example, an HTTP server sits between the Internet and a Web server application that provides content and responds to HTTP request messages.

Sockets provide the interface between your network server or client application and the networking software. You must provide the interface between your application and the clients that use it. You can copy the API of a standard third party server (such as Apache), or you can design and publish your own API.

Services and ports

Most standard services are associated, by convention, with specific port numbers. We will discuss port numbers in greater detail later. For now, consider the port number a numeric code for the service.

If you are implementing a standard service, Linux socket objects provide methods for you to look up the port number for the service. If you are providing a new service, you can specify the associated port number in the /etc/services file. See your Linux documentation for more information on the services file.

Types of socket connections

Socket connections can be divided into three basic types, which reflect how the connection was initiated and what the local socket is connected to. These are

- Client connections.
- Listening connections.
- Server connections.

Once the connection to a client socket is completed, the server connection is indistinguishable from a client connection. Both end points have the same capabilities and receive the same types of events. Only the listening connection is fundamentally different, as it has only a single endpoint.

Client connections

Client connections connect a client socket on the local system to a server socket on a remote system. Client connections are initiated by the client socket. First, the client socket must describe the server socket to which it wishes to connect. The client socket then looks up the server socket and, when it locates the server, requests a connection. The server socket may not complete the connection right away. Server sockets maintain a queue of client requests, and complete connections as they find time. When the server socket accepts the client connection, it sends the client socket a full description of the server socket to which it is connecting, and the connection is completed by the client.

Listening connections

Server sockets do not locate clients. Instead, they form passive “half connections” that listen for client requests. Server sockets associate a queue with their listening connections; the queue records client connection requests as they come in. When the server socket accepts a client connection request, it forms a new socket to connect to the client, so that the listening connection can remain open to accept other client requests.

Server connections

Server connections are formed by server sockets when a listening socket accepts a client request. A description of the server socket that completes the connection to the client is sent to the client when the server accepts the connection. The connection is established when the client socket receives this description and completes the connection.

Describing sockets

Sockets let your network application communicate with other systems over the network. Each socket can be viewed as an endpoint in a network connection. It has an address that specifies

- The system on which it is running.
- The types of interfaces it understands.
- The port it is using for the connection.

A full description of a socket connection includes the addresses of the sockets on both ends of the connection. You can describe the address of each socket endpoint by supplying both the IP address or host and the port number.

Before you can make a socket connection, you must fully describe the sockets that form its endpoints. Some of the information is available from the system your application is running on. For instance, you do not need to describe the local IP address of a client socket—this information is available from the operating system.

The information you must provide depends on the type of socket you are working with. Client sockets must describe the server they want to connect to. Listening server sockets must describe the port that represents the service they provide.

Describing the host

The host is the system that is running the application that contains the socket. You can describe the host for a socket by giving its IP address, which is a string of four numeric (byte) values in the standard Internet dot notation, such as

```
123.197.1.2
```

A single system may support more than one IP address.

IP addresses are often difficult to remember and easy to mistype. An alternative is to use the host name. Host names are aliases for the IP address that you often see in Uniform Resource Locators (URLs). They are strings containing a domain name and service, such as

```
http://www.ASite.com
```

Most Intranets provide host names for the IP addresses of systems on the Internet. You can learn the host name associated with any IP address (if one already exists) by executing the following command from a command prompt:

```
nslookup IPADDRESS
```

where *IPADDRESS* is the IP address you're interested in. If your local IP address doesn't have a host name and you decide you want one, contact your network administrator.

Server sockets do not need to specify a host. The local IP address can be read from the system. If the local system supports more than one IP address, server sockets will listen for client requests on all IP addresses simultaneously. When a server socket accepts a connection, the client socket provides the remote IP address.

Client sockets must specify the remote host by providing either its host name or IP address.

Choosing between a host name and an IP address

Most applications use the host name to specify a system. Host names are easier to remember, and easier to check for typographical errors. Further, servers can change the system or IP address that is associated with a particular host name. Using a host name allows the client socket to find the abstract site represented by the host name, even when it has moved to a new IP address.

If the host name is unknown, the client socket must specify the server system using its IP address. Specifying the server system by giving the IP address is faster. When you provide the host name, the socket must search for the IP address associated with the host name, before it can locate the server system.

Using ports

While the IP address provides enough information to find the system on the other end of a socket connection, you also need a port number on that system. Without port numbers, a system could only form a single connection at a time. Port numbers are unique identifiers that enable a single system to host multiple connections simultaneously, by giving each connection a separate port number.

Earlier, we described port numbers as numeric codes for the services implemented by network applications. This is actually just a convention that allows listening server connections to make themselves available on a fixed port number so that they can be found by client sockets. Server sockets listen on the port number associated with the service they provide. When they accept a connection to a client socket, they create a separate socket connection that uses a different, arbitrary, port number. This way, the listening connection can continue to listen on the port number associated with the service.

Client sockets use an arbitrary local port number, as there is no need for them to be found by other sockets. They specify the port number of the server socket to which they want to connect so that they can find the server application. Often, this port number is specified indirectly, by naming the desired service.

Using socket components

The Internet palette page includes three socket components that allow your network application to form connections to other machines, and that allow you to read and write information over that connection. These are:

- *TcpServer*
- *TcpClient*
- *UdpSocket*

Associated with each of these socket components are socket objects, which represent the endpoint of an actual socket connection. The socket components use the socket objects to encapsulate the socket server calls, so that your application does not need to be concerned with the details of establishing the connection or managing the socket messages.

If you want to customize the details of the connections that the socket components make on your behalf, you can use the properties, events, and methods of the socket objects.

Getting information about the connection

After completing the connection to a client or server socket, you can use the client or server socket object associated with your socket component to obtain information about the connection. Use the *LocalHost* and *LocalPort* properties to determine the address and port number used by the local client or server socket, or use the *RemoteHost* and *RemotePort* properties to determine the address and port number used by the remote client or server socket. Use the *GetSocketAddr* method to build a valid socket address based on the host name and port number. You can use the *LookupPort* method to look up the port number. Use the *LookupProtocol* method to look up the protocol number. Use the *LookupHostName* method to look up the host name based on the host machine's IP address.

To view network traffic in and out of the socket, use the *BytesSent* and *BytesReceived* properties.

Using client sockets

Add a *TcpClient* or *UdpSocket* component to your form or data module to turn your application into a TCP/IP or UDP client. Client sockets allow you to specify the server socket you want to connect to, and the service you want that server to provide. Once you have described the desired connection, you can use the client socket component to complete the connection to the server.

Each client socket component uses a single client socket object to represent the client endpoint in a connection.

Specifying the desired server

Client socket components have a number of properties that allow you to specify the server system and port to which you want to connect. Use the *RemoteHost* property to specify the remote host server by either its host name or IP address.

In addition to the server system, you must specify the port on the server system that your client socket will connect to. You can use the *RemotePort* property to specify the server port number directly or indirectly by naming the target service.

Forming the connection

Once you have set the properties of your client socket component to describe the server you want to connect to, you can form the connection at runtime by calling the *Open* method. If you want your application to form the connection automatically when it starts up, set the *Active* property to *True* at design time, using the Object Inspector.

Getting information about the connection

After completing the connection to a server socket, you can use the client socket object associated with your client socket component to obtain information about the connection. Use the *LocalHost* and *LocalPort* properties to determine the address and port number used by the client and server sockets to form the end points of the connection. You can use the *Handle* property to obtain a handle to the socket connection to use when making socket calls.

Closing the connection

When you have finished communicating with a server application over the socket connection, you can shut down the connection by calling the *Close* method. The connection may also be closed from the server end. If that is the case, you will receive notification in an *OnDisconnect* event.

Using server sockets

Add a server socket component (*TcpServer* or *UdpSocket*) to your form or data module to turn your application into an IP server. Server sockets allow you to specify the service you are providing or the port you want to use to listen for client requests. You can use the server socket component to listen for and accept client connection requests.

Each server socket component uses a single server socket object to represent the server endpoint in a listening connection. It also uses a server client socket object for the server endpoint of each active connection to a client socket that the server accepts.

Specifying the port

Before your server socket can listen to client requests, you must specify the port that your server will listen on. You can specify this port using the *LocalPort* property. If your server application is providing a standard service that is associated by convention with a specific port number, you can also specify the service name using the *LocalPort* property. It is a good idea to use the service name instead of a port number, because it is easy to introduce typographical errors when specifying the port number.

Listening for client requests

Once you have set the port number of your server socket component, you can form a listening connection at runtime by calling the *Open* method. If you want your application to form the listening connection automatically when it starts up, set the *Active* property to *True* at design time, using the Object Inspector.

Connecting to clients

A listening server socket component automatically accepts client connection requests when they are received. You receive notification every time this occurs in an *OnAccept* event.

Closing server connections

When you want to shut down the listening connection, call the *Close* method or set the *Active* property to *False*. This shuts down all open connections to client applications, cancels any pending connections that have not been accepted, and then shuts down the listening connection so that your server socket component does not accept any new connections.

When TCP clients shut down their individual connections to your server socket, you are informed by an *OnDisconnect* event.

Responding to socket events

When writing applications that use sockets, you can write or read to the socket anywhere in the program. You can write to the socket using the *SendBuf* , *SendStream*, or *Sendln* methods in your program after the socket has been opened. You can read from the socket using the similarly-named methods *ReceiveBuf* and *Receiveln.* The *OnSend* and *OnReceive* events are triggered every time something is written or read from the socket. They can be used for filtering. Every time you read or write, a read or write event is triggered.

Both client sockets and server sockets generate error events when they receive error messages from the connection.

Socket components also receive two events in the course of opening and completing a connection. If your application needs to influence how the opening of the socket proceeds, you must use the *SendBuf* and *ReceiveBuf* methods to respond to these client events or server events.

Error events

Client and server sockets generate *OnError* events when they receive error messages from the connection. You can write an *OnError* event handler to respond to these error messages. The event handler is passed information about

- What socket object received the error notification.
- What the socket was trying to do when the error occurred.
- The error code that was provided by the error message.

You can respond to the error in the event handler, and change the error code to 0 to prevent the socket from raising an exception.

Client events

When a client socket opens a connection, the following events occur:

- The socket is set up and initialized for event notification.
- An *OnCreateHandle* event occurs after the server and server socket is created. At this point, the socket object available through the *Handle* property can provide information about the server or client socket that will form the other end of the connection. This is the first chance to obtain the actual port used for the connection, which may differ from the port of the listening sockets that accepted the connection.
- The connection request is accepted by the server and completed by the client socket.
- When the connection is established, the *OnConnect* notification event occurs.

Server events

Server socket components form two types of connections: listening connections and connections to client applications. The server socket receives events during the formation of each of these connections.

Events when listening

Just before the listening connection is formed, the *OnListening* event occurs. You can use its *Handle* property to make changes to the socket before it is opened for listing. For example, if you want to restrict the IP addresses the server uses for listening, you would do that in an *OnListening* event handler.

Events with client connections

When a server socket accepts a client connection request, the following events occur:

- An *OnAccept* event occurs, passing in the new *TTcpClient* object to the event handler. This is the first point when you can use the properties of *TTcpClient* to obtain information about the server endpoint of the connection to a client.
- If *BlockMode* is *bmThreadBlocking* an *OnGetThread* event occurs. If you want to provide your own customized descendant of *TServerSocketThread*, you can create one in an *OnGetThread* event handler, and that will be used instead of *TServerSocketThread*. If you want to perform any initialization of the thread, or make any socket API calls before the thread starts reading or writing over the connection, you should use the *OnGetThread* event handler for these tasks as well.
- The client completes the connection and an *OnAccept* event occurs. With a non-blocking server, you may want to start reading or writing over the socket connection at this point.

Reading and writing over socket connections

The reason you form socket connections to other machines is so that you can read or write information over those connections. What information you read or write, or when you read it or write it, depends on the service associated with the socket connection.

Reading and writing over sockets can occur asynchronously, so that it does not block the execution of other code in your network application. This is called a non-blocking connection. You can also form blocking connections, where your application waits for the reading or writing to be completed before executing the next line of code.

Non-blocking connections

Non-blocking connections read and write asynchronously, so that the transfer of data does not block the execution of other code in you network application. To create a non-blocking connection for client or server sockets, set the *BlockMode* property to *bmNonBlocking.*

When the connection is non-blocking, reading and writing events inform your socket when the socket on the other end of the connection tries to read or write information.

Reading and writing events

Non-blocking sockets generate reading and writing events when it needs to read or write over the connection. You can respond to these notifications in an *OnReceive* or *OnSend* event handler.

The socket object associated with the socket connection is provided as a parameter to the read or write event handlers. This socket object provides a number of methods to allow you to read or write over the connection.

To read from the socket connection, use the *ReceiveBuf* or *Receiveln* method. To write to the socket connection, use the *SendBuf*, *SendStream*, or *Sendln* method.

Blocking connections

When the connection is blocking your socket must initiate reading or writing over the connection rather than waiting passively for a notification from the socket connection. Use a blocking socket when your end of the connection is in charge of when reading and writing takes place.

For client or server sockets, set the *BlockMode* property to *bmBlocking* to form a blocking connection. Depending on what else your client application does, you may want to create a new execution thread for reading or writing, so that your application can continue executing code on other threads while it waits for the reading or writing over the connection to be completed.

For server sockets, set the *BlockMode* property to *bmBlocking* or *bmThreadBlocking* to form a blocking connection. Because blocking connections hold up the execution of all other code while the socket waits for information to be written or read over the connection, server socket components always spawn a new execution thread for every client connection when the *BlockMode* is *bmThreadBlocking*. When the *BlockMode* is *bmBlocking*, program execution is blocked until a new connection is established.

IV

Developing COM-based applications

The chapters in “Developing COM-based applications” present concepts necessary for building COM-based applications, including Automation controllers, Automation servers, ActiveX controls, and COM+ applications.

Note Support for COM clients is available in all editions of Delphi. However, to create servers, you need the Professional or Enterprise edition.

Chapter

33

Overview of COM technologies

Delphi provides wizards and classes to make it easy to implement applications based on the Component Object Model (COM) from Microsoft. With these wizards, you can create COM-based classes and components to use within applications or you can create fully functional COM clients or servers that implement COM objects, Automation servers (including Active Server Objects), ActiveX controls, or ActiveForms.

Note COM components such as those on the ActiveX, COM+, and Servers tabs of the Component palette are not available for use in CLX applications. This technology is for use on Windows only and is not cross-platform.

COM is a language-independent software component model that enables interaction between software components and applications running on a Windows platform. The key aspect of COM is that it enables communication between components, between applications, and between clients and servers through clearly defined interfaces. Interfaces provide a way for clients to ask a COM component which features it supports at runtime. To provide additional features for your component, you simply add an additional interface for those features.

Applications can access the interfaces of COM components that exist on the same computer as the application or that exist on another computer on the network using a mechanism called Distributed COM (DCOM). For more information on clients, servers, and interfaces see, “Parts of a COM application,” on page 33-3.

This chapter provides a conceptual overview of the underlying technology on which Automation and ActiveX controls are built. Later chapters provide details on creating Automation objects and ActiveX controls in Delphi.

COM as a specification and implementation

COM is both a specification and an implementation. The COM specification defines how objects are created and how they communicate with each other. According to this specification, COM objects can be written in different languages, run in different process spaces and on different platforms. As long as the objects adhere to the written specification, they can communicate. This allows you to integrate legacy code as a component with new components implemented in object-oriented languages.

The COM implementation is built into the Win32 subsystem, which provides a number of core services that support the written specification. The COM library contains a set of standard interfaces that define the core functionality of a COM object, and a small set of API functions designed for the purpose of creating and managing COM objects.

When you use Delphi wizards and VCL objects in your application, you are using Delphi's implementation of the COM specification. In addition, Delphi provides some wrappers for COM services for those features that it does not implement directly (such as Active Documents). You can find these wrappers defined in the ComObj unit and the API definitions in the AxCtrls unit.

Note Delphi's interfaces and language follow the COM specification. Delphi implements objects conforming to the COM spec using a set of classes called the Delphi ActiveX framework (DAX). These classes are found in the AxCtrls, OleCtrls, and OleServer units. In addition, the Pascal interface to the COM API is in ActiveX.pas and ComSvcs.pas.

COM extensions

As COM has evolved, it has been extended beyond the basic COM services. COM serves as the basis for other technologies such as Automation, ActiveX controls, Active Documents, and Active Directories. For details on COM extensions, see "COM extensions" on page 33-10.

In addition, when working in a large, distributed environment, you can create transactional COM objects. Prior to Windows 2000, these objects were not architecturally part of COM, but rather ran in the Microsoft Transaction Server (MTS) environment. With the advent of Windows 2000, this support is integrated into COM+. Transactional objects are described in detail in Chapter 39, "Creating MTS or COM+ objects."

Delphi provides wizards to easily implement applications that incorporate the above technologies in the Delphi environment. For details, see "Implementing COM objects with wizards" on page 33-18.

Parts of a COM application

When implementing a COM application, you supply the following:

COM Interface The way in which an object exposes its services externally to clients. A COM object provides an interface for each set of related methods and properties. Note that COM properties are not identical to properties on VCL objects. COM properties always use read and write access methods.

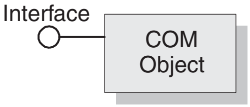
COM server A module, either an EXE, DLL, or OCX, that contains the code for a COM object. Object implementations reside in servers. A COM object implements one or more interfaces.

COM client The code that calls the interfaces to get the requested services from the server. Clients know what they want to get from the server (through the interface); clients do not know the internals of how the server provides the services. Delphi eases the process in creating a client by letting you install COM servers (such as a Word document or PowerPoint slide) as components on the Component Palette. This allows you to connect to the server and hook its events through the Object Inspector.

COM interfaces

COM clients communicate with objects through COM interfaces. Interfaces are groups of logically or semantically related routines which provide communication between a provider of a service (server object) and its clients. The standard way to depict a COM interface is shown in Figure 33.1:

Figure 33.1 A COM interface



For example, every COM object implements the basic interface, *IUnknown,* which tells the client what interfaces are available on the COM object.

Objects can have multiple interfaces, where each interface implements a feature. An interface provides a way to convey to the client what service it provides, without providing implementation details of how or where the object provides this service.

Key aspects of COM interfaces are as follows:

- Once published, interfaces are immutable; that is, they do not change. You can rely on an interface to provide a specific set of functions. Additional functionality is provided by additional interfaces.
- By convention, COM interface identifiers begin with a capital I and a symbolic name that defines the interface, such as *IMalloc* or *IPersist*.

- Interfaces are guaranteed to have a unique identification, called a **Globally Unique Identifier (GUID)**, which is a 128-bit randomly generated number. Interface GUIDs are called **Interface Identifiers (IIDs)**. This eliminates naming conflicts between different versions of a product or different products.
- Interfaces are language independent. You can use any language to implement a COM interface as long as the language supports a structure of pointers, and can call a function through a pointer either explicitly or implicitly.
- Interfaces are not objects themselves; they provide a way to access an object. Therefore, clients do not access data directly; clients access data through an interface pointer. Windows 2000 adds an additional layer of indirection known as an interceptor through which it provides COM+ features such as just-in-time activation and object pooling.
- Interfaces are always inherited from the fundamental interface, *IUnknown*.
- Interfaces can be redirected by COM through proxies to enable interface method calls to call between threads, processes, and networked machines, all without the client or server objects ever being aware of the redirection. For more information see , "In-process, out-of-process, and remote servers," on page 33-6.

The fundamental COM interface, IUnknown

All COM objects must support the fundamental interface, called *IUnknown*, a **typedef** to the base interface type *IInterface*. *IUnknown* contains the following routines:

QueryInterface	Provides pointers to other interfaces that the object supports.
AddRef and Release	Simple reference counting methods that keep track of the object's lifetime so that an object can delete itself when the client no longer needs its service.

Clients obtain pointers to other interfaces through the *IUnknown* method, *QueryInterface. QueryInterface* knows about every interface in the server object and can give a client a pointer to the requested interface. When receiving a pointer to an interface, the client is assured that it can call any method of the interface.

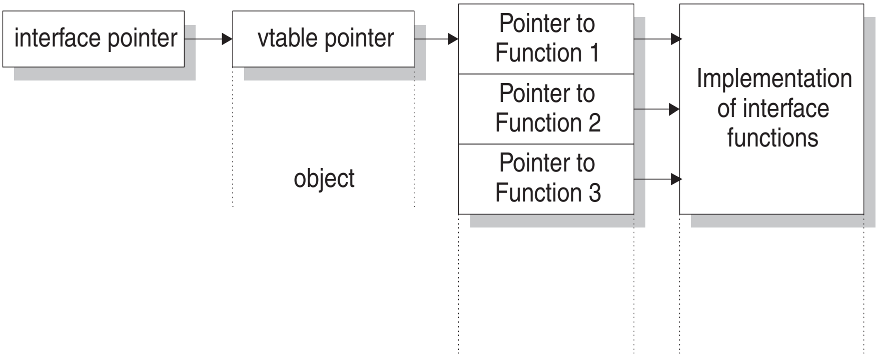
Objects track their own lifetime through the *IUnknown* methods, *AddRef* and *Release*, which are simple reference counting methods. As long as an object's reference count is nonzero, the object remains in memory. Once the reference count reaches zero, the interface implementation can safely dispose of the underlying object(s).

COM interface pointers

An interface pointer is a 32-bit pointer to an object instance that points, in turn, to the implementation of each method in the interface. The implementation is accessed through an array of pointers to these methods, which is called a **vtable**. Vtables are similar to the mechanism used to support virtual functions in Object Pascal. Because of this similarity, the compiler can resolve calls to methods on the interface the same way it resolves calls to methods on Object Pascal classes.

The vtable is shared among all instances of an object class, so for each object instance, the object code allocates a second structure that contains its private data. The client's interface pointer, then, is a pointer *to the pointer* to the vtable, as shown in the following diagram.

Figure 33.2 Interface vtable



In Windows 2000 and subsequent versions of Windows, when an object is running under COM+, an added level of indirection is provided between the interface pointer and the vtable pointer. The interface pointer available to the client points at an interceptor, which in turn points at the vtable. This allows COM+ to provide such services as just-in-time activation, whereby the server can be deactivated and reactivated dynamically in a way that is opaque to the client. To achieve this, COM+ guarantees that the interceptor behaves as if it were an ordinary vtable pointer.

COM servers

A COM server is an application or a library that provides services to a client application or library. A COM server consists of one or more COM objects, where a COM object is a set of properties and methods.

Clients do not know *how* a COM object performs its service; the object's implementation remains encapsulated. An object makes its services available through its interfaces as described previously.

In addition, clients do not need to know *where* a COM object resides. COM provides transparent access regardless of the object's location.

When a client requests a service from a COM object, the client passes a class identifier (CLSID) to COM. A CLSID is simply a GUID that identifies a COM object. COM uses this CLSID, which is registered in the system registry, to locate the appropriate server implementation. Once the server is located, COM brings the code into memory, and has the server instantiate an object instance for the client. This process is handled indirectly, through a special object called a class factory (based on interfaces) that creates instances of objects on demand.

As a minimum, a COM server must perform the following:

- Register entries in the system registry that associate the server module with the class identifier (CLSID).

- Implement a class factory object, which manufactures another object of a particular CLSID.
- Expose the class factory to COM.
- Provide an unloading mechanism through which a server that is not servicing clients can be removed from memory.

Note Delphi wizards automate the creation of COM objects and servers as described in "Implementing COM objects with wizards" on page 33-18.

CoClasses and class factories

A COM object is an instance of a **CoClass**, which is a class that implements one or more COM interfaces. The COM object provides the services as defined by its interfaces.

CoClasses are instantiated by a special type of object called a *class factory*. Whenever an object's services are requested by a client, a class factory creates an object instance for that particular client. Typically, if another client requests the object's services, the class factory creates another object instance to service the second client. (Clients can also bind to running COM objects that register themselves to support it.)

A CoClass must have a class factory and a class identifier (CLSID) so that it can be instantiated externally, that is, from another module. Using these unique identifiers for CoClasses means that they can be updated whenever new interfaces are implemented in their class. A new interface can modify or add methods without affecting older versions, which is a common problem when using DLLs.

Delphi wizards take care of assigning class identifiers and of implementing and instantiating class factories.

In-process, out-of-process, and remote servers

With COM, a client does not need to know where an object resides, it simply makes a call to an object's interface. COM performs the necessary steps to make the call. These steps differ depending on whether the object resides in the same process as the client, in a different process on the client machine, or in a different machine across the network. The different types of servers are known as:

In-process server A library (DLL) running in the *same process space* as the client, for example, an ActiveX control embedded in a Web page viewed under Internet Explorer or Netscape. Here, the ActiveX control is downloaded to the client machine and invoked within the same process as the Web browser.

The client communicates with the in-process server using direct calls to the COM interface.

Out-of-process server (or local server) Another application (EXE) running in a *different process space* but on the *same machine* as the client. For example, an Excel spreadsheet embedded in a Word document are two separate applications running on the same machine.

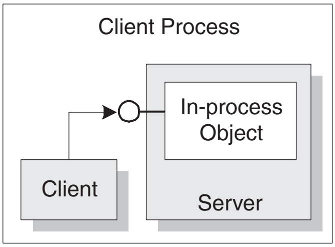
The local server uses COM to communicate with the client.

Remote server A DLL or another application running on a *different machine* from that of the client. For example, a Delphi database application is connected to an application server on another machine in the network.

The remote server uses distributed COM (DCOM) to access interfaces and communicate with the application server.

As shown in Figure 33.3, for in-process servers, pointers to the object interfaces are in the same process space as the client, so COM makes direct calls into the object implementation.

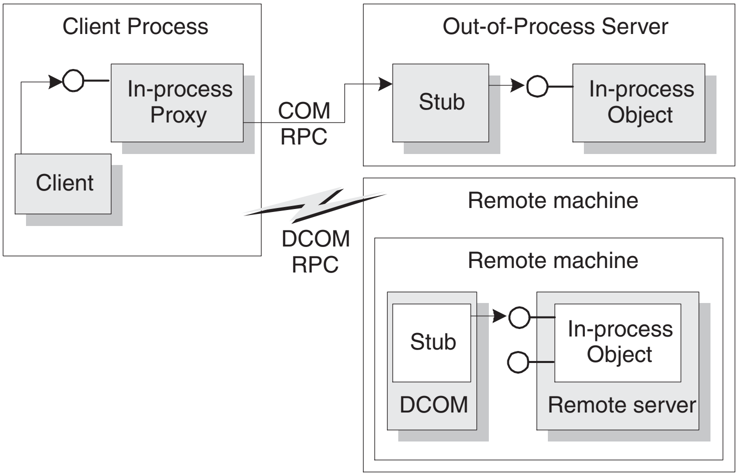
Figure 33.3 In-process server



Note This is not always true under COM+. When a client makes a call to an object in a different context, COM+ intercepts the call so that it behaves like a call to an out-of-process server (see below), even if the server is in-process. See Chapter 39, “Creating MTS or COM+ objects” for more information working with COM+.

As shown in Figure 33.4, when the process is either in a different process or in a different machine altogether, COM uses a proxy to initiate remote procedure calls. The **proxy** resides in the same process as the client, so from the client’s perspective, all interface calls look alike. The proxy intercepts the client’s call and forwards it to where the real object is running. The mechanism that enables the client to access objects in a different process space, or even different machine, as if they were in their own process, is called **marshaling.**

Figure 33.4 Out-of-process and remote servers



The difference between out-of-process and remote servers is the type of interprocess communication used. The proxy uses COM to communicate with an out-of-process server, it uses distributed COM (DCOM) to communicate with a remote machine. DCOM transparently transfers a local object request to the remote object running on a different machine.

Note For remote procedure calls, DCOM uses the RPC protocol provided by Open Group's Distributed Computing Environment (DCE). For distributed security, DCOM uses the NT LAN Manager (NTLM) security protocol. For directory services, DCOM uses the Domain Name System (DNS).

The marshaling mechanism

Marshaling is the mechanism that allows a client to make interface function calls to remote objects in another process or on a different machine. Marshaling

- Takes an interface pointer in the server's process and makes a proxy pointer available to code in the client process.
- Transfers the arguments of an interface call as passed from the client and places the arguments into the remote object's process space.

For any interface call, the client pushes arguments onto a stack and makes a function call through the interface pointer. If the call to the object is not in-process, the call gets passed to the proxy. The proxy packs the arguments into a marshaling packet and transmits the structure to the remote object. The object's stub unpacks the packet, pushes the arguments onto the stack, and calls the object's implementation. In essence, the object recreates the client's call in its own address space.

What type of marshaling occurs depends on what the COM object implements. Objects can use a standard marshaling mechanism provided by the *IDispatch* interface. This is a generic marshaling mechanism that enables communication through a system-standard remote procedure call (RPC). For details on the *IDispatch* interface, see "Automation interfaces" on page 36-12. Even if the object does not implement *IDispatch*, if it limits itself to automation-compatible types and has a registered type library, COM automatically provides marshaling support.

Applications that do not limit themselves to automation-compatible types or register a type library must provide their own marshaling. Marshaling is provided either through an implementation of the *IMarshal* interface, or by using a separately generated proxy/stub DLL. Delphi does not support the automatic generation of proxy/stub DLLs.

Aggregation

Sometimes, a server object makes use of another COM object to perform some of its functions. For example, an inventory management object might make use of a separate invoicing object to handle customer invoices. If the inventory management object wants to present the invoice interface to clients, however, there is a problem: Although a client that has the inventory interface can call *QueryInterface* to obtain the invoice interface, when the invoice object was created it did not know about the inventory management object and can't return an inventory interface in response to a call to *QueryInterface*. A client that has the invoice interface can't get back to the inventory interface.

To avoid this problem, some COM objects support **aggregation**. When the inventory management object creates an instance of the invoice object, it passes it a copy of its own *IUnknown* interface. The invoice object can then use that *IUnknown* interface to handle any *QueryInterface* calls that request an interface, such as the inventory interface, that it does not support. When this happens, the two objects together are called an aggregate. The invoice object is called the inner, or contained object of the aggregate, and the inventory object is called the outer object.

Note In order to act as the outer object of an aggregate, a COM object must create the inner object using the Windows API *CoCreateInstance* or *CoCreateInstanceEx*, passing its *IUnknown* pointer as a parameter that the inner object can use for *QueryInterface* calls.

In order to create an object that can act as the inner object of an aggregate, it must descend from *TContainedObject*. When the object is created, the *IUnknown* interface of the outer object is passed to the constructor so that it can be used by the *QueryInterface* method on calls that the inner object can't handle.

COM clients

Clients can always query the interfaces of a COM object to determine what it is capable of providing. All COM objects allow clients to request known interfaces. In addition, if the server supports the *IDispatch* interface, clients can query the server for information about what methods the interface supports. Server objects have no expectations about the client using its objects. Similarly, clients don't need to know how (or even where) an object provides the services; they simply rely on server objects to provide the services they advertise through their interfaces.

There are two types of COM clients, controllers and containers. Controllers launch the server and interact with it through its interface. They request services from the COM object or drive it as a separate process. Containers host visual controls or objects that appear in the container’s user interface. They use predefined interfaces to negotiate display issues with server objects. It is impossible to have a container relationship over DCOM; for example, visual controls that appear in the container's user interface must be located locally. This is because the controls are expected to paint themselves, which requires that they have access to local GDI resources.

Delphi makes it easier for you to develop COM clients by letting you import a type library or ActiveX control into a component wrapper so that server objects look like other VCL components. For details on this process, see Chapter 35, “Creating COM clients”.

COM extensions

COM was originally designed to provide core communication functionality and to enable the broadening of this functionality through extensions. COM itself has extended its core functionality by defining specialized sets of interfaces for specific purposes.

The following lists some of the services COM extensions currently provide. Subsequent sections describe these services in greater detail.

Automation servers Automation refers to the ability of an application to control the objects in another application programmatically. Automation servers are the objects that can be controlled by other executables at runtime.

ActiveX controls ActiveX controls are specialized in-process servers, typically intended for embedding in a client application. The controls offer both design and runtime behaviors as well as events.

Active Server Pages Active Server Pages are scripts that generate HTML pages. The scripting language includes constructs for creating and running Automation objects. That is, the Active Server Page acts as an Automation controller.

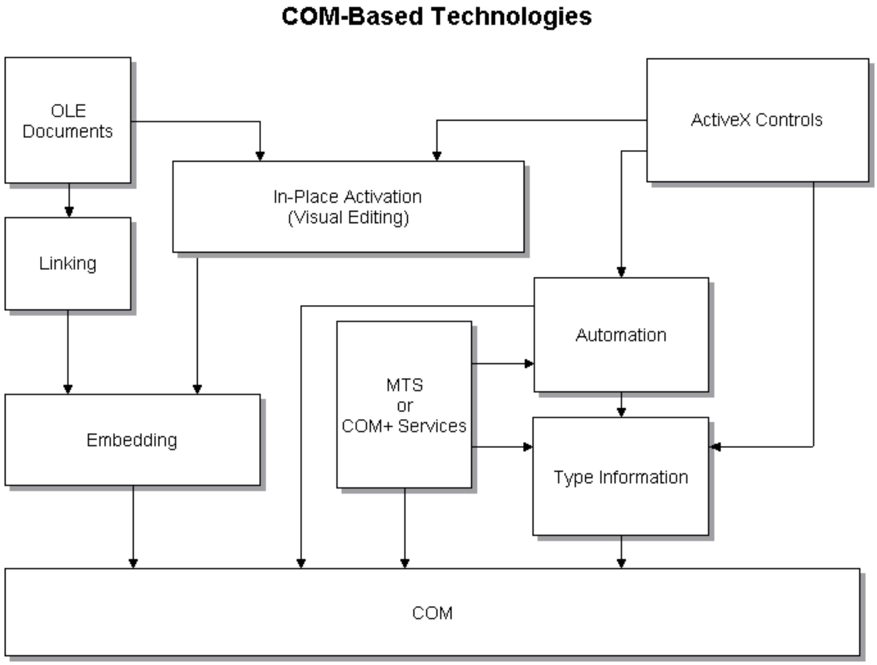
Active Documents Objects that support linking and embedding, drag-and-drop, visual editing, and in-place activation. Word documents and Excel spreadsheets are examples of Active Documents.

Transactional objects Objects that include additional support for responding to large numbers of clients. This includes features such as just-in-time activation, transactions, resource pooling, and security services. These features were originally handled by MTS but have been built into COM with the advent of COM+.

Type libraries A collection of static data structures, often saved as a resource, that provides detailed type information about an object and its interfaces. Clients of Automation servers, ActiveX controls, and transactional objects expect type information to be available.

The following diagram illustrates the relationship of the COM extensions and how they are built upon COM:

Figure 33.5 COM-based technologies



COM objects can be visual or non-visual. Some must run in the same process space as their clients; others can run in different processes or remote machines, as long as the objects provide marshaling support. Table 33.1 summarizes the types of COM objects that you can create, whether they are visual, process spaces they can run in, how they provide marshaling, and whether they require a type library.

Table 33.1 COM object requirements

Object	Visual Object?	Process space	Communication	Type library
Active Document	Usually	In-process, or out-of-process	OLE Verbs	No
Automation	Occasionally	In-process, out-of-process, or remote	Automatically marshaled using the *IDispatch* interface (for out-of process and remote servers)	Required for automatic marshaling
ActiveX Control	Usually	In-process	Automatically marshaled using the *IDispatch* interface	Required
MTS or COM+	Occasionally	In-process for MTS, any for COM+	Automatically marshaled via a type library	Required

Table 33.1 COM object requirements (continued)

Object	Visual Object?	Process space	Communication	Type library
In-process custom interface object	Optionally	In-process	No marshaling required for in-process servers	Recommended
Other custom interface object	Optionally	In-process, out-of-process, or remote	Automatically marshaled via a type library; otherwise, manually marshaled using custom interfaces	Recommended

Automation servers

Automation refers to the ability of an application to control the objects in another application programmatically, like a macro that can manipulate more than one application at the same time. The server object being manipulated is called the Automation object, and the client of the Automation object is referred to as an Automation controller.

Automation can be used on in-process, local, and remote servers.

Automation is characterized by two key points:

- The Automation object defines a set of properties and commands, and describes their capabilities through type descriptions. In order to do this, it must have a way to provide information about its interfaces, the interface methods, and those methods' arguments. Typically, this information is available in a type library. The Automation server can also generate type information dynamically when queried via its *IDispatch* interface (see following).
- Automation objects make their methods accessible so that other applications can use them. For this, they implement the *IDispatch* interface. Through this interface an object can expose all of its methods and properties. Through the primary method of this interface, the object's methods can be invoked, once having been identified through type information.

Developers often use Automation to create and use non-visual OLE objects that run in any process space because the Automation *IDispatch* interface automates the marshaling process. Automation does, however, restrict the types that you can use.

For a list of types that are valid for type libraries in general, and Automation interfaces in particular, see "Valid types" on page 34-11.

For information on writing an Automation server, see Chapter 36, "Creating simple COM servers."

Active Server Pages

The Active Server Page (ASP) technology lets you write simple scripts, called Active Server Pages, that can be launched by clients via a Web server. Unlike ActiveX controls, which run on the client, Active Server Pages run on the server, and return a resulting HTML page to clients.

Active Server Pages are written in Jscript or VB script. The script runs every time the server loads the Web page. That script can then launch an embedded Automation server (or Enterprise Java Bean). For example, you can write an Automation server, such as one to create a bitmap or connect to a database, and this server accesses data that gets updated every time a client loads the Web page.

Active Server Pages rely on the Microsoft Internet Information Server (IIS) environment to serve your Web pages.

Delphi wizards let you create an Active Server Object, which is an Automation object specifically designed to work with an Active Server Page. For more information about creating and using these types of objects, see Chapter 37, "Creating an Active Server Page."

ActiveX controls

ActiveX is a technology that allows COM components, especially controls, to be more compact and efficient. This is especially necessary for controls that are intended for Intranet applications that need to be downloaded by a client before they are used.

ActiveX controls are visual controls that run only as in-process servers, and can be plugged into an ActiveX control container application. They are not complete applications in themselves, but can be thought of as prefabricated OLE controls that are reusable in various applications. ActiveX controls have a visible user interface, and rely on predefined interfaces to negotiate I/O and display issues with their host containers.

ActiveX controls make use of Automation to expose their properties, methods, and events. Features of ActiveX controls include the ability to fire events, bind to data sources, and support licensing.

One use of ActiveX controls is on a Web site as interactive objects in a Web page. As such, ActiveX is a standard that targets interactive content for the World Wide Web, including the use of ActiveX Documents used for viewing non-HTML documents through a Web browser. For more information about ActiveX technology, see the Microsoft ActiveX Web site.

Delphi wizards allow you to easily create ActiveX controls. For more information about creating and using these types of objects, see Chapter 38, "Creating an ActiveX control."

Active Documents

Active Documents (previously referred to as OLE documents) are a set of COM services that support linking and embedding, drag-and-drop, and visual editing. Active Documents can seamlessly incorporate data or objects of different formats, such as sound clips, spreadsheets, text, and bitmaps.

Unlike ActiveX controls, Active Documents are not limited to in-process servers; they can be used in cross-process applications.

Unlike Automation objects, which are almost never visual, Active Document objects can be visually active in another application. Thus, Active Document objects are associated with two types of data: presentation data, used for visually displaying the object on a display or output device, and native data, used to edit an object.

Active Document objects can be document containers or document servers. While Delphi does not provide an automatic wizard for creating Active Documents, you can use the VCL class, *TOleContainer*, to support linking and embedding of existing Active Documents.

You can also use *TOleContainer* as a basis for an Active Document container. To create objects for Active Document servers, use the COM object wizard and add the appropriate interfaces, depending on the services the object needs to support. For more information about creating and using Active Document servers, see the Microsoft ActiveX Web site.

Note While the specification for Active Documents has built-in support for marshaling in cross-process applications, Active Documents do not run on remote servers because they use types that are specific to a system on a given machine such as window handles, menu handles, and so on.

Transactional objects

Delphi uses the term “transactional objects” to refer to objects that take advantage of the transaction services, security, and resource management supplied by Microsoft Transaction Server (MTS) (for versions of Windows prior to Windows 2000) or COM+ (for Windows 2000 and later). These objects are designed to work in a large, distributed environment.

The transaction services provide robustness so that activities are always completed or rolled back (the server never partially completes an activity). The security services allow you to expose different levels of support to different classes of clients. The resource management allows an object to handle more clients by pooling resources or keeping objects active only when they are in use. To enable the system to provide these services, the object must implement the *IObjectControl* interface. To access the services, transactional objects use an interface called *IObjectContext*, which is created on their behalf by MTS or COM+.

Under MTS, the server object must be built into a library (DLL), which is then installed in the MTS runtime environment. That is, the server object is an in-process server that runs in the MTS runtime process space. Under COM+, this restriction does not apply because all COM calls are routed through an interceptor. To clients, the difference between MTS and COM+ is transparent.

MTS or COM+ servers group transactional objects that run in the same process space. Under MTS, this group is called an MTS package, while under COM+ it is called a COM+ application. A single machine can be running several different MTS packages (or COM+ applications), where each one is running in a separate process space.

To clients, the transactional object may appear like any other COM server object. The client need never know about transactions, security, or just-in-time activation unless it is initiating a transaction itself.

Both MTS and COM+ provide a separate tool for administering transactional objects. This tool lets you configure objects into packages or COM+ applications, view the packages or COM+ applications installed on a computer, view or change the attributes of the included objects, monitor and manage transactions, make objects available to clients, and so on. Under MTS, this tool is the MTS Explorer. Under COM+ it is the COM+ Component Manager.

Type libraries

Type libraries provide a way to get more type information about an object than can be determined from an object's interface. The type information contained in type libraries provides needed information about objects and their interfaces, such as what interfaces exist on what objects (given the CLSID), what member functions exist on each interface, and what arguments those functions require.

You can obtain type information either by querying a running instance of an object or by loading and reading type libraries. With this information, you can implement a client which uses a desired object, knowing specifically what member functions you need, and what to pass those member functions.

Clients of Automation servers, ActiveX controls, and transactional objects expect type information to be available. All of Delphi's wizards generate a type library automatically, although the COM object wizard makes this optional. You can view or edit this type information by using the Type Library Editor as described in Chapter 34, "Working with type libraries."

This section describes what a type library contains, how it is created, when it is used, and how it is accessed. For developers wanting to share interfaces across languages, the section ends with suggestions on using type library tools.

The content of type libraries

Type libraries contain *type information*, which indicates which interfaces exist in which COM objects, and the types and numbers of arguments to the interface methods. These descriptions include the unique identifiers for the CoClasses (CLSIDs) and the interfaces (IIDs), so that they can be properly accessed, as well as the dispatch identifiers (dispIDs) for Automation interface methods and properties.

Type libraries can also contain the following information:

- Descriptions of custom type information associated with custom interfaces
- Routines that are exported by the Automation or ActiveX server, but that are not interface methods
- Information about enumeration, record (structures), unions, alias, and module data types
- References to type descriptions from other type libraries

Creating type libraries

With traditional development tools, you create type libraries by writing scripts in the Interface Definition Language (IDL) or the Object Description Language (ODL), then running that script through a compiler. However, Delphi automatically generates a type library when you create a COM object (including ActiveX controls, Automation objects, remote data modules, and so on) using any of the wizards on the ActiveX or Multitier page of the new items dialog. (You can opt not to create a type library when using the COM object wizard.) You can also create a type library by choosing from the main menu, File | New | Other, select the ActiveX tab, and choose Type Library.

You can view the type library using Delphi's Type Library editor. You can easily edit your type library using the Type Library editor and Delphi automatically updates the corresponding .tlb file (binary type library file) when the type library is saved. For any changes to Interfaces and CoClasses that were created using a wizard, the Type Library editor also updates your implementation files. For more information on using the Type Library editor to write interfaces and CoClasses, see Chapter 34, "Working with type libraries."

When to use type libraries

It is important to create a type library for each set of objects that is exposed to external users, for example,

- ActiveX controls require a type library, which must be included as a resource in the DLL that contains the ActiveX controls.
- Exposed objects that support vtable binding of custom interfaces must be described in a type library because vtable references are bound at compile time. Clients import information about the interfaces from the type library and use that information to compile. For more information about vtable and compile time binding, see "Automation interfaces" on page 36-12.
- Applications that implement Automation servers should provide a type library so that clients can early bind to it.
- Objects instantiated from classes that support the *IProvideClassInfo* interface, such as all descendants of the VCL *TTypedComObject* class, must have a type library.
- Type libraries are not required, but are useful for identifying the objects used with OLE drag-and-drop.

When defining interfaces for internal use only (within an application) you do not need to create a type library.

Accessing type libraries

The binary type library is normally a part of a resource file (.res) or a stand-alone file with a .tlb file-name extension. When included in a resource file, the type library can be bound into a server (.dll, .ocx, or .exe).

Once a type library has been created, object browsers, compilers, and similar tools can access type libraries through special type interfaces:

Interface	Description
ITypeLib	Provides methods for accessing a library of type descriptions.
ITypeLib2	Augments *ITypeLib* to include support for documentation strings, custom data, and statistics about the type library.
ITypeInfo	Provides descriptions of individual objects contained in a type library. For example, a browser uses this interface to extract information about objects from the type library.
ITypeInfo2	Augments *ITypeInfo* to access additional type library information, including methods for accessing custom data elements.
ITypeComp	Provides a fast way to access information that compilers need when binding to an interface.

Delphi can import and use type libraries from other applications by choosing Project | Import Type Library. Most of the VCL classes used for COM applications support the essential interfaces that are used to store and retrieve type information from type libraries and from running instances of an object. The VCL class *TTypedComObject* supports interfaces that provide type information, and is used as a foundation for the ActiveX object framework.

Benefits of using type libraries

Even if your application does not require a type library, you can consider the following benefits of using one:

- Type checking can be performed at compile time.
- You can use early binding with Automation, and controllers that do not support vtables or dual interfaces can encode dispIDs at compile time, improving runtime performance.
- Type browsers can scan the library, so clients can see the characteristics of your objects.
- The *RegisterTypeLib* function can be used to register your exposed objects in the registration database.
- The *UnRegisterTypeLib* function can be used to completely uninstall an application’s type library from the system registry.
- Local server access is improved because Automation uses information from the type library to package the parameters that are passed to an object in another process.

Using type library tools

The tools for working with type libraries are listed below.

- The TLIBIMP (Type Library Import) tool, which takes existing type libraries and creates Delphi Interface files (_TLB.pas files), is incorporated into the Type Library editor. TLIBIMP provides additional configuration options not available inside the Type Library editor.
- TRegSvr is a tool for registering and unregistering servers and type libraries, which comes with Delphi. The source to TRegSvr is available as an example in the Demos directory.
- The Microsoft IDL compiler (MIDL) compiles IDL scripts to create a type library.
- RegSvr32.exe is a tool for registering and unregistering servers and type libraries, which is a standard Windows utility.
- OLEView is a type library browser tool, found on Microsoft's Web site.

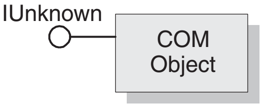
Implementing COM objects with wizards

Delphi makes it easier to write COM server applications by providing wizards that handle many of the details involved. Delphi provides separate wizards to create the following:

- A simple COM object
- An Automation object
- An Active Server Object (for embedding in an Active Server page)
- An ActiveX control
- An ActiveX Form
- A transactional object
- A Property page
- A Type library
- An ActiveX library

The wizards handle many of the tasks involved in creating each type of COM object. They provide the required COM interfaces for each type of object. As shown in Figure 33.6, with a simple COM object, the wizard implements the one required COM interface, *IUnknown*, which provides an interface pointer to the object.

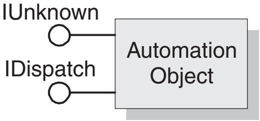
Figure 33.6 Simple COM object interface



The COM object wizard also provides an implementation for *IDispatch* if you specify that you are creating an object that supports an *IDispatch* descendant.

As shown inFigure 33.7, for Automation and Active Server objects, the wizard implements *IUnknown* and *IDispatch*, which provides automatic marshaling.

Figure 33.7 Automation object interface



As shown in Figure 33.8, for ActiveX control objects and ActiveX forms, the wizard implements all the required ActiveX control interfaces, from *IUnknown*, *IDispatch*, *IOleObject*, *IOleControl*, and so on. For a complete list of interfaces, see the reference page for *TActiveXControl* object.

Figure 33.8 ActiveX object interface

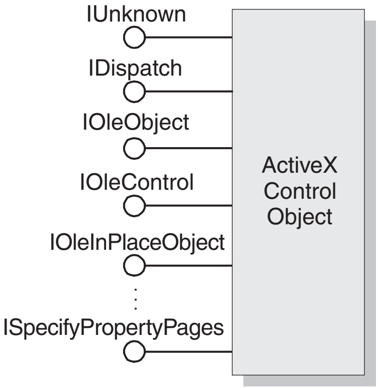


Table 33.2 lists the various wizards and the interfaces they implement:

Table 33.2 Delphi wizards for implementing COM, Automation, and ActiveX objects

Wizard	Implemented interfaces	What the wizard does
COM server	*IUnknown* (and *IDispatch* if you select a default interface that descends from *IDispatch*)	Exports routines that handle server registration, class registration, loading and unloading the server, and object instantiation. Creates and manages class factories for objects implemented on the server. Provides registry entries for the object that specify the selected threading model. Declares the methods that implement a selected interface, providing skeletal implementations for you to complete. Provides a type library, if requested. Allows you to select an arbitrary interface that is registered in the type library and implement it. If you do this, you must use a type library.

Table 33.2 Delphi wizards for implementing COM, Automation, and ActiveX objects (continued)

Wizard	Implemented interfaces	What the wizard does
Automation server	*IUnknown*, *IDispatch*	Performs the tasks of a COM server wizard (described above), plus: Implements the interface that you specify, either dual or dispatch. Provides server-side support for generating events, if requested. Provides a type library automatically.
Active Server Object	*IUnknown*, *IDispatch*, *(IASPObject)*	Performs the tasks of an Automation object wizard (described above) and optionally generates an .ASP page which can be loaded into a Web browser. It leaves you in the Type Library editor so that you can modify the object's properties and methods if needed. Surfaces the ASP intrinsics as properties so that you can easily obtain information about the ASP application and the HTTP messages that launched it.
ActiveX Control	*IUnknown*, *IDispatch*, *IPersistStreamInit*, *IOleInPlaceActiveObject*, *IPersistStorage*, *IViewObject*, *IOleObject*, *IViewObject2*, *IOleControl*, *IPerPropertyBrowsing*, *IOleInPlaceObject*, *ISpecifyPropertyPages*	Performs the tasks of the Automation server wizard (described above), plus: Generates a CoClass that corresponds to the VCL control on which the ActiveX control is based and which implements all the ActiveX interfaces. Leaves you in the source code editor so that you can modify the implementation class.
ActiveForm	Same interfaces as ActiveX Control	Performs the tasks of the ActiveX control wizard, plus: Creates a *TActiveForm* descendant that takes the place of the pre-existing VCL class in the ActiveX control wizard. This new class lets you design the Active Form the same way you design a form in a Windows application.
Transactional object	*IUnknown*, *IDispatch*, *IObjectControl*	Adds a new unit to the current project containing the MTS or COM+ object definition. It inserts proprietary GUIDs into the type library so that Delphi can install the object properly, and leaves you in the Type Library editor so that you can define the interface that the object exposes to clients. You must install the object separately after it is built.
Property Page	*IUnknown*, *IPropertyPage*	Creates a new property page that you can design in the Forms designer.
COM+ Event object	None, by default	Creates a COM+ event object that you can define using the Type Library editor. Unlike the other object wizards, the COM+ Event object wizard does not create an implementation unit because event objects have no implementation (it is provided by client sinks).

Table 33.2 Delphi wizards for implementing COM, Automation, and ActiveX objects (continued)

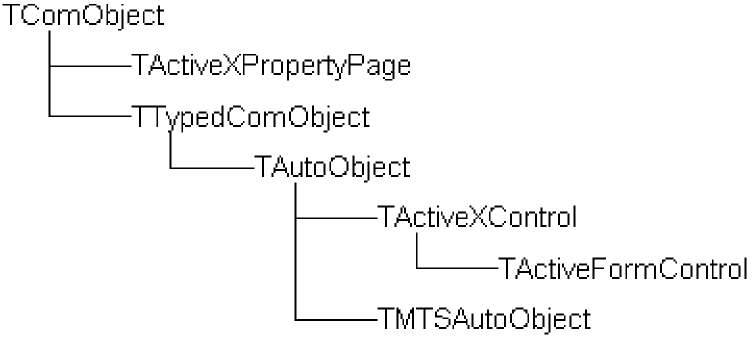
Wizard	Implemented interfaces	What the wizard does
Type Library	None, by default	Creates a new type library and associates it with the active project.
ActiveX library	None, by default	Creates a new ActiveX or Com server DLL and exposes the necessary export functions.

You can add additional COM objects or reimplement an existing implementation. To add a new object, it is easiest to use the wizard a second time. This is because the wizard sets up an association between the type library and an implementation class, so that changes you make in the type library editor are automatically applied to your implementation object.

Code generated by wizards

Delphi's wizards generate classes that are derived from the Delphi ActiveX framework (DAX). Despite its name, the Delphi ActiveX framework supports all types of COM objects, not just ActiveX controls. The classes in this framework provide the underlying implementation of the standard COM interfaces for the objects you create using a wizard. Figure 33.9 illustrates the objects in the Delphi ActiveX framework:

Figure 33.9 Delphi ActiveX framework



Each wizard generates an implementation unit that implements your COM server object. The COM server object (the implementation object) descends from one of the classes in DAX:

Table 33.3 DAX Base classes for generated implementation classes

Wizard	Base class from DAX	Inherited support
COM server	TTypedCOMObject	Support for *IUnknown* and *ISupportErrorInfo* interfaces. Support for aggregation, OLE exception handling, and safecall calling convention on dual interfaces. Support for reading type library information.

Table 33.3 DAX Base classes for generated implementation classes (continued)

Wizard	Base class from DAX	Inherited support
Automation server Active Server Object	TAutoObject	Everything provided by *TTypedCOMObject*, plus: Support for the *IDispatch* interface. Auto-marshaling support.
ActiveX Control	TActiveXControl	Everything provided by *TAutoObject*, plus: Support for embedding in a container. Support for in-place activation. Support for properties and property pages. The ability to delegate to an associated windowed control that it creates.
ActiveForm	TActiveFormControl	Everything provided by *TAutoObject*, except that it works with a descendant of *TActiveForm* rather than another windowed control class.
MTS object	TMTSAutoObject	Everything provided by *TAutoObject*, plus: Support for the *IObjectControl* interface.
Property Page	TPropertyPage (uses TActiveXPropertyPage internally)	Support for *IUnknown* and *ISupportErrorInfo* interfaces. Support for aggregation, OLE exception handling, and safecall calling convention on dual interfaces. Support for the *IPropertyPage* interface.

Corresponding to the classes in Figure 33.9 is a hierarchy of class factory objects that handle the creation of these COM objects. The wizard adds code to the initialization section of your implementation unit that instantiates the appropriate class factory for your implementation class.

The wizards also generate a type library and its associated unit, which has a name of the form Project1_TLB. The Project1_TLB unit includes the definitions your application needs to use the type definitions and interfaces defined in the type library. For more information on the contents of this file, see “Code generated when you import type library information” on page 35-5.

You can modify the interface generated by the wizard using the type library editor. When you do this, the implementation class is automatically updated to reflect those changes. You need only fill in the bodies of the generated methods to complete the implementation.

Chapter

34

Working with type libraries

This chapter describes how to create and edit type libraries using Delphi's Type Library editor. Type libraries are files that include information about data types, interfaces, member functions, and object classes exposed by a COM object. They provide a way to identify what types of objects and interfaces are available on a server. For a detailed overview on why and when to use type libraries, see "Type libraries" on page 33-15.

A type library can contain any and all of the following:

- Information about custom data types such as aliases, enumerations, structures, and unions.
- Descriptions of one or more COM elements, such as an interface, dispinterface, or CoClass. Each of these descriptions is commonly referred to as *type information.*
- Descriptions of constants and methods defined in external units.
- References to type descriptions from other type libraries.

By including a type library with your COM application or ActiveX library, you make information about the objects in your application available to other applications and programming tools through COM's type library tools and interfaces.

With traditional development tools, you create type libraries by writing scripts in the Interface Definition Language (IDL) or the Object Description Language (ODL), then run that script through a compiler. The Type Library editor automates some of this process, easing the burden of creating and modifying your own type libraries.

When you create a COM server of any type (ActiveX control, Automation object, remote data module, and so on) using Delphi's wizards, the wizard automatically generates a type library for you (although in the case of the COM object wizard, this is optional). Most of the work you do in customizing the generated object starts with the type library, because that is where you define the properties and methods it exposes to clients: you change the interface of the CoClass generated by the wizard, using the Type Library editor. The Type Library editor automatically updates the implementation unit for your object, so that all you need do is fill in the bodies of the generated methods.

You can also use the Delphi Type Library Editor in the development of Common Object Request Broker Architecture (CORBA) applications. With traditional CORBA tools, you must define object interfaces separately from your application, using the CORBA Interface Definition Language (IDL). You then run a utility that generates stub-and-skeleton code from that definition. However, Delphi generates the stub, skeleton, and IDL for you automatically. You can easily edit your interface using the Type Library editor and Delphi automatically updates the appropriate source files.

Type Library editor

The Type Library editor enables developers to examine and create type information for COM objects. Using the Type Library editor can greatly simplify the task of developing COM objects by centralizing the tasks of defining interfaces, CoClasses, and types, obtaining GUIDs for new interfaces, associating interfaces with CoClasses, updating implementation units, and so on.

Note The Type Library editor is also used to define CORBA interfaces in projects that use the CORBA Object or CORBA Data Module wizard.

The Type Library editor outputs two types of file that represent the contents of the type library:

Table 34.1 Type Library editor files

File	Description
.TLB file	The binary type library file. By default, you do not need to use this file, because the type library is automatically compiled into the application as a resource. However, you can use this file to explicitly compile the type library into another project or to deploy the type library separately from the .exe or .ocx. For more information, see “Opening an existing type library” on page 34-19 and “Deploying type libraries” on page 34-27. **Note:** When using the Type Library editor for CORBA interfaces, the Type Library editor does not create the .tlb file.
_TLB unit	This unit interprets the contents of the type library for use by your application. It contains all the declarations your application needs to use the elements defined in the type library. Although you can open this file in the code editor, you should never edit it—it is maintained by the Type Library editor, so any changes you make will be overwritten by the Type Library editor. For more details on the contents of this file, see “Code generated when you import type library information” on page 35-5. **Note:** When using the Type Library editor for CORBA interfaces, this unit defines the stub and skeleton objects required by the CORBA application.

Parts of the Type Library editor

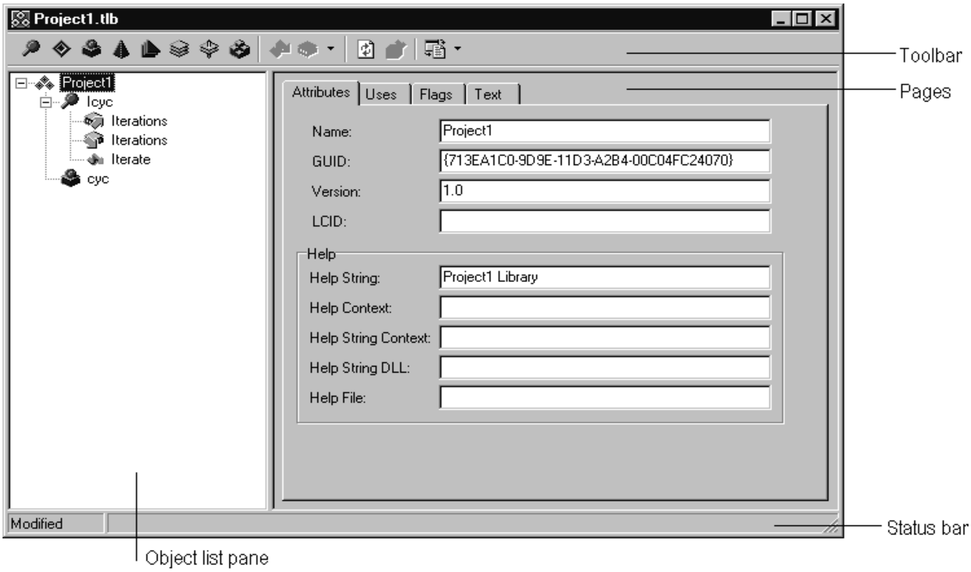
The main elements of the Type Library editor are described in Table 34.2:

Table 34.2 Type Library editor parts

Part	Description
Toolbar	Includes buttons to add new types, CoClasses, interfaces, and interface members to your type library. The toolbar also includes buttons for refreshing your implementation unit, registering the type library, and saving an IDL file with the information in your type library.
Object list pane	Displays all the existing elements in the type library. When you click on an item in the object list pane, it displays pages valid for that object.
Status bar	Displays syntax errors if you try to add invalid types to your type library.
Pages	Display information about the selected object. Which pages appear here depends on the type of object selected.

These parts are illustrated in Figure 34.1, which shows the Type Library editor displaying type information for a COM object named cyc.

Figure 34.1 Type Library editor



Name: Project1

Help String: Project1 Library
Help Context:
Help String Context:
Help String DLL:
Help File:

Toolbar

The Type Library editor's toolbar located at the top of the Type Library Editor, contains buttons that you click to add new objects into your type library.

The first group of buttons let you add elements to the type library. When you click a toolbar button, the icon for that element appears in the object list pane. You can then customize its attributes in the right pane. Depending on the type of icon you select, different pages of information appear to the right.

The following table lists the elements you can add to your type library:

Icon	Meaning
	An interface description.
	A dispinterface description. (not used for CORBA interface definitions)
	A CoClass.
	An enumeration.
	An alias.
	A record.
	A union.
	A module.

When you select one of the elements listed above in the object list pane, the second group of buttons displays members that are valid for that element. For example, when you select Interface, the Method and Property icons in the second box become enabled because you can add methods and properties to your interface definition. When you select Enum, the second group of buttons changes to display the Const member, which is the only valid member for Enum type information.

The following table lists the members that can be added to elements in the object list pane:

Icon	Meaning
	A method of the interface, dispinterface, or an entry point in a module.
	A property on an interface or dispinterface.
	A write-only property. (available from the drop-down list on the property button)
	A read-write property. (available from the drop-down list on the property button)
	A read-only property. (available from the drop-down list on the property button)
	A field in a record or union.
	A constant in an enum or a module.

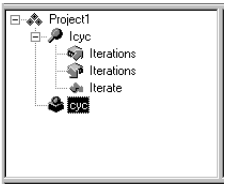
In the third box, you can choose to refresh, register, or export your type library (save it as an IDL file), as described in “Saving and registering type library information” on page 34-24.

Object list pane

The Object list pane displays all the elements of the current type library in a tree view. The root of the tree represents the type library itself, and appears as the following icon:

Descending from the type library node are the elements in the type library:

Figure 34.2 Object list pane



When you select any of these elements (including the type library itself), the pages of type information to the right change to reflect only the relevant information for that element. You can use these pages to edit the definition and properties of the selected element.

You can manipulate the elements in the object list pane by right clicking to get the object list pane context menu. This menu includes commands that let you use the Windows clipboard to move or copy existing elements as well as commands to add new elements or customize the appearance of the Type Library editor.

Status bar

When editing or saving a type library, syntax, translation errors, and warnings are listed in the Status bar pane.

For example, if you specify a type that the Type Library editor does not support, you will get a syntax error. For a complete list of types supported by the Type Library editor, see “Valid types” on page 34-11.

Pages of type information

When you select an element in the object list pane, pages of type information appear in the Type Library editor that are valid for the selected element. Which pages appear depends on the element selected in the object list panel, as follows:

Table 34.3 Type library pages

Type Info element	Page of type information	Contents of page
Type library	Attributes	Name, version, and GUID for the type library, as well as information linking the type library to help.
	Uses	List of other type libraries that contain definitions on which this one depends.
	Flags	Flags that determine how other applications can use the type library.
	Text	All definitions and declarations defining the type library itself (see discussion below).
Interface	Attributes	Name, version, and GUID for the interface, the name of the interface from which it descends, and information linking the interface to help.
	Flags	Flags that indicate whether the interface is hidden, dual, Automation-compatible, and/or extensible.
	Text	The definitions and declarations for the Interface (see discussion below).
Dispinterface	Attributes	Name, version, and GUID for the interface, and information linking it to help.
	Flags	Flags that indicate whether the Dispinterface is hidden, dual, and/or extensible.
	Text	The definitions and declarations for the Dispinterface. (see discussion below).
CoClass	Attributes	Name, version, and GUID for the CoClass, and information linking it to help.
	Implements	A List of interfaces that the CoClass implements, as well as their attributes.
	COM+	The attributes of transactional objects, such as the transaction model, call synchronization, just-in-time activation, object pooling, and so on. Also includes the attributes of COM+ event objects.
	Flags	Flags that indicate various attributes of the CoClass, including how clients can create and use instances, whether it is visible to users in a browser, whether it is an ActiveX control, and whether it can be aggregated (act as part of a composite).
	Text	The definitions and declarations for the CoClass (see discussion below).
Enumeration	Attributes	Name, version, and GUID for the enumeration, and information linking it to help.
	Text	The definitions and declarations for the enumerated type (see discussion below).
Alias	Attributes	Name, version, and GUID for the enumeration, the type the alias represents, and information linking it to help.

Table 34.3 Type library pages (continued)

Type Info element	Page of type information	Contents of page
	Text	The definitions and declarations for the alias (see discussion below).
Record	Attributes	Name, version, and GUID for the record, and information linking it to help.
	Text	The definitions and declarations for the record (see discussion below).
Union	Attributes	Name, version, and GUID for the union, and information linking it to help.
	Text	The definitions and declarations for the union (see discussion below).
Module	Attributes	Name, version, GUID, and associated DLL for the module, and information linking it to help.
	Text	The definitions and declarations for the module (see discussion below).
Method	Attributes	Name, dispatch ID or DLL entry point, and information linking it to help.
	Parameters	Method return type, and a list of all parameters with their types and any modifiers.
	Flags	Flags to indicate how clients can view and use the method, whether this is a default method for the interface, and whether it is replaceable.
	Text	The definitions and declarations for the method (see discussion below).
Property	Attributes	Name, dispatch ID, type of property access method (getter vs. setter), and information linking it to help.
	Parameters	Property access method return type, and a list of all parameters with their types and any modifiers.
	Flags	Flags to indicate how clients can view and use the property, whether this is a default for the interface, whether the property is replaceable, bindable, and so on.
	Text	The definitions and declarations for the property access method (see discussion below).
Const	Attributes	Name, value, type (for module consts), and information linking it to help.
	Flags	Flags to indicate how clients can view and use the constant, whether this represents a default value, whether the constant is bindable, and so on.
	Text	The definitions and declarations for the constant (see discussion below).
Field	Attributes	Name, type, and information linking it to help.
	Flags	Flags to indicate how clients can view and use the field, whether this represents a default value, whether the field is bindable, and so on.
	Text	The definitions and declarations for the field (see discussion below).

Note For more detailed information about the various options you can set on type information pages, see the online Help for the Type Library editor.

You can use each of the pages of type information to view or edit the values it displays. Most of the pages organize the information into a set of controls so that you can type in values or select them from a list without requiring that you know the syntax of the corresponding declarations. This can prevent many small mistakes such as typographic errors when specifying values from a limited set. However, you may find it faster to type in the declarations directly. To do this, use the Text page.

All type library elements have a text page that displays the syntax for the element. This syntax appears in an IDL subset of Microsoft Interface Definition Language, or Object Pascal. Any changes you make in other pages of the element are reflected on the text page. If you add code directly in the text page, changes are reflected in the other pages of the Type Library editor.

The Type Library editor generates syntax errors if you add identifiers that are currently not supported by the editor; the editor currently supports only those identifiers that relate to type library support (not RPC support or constructs used by the Microsoft IDL compiler for C++ code generation or marshaling support).

Type library elements

The Type Library interface can seem overwhelmingly complicated at first. This is because it represents information about a great number of elements, each of which has its own characteristics. However, many of these characteristics are common to all elements. For example, every element (including the type library itself) has the following:

- A Name, which is used to describe the element and which is used when referring to the element in code.
- A GUID (globally unique identifier), which is a globally unique 128-bit value that COM uses to identify the element. This should always be supplied for the type library itself and for CoClasses and interfaces. It is optional otherwise.
- A Version number, which distinguishes between multiple versions of the element. This is always optional, but should be provided for CoClasses and interfaces, because some tools can’t use them without a version number.
- Information linking the element to a Help topic. These include a Help String, and Help Context or Help String Context value. The Help Context is used for a traditional Windows Help system where the type library has a stand-alone Help file. The Help String Context is used when help is supplied by a separate DLL instead. The Help Context or Help String Context refers to a Help file or DLL that is specified on the type library’s Attributes page. This is always optional.

Interfaces

An interface describes the methods (and any properties expressed as ‘get’ and ‘set’ functions) for an object that must be accessed through a virtual function table (VTable). If an interface is flagged as dual, a dispinterface is also implied and can be accessed through OLE automation. By default, the type library flags all interfaces you add as dual.

Interfaces can be assigned members: methods and properties. These appear in the object list pane as children of the interface node. Properties for interfaces are represented by the 'get' and 'set' methods used to read and write the property's underlying data. They are represented in the tree view using special icons that indicate their purpose.

Note When a property is specified as Write By Reference, it means it is passed as a pointer rather than by value. Some applications, such a Visual Basic, use Write By Reference, if it is present, to optimize performance. To pass the property only by reference rather than by value, use the property type *By Reference Only*. To pass the property by reference as well as by value, select Read | Write | Write By Ref. To invoke this menu, go to the toolbar and select the arrow next to the property icon.

Once you add the properties or methods using the toolbar button or the object list pane context menu, you desribe their syntax and attributes by selecting the property or method and using the pages of type information.

The Attributes page lets you give the property or method a name and dispatch ID (so that it can be called using IDispatch). For properties, you also assign a type. The function signature is created using the Parameters page, where you can add, remove, and rearrange parameters, set their type and any modifiers, and specify function return types.

Note Members of interfaces that need to raise exceptions should return an HRESULT and specify a return value parameter (PARAM_RETVAL) for the actual return value. Declare these methods using the **safecall** calling convention.

Note that when you assign properties and methods to an interface, they are implicitly assigned to its associated CoClass. This is why the Type Library editor does not let you add properties and methods directly to a CoClass.

Dispinterfaces

Interfaces are more commonly used than dispinterfaces to describe the properties and methods of an object. Dispinterfaces are only accessible through dynamic binding, while interfaces can have static binding through a vtable.

You can add methods and properties to dispinterfaces in the same way you add them to interfaces. However, when you create a property for a dispinterface, you can't specify a function kind or parameter types.

CoClasses

A CoClass describes a unique COM object that implements one or more interfaces. When defining a CoClass, you must specify which implemented interface is the default for the object, and optionally, which dispinterface is the default source for events. Note that you do not add properties or methods to a CoClass in the Type Library editor. Properties and methods are exposed to clients by interfaces, which are associated with the CoClass using the Implements page.

Type definitions

Enumerations, aliases, records, and unions all declare types that can then be used elsewhere in the type library.

Enums consist of a list of constants, each of which must be numeric. Numeric input is usually an integer in decimal or hexadecimal format. The base value is zero by default. You can add constants to your enumeration by selecting the enumeration in the object list pane and clicking the Const button on the toolbar or selecting New | Const command from the object list pane context menu.

Note It is strongly recommended that you provide help strings for your enumerations to make their meaning clearer. The following is a sample entry of an enumeration type for a mouse button and includes a help string for each enumeration element.

```
mbLeft = 0 [helpstring 'mbLeft'];

mbRight = 1 [helpstring 'mbRight'];

mbMiddle = 3 [helpstring 'mbMiddle'];
```

An alias creates an alias (type definition) for a type. You can use the alias to define types that you want to use in other type info such as records or unions. Associate the alias with the underlying type definition by setting the Type attribute on the Attributes page.

A record consists of a list of structure members or fields. A union is a record with only a variant part. Like a record, a union consists of a list of structure members or fields. However, unlike the members of records, each member of a union occupies the same physical address, so that only one logical value can be stored.

Add the fields to a record or union by selecting it in the object list pane and clicking the field button in the toolbar or right clicking and choosing field from the object list pane context menu. Each field has a name and a type, which you assign by selecting the field and assigning values using the Attributes page. Records and unions can be defined with an optional tag.

Members can be of any built-in type, or you can specify a type using alias before you define the record.

Modules

A module defines a group of functions, typically a set of DLL entry points. You define a module by

- Specifying a DLL that it represents on the attributes page.
- Adding methods and constants using the toolbar or the object list pane context menu. For each method or constant, you must then define its attributes by selecting the it in the object list pane and setting the values on the Attributes page.

For module methods, you must assign a name and DLL entry-point using the attributes page. Declare the function's parameters and return type using the parameters page.

For module constants, use the Attributes page to specify a name, type, and value.

Note The Type Library editor does not generate any declarations or implementation related to a module. The specified DLL must be created as a separate project.

Using the Type Library editor

Using the type library editor, you can create new type libraries or edit existing ones. Typically, an application developer uses a wizard to create the objects that are exposed in the type libarary, letting Delphi generate the type library automatically. Then, the automatically-generated type library is opened in the Type Library editor so that the interfaces can be defined (or modified), type definitions added, and so on.

However, even if you are not using a wizard to define the objects, you can use the Type Library editor to define a new type library. In this case, you must create any implementation classes yourself, because the Type Library editor does not generate code for CoClasses that were not associated with a type library by a wizard.

The editor supports a subset of valid types in a type library as described below.

The final topics in this section describe how to:

- Create a new type library
- Open an existing type library
- Add an interface to the type library
- Modify an interface
- Add properties and methods to the type library
- Add a CoClass to the type library
- Add an interface to a CoClass
- Add an enumeration to the type library
- Add an alias to the type library
- Add a record or union to the type library
- Add a module to the type library
- Save and register type library information

Valid types

In the Type Library editor, you use different type identifiers, depending on whether you are working in IDL or Object Pascal. Specify the language you want to use in the Environment options dialog.

The following types are valid in a type library for COM development. The Automation compatible column specifies whether the type can be used by an interface that has its Automation or Dispinterface flag checked.

These are the types that COM can marshal via the type library automatically.

Table 34.4 Valid types

Pascal type	IDL type	variant type	Automation compatible	Description
Smallint	short	VT_I2	Yes	2-byte signed integer
Integer	long	VT_I4	Yes	4-byte signed integer
Single	single	VT_R4	Yes	4-byte real
Double	double	VT_R8	Yes	8-byte real
Currency	CURRENCY	VT_CY	Yes	currency
TDateTime	DATE	VT_DATE	Yes	date
WideString	BSTR	VT_BSTR	Yes	binary string
IDispatch	IDispatch	VT_DISPATCH	Yes	pointer to IDispatch interface
SCODE	SCODE	VT_ERROR	Yes	Ole Error Code
WordBool	VARIANT_BOOL	VT_BOOL	Yes	True = -1, False = 0
OleVariant	VARIANT	VT_VARIANT	Yes	Ole Variant
IUnknown	IUnknown	VT_UNKNOWN	Yes	pointer to IUnknown interface
Shortint	byte	VT_I1	No	1 byte signed integer
Byte	unsigned char	VT_UI1	Yes	1 byte unsigned integer
Word	unsigned short	VT_UI2	Yes*	2 byte unsigned integer
LongWord	unsigned long	VT_UI4	Yes*	4 byte unsigned integer
Int64	__int64	VT_I8	No	8 byte signed integer
Largeuint	uint64	VT_UI8	No	8 byte unsigned integer
SYSINT	int	VT_INT	Yes*	system dependent integer (Win32=Integer)
SYSUINT	unsigned int	VT_UINT	Yes*	system dependent unsigned integer
HResult	HRESULT	VT_HRESULT	No	32 bit error code
Pointer		VT_PTR -> VT_VOID	No	untyped pointer
SafeArray	SAFEARRAY	VT_SAFEARRAY	No	OLE Safe Array
PChar	LPSTR	VT_LPSTR	No	pointer to Char
PWideChar	LPWSTR	VT_LPWSTR	No	pointer to WideChar

* Word, LongWord, SYSINT, and SYSUINT are Automation-compatible in most applications, but in older applications they may not be.

Note The Byte (VT_UI1) is Automation-compatible, but is not allowed in a Variant or OleVariant since many Automation servers do not handle this value correctly.

Besides these IDL types, any interfaces and types defined in the library or defined in referenced libraries can be used in a type library definition.

The Type Library editor stores type information in the generated type library (.TLB) file in binary form.

If a parameter type is specified as a Pointer type, the Type Library editor usually translates that type into a variable parameter. When the type library is saved, the variable parameter’s associated ElemDesc’s IDL flags are marked IDL_FIN or IDL_FOUT.

Often, ElemDesc IDL flags are not marked by IDL_FIN or IDL_FOUT when the type is preceded with a Pointer. Or, in the case of dispinterfaces, IDL flags are not typically used. In these cases, you may see a comment next to the variable identifier such as {IDL_None} or {IDL_In}. These comments are used when saving a type library to correctly mark the IDL flags.

SafeArrays

COM requires that arrays be passed via a special data type known as a SafeArray. You can create and destroy SafeArrays by calling special COM functions to do so, and all elements within a SafeArray must be valid automation-compatible types. The Delphi compiler has built-in knowledge of COM SafeArrays and automatically calls the COM API to create, copy, and destroy SafeArrays.

In the Type Library editor, a *SafeArray* must specify the type of its elements. For example, the following line from the text page declares a method with a parameter that is a *SafeArray* with an element type of Integer:

```
procedure HighLightLines(Lines: SafeArray of Integer);
```

Note Although you must specify the element type when declaring a *SafeArray* type in the Type Library editor, the declaration in the generated _TLB unit does not indicate the element type.

Using Object Pascal or IDL syntax

The Text page of the Type Library editor displays your type information in one of two ways:

- Using an extension of Object Pascal syntax.
- Using the Microsoft IDL.

Note When working on a CORBA object, you use neither of these on the text page. Instead, you must use the CORBA IDL.

You can select which language you want to use by changing the setting in the Environment Options dialog. Choose Tools | Environment Options, and specify either Pascal or IDL as the Language on the Type Library page of the dialog.

Note The choice of Object Pascal or IDL syntax also affects the choices available on the parameters attributes page.

Like Object Pascal applications in general, identifiers in type libraries are case insensitive. They can be up to 255 characters long, and must begin with a letter or an underscore (_).

Attribute specifications

Object Pascal has been extended to allow type libraries to include attribute specifications. Attribute specifications appear enclosed in square brackets and separated by commas. Each attribute specification consists of an attribute name followed (if appropriate) by a value.

The following table lists the attribute names and their corresponding values.

Table 34.5 Attribute syntax

Attribute name	Example	Applies to
aggregatable	[aggregatable]	typeinfo
appobject	[appobject]	CoClass typeinfo
bindable	[bindable]	members except CoClass members
control	[control]	type library, typeinfo
custom	[custom '{7B5687A1-F4E9-11D1-92A8-00C04F8C8FC4}' 0]	anything
default	[default]	CoClass members
defaultbind	[defaultbind]	members except CoClass members
defaultcollection	[defaultcollection]	members except CoClass members
defaultvtbl	[defaultvtbl]	CoClass members
dispid	[dispid]	members except CoClass members
displaybind	[displaybind]	members except CoClass members
dllname	[dllname 'Helper.dll']	module typeinfo
dual	[dual]	interface typeinfo
helpfile	[helpfile 'c:\help\myhelp.hlp']	type library
helpstringdll	[helpstringdll 'c:\help\myhelp.dll']	type library
helpcontext	[helpcontext 2005]	anything except CoClass members and parameters
helpstring	[helpstring 'payroll interface']	anything except CoClass members and parameters
helpstringcontext	[helpstringcontext $17]	anything except CoClass members and parameters
hidden	[hidden]	anything except parameters
immediatebind	[immediatebind]	members except CoClass members
lcid	[lcid $324]	type library
licensed	[licensed]	type library, CoClass typeinfo
nonbrowsable	[nonbrowsable]	members except CoClass members
nonextensible	[nonextensible]	interface typeinfo
oleautomation	[oleautomation]	interface typeinfo
predeclid	[predeclid]	typeinfo
propget	[propget]	members except CoClass members
propput	[propput]	members except CoClass members

Table 34.5 Attribute syntax (continued)

Attribute name	Example	Applies to
propputref	[propputref]	members except CoClass members
public	[public]	alias typeinfo
readonly	[readonly]	members except CoClass members
replaceable	[replaceable]	anything except CoClass members and parameters
requestedit	[requestedit]	members except CoClass members
restricted	[restricted]	anything except parameters
source	[source]	all members
uidefault	[uidefault]	members except CoClass members
usesgetlasterror	[usesgetlasterror]	members except CoClass members
uuid	[uuid '{7B5687A1-F4E9-11D1-92A8-00C04F8C8FC4}']	type library, typeinfo (required)
vararg	[vararg]	members except CoClass members
version	[version 1.1]	type library, typeinfo

Interface syntax

The Object Pascal syntax for declaring interface type information has the form

```
interfacename = interface[(baseinterface)] [attributes]
functionlist
[propertymethodlist]
end;
```

For example, the following text declares an interface with two methods and one property:

```
Interface1 = interface (IDispatch)
  [uuid '{7B5687A1-F4E9-11D1-92A8-00C04F8C8FC4}', version 1.0]
  function Calculate(optional seed:Integer=0): Integer;
  procedure Reset;
  procedure PutRange(Range: Integer) [propput, dispid $00000005]; stdcall;
  function GetRange: Integer;[propget, dispid $00000005]; stdcall;
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid ‘{5FD36EEF-70E5-11D1-AA62-00C04FB16F42}’,version 1.0]
interface Interface1 :IDispatch
{
  long Calculate([in, optional, defaultvalue(0)] long seed);
  void Reset(void);
  [propput, id(0x00000005)] void _stdcall PutRange([in] long Value);
  [propput, id(0x00000005)] void _stdcall getRange([out, retval] long *Value);
};
```

Dispatch interface syntax

The Object Pascal syntax for declaring dispinterface type information has the form

```
dispinterfacename = dispinterface [attributes]
functionlist
[propertylist]
end;
```

For example, the following text declares a dispinterface with the same methods and property as the previous interface:

```
MyDispObj = dispinterface
[uuid '{5FD36EEF-70E5-11D1-AA62-00C04FB16F42}',
  version 1.0,
  helpstring 'dispatch interface for MyObj']
  function Calculate(seed:Integer): Integer [dispid 1];
  procedure Reset [dispid 2];
  property Range: Integer [dispid 3];
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{5FD36EEF-70E5-11D1-AA62-00C04FB16F42}',
  version 1.0,
  helpstring "dispatch interface for MyObj"]
dispinterface Interface1
{
  methods:
    [id(1)] int Calculate([in] int seed);
    [id(2)] void Reset(void);
  properties:
    [id(3)] int Value;
};
```

CoClass syntax

The Object Pascal syntax for declaring CoClass type information has the form

```
classname = coclass(interfacename[interfaceattributes], ...); [attributes];
```

For example, the following text declares a coclass for the interface *IMyInt* and dispinterface *DmyInt*:

```
myapp = coclass(IMyInt [source], DMyInt);
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
  version 1.0,
  helpstring 'A class',
  appobject]
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
  version 1.0,
  helpstring 'A class',
  appobject]
coclass myapp
{
  methods:
  [source] interface IMyInt);
  dispinterface DMyInt;
};
```

Enum syntax

The Object Pascal syntax for declaring Enum type information has the form

```
enumname = ([attributes] enumlist);
```

For example, the following text declares an enumerated type with three values:

```
location = ([uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
         helpstring 'location of booth']
  Inside = 1 [helpstring 'Inside the pavillion'];
  Outside = 2 [helpstring 'Outside the pavillion'];
  Offsite = 3 [helpstring 'Not near the pavillion'];);
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
        helpstring 'location of booth']
typedef enum
{
  [helpstring 'Inside the pavillion'] Inside = 1,
  [helpstring 'Outside the pavillion'] Outside = 2,
  [helpstring 'Not near the pavillion'] Offsite = 3
} location;
```

Alias syntax

The Object Pascal syntax for declaring Alias type information has the form

```
aliasname = basetype[attributes];
```

For example, the following text declares DWORD as an alias for integer:

```
DWORD = Integer [uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}'];
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}'] typedef long DWORD;
```

Record syntax

The Object Pascal syntax for declaring Record type information has the form

```
recordname = record [attributes] fieldlist end;
```

For example, the following text declares a record:

```
Tasks = record [uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
               helpstring 'Task description']
  ID: Integer;
  StartDate: TDate;
  EndDate: TDate;
  Ownername: WideString;
  Subtasks: safearray of Integer;
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
        helpstring 'Task description']
typedef struct
{
  long ID;
  DATE StartDate;
  DATE EndDate;
  BSTR Ownername;
  SAFEARRAY (int) Subtasks;
} Tasks;
```

Union syntax

The Object Pascal syntax for declaring Union type information has the form

```
unionname = record [attributes]
case Integer of
  0: field1;
  1: field2;
  ...
end;
```

For example, the following text declares a union:

```
MyUnion = record [uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
                  helpstring 'item description']
case Integer of
  0: (Name: WideString);
  1: (ID: Integer);
  3: (Value: Double);
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
        helpstring 'item description']
typedef union
{
  BSTR Name;
  long ID;
  double Value;
  } MyUnion;
```

Module syntax

The Object Pascal syntax for declaring Module type information has the form

```
modulename = module constants entrypoints end;
```

For example, the following text declares the type information for a module:

```
MyModule = module [uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
                   dllname 'circle.dll']
  PI: Double = 3.14159;
  function area(radius: Double): Double [ entry 1 ]; stdcall;
  function circumference(radius: Double): Double [ entry 2 ]; stdcall;
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
       dllname("circle.dll")]
module MyModule
{
  double PI = 3.14159;
  [entry(1)] double _stdcall area([in] double radius);
  [entry(2)] double _stdcall circumference([in] double radius);
};
```

Creating a new type library

You may want to create a type library that is independent of a particular COM object. For example, you might want to define a type library that contains type definitions that you use in several other type libraries. You can then create a type library of basic definitions and add it to the uses page of other type libraries.

You can also create a type library for an object that is not yet implemented. Once the type library contains the interface definition, you can use the COM object wizard to generate a CoClass and implementation.

To create a new type library,

1 Choose File | New | Other to open the New Items dialog box.

2 Choose the ActiveX page.

3 Select the Type Library icon.

4 Choose OK.

   The Type Library editor opens with a prompt to enter a name for the type library.

5 Enter a name for the type library. Continue by adding elements to your type library.

Opening an existing type library

When you use the wizards to create an ActiveX control, Automation object, Active form, Active Server Page object, COM object, transactional object, remote data module, or transactional data module, a type library is automatically created with an implementation unit. In addition, you may have type libraries that are associated with other products (servers) that are available on your system.

To open a type library that is not currently part of your project,

1 Choose File | Open from the main menu in the IDE.

2 In the Open dialog box, set the File Type to type library.

3 Navigate to the desired type library files and choose Open.

To open a type library associated with the current project,

1 Choose View | Type Library.

Note When you use the CORBA Object wizard, you can also choose View | Type Library to edit the CORBA Object interfaces. What you see is not, technically speaking, a type library, but you can use it in much the same way.

Now, you can add interfaces, CoClasses, and other elements of the type library such as enumerations, properties, and methods.

Note Changes you make to any type library information with the Type Library editor can be automatically reflected in the associated implementation class. If you want to review the changes before they are added, be sure that the Apply Updates dialog is on. It is on by default and can be changed in the setting, "Display updates before refreshing," on the Tools | Environment Options | Type Library page. For more information, see "Apply Updates dialog" on page 34-25.

Tip When writing client applications, you do not need to open the type library. You only need the *Project*_TLB unit that the Type Library editor creates from a type library, not the type library itself. You can add this file directly to a client project, or, if the type library is registered on your system, you can use the Import Type Library dialog (Project | Import Type Library).

Adding an interface to the type library

To add an interface,

1. On the toolbar, click on the interface icon.

   An interface is added to the object list pane prompting you to add a name.

2. Type a name for the interface.

The new interface contains default attributes that you can modify as needed.

You can add properties (represented by getter/setter functions) and methods to suit the purpose of the interface.

Modifying an interface using the type library

There are several ways to modify an interface or dispinterface once it is created.

- You can change the interface's attributes using the page of type information that contains the information you want to change. Select the interface in the object list pane and then use the controls on the appropriate page of type information. For example, you may want to change the parent interface using the attributes page, or use the flags page to change whether or not it is a dual interface.
- You can edit the interface declaration directly by selecting the interface in the object list pane and then editing the declarations on the Text page.
- You can Add properties and methods to the interface (see the next section).
- You can modify the properties and methods already in your interface by changing their type information.
- You can associate it with a CoClass by selecting the CoClass in the object list pane, right-clicking on the Implements page, and choosing Insert Interface.

Note When using the type library to add a CORBA interface, most of the information on the attributes page is irrelevent. You will also not need the Flags page.

If the interface is associated with a CoClass that was generated by a wizard, you can tell the Type Library editor to apply your changes to the implementation file by clicking the Refresh button on the toolbar. If you have the Apply Updates dialog enabled, the Type Library editor notifies you before updating the sources and warns you of potential problems. For example, if you rename an event interface by mistake, you may get a warning in your source file that looks like this:

```
Because of the presence of instance variables in your implementation file,
Delphi was not able to update the file to reflect the change in your event
interface name. As Delphi has updated the type library for you, however, you
must update the implementation file by hand.
```

You also get a TODO comment in your source file immediately above it.

Warning If you ignore this warning and TODO comment, the code will not compile.

Adding properties and methods to an interface or dispinterface

To add properties or methods to an interface or dispinterface,

1. Select the interface, and choose either a property or method icon from the toolbar. If you are adding a property, you can click directly on the property icon to create a read/write property (with both a getter and a setter), or click the down arrow to display a menu of property types.

   The property access method members or method member is added to the object list pane, prompting you to add a name.

2. Type a name for the member.

The new member contains default settings on its attributes, parameters, and flags pages that you can modify to suit the member. For example, you will probably want to assign a type to a property on the attributes page. If you are adding a method, you will probably want to specify its parameters on the parameters page.

As an alternate approach, you can add properties and methods by typing directly into the text page using Pascal or IDL syntax. For example, if you are working in Pascal syntax, you can type the following property declarations into the text page of an interface:

```
Interface1 = interface(IDispatch)
  [ uuid '{5FD36EEF-70E5-11D1-AA62-00C04FB16F42}',
    version 1.0,
    dual,
    oleautomation ]
 function AutoSelect: Integer [propget, dispid $00000002]; safecall; // Add this
 function AutoSize: WordBool [propget, dispid $00000001]; safecall; // And this
 procedure AutoSize(Value: WordBool) [propput, dispid $00000001]; safecall; // And this
end;
```

If you are working in IDL, you can add the same declarations as follows:

```
[
  uuid(5FD36EEF-70E5-11D1-AA62-00C04FB16F42),
  version(1.0),
  dual,
  oleautomation
]
interface Interface1: IDispatch
{ // Add everything between the curly braces
[propget, id(0x00000002)]
  HRESULT _stdcall AutoSelect([out, retval] long Value );
  [propget, id(0x00000003)]
  HRESULT _stdcall AutoSize([out, retval] VARIANT_BOOL Value );
  [propput, id(0x00000003)]
  HRESULT _stdcall AutoSize([in] VARIANT_BOOL Value );
};
```

After you have added members to an interface using the interface text page, the members appear as separate items in the object list pane, each with its own attributes, flags, and parameters pages. You can modify each new property or method by selecting it in the object list pane and using these pages, or by making edits directly in the text page.

If the interface is associated with a CoClass that was generated by a wizard, you can tell the Type Library editor to apply your changes to the implementation file by clicking the Refresh button on the toolbar. The Type Library editor adds new methods to your implementation class to reflect the new members. You can then locate the new methods in implementation unit's source code and fill in their bodies to complete the implementation.

If you have the Apply Updates dialog enabled, the Type Library editor notifies you of all changes before updating the sources and warns you of potential problems.

Adding a CoClass to the type library

The easiest way to add a CoClass to your project is to choose File | New | Other from the main menu in the IDE and use the appropriate wizard on the ActiveX or Multitier page of the New Items dialog. The advantage to this approach is that, in addition to adding the CoClass and its interface to the type library, the wizard adds an implementation unit and updates the project file to include the new implementation unit in its uses clause.

If you are not using a wizard, however, you can create a CoClass by clicking the CoClass icon on the toolbar and then specifying its attributes. You will probably want to give the new CoClass a name (on the Attributes page), and may want to use the Flags page to indicate information such as whether the CoClass is an application object, whether it represents an ActiveX control, and so on.

Note When you add a CoClass to a type library using the toolbar instead of a wizard, you must generate the implementation for the CoClass yourself and update it by hand every time you change an element on one of the CoClass's interfaces. You can't add members directly to a CoClass. Instead, you implicitly add members when you add an interface to the CoClass.

Adding an interface to a CoClass

CoClasses are defined by the interfaces they present to clients. While you can add any number of properties and methods to the implementation class of a CoClass, clients can only see those properties and methods that are exposed by interfaces associated with the CoClass.

To associate an interface with a CoClass, right-click in the Implements page for the class and choose Insert Interface to display a list of interfaces from which you can choose. The list includes interfaces that are defined in the current type library and those defined in any type libraries that the current type library references. Choose an interface you want the class to implement. The interface is added to the page with its GUID and other attributes.

If the CoClass was generated by a wizard, the Type Library editor automatically updates the implementation class to include skeletal methods for the methods (including property access methods) of any interfaces you add this way.If you have the Apply Updates dialog enabled, the Type Library editor notifies you before updating the sources and warns you of potential problems.

Adding an enumeration to the type library

To add enumerations to a type library,

1 On the toolbar, click on the enum icon.

   An enum type is added to the object list pane prompting you to add a name.

2 Type a name for the enumeration.

   The new enum is empty and contains default attributes in its attributes page for you to modify.

Add values to the enum by clicking on the New Const button. Then, select each enumerated value and assign it a name (and possibly a value) using the attributes page.

Once you have added an enumeration, the new type is available for use by the type library or any other type library that references it from its uses page. For example, you can use the enumeration as the type for a property or parameter.

Adding an alias to the type library

To add an alias to a type library,

1 On the toolbar, click on the alias icon.

   An alias type is added to the object list pane prompting you to add a name.

2 Type a name for the alias.

   By default, the new alias stands for an Integer type. Use the Attributes page to change this to the type you want the alias to represent.

Once you have added an alias, the new type is available for use by the type library or any other type library that references it from its uses page. For example, you can use the alias as the type for a property or parameter.

Adding a record or union to the type library

To add a record or union to a type library,

1 On the toolbar, click on the record icon or the union icon.

The selected type element is added to the object list pane prompting you to add a name.

2 Type a name for the record or union.

At this point, the new record or union contains no fields.

3 With the record or union selected in the object list pane, click on the field icon in the toolbar. Specify the field's name and type, using the Attributes page.

4 Repeat step 3 for as many fields as you need.

Once you have defined the record or union, the new type is available for use by the type library or any other type library that references it from its uses page. For example, you can use the record or union as the type for a property or parameter.

Adding a module to the type library

To add a module to a type library,

1 On the toolbar, click on the module icon.

The selected module is added to the object list pane prompting you to add a name.

2 Type a name for the module.

3 On the Attributes page, specify the name of the DLL whose entry points the Module represents.

4 Add any methods from the DLL you specified in step 3 by clicking on the Method icon in the toolbar and then using the attributes pages to describe the method.

5 Add any constants you want the module to define by clicking on the Const icon on the toolbar. For each constant, specify a name, type, and value.

Saving and registering type library information

After modifying your type library, you'll want to save and register the type library information.

Saving the type library automatically updates:

- The binary type library file (.tlb extension).
- The *Project*_TLB unit that represents its contents
- The implementation code for any CoClasses that were generated by a wizard.

Note The type library is stored as a separate binary (.TLB) file, but is also linked into the server (.EXE, DLL, or .OCX).

Note When using the Type Library editor for CORBA interfaces, the *Project*_TLB.pas unit defines the stub and skeleton objects required by the CORBA application.

The Type Library editor gives you options for storing your type library information. Which way you choose depends on what stage you are at in implementing the type library:

- Save, to save both the .TLB and the *Project*_TLB unit to disk.
- Refresh, to update the type library units in memory only.
- Register, to add an entry for the type library in your system's Windows registry. This is done automatically when the server with which the .TLB is associated is itself registered.
- Export, to save a .IDL file that contains the type and interface definitions in IDL syntax.

All the above methods perform syntax checking. When you refresh, register, or save the type library, Delphi automatically updates the implementation unit of any CoClasses that were created using a wizard. Optionally, you can review these updates before they are committed, if you have the Type Library editor option, Apply Updates on.

Apply Updates dialog

The Apply Updates dialog appears when you refresh, register, or save the type library if you have selected "Display updates before refreshing' in the Tools | Environment Options | Type Library page (which is on by default).

Without this option, the Type Library editor automatically updates the sources of the associated object when you make changes in the editor. With this option, you have a chance to veto the proposed changes when you attempt to refresh, save, or register the type library.

The Apply Updates dialog will warn you about potential errors, and will insert TODO comments in your source file. For example, if you rename an event by mistake, you will get a warning in your source file that looks like this:

```
Because of the presence of instance variables in your implementation file,
Delphi was not able to update the file to reflect the change in your event
interface name. As Delphi has updated the type library for you, however, you
must update the implementation file by hand.
```

You will also get a TODO comment in your source file immediately above it.

Note If you ignore this warning and TODO comment, the code will not compile.

Saving a type library

Saving a type library

- Performs a syntax and validity check.
- Saves information out to a .TLB file.
- Saves information out to the *Project*_TLB unit.
- Notifies the IDE's module manager to update the implementation, if the type library is associated with a CoClass that was generated by a wizard.

To save the type library, choose File | Save from the Delphi main menu.

Refreshing the type library

Refreshing the type library

- Performs a syntax check.
- Regenerates the Delphi type library units in memory only. It does not save any files to disk.
- Notifies the IDE's module manager to update the implementation, if the type library is associated with a CoClass that was generated by a wizard.

To refresh the type library choose the Refresh icon on the Type Library editor toolbar.

Note If you have renamed items in the type library, refreshing the implementation may create duplicate entries. In this case, you must move your code to the correct entry and delete any duplicates. Similarly, if you delete items in the type library, refreshing the implementation does not remove them from CoClasses (under the assumption that you are merely removing them from visibility to clients). You must delete these items manually in the implementation unit if they are no longer needed.

Registering the type library

Typically, you do not need to explicitly register a type library because it is registered automatically when you register your COM server application (see "Registering a COM object" on page 36-16). However, when you create a type library using the Type Library wizard, it is not associated with a server object. In this case, you can register the type library directly using the toolbar.

Registering the type library,

- Performs a syntax check
- Adds an entry to the Windows Registry for the type library

To register the type library, choose the Register icon on the Type Library editor toolbar.

Exporting an IDL file

Exporting the type library,

- Performs a syntax check.
- Creates an IDL file that contains the type information declarations. This file describes the type information in either CORBA IDL or Microsoft IDL.

To export the type library, choose the Export icon on the Type Library editor toolbar.

Deploying type libraries

By default, when you have a type library that was created as part of an ActiveX or Automation server project, the type library is automatically linked into the .DLL, .OCX, or EXE as a resource.

You can, however, deploy your application with the type library as a separate .TLB, as Delphi maintains the type library, if you prefer.

Historically, type libraries for Automation applications were stored as a separate file with the .TLB extension. Now, typical Automation applications compile the type libraries into the .OCX or .EXE file directly. The operating system expects the type library to be the first resource in the executable (.DLL, .OCX, or .EXE) file.

When you make type libraries other than the primary project type library available to application developers, the type libraries can be in any of the following forms:

- A resource. This resource should have the type TYPELIB and an integer ID. If you choose to build type libraries with a resource compiler, it must be declared in the resource (.RC) file as follows:

  ```
  1 typelib mylib1.tlb
  2 typelib mylib2.tlb
  ```

  There can be multiple type library resources in an ActiveX library. Application developers use the resource compiler to add the .TLB file to their own ActiveX library.

- Stand-alone binary files. The .TLB file output by the Type Library editor is a binary file.

Chapter

35

Creating COM clients

COM clients are applications that make use of a COM object implemented by another application or library. The most common types are applications that control an Automation server (Automation controllers) and applications that host an ActiveX control (ActiveX containers).

At first glance these two types of COM client are very different: The typical Automation controller launches an external server EXE and issues commands to make that server perform tasks on its behalf. The Automation server is usually nonvisual and out-of-process. The typical ActiveX client, on the other hand, hosts a visual control, using it much the same way you use any control on the Component palette. ActiveX servers are always in-process servers.

However, the task of writing these two types of COM client is remarkably similar: The client application obtains an interface for the server object and uses its properties and methods. Delphi makes this particularly easy by letting you wrap the server CoClass in a component on the client, which you can even install on the Component palette. Samples of such component wrappers appear on two pages of the Component palette: sample ActiveX wrappers appear on the ActiveX page and sample Automation objects appear on the Servers page.

When writing a COM client, you must understand the interface that the server exposes to clients, just as you must understand the properties and methods of a component from the Component palette to use it in your application. This interface (or set of interfaces) is determined by the server application, and typically published in a type library. For specific information on a particular server application's published interfaces, you should consult that application's documentation.

Even if you do not choose to wrap a server object in a component wrapper and install it on the Component palette, you must make its interface definition available to your application. To do this, you can import the server's type information.

Note You can also query the type information directly using COM APIs, but Delphi provides no special support for this.

Some older COM technologies, such as object linking and embedding (OLE), do not provide type information in a type library. Instead, they rely on a standard set of predefined interfaces. These are discussed in “Creating Clients for servers that do not have a type library” on page 35-15.

Importing type library information

To make information about the COM server available to your client application, you must import the information about the server that is stored in the server’s type library. Your application can then use the resulting generated classes to control the server object.

There are two ways to import type library information:

- You can use the Import Type Library dialog to import all available information about the server types, objects, and interfaces. This is the most general method, because it lets you import information from any type library and can optionally generate component wrappers for all creatable CoClasses in the type library that are not flagged as Hidden, Restricted, or PreDeclID.
- You can use the Import ActiveX dialog if you are importing from the type library of an ActiveX control. This imports the same type information, but only creates component wrappers for CoClasses that represent ActiveX controls.
- You can use the command line utility tlibimp.exe which provides additional configuration options not available from within the IDE.
- A type library generated using a wizard is automatically imported using the same mechanism as the import type library menu item.

Regardless of which method you choose to import type library information, the resulting dialog creates a unit with the name *TypeLibName*_TLB, where *TypeLibName* is the name of the type library. This file contains declarations for the classes, types, and interfaces defined in the type library. By including it in your project, those definitions are available to your application so that you can create objects and call their interfaces. This file may be recreated by the IDE from time to time; as a result, making manual changes to the file is not recommended.

In addition to adding type definitions to the *TypeLibName*_TLB unit, the dialog can also create VCL class wrappers for any CoClasses defined in the type library. When you use the Import Type Library dialog, these wrappers are optional. When you use the Import ActiveX dialog, they are always generated for all CoClasses that represent controls.

The generated class wrappers represent the CoClasses to your application, and expose the properties and methods of its interfaces. If a CoClass supports the interfaces for generating events (*IConnectionPointContainer* and *IConnectionPoint*), the VCL class wrapper creates an event sink so that you can assign event handlers for the events as simply as you can for any other component. If you tell the dialog to install the generated VCL classes on the Component palette, you can use the Object Inspector to assign property values and event handlers.

Note The Import Type Library dialog does not create class wrappers for COM+ event objects. To write a client that responds to events generated by a COM+ event object, you must create the event sink programmatically. This process is described in "Handling COM+ events" on page 35-14.

For more details about the code generated when you import a type library, see "Code generated when you import type library information" on page 35-5.

Using the Import Type Library dialog

To import a type library,

1 Choose Project | Import Type Library.
2 Select the type library from the list.

   The dialog lists all the libraries registered on this system. If the type library is not in the list, choose the Add button, find and select the type library file, choose OK. This registers the type library, making it available. Then repeat step 2. Note that the type library could be a stand-alone type library file (.tlb, .olb), or a server that provides a type library (.dll, .ocx, .exe).

3 If you want to generate a VCL component that wraps a CoClass in the type library, check Generate Component Wrapper. If you do not generate the component, you can still use the CoClass by using the definitions in the *TypeLibName*_TLB unit. However, you will have to write your own calls to create the server object and, if necessary, to set up an event sink.

   The Import Type Library dialog only imports CoClasses that are have the CanCreate flag set and that do not have the Hidden, Restricted, or PreDeclID flags set. These flags can be overridden using the command-line utility tlibimp.exe.

4 If you do not want to install a generated component wrapper on the Component palette, choose Create Unit. This generates the *TypeLibName*_TLB unit and, if you checked Generate Component Wrapper in step 3, adds the declaration of the component wrapper. This exits the Import Type Library dialog.
5 If you want to install the generated component wrapper on the Component palette, select the Palette page on which this component will reside and then choose Install. This generates the *TypeLibName*_TLB unit, like the Create Unit button, and then displays the Install component dialog, letting you specify the package where the components should reside (either an existing package or a new one). This button is grayed out if no component can be created for the type library.

When you exit the Import Type Library dialog, the new *TypeLibName*_TLB unit appears in the directory specified by the Unit dir name control. This file contains declarations for the elements defined in the type library, as well as the generated component wrapper if you checked Generate Component Wrapper.

In addition, if you installed the generated component wrapper, a server object that the type library described now resides on the Component palette. You can use the Object Inspector to set properties or write an event handler for the server. If you add the component to a form or data module, you can right-click on it at design time to see its property page (if it supports one).

Note The Servers page of the Component palette contains a number of example Automation servers that were imported this way for you.

Using the Import ActiveX dialog

To import an ActiveX control,

1 Choose Component | Import ActiveX Control.

2 Select the type library from the list.

The dialog lists all the registered libraries that define ActiveX controls. (This is a subset of the libraries listed in the Import Type Library dialog.) If the type library is not in the list, choose the Add button, find and select the type library file, choose OK. This registers the type library, making it available. Then repeat step 2. Note that the type library could be a stand-alone type library file (.tlb, .olb), or an ActiveX server (.dll, .ocx).

3 If you do not want to install the ActiveX control on the Component palette, choose Create Unit. This generates the *TypeLibName*_TLB unit and adds the declaration of its component wrapper. This exits the Import ActiveX dialog.

4 If you want to install the ActiveX control on the Component palette, select the Palette page on which this component will reside and then choose Install. This generates the *TypeLibName*_TLB unit, like the Create Unit button, and then displays the Install component dialog, letting you specify the package where the components should reside (either an existing package or a new one).

When you exit the Import ActiveX dialog, the new *TypeLibName*_TLB unit appears in the directory specified by the Unit dir name control. This file contains declarations for the elements defined in the type library, as well as the generated component wrapper for the ActiveX control.

Note Unlike the Import Type Library dialog where it is optional, the import ActiveX dialog always generates a component wrapper. This is because, as a visual control, an ActiveX control needs the additional support of the component wrapper so that it can fit in with VCL forms.

If you installed the generated component wrapper, an ActiveX control now resides on the Component palette. You can use the Object Inspector to set properties or write event handlers for this control. If you add the control to a form or data module, you can right-click on it at design time to see its property page (if it supports one).

Note The ActiveX page of the Component palette contains a number of example ActiveX controls that were imported this way for you.

Code generated when you import type library information

Once you import a type library, you can view the generated *TypeLibName*_TLB unit. At the top, you will find the following:

- Constant declarations giving symbolic names to the GUIDS of the type library and its interfaces and CoClasses. The names for these constants are generated as follows:
    - The GUID for the type library has the form LBID_*TypeLibName*, where *TypeLibName* is the name of the type library.
    - The GUID for an interface has the form IID_*InterfaceName*, where *InterfaceName* is the name of the interface.
    - The GUID for a dispinterface has the form DIID_*InterfaceName*, where *InterfaceName* is the name of the dispinterface.
    - The GUID for a CoClass has the form CLASS_*ClassName*, where *ClassName* is the name of the CoClass.
- Declarations for the CoClasses in the type library. These map each CoClass to its default interface.
- Declarations for the interfaces and dispinterfaces in the type library.
- Declarations for a creator class for each CoClass whose default interface supports Vtable binding. The creator class has two class methods, *Create* and *CreateRemote*, that can be used to instantiate the CoClass locally (*Create*) or remotely (*CreateRemote*).These methods return the default interface for the CoClass.

These declarations provide you with what you need to create instances of the CoClass and access its interface. All you need do is add the generated *TypeLibName*_TLB.pas file to the uses clause of the unit where you wish to bind to a CoClass and call its interfaces.

Note This portion of the *TypeLibName*_TLB unit is also generated when you use the Type Library editor or the command-line utility TLIBIMP.

If you want to use an ActiveX control, you also need the generated VCL wrapper in addition to the declarations described above. The VCL wrapper handles window management issues for the control. You may also have generated a VCL wrapper for other CoClasses in the Import Type Library dialog. These VCL wrappers simplify the task of creating server objects and calling their methods. They are especially recommended if you want your client application to respond to events.

The declarations for generated VCL wrappers appear at the bottom of the interface section. Component wrappers for ActiveX controls are descendants of *TOleControl*. Component wrappers for Automation objects descend from *TOleServer*. The generated component wrapper adds the properties, events, and methods exposed by the CoClass's interface. You can use this component like any other VCL component.

Warning You should not edit the generated *TypeLibName*_TLB unit. It is regenerated each time the type library is refreshed, so any changes will be overwritten.

Note For the most up-to-date information about the generated code, refer to the comments in the automatically-generated *TypeLibName*_TLB unit.

Controlling an imported object

After importing type library information, you are ready to start programming with the imported objects. How you proceed depends in part on the objects, and in part on whether you have chosen to create component wrappers.

Using component wrappers

If you generated a component wrapper for your server object, writing your COM client application is not very different from writing any other application that contains VCL components. The server object's properties, methods, and events are already encapsulated in the VCL component. You need only assign event handlers, set property values, and call methods.

To use the properties, methods, and events of the server object, see the documentation for your server. The component wrapper automatically provides a dual interface where possible. Delphi determines the VTable layout from information in the type library.

In addition, your new component inherits certain important properties and methods from its base class.

ActiveX wrappers

You should always use a component wrapper when hosting ActiveX controls, because the component wrapper integrates the control's window into the VCL framework.

The properties and methods an ActiveX control inherits from *TOleControl* allow you to access the underlying interface or obtain information about the control. Most applications, however, do not need to use these. Instead, you use the imported control the same way you would use any other VCL control.

Typically, ActiveX controls provide a property page that lets you set their properties. Property pages are similar to the component editors some components display when you double-click on them in the form designer. To display an ActiveX control's property page, right click and choose Properties.

The way you use most imported ActiveX controls is determined by the server application. However, ActiveX controls use a standard set of notifications when they represent the data from a database field. See "Using data-aware ActiveX controls" on page 35-8 for information on how to host such ActiveX controls.

Automation object wrappers

The wrappers for Automation objects let you control how you want to form the connection to your server object:

- The *ConnectKind* property indicates whether the server is local or remote and whether you want to connect to a server that is already running or if a new instance should be launched. When connecting to a remote server, you must specify the machine name using the *RemoteMachineName* property.
- Once you have specified the *ConnectKind*, there are three ways you can connect your component to the server:
  - you can explicitly connect to the server by calling the component's *Connect* method.
  - You can tell the component to connect automatically when your application starts up by setting the *AutoConnect* property to *True*.
  - You do not need to explicitly connect to the server. The component automatically forms a connection when you use one of the server's properties or methods using the component.

Calling methods or accessing properties is the same as using any other component:

```
TServerComponent1.DoSomething;
```

Handling events is easy, because you can use the Object Inspector to write event handlers. Note, however, that the event handler on your component may have slightly different parameters than those defined for the event in the type library. Specifically, pointer types (var parameters and interface pointers) are changed to Variants. You must explicitly cast var parameters to the underlying type before assigning a value. Interface pointers can be cast to the appropriate interface type using the **as** operator.For example, the following code shows an event handler for the ExcelApplication event, OnNewWorkBook. The event handler has a parameter that provides the interface of another CoClass (ExcelWorkbook). However, the interface is not passed as an ExcelWorkbook interface pointer, but rather as an OleVariant.

```
procedure TForm1.XLappNewWorkbook(Sender: TObject; var Wb:OleVariant);
begin
  { Note how the OleVariant for the interface must be cast to the correct type }
  ExcelWorkbook1.ConnectTo((iUnknown(wb) as ExcelWorkbook));
end;
```

In this example, the event handler assigns the workbook to an ExcelWorkbook component (ExcelWorkbook1). This demonstrates how to connect a component wrapper to an existing interface by using the *ConnectTo* method. The *ConnectTo* method is added to the generated code for the component wrapper.

Servers that have an application object expose a Quit method on that object to let clients terminate the connection. Quit typically exposes functionality that is equivalent to using the File menu to quit the application. Code to call the Quit method is generated in your component's *Disconnect* method. If it is possible to call the Quit method with no parameters, the component wrapper also has an *AutoQuit* property. *AutoQuit* causes your controller to call Quit when the component is freed. If you want to disconnect at some other time, or if the Quit method requires parameters, you must call it explicitly. Quit appears as a public method on the generated component.

Using data-aware ActiveX controls

When you use a data-aware ActiveX control in a Delphi application, you must associate it with the database whose data it represents. To do this, you need a data source component, just as you need a data source for any data-aware VCL control.

After you place the data-aware ActiveX control in the form designer, assign its *DataSource* property to the data source that represents the desired dataset. Once you have specified a data source, you can use the Data Bindings editor to link the control's data-bound property to a field in the dataset.

To display the Data Bindings editor, right-click the data-aware ActiveX control to display a list of options. In addition to the basic   options, the additional Data Bindings item appears. Select this item to see the Data Bindings editor, which lists the names of fields in the dataset and the bindable properties of the ActiveX control.

To bind a field to a property,

1. In the ActiveX Data Bindings Editor dialog, select a field and a property name.

   Field Name lists the fields of the database and Property Name lists the ActiveX control properties that can be bound to a database field. The dispID of the property is in parentheses, for example, Value(12).

2. Click Bind and OK.

Note If no properties appear in the dialog, the ActiveX control contains no data-aware properties. To enable simple data binding for a property of an ActiveX control, use the type library as described in "Enabling simple data binding with the type library" on page 38-10.

The following example walks you through the steps of using a data-aware ActiveX control in the Delphi container. This example uses the Microsoft Calendar Control, which is available if you have Microsoft Office 97 installed on your system.

1. From the Delphi main menu, choose Component | Import ActiveX Control.
2. Select a data-aware ActiveX control, such as the Microsoft Calendar control 8.0, change its class name to *TCalendarAXControl*, and click Install.
3. In the Install dialog, click OK to add the control to the default user package, which makes the control available on the Palette.
4. Choose Close All and File | New | Application to begin a new application.
5. From the ActiveX tab, drop a *TCalendarAXControl* object, which you just added to the Palette, onto the form.
6. From the Data Access tab, drop a *DataSource* and *Table* object onto the form.
7. Select the *DataSource* object and set its *DataSet* property to *Table1*.
8. Select the *Table* object and do the following:
   - Set the *DatabaseName* property to DBDEMOS
   - Set the *TableName* property to EMPLOYEE.DB
   - Set the *Active* property to *True*

9 Select the *TCalendarAXControl* object and set its *DataSource* property to *DataSource1*.

10 Select the *TCalendarAXControl* object, right-click, and choose Data Bindings to invoke the ActiveX Control Data Bindings Editor.

Field Name lists all the fields in the active database. Property Name lists those properties of the ActiveX Control that can be bound to a database field. The dispID of the property is in parentheses.

11 Select the *HireDate* field and the *Value* property name, choose Bind, and OK.

The field name and property are now bound.

12 From the Data Controls tab, drop a *DBGrid* object onto the form and set its *DataSource* property to *DataSource1*.

13 From the Data Controls tab, drop a *DBNavigator* object onto the form and set its *DataSource* property to *DataSource1*.

14 Run the application.

15 Test the application as follows:

With the *HireDate* field displayed in the *DBGrid* object, navigate through the database using the Navigator object. The dates in the ActiveX control change as you move through the database.

Example: Printing a document with Microsoft Word

The following steps show how to create an Automation controller that prints a document using Microsoft Word 8 from Office 97.

Before you begin: Create a new project that consists of a form, a button, and an open dialog box (*TOpenDialog*). These controls constitute the Automation controller.

Step 1: Prepare Delphi for this example

For your convenience, Delphi has provided many common servers, such as Word, Excel, and PowerPoint, on the Component palette. To demonstrate how to import a server, we use Word. Since it already exists on the Component palette, this first step asks you to remove the package containing Word so that you can see how to install it on the palette. Step 4 describes how to return the Component palette to its normal state.

To remove Word from the Component palette,

1 Choose Component | Install packages.

2 Click Borland Sample Automation Server components and choose Remove.

The Servers page of the Component palette no longer contains any of the servers supplied with Delphi. (If no other servers have been imported, the Servers page also disappears.)

Step 2: Import the Word type library

To import the Word type library,

1 Choose Project|Import Type Library.

2 In the Import Type Library dialog,

   1 Select Microsoft Office 8.0 Object Library.

   If Word (Version 8) is not in the list, choose the Add button, go to Program Files\Microsoft Office\Office, select the Word type library file, MSWord8.olb choose Add, and then select Word (Version 8) from the list.

   2 For Palette Page, choose Servers.

   3 Choose Install.

   The Install dialog appears. Select the Into New Packages tab and type WordExample to create a new package containing this type library.

3 Go to the Servers Palette Page, select WordApplication and place it on a form.

4 Write an event handler for the button object as described in the next step.

Step 3: Use a VTable or dispatch interface object to control Microsoft Word

You can use either a VTable or a dispatch object to control Microsoft Word.

Using a VTable interface object

By dropping an instance of the WordApplication object onto your form, you can easily access the control using a VTable interface object. You simply call on methods of the class you just created. For Word, this is the *TWordApplication* class.

1 Select the button, double-click its *OnClick* event handler and supply the following event handling code:

```
procedure TForm1.Button1Click(Sender: TObject);

var
   FileName: OleVariant;
begin
 if OpenDialog1.Execute then
  begin
     FileName := OpenDialog1.FileName;

WordApplication1.Documents.Open(FileName,
   EmptyParam,EmptyParam,EmptyParam,
   EmptyParam,EmptyParam,EmptyParam,
   EmptyParam,EmptyParam,EmptyParam);

WordApplication1.ActiveDocument.PrintOut(
   EmptyParam,EmptyParam,EmptyParam,
   EmptyParam, EmptyParam,EmptyParam,
   EmptyParam,EmptyParam,EmptyParam,
   EmptyParam,EmptyParam,EmptyParam,
   EmptyParam,EmptyParam);
   end;

end;
```

2 Build and run the program. By clicking the button, Word prompts you for a file to print.

Using a dispatch interface object

As an alternate, you can use a dispatch interface for late binding. To use a dispatch interface object, you create and initialize the Application object using the _ApplicationDisp dispatch wrapper class as follows. Notice that dispinterface methods are "documented" by the source as returning Vtable interfaces, but, in fact, you must cast them to dispatch interfaces.

1 Select the button, double-click its *OnQuit* event handler and supply the following event handling code:

```
procedure TForm1.Button1Click(Sender: TObject);
var
MyWord : _ApplicationDisp;
FileName : OleVariant;
begin
  if OpenDialog1.Execute then
  begin
    FileName := OpenDialog1.FileName;
    MyWord := CoWordApplication.Create as
        _ApplicationDisp;
    (MyWord.Documents as DocumentsDisp).Open(FileName,EmptyParam,
        EmptyParam,EmptyParam,EmptyParam,EmptyParam,EmptyParam,
        EmptyParam,EmptyParam,EmptyParam);
    (MyWord.ActiveDocument as _DocumentDisp).PrintOut(EmptyParam,
        EmptyParam,EmptyParam,EmptyParam,EmptyParam,EmptyParam,
        EmptyParam,EmptyParam,EmptyParam,EmptyParam,EmptyParam,
        EmptyParam,EmptyParam,EmptyParam);
    MyWord.Quit(EmptyParam,EmptyParam,EmptyParam);
  end;
end;
```

2 Build and run the program. By clicking the button, Word prompts you for a file to print.

Step 4: Clean up the example

After completing this example, you will want to restore Delphi to its original form.

1 Delete the objects on this Servers page:

- Choose Component | Install Packages.
- From the list, select the WordExample package and click remove.
- Click Yes to the message box asking for confirmation.
- Exit the Install Packages dialog by clicking OK.

2 Return the Borland Sample Automation Server Components package:

- Choose Component | Install Packages.
- Click the Add button.

- In the resulting dialog, choose dclaxserver50.bpl.
- Exit the Install Packages dialog by clicking OK.

Writing client code based on type library definitions

Although you must use a component wrapper for hosting an ActiveX control, you can write an Automation controller using only the definitions from the type library that appear in the *TypeLibName*_TLB unit. This process is a bit more involved that letting a component do the work, especially if you need to respond to events.

Connecting to a server

Before you can drive an Automation server from your controller application, you must obtain a reference to an interface it supports. Typically, you connect to a server through its main interface. For example, you connect to Microsoft Word through the WordApplication component.

If the main interface is a dual interface, you can use the creator objects in the *TypeLibName*_TLB.pas file. The creator classes have the same name as the CoClass, with the prefix "Co" added. You can connect to a server on the same machine by calling the *Create* method, or a server on a remote machine using the *CreateRemote* method. Because *Create* and *CreateRemote* are class methods, you do not need an instance of the creator class to call them.

```
MyInterface := CoServerClassName.Create;
MyInterface := CoServerClassName.CreateRemote('Machine1');
```

Create and *CreateRemote* return the default interface for the CoClass.

If the default interface is a dispatch interface, then there is no Creator class generated for the CoClass. Instead, you can call the global *CreateOleObject* function, passing in the GUID for the CoClass (there is a constant for this GUID defined at the top of the _TLB unit). *CreateOleObject* returns an IDispatch pointer for the default interface.

Controlling an Automation server using a dual interface

After using the automatically generated creator class to connect to the server, you call methods of the interface. For example,

```
var
  MyInterface : _Application;
begin
  MyInterface := CoWordApplication.Create;
  MyInterface.DoSomething;
```

The interface and creator class are defined in the *TypeLibName*_TLB unit that is generated automatically when you import a type library.

For information about dual interfaces, see "Dual interfaces" on page 36-13.

Controlling an Automation server using a dispatch interface

Typically, you use the dual interface to control the Automation server, as described above. However, you may find a need to control an Automation server with a dispatch interface because no dual interface is available.

To call the methods of a dispatch interface,

1. Connect to the server, using the global *CreateOleObject* function.
2. Use the **as** operator to cast the *IDispatch* interface returned by *CreateOleObject* to the dispinterface for the CoClass. This dispinterface type is declared in the *TypeLibName*_TLB unit.
3. Control the Automation server by calling methods of the dispinterface.

   Another way to use dispatch interfaces is to assign them to a *Variant*. By assigning the interface returned by *CreateOleObject* to a *Variant*, you can take advantage of the *Variant* type's built-in support for interfaces. Simply call the methods of the interface, and the *Variant* automatically handles all *IDispatch* calls, fetching the dispatch ID and invoking the appropriate method. The Variant type includes built-in support for calling dispatch interfaces, through its **var.**

```
  V: Variant;
begin
  V:= CreateOleObject('TheServerObject');
  V.MethodName; { calls the specified method }
  ...
```

An advantage of using *Variants* is that you do not need to import the type library, because *Variants* use only the standard *IDispatch* methods to call the server. The trade-off is that *Variants* are slower, because they use dynamic binding at runtime.

For more information on dispatch interfaces, see “Automation interfaces” on page 36-12.

Handling events in an automation controller

When you generate a Component wrapper for an object whose type library you import, you can respond to events simply using the events that are added to the generated component. If you do not use a Component wrapper, however, (or if the server uses COM+ events), you must write the event sink code yourself.

Handling Automation events programmatically

Before you can handle events, you must define an event sink. This is a class that implements the event dispatch interface that is defined in the server's type library.

To write the event sink, create an object that implements the event dispatch interface:

```
TServerEventsSink = class(TObject, _TheServerEvents)
...{ declare the methods of _TheServerEvents here }
end;
```

Once you have an instance of your event sink, you must inform the server object of its existence so that the server can call it. To do this, you call the global *InterfaceConnect* procedure, passing it

- The interface to the server that generates events.
- The GUID for the event interface that your event sink handles.
- An IUnknown interface for your event sink.
- A variable that receives a Longint that represents the connection between the server and your event sink.

```
{MyInterface is the server interface you got when you connected to the server }
InterfaceConnect(MyInterface, DIID_TheServerEvents,
                 MyEventSinkObject as IUnknown, cookievar);
```

After calling *InterfaceConnect*, your event sink is connected and receives calls from the server when events occur.

You must terminate the connection before you free your event sink. To do this, call the global *InterfaceDisconnect* procedure, passing it all the same parameters except for the interface to your event sink (and the final parameter is ingoing rather than outgoing):

```
InterfaceDisconnect(MyInterface, DIID_TheServerEvents, cookievar);
```

Note You must be certain that the server has released its connection to your event sink before you free it. Because you don't know how the server responds to the disconnect notification initiated by *InterfaceDisconnect*, this may lead to a race condition if you free your event sink immediately after the call. The easiest way to guard against problems is to have your event sink maintain its own reference count that is not decremented until the server releases the event sink's interface.

Handling COM+ events

Under COM+, servers use a special helper object to generate events rather than a set of special interfaces (*IConnectionPointContainer* and *IConnectionPoint*). Because of this, you can't use an event sink that descends from *TEventDispatcher. TEventDispatcher* is designed to work with those interfaces, not COM+ event objects.

Instead of defining an event sink, your client application defines a subscriber object. Subscriber objects, like event sinks, provide the implementation of the event interface. They differ from event sinks in that they subscribe to a particular event object rather than connecting to a server's connection point.

To define a subscriber object, use the COM Object wizard, selecting the event object's interface as the one you want to implement. The wizard generates an implementation unit with skeletal methods that you can fill in to create your event handlers. For more information about using the COM Object wizard to implement an existing interface, see "Using the COM object wizard" on page 36-2.

Note You may need to add the event object's interface to the registry using the wizard if it does not appear in the list of interfaces you can implement.

Once you create the subscriber object, you must subscribe to the event object's interface or to individual methods (events) on that interface. There are three types of subscriptions from which you can choose:

- **Transient subscriptions.** Like traditional event sinks, transient subscriptions are tied to the lifetime of an object instance. When the subscriber object is freed, the subscription ends and COM+ no longer forwards events to it.

- **Persistent subscriptions.** These are tied to the object class rather than a specific object instance. When the event occurs, COM locates or launches an instance of the subscriber object and calls its event handler. In-process objects (DLLs) use this type of subscription.
- **Per-user subscriptions.** These subscriptions provide a more secure version of transient subscriptions. Both the subscriber object and the server object that fires events must be running under the same user account on the same machine.

Note Objects that subscribe to COM+ events must be installed in a COM+ application.

Creating Clients for servers that do not have a type library

Some older COM technologies, such as object linking and embedding (OLE), do not provide type information in a type library. Instead, they rely on a standard set of predefined interfaces. To write clients that host such objects, you can use the *TOleContainer* component. This component appears on the System page of the Component palette.

TOleContainer acts as a host site for an Ole2 object. It implements the *IOleClientSite* interface and, optionally, *IOleDocumentSite*. Communication is handled using OLE verbs.

To use *TOleContainer*,

1. Place a *TOleContainer* component on your form.
2. Set the *AllowActiveDoc* property to *True* if you want to host an Active document.
3. Set the *AllowInPlace* property to indicate whether the hosted object should appear in the *TOleContainer*, or in a separate window.
4. Write event handlers to respond when the object is activated, deactivated, moved, or resized.
5. To bind the *TOleContainer* object at design time, right click and choose Insert Object. In the Insert Object dialog, choose a server object to host.
6. To bind the *TOleContainer* object at runtime, you have several methods to choose from, depending on how you want to identify the server object. These include *CreateObject*, which takes a program id, *CreateObjectFromFile*, which takes the name of a file to which the object has been saved, *CreateObjectFromInfo*, which takes a record containing information on how to create the object, or *CreateLinkToFile*, which takes the name of a file to which the object was saved and links to it rather than embeds it.
7. Once the object is bound, you can access its interface using the *OleObjectInterface* property. However, because communication with Ole2 objects was based on OLE verbs, you will most likely want to send commands to the server using the *DoVerb* method.
8. When you want to release the server object, call the *DestroyObject* method.

Chapter

36

Creating simple COM servers

Delphi provides wizards to help you create various COM objects. The simplest COM objects are servers that expose properties and methods (and possibly events) through a default interface that clients can call.

Note COM servers and Automation is not available for use in CLX applications. This technology is for use on Windows only and is not cross-platform.

Two wizards, in particular, ease the process of creating simple COM objects:

- The COM Object wizard builds a lightweight COM object whose default interface descends from *IUnknown* or that implements an interface already registered on your system. This wizard provides the most flexibility in the types of COM objects you can create.
- The Automation Object wizard creates a simple Automation object whose default interface descends from *IDispatch*. *IDispatch* introduces a standard marshaling mechanism and support for late binding of interface calls.

Note COM defines many standard interfaces and mechanisms for handling specific situations. The Delphi wizards automate the most common tasks. However, some tasks, such as custom marshaling, are not supported by any Delphi wizards. For information on that and other technologies not explicitly supported by Delphi, refer to the Microsoft Developer's Network (MSDN) documentation. The Microsoft Web site also provides current information on COM support.

Overview of creating a COM object

Whether you use the Automation object wizard to create a new Automation server or the COM object wizard to create some other type of COM object, the process you follow is the same. It involves these steps:

1. Design the COM object.
2. Use the COM Object wizard or the Automation Object wizard to create the server object.
3. Define the interface that the object exposes to clients.
4. Register the COM object.
5. Test and debug the application.

Designing a COM object

When designing the COM object, you need to decide what COM interfaces you want to implement. You can write a COM object to implement an interface that has already been defined, or you can define a new interface for your object to implement. In addition, you can have your object support more than one interface. For information about standard COM interfaces that you might want to support, see the MSDN documentation.

- To create a COM object that implements an existing interface, use the COM Object wizard.
- To create a COM object that implements a new interface that you define, use either the COM Object wizard or the Automation Object wizard. The COM object wizard can generate a new default interface that descends from *IUnknown*, and the Automation object gives your object a default interface that descends from *IDispatch*. No matter which wizard you use, you can always use the Type Library editor later to change the parent interface of the default interface that the wizard generates.

In addition to deciding what interfaces to support, you must decide whether the COM object is an in-process server, out-of-process server, or remote server. For in-process servers and for out-of-process and remote servers that use a type library, COM marshals the data for you. Otherwise, you must consider how to marshal the data to out-of-process servers. For information on server types, see, “In-process, out-of-process, and remote servers,” on page 33-6.

Using the COM object wizard

The COM object wizard performs the following tasks:

- Creates a new unit.

- Defines a new class that descends from *TCOMObject* and sets up the class factory constructor. For more information on the base class, see “Code generated by wizards” on page 33-21.
- Optionally, adds a type library to your project and adds your object and its interface to the type library.

Before you create a COM object, create or open the project for the application containing functionality that you want to implement. The project can be either an application or ActiveX library, depending on your needs.

To bring up the COM object wizard,

1 Choose File | New | Other to open the New Items dialog box.

2 Select the tab labeled, ActiveX.

3 Double-click the COM object icon.

In the wizard, you must specify the following:

- **CoClass name:** This is the name of the object as it appears to clients. The class created to implement your object has this name with a ‘T’ prepended. If you do not choose to implement an existing interface, the wizard gives your CoClass a default interface that has this name with an ‘I’ prepended.
- **Interface to implement:** By default, the wizard gives your object a default interface that descends from *IUnknown*. After exiting the wizard, you can then use the Type Library editor to add properties and methods to this interface. However, you can also select a pre-defined interface for your object to implement. Click the List button in the COM object wizard to bring up the Interface Selection wizard, where you can select any dual or custom interface defined in a type library registered on your system. The interface you select becomes the default interface for your new CoClass. The wizard adds all the methods on this interface to the generated implementation class, so that you only need to fill in the bodies of the methods in the implementation unit. Note that if you select an existing interface, the interface is not added to your project’s type library. This means that when deploying your object, you must also deploy the type library that defines the interface.
- **Instancing:** Unless you are creating an in-process server, you need to indicate how COM launches the application that houses your COM object. If your application implements more than one COM object, you should specify the same instancing for all of them. For information on the different possibilities, see “COM object instancing types” on page 36-5.
- **Threading Model**: Typically, client requests to your object enter on different threads of execution. You can specify how COM serializes these threads when it calls your object. Your choice of threading model determines how the object is registered. You are responsible for providing any threading support implied by the model you choose. For information on the different possibilities, see “Choosing a threading model” on page 36-6. For information on how to provide thread support to your application, see Chapter 9, “Writing multi-threaded applications.”

- **Type Library:** You can choose whether you want to include a type library for your object. This is recommended for two reasons: it lets you use the Type Library editor to define interfaces, thereby updating much of the implementation, and it gives clients an easy way to obtain information about your object and its interfaces. If you are implementing an existing interface, Delphi requires your project to use a type library. This is the only way to provide access to the original interface declaration. For information on type libraries, see “Type libraries” on page 33-15 and Chapter 34, “Working with type libraries”.
- **Marshaling:** If you have opted to create a type library and are willing to confine yourself to Automation-compatible types, you can let COM handle the marshaling for you when you are not generating an in-process server. By marking your object’s interface as OleAutomation in the type library, you enable COM to set up the proxies and stubs for you and handles passing parameters across process boundaries. For more information on this process, see “The marshaling mechanism” on page 33-8. You can only specify whether your interface is Automation-compatible if you are generating a new interface. If you select an existing interface, its attributes are already specified in its type library. If your object’s interface is not marked as OleAutomation, you must either create an in-process server or write your own marshaling code.

You can optionally add a description of your COM object. This description appears in the type library for your object if you create one.

Using the Automation object wizard

The Automation object wizard performs the following tasks:

- Creates a new unit.
- Defines a new class that descends from *TAutoObject* and sets up the class factory constructor. For more information on the base class, see “Code generated by wizards” on page 33-21.
- Adds a type library to your project and adds your object and its interface to the type library.

Before you create an Automation object, create or open the project for an application containing functionality that you want to expose. The project can be either an application or ActiveX library, depending on your needs.

To display the Automation wizard:

1. Choose File | New | Other.
2. Select the tab labeled, ActiveX.
3. Double-click the Automation Object icon.

In the wizard dialog, specify the following:

- **CoClass name:** This is the name of the object as it appears to clients. Your object's default interface is created with a name based on this CoClass name with an 'I' prepended, and the class created to implement your object has this name with a 'T' prepended.
- **Instancing:** Unless you are creating an in-process server, you need to indicate how COM launches the application that houses your COM object. If your application implements more than one COM object, you should specify the same instancing for all of them. For information on the different possibilities, see "COM object instancing types" on page 36-5.
- **Threading Model**: Typically, client requests to your object enter on different threads of execution. You can specify how COM serializes these threads when it calls your object. Your choice of threading model determines how the object is registered. You are responsible for providing any threading support implied by the model you choose. For information on the different possibilities, see "Choosing a threading model" on page 36-6. For information on how to provide thread support to your application, see Chapter 9, "Writing multi-threaded applications."
- **Event support**: You must indicate whether you want your object to generate events to which clients can respond. The wizard can provide support for the interfaces required to generate events and the dispatching of calls to client event handlers. For information on how events work and what you need to do when implementing them, see "Exposing events to clients" on page 36-10.

You can optionally add a description of your COM object. This description appears in the type library for your object.

The Automation object implements a **dual interface**, which supports both early (compile-time) binding through the VTable and late (runtime) binding through the *IDispatch* interface. For more information, see "Dual interfaces" on page 36-13.

COM object instancing types

Many of the COM wizards require you to specify an instancing mode for the object. Instancing determines how many instances of your object clients can create in a single executable. If you specify a Single Instance model, for example, then COM once a client has instantiated your object, COM removes the application from view so that other clients must launch their own instances of the application. Because this affects the visibility of your application as a whole, the instancing mode must be consistent across all objects in your application that can be instantiated by clients. That is, you should not create one object in your application that uses Single Instance mode and another in the same application that uses Multiple Instance mode.

Note Instancing is ignored when your COM object is used only as an in-process server.

When the wizard creates a new COM object, it can have any of the following instancing types:

Instancing	Meaning
Internal	The object can only be created internally. An external application cannot create an instance of the object directly, although your application can create the object hand pass an interface for it to clients.
Single Instance	Allows clients to create only a single instance of the object for each executable (application), so creating multiple instances results in launching multiple instances of the application. Each client has its own dedicated instance of the server application. This option is commonly used for multiple document interface (MDI) applications.
Multiple Instances	Specifies that multiple clients can create instances of the object in the same process space. Any time a client requests service, a separate instance of the object is created. (That is, there can be multiple instances in a single executable.)

Choosing a threading model

When creating an object using a wizard, you select a threading model that your object agrees to support. By adding thread support to your COM object, you can improve its performance, because multiple clients can access your application at the same time.

Table 36.1 lists the different threading models you can specify.

Table 36.1 Threading models for COM objects

Threading model	Description	Implementation pros and cons
Single	The server provides no thread support. COM serializes client requests so that the application receives one request at a time.	Clients are handled one at a time so no threading support is needed. No performance benefit.
Apartment (or Single-threaded apartment)	COM ensures that only one client thread can call the object at a time. All client calls use the thread in which the object was created.	Objects can safely access their own instance data, but global data must be protected using critical sections or some other form of serialization. The thread's local variables are reliable across multiple calls. Some performance benefits.
Free (also called multi-threaded apartment)	Objects can receive calls on any number of threads at any time.	Objects must protect all instance and global data using critical sections or some other form of serialization. Thread local variables are *not* reliable across multiple calls.

Table 36.1 Threading models for COM objects (continued)

Threading model	Description	Implementation pros and cons
Both	This is the same as the Free-threaded model except that outgoing calls (for example, callbacks) are guaranteed to execute in the same thread.	Maximum performance and flexibility. Does not require the application to provide thread support for parameters supplied to outgoing calls.
Neutral	Multiple clients can call the object on different threads at the same time, but COM ensures that no two calls conflict.	You must guard against thread conflicts involving global data and any instance data that is accessed by multiple methods. This model should not be used with objects that have a user interface (visual controls). This model is only available under COM+. Under COM, it is mapped to the Apartment model.

Note Local variables (except those in callbacks) are always safe, regardless of the threading model. This is because local variables are stored on the stack and each thread has its own stack. Local variables may not be safe in callbacks when using free-threading.

The threading model you choose in the wizard determines how the object is registered in the system Registry. You must make sure that your object implementation adheres to the threading model you have chosen. For general information on writing thread-safe code, see Chapter 9, “Writing multi-threaded applications.”

For in-process servers, setting the threading model in the wizard sets the threading model key in the CLSID registry entry.

Out-of-process servers are registered as EXE, and Delphi initializes COM for the highest threading model required. For example, if an EXE includes a free-threaded object, it is initialized for free threading, which means that it can provide the expected support for any free-threaded or apartment-threaded objects contained in the EXE. To manually override threading behavior in EXEs, use the CoInitFlags variable, which is described in the online help.

Writing an object that supports the free threading model

Use the free threading (or both) model rather than apartment threading whenever the object needs to be accessed from more than one thread. A common example is a client application connected to an object on a remote machine. When the remote client calls a method on that object, the server receives the call on a thread from the thread pool on the server machine. This receiving thread makes the call locally to the actual object; and, because the object supports the free threading model, the thread can make a direct call into the object.

If the object supported the apartment threading model instead, the call would have to be transferred to the thread on which the object was created, and the result would have to be transferred back into the receiving thread before returning to the client. This approach requires extra marshaling.

To support free threading, you must consider how instance data can be accessed for *each* method. If the method is writing to instance data, you must use critical sections or some other form of serialization, to protect the instance data. Likely, the overhead of serializing critical calls is less than executing COM's marshaling code.

Note that if the instance data is read-only, serialization is not needed.

Free-threaded in-process servers can improve performance by acting as the outer object in an aggregation with the free-threaded marshaler. The free-threaded marshaler provides a shortcut for COM's standard thread handling when a free-threaded DLL is called by a host (client) that is not free-threaded.

To aggregate with the free threaded marshaler, you must

- Call *CoCreateFreeThreadedMarshaler*, passing your object's *IUnknown* interface for the resulting free-threaded marshaler to use:

  ```
  CoCreateFreeThreadedMarshaler(self as IUnknown, FMarshaler);
  ```

  This line assigns the interface for the free-threaded marshaler to a class member, *FMarshaler*.
- Using the Type Library editor, add the *IMarshal* interface to the set of interfaces your CoClass implements.
- In your object's *QueryInterface* method, delegate calls for IDD_IMarshal to the free-threaded marshaler (stored as *FMarshaler* above).

Warning The free-threaded marshaler violates the normal rules of COM marshaling to provide additional efficiency. It should be used with care. In particular, it should only be aggregated with free-threaded objects in in-process servers, and should only be instantiated by the object that uses it (not another thread).

Writing an object that supports the apartment threading model

To implement the (single-threaded) apartment threading model, you must follow a few rules:

- The first thread in the application that gets created is COM's main thread. This is typically the thread on which WinMain was called. This must also be the last thread to uninitialize COM.
- Each thread in the apartment threading model must have a message loop, and the message queue must be checked frequently.
- When a thread gets a pointer to a COM interface, that pointer may only be used in that thread.

The single-threaded apartment model is the middle ground between providing no threading support and full, multi-threading support of the free threading model. A server committing to the apartment model promises that the server has serialized access to all of its global data (such as its object count). This is because different objects may try to access the global data from different threads. However, the object's instance data is safe because the methods are always called on the same thread.

Typically, controls for use in Web browsers use the apartment threading model because browser applications always initialize their threads as apartment.

Writing an object that supports the neutral threading model

Under COM+, you can use another threading model that is in between free threading and apartment threading: the neutral model. Like the free-threading model, this model allows multiple threads to access your object at the same time. There is no extra marshaling to transfer to the thread on which the object was created. However, your object is guaranteed to receive no conflicting calls.

Writing an object that uses the neutral threading model follows much the same rules as writing an apartment-threaded object, except that you do need to guard instance data against thread conflicts if it can be accessed by different methods in the object's interface. Any instance data that is only accessed by a single interface method is automatically thread-safe.

Defining a COM object's interface

When you use a wizard to create a COM object, the wizard automatically generates a type library (unless you specify otherwise in the COM object wizard). The type library provides a way for host applications to find out what the object can do. It also lets you define your object's interface using the Type Library editor. The interfaces you define in the Type Library editor define what properties, methods, and events your object exposes to clients.

Note If you selected an existing interface in the COM object wizard, you do not need to add properties and methods. The definition of the interface is imported from the type library in which it was defined. Instead, simply locate the methods of the imported interface in the implementation unit and fill in their bodies.

Adding a property to the object's interface

When you add a property to your object's interface using the Type Library editor, it automatically adds a method to read the property's value and/or a method to set the property's value. The Type Library editor, in turn, adds these methods to your implementation class, and in your implementation unit creates empty method implementations for you to complete.

To add a property to your object's interface,

1 In the type library editor, select the default interface for the object.

The default interface should be the name of the object preceded by the letter "I". To determine the default, in the Type Library editor, choose the CoClass and Implements tab, and check the list of implemented interfaces for the one marked, "Default."

2. To expose a read/write property, click the Property button on the toolbar; otherwise, click the arrow next to the Property button on the toolbar, and then click the type of property to expose.
3. In the Attributes pane, specify the name and type of the property.
4. On the toolbar, click the Refresh button.

   A definition and skeletal implementations for the property access methods are inserted into the object's implementation unit.
5. In the implementation unit, locate the access methods for the property. These have names of the form Get_PropertyName and Set_PropertyName. Add code that gets or sets the property value of your object. This code may simply call an existing function inside the application, access a data member that you add to the object definition, or otherwise implement the property.

Adding a method to the object's interface

When you add a method to your object's interface using the Type Library editor, the Type Library editor can, in turn, add the methods to your implementation class, and in your implementation unit create empty implementation for you to complete.

To expose a method via your object's interface,

1. In the Type Library editor, select the default interface for the object.

   The default interface should be the name of the object preceded by the letter "I". To determine the default, in the Type Library editor, choose the CoClass and Implements tab, and check the list of implemented interfaces for the one marked, "Default."
2. Click the Method button.
3. In the Attributes pane, specify the name of the method.
4. In the Parameters pane, specify the method's return type and add the appropriate parameters.
5. On the toolbar, click the Refresh button.

   A definition and skeletal implementation for the method is inserted into the object's implementation unit.
6. In the implementation unit, locate the newly inserted method implementation. The method is completely empty. Fill in the body to perform whatever task the method represents.

Exposing events to clients

There are two types of events that a COM object can generate: traditional events and COM+ events.

- COM+ events require that you create a separate event object using the event object wizard and add code to call that event object from your server object. For more information about generating COM+ events, see "Generating events under COM+" on page 39-18.

- You can use the wizard to handle much of the work in generating traditional events. This process is described below.

Note The COM object wizard does not generate event support code. If you want your object to generate traditional events, you should use the Automation object wizard.

In order for an object to generate events, you need to do the following:

1. In the Automation wizard, check the box, Generate event support code.

   The wizard creates an object that includes an Events interface as well as the default interface. This Events interface has a name of the form I*CoClassname*Events. It is an outgoing (source) interface, which means that it is not an interface your object implements, but rather is an interface that clients must implement and which your object calls. (You can see this by selecting your CoClass, going to the Implements page, and noting that the Source column on the Events interface says *True*.)

   In addition to the Events interface, the wizard adds the *IConnectionPointContainer* interface to the declaration of your implementation class, and adds several class members for handling events. Of these new class members, the most important are *FConnectionPoint* and *FConnectionPoints*, which implement the *IConnectionPoint* and *IConnectionPointContainer* interfaces using built-in VCL classes. *FConnectionPoint* is maintained by another method that the wizard adds, *EventSinkChanged*.

2. In the Type Library editor, select the outgoing Events interface for your object. (This is the one with a name of the form I*CoClassName*Events)
3. Click the Method button from the Type Library toolbar. Each method you add to the Events interface represents an event handler that the client must implement.
4. In the Attributes pane, specify the name of the event handler, such as MyEvent.
5. On the toolbar, click the Refresh button.

   Your object implementation now has everything it needs to accept client event sinks and maintain a list of interfaces to call when the event occurs. To call these interfaces, you can create a method to generate each event on clients.

6. In the Code Editor, add a method to your object for firing each event. For example,

```
unit ev;
interface
uses
   ComObj, AxCtrls, ActiveX, Project1_TLB;
type
   TMyAutoObject = class (TAutoObject,IConnectionPointContainer, IMyAutoObject)
private
   .
   .
   .
public
   procedure Initialize; override;
   procedure Fire_MyEvent; { Add a method to fire the event}
```

7 Implement the method you added in the last step so that it iterates through all the event sinks maintained by your object's *FConnectionPoint* member:

```
procedure TMyAutoObject.Fire_MyEvent;
var
  I: Integer;
  EventSinkList: TList;
  EventSink: IMyAutoObjectEvents;
begin
  if FConnectionPoint <> nil then
  begin
    EventSinkList :=FConnectionPoint.SinkList; {get the list of client sinks }
    for I := 0 to EventSinkList.Count - 1 do
    begin
      EventSink := IUnknown(FEvents[I]) as IMyAutoObjectEvents;
      EventSink.MyEvent;
    end;
  end;
end;
```

8 Whenever you need to fire the event so that clients are informed of its occurrence, call the method that dispatches the event to all event sinks:

```
if EventOccurs then Fire_MyEvent; { Call method you created to fire events.}
```

Managing events in your Automation object

For a server to support traditional COM events, it must provide the definition of an outgoing interface which is implemented by a client. This outgoing interface includes all the event handlers the client must implement to respond to server events.

When a client has implemented the outgoing event interface, it registers its interest in receiving event notification by querying the server's *IConnectionPointContainer* interface. The *IConnectionPointContainer* interface returns the server's *IConnectionPoint* interface, which the client then uses to pass the server a pointer to its implementation of the event handlers (known as a sink).

The server maintains a list of all client sinks and calls methods on them when an event occurs, as described above.

Automation interfaces

The Automation Object wizard implements a dual interface by default, which means that the Automation object supports both

- Late binding at runtime, which is through the *IDispatch* interface. This is implemented as a dispatch interface, or **dispinterface**.
- Early binding at compile-time, which is accomplished through directly calling one of the member functions in the object's virtual function table (VTable). This is referred to as a **custom interface**.

Note Any interfaces generated by the COM object wizard that do not descend from *IDispatch* only support VTable calls.

Dual interfaces

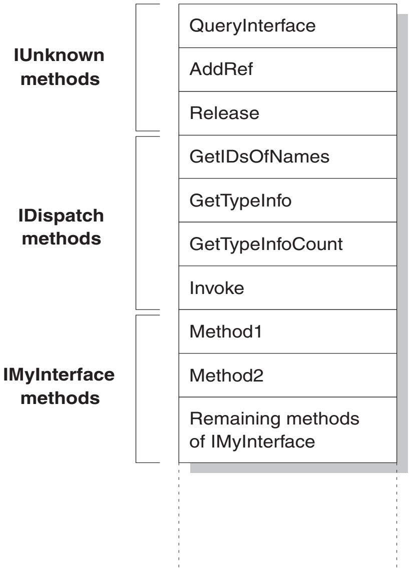
A dual interface is a custom interface and a dispinterface at the same time. It is implemented as a COM VTable interface that derives from *IDispatch*. For those controllers that can access the object only at runtime, the dispinterface is available. For objects that can take advantage of compile-time binding, the more efficient VTable interface is used.

Dual interfaces offer the following combined advantages of VTable interfaces and dispinterfaces:

- For VTable interfaces, the compiler performs type checking and provides more informative error messages.
- For Automation controllers that cannot obtain type information, the dispinterface provides runtime access to the object.
- For in-process servers, you have the benefit of fast access through VTable interfaces.
- For out-of-process servers, COM marshals data for both VTable interfaces and dispinterfaces. COM provides a generic proxy/stub implementation that can marshal the interface based on the information contained in a type library. For more information on marshaling, see, "Marshaling data," on page 36-15.

The following diagram depicts the *IMyInterface* interface in an object that supports a dual interface named *IMyInterface.* The first three entries of the VTable for a dual interface refer to the *IUnknown* interface, the next four entries refer to the *IDispatch* interface, and the remaining entries are COM entries for direct access to members of the custom interface.

Figure 36.1 Dual interface VTable



Dispatch interfaces

Automation controllers are clients that use the COM *IDispatch* interface to access the COM server objects. The controller must first create the object, then query the object's *IUnknown* interface for a pointer to its *IDispatch* interface. *IDispatch* keeps track of methods and properties internally by a dispatch identifier (dispID), which is a unique identification number for an interface member. Through *IDispatch*, a controller retrieves the object's type information for the dispatch interface and then maps interface member names to specific dispIDs. These dispIDs are available at runtime, and controllers get them by calling the *IDispatch* method, *GetIDsOfNames*.

Once it has the dispID, the controller can then call the *IDispatch* method, *Invoke*, to execute the appropriate code (property or method), packaging the parameters for the property or method into one of the *Invoke* parameters. *Invoke* has a fixed compile-time signature that allows it to accept any number of arguments when calling an interface method.

The Automation object's implementation of *Invoke* must then unpackage the parameters, call the property or method, and be prepared to handle any errors that occur. When the property or method returns, the object passes its return value back to the controller.

This is called late binding because the controller binds to the property or method at runtime rather than at compile time.

Note When importing a type library, Delphi will query for dispIDs at the time it generates the code, thereby allowing generated wrapper classes to call *Invoke* without calling *GetIDsOfNames*. This can significantly increase the runtime performance of controllers.

Custom interfaces

Custom interfaces are user-defined interfaces that allow clients to invoke interface methods based on their order in the VTable and knowledge of the argument types. The VTable lists the addresses of all the properties and methods that are members of the object, including the member functions of the interfaces that it supports. If the object does not support *IDispatch*, the entries for the members of the object's custom interfaces immediately follow the members of *IUnknown*.

If the object has a type library, you can access the custom interface through its VTable layout, which you can get using the Type Library editor. If the object has a type library and also supports *IDispatch*, a client can also get the dispIDs of the *IDispatch* interface and bind directly to a VTable offset. Delphi's type library importer (TLIBIMP) retrieves dispIDs at import time, so clients that use dispinterfaces can avoid calls to *GetIDsOfNames*; this information is already in the _TLB unit. However, clients still need to call *Invoke*.

Marshaling data

For out-of-process and remote servers, you must consider how COM marshals data outside the current process. You can provide marshaling:

- Automatically, using the *IDispatch* interface.
- Automatically, by creating a type library with your server and marking the interface with the OLE Automation flag. COM knows how to marshal all the **Automation-compatible** types in the type library and can set up the proxies and stubs for you. Some type restrictions apply to enable automatic marshaling.
- Manually by implementing all the methods of the *IMarshal* interface. This is called **custom marshaling**.

Note The first method (using *IDispatch*) is only available on Automation servers. The second method is automatically available on all objects that are created by wizards and which use a type library.

Automation compatible types

Function result and parameter types of the methods declared in dual and dispatch interfaces and interfaces that you mark as OLE Automation must be *Automation-compatible* types. The following types are OLE Automation-compatible:

- The predefined valid types such as *Smallint*, *Integer*, *Single*, *Double*, *WideString*. For a complete list, see “Valid types” on page 34-11.
- Enumeration types defined in a type library. OLE Automation-compatible enumeration types are stored as 32-bit values and are treated as values of type *Integer* for purposes of parameter passing.
- Interface types defined in a type library that are OLE Automation safe, that is, derived from *IDispatch* and containing only OLE Automation compatible types.
- Dispinterface types defined in a type library.
- Any custom record type defined within the type library.
- *IFont*, *IStrings*, and *IPicture*. Helper objects must be instantiated to map
  - an *IFont to* a *TFont*
  - an *IStrings* to a *TStrings*
  - an *IPicture* to a *TPicture*

  The ActiveX control and ActiveForm wizards create these helper objects automatically when needed. To use the helper objects, call the global routines, *GetOleFont*, *GetOleStrings*, *GetOlePicture*, respectively.

Type restrictions for automatic marshaling

For an interface to support automatic marshaling (also called Automation marshaling or type library marshaling), the following restrictions apply. When you edit your object using the type library editor, the editor enforces these restrictions:

- Types must be compatible for cross-platform communication. For example, you cannot use data structures (other than implementing another property object), unsigned arguments, AnsiStrings, and so on.
- String data types must be transferred as wide strings (BSTR). PChar and AnsiString cannot be marshaled safely.
- All members of a dual interface must pass an HRESULT as the function's return value. If the method is declared using the safecall calling convention, this condition is imposed automatically, with the declared return type converted to an output parameter.
- Members of a dual interface that need to return other values should specify these parameters as **var** or **out**, indicating an output parameter that returns the value of the function.

Note One way to bypass the Automation types restrictions is to implement a separate *IDispatch* interface and a custom interface. By doing so, you can use the full range of possible argument types. This means that COM clients have the option of using the custom interface, which Automation controllers can still access. In this case, though, you must implement the marshaling code manually.

Custom marshaling

Typically, you use automatic marshaling in out-of-process and remote servers because it is easier—COM does the work for you. However, you may decide to provide custom marshaling if you think you can improve marshaling performance. When implementing your own custom marshaling, you must support the *IMarshal* interface. For more information, on this approach, see the Microsoft documentation.

Registering a COM object

You can register your server object as an in-process or an out-of-process server. For more information on the server types, see"In-process, out-of-process, and remote servers" on page 33-6.

Note Before you remove a COM object from your system, you should unregister it.

Registering an in-process server

To register an in-process server (DLL or OCX),

- Choose Run | Register ActiveX Server.

To unregister an in-process server,

- Choose Run | Unregister ActiveX Server.

Registering an out-of-process server

To register an out-of-process server,

- Run the server with the **/regserver** command-line option.

  You can set command-line options with the Run | Parameters dialog box.

  You can also register the server by running it.

To unregister an out-of-process server,

- Run the server with the **/unregserver** command-line option.

As an alternative, you can use the **tregsvr** command from the command line or run the regsvr32.exe from the operating system.

Note If the COM server is intended for use under COM+, you should install it in a COM+ application rather than register it. (Installing the object in a COM+ application automatically takes care of registration.) For information on how to install an object in a COM+ application, see "Installing transactional objects" on page 39-22.

Testing and debugging the application

To test and debug your COM server application,

1. Turn on debugging information using the Compiler tab on the Project | Options dialog box, if necessary. Also, turn on Integrated Debugging in the Tools | Debugger Options dialog.
2. For an in-process server, choose Run | Parameters, type the name of the Automation controller in the Host Application box, and choose OK.
3. Choose Run | Run.
4. Set breakpoints in the Automation server.
5. Use the Automation controller to interact with the Automation server.

The Automation server pauses when the breakpoints are reached.

Note As an alternate approach, if you are also writing the Automation controller, you can debug into an in-process server by enabling COM cross-process support. Use the General page of the Tools | Debugger Options dialog to enable cross-process support.

Chapter

37

Creating an Active Server Page

If you are using the Microsoft Internet Information Server (IIS) environment to serve your Web pages, you can use Active Server Pages (ASP) to create dynamic Web-based client-server applications. Active Server Pages let you write a script that gets called every time the server loads the Web page. This script can, in turn, call on Automation objects to obtain information that it includes in a generated HTML page. For example, you can write a Delphi Automation server, such as one to create a bitmap or connect to a database, and use this control to access data that gets updated every time the server loads the Web page.

On the client side, the ASP acts like a standard HTML document and can be viewed by users on any platform using any Web Browser.

ASP applications are analogous to applications you write using Delphi's Web broker technology. For more information about the Web broker technology, see Chapter 27, "Creating Internet applications". ASP differs, however, in the way it separates the UI design from the implementation of business rules or complex application logic.

- The UI design is managed by the Active Server Page. This is essentially an HTML document, but it can include embedded script that calls on Active Server objects to supply it with content that reflects your business rules or application logic.
- The application logic is encapsulated by Active Server objects that expose simple methods to the Active Server Page, supplying it with the content it needs.

Note Although ASP provides the advantage of separating UI design from application logic, its performance is limited in scale. For Web sites that respond to extremely large numbers of clients, an approach based on the Web broker technology is recommended instead.

The script in your Active Server Pages and the Automation objects you embed in an active server page can make use of the ASP intrinsics (built-in objects that provide information about the current application, HTTP messages from the browser, and so on).

This chapter shows how to create an Active Server Object using the Delphi Active Server Object wizard. This special Automation control can then be called by an Active Server Page and supply it with content.

Here are the steps for creating an Active Server Object:

- Create an Active Server Object for the application.
- Define the Active Server Object's interface.
- Register the Active Server Object.
- Test and debug the application.

Creating an Active Server Object

An Active Server Object is an Automation object that has access to information about the entire ASP application and the HTTP messages it uses to communicate with browsers. It descends from *TASPObject* or *TASPMTSObject* (which is in turn a descendant of *TAutoObject*), and supports Automation protocols, exposing itself for other applications (or the script in the Active Server page) to use. You create an Active Server Object using the Active Server Object wizard.

Your Active Server Object project can be either an executable (exe) or library (dll), depending on your needs. However, you should be aware of the drawbacks of using an out-of-process server. These drawbacks are discussed in "Creating ASPs for in-process or out-of-process servers" on page 37-7.

To display the Active Server Object wizard:

1. Choose File | New | Other.
2. Select the tab labeled, ActiveX.
3. Double-click the Active Server Object icon.

In the wizard, give your new Active Server Object a name, and specify the instancing and threading models you want to support. These details influence the way your object can be called. You must write the implementation so that it adheres to the model (for example, avoiding thread conflicts). The instancing and threading models involve the same choices that you make for other COM objects. For details, see "COM object instancing types" on page 36-5 and "Choosing a threading model" on page 36-6.

The thing that makes an Active Server Object unique is its ability to access information about the ASP application and the HTTP messages that pass between the Active Server page and client Web browsers. This information is accessed using the ASP intrinsics. In the wizard, you can specify how your object accesses these by setting the Active Server Type:

- If you are working with IIS 3 or IIS 4, you use Page Level Event Methods. Under this model, your object implements the methods, *OnStartPage* and *OnEndPage*, which are called when the Active Server page loads and unloads. When your object is loaded, it automatically obtains an *IScriptingContext* interface, which it uses to access the ASP intrinsics. These interfaces are, in turn, surfaced as properties inherited from the base class (*TASPObject*).

- If you are working with IIS5 or later, you use the Object Context type. Under this model, your object fetches an *IObjectContext* interface, which it uses to access the ASP intrinsics. Again, these interfaces are surfaced as properties in the inherited base class (*TASPMTSObject*). One advantage of this latter approach is that your object has access to all of the other services available through *IObjectContext*. To access the *IObjectContext* interface, simply call *GetObjectContext* (defined in the mtx unit) as follows:

  ```
  ObjectContext := GetObjectContext;
  ```

  For more information about the services available through *IObjectContext*, see Chapter 39, “Creating MTS or COM+ objects”.

You can tell the wizard to generate a simple ASP page to host your new Active Server Object. The generated page provides a minimal script (written in VBScript) that creates your Active Server Object based on its ProgID, and indicates where you can call its methods. This script calls **Server.CreateObject** to launch your Active Server Object.

Note Although the generated test script uses VBScript, Active Server Pages also can be written using Jscript.

When you exit the wizard, a new unit is added to the current project that contains the definition for the Active Server Object. In addition, the wizard adds a type library project and opens the Type Library editor. Now you can expose the properties and methods of the interface through the type library as described in “Defining a COM object’s interface” on page 36-9. As you write the implementation of your object’s properties and methods, you can take advantage of the ASP intrinsics (described below) to obtain information about the ASP application and the HTTP messages it uses to communicate with browsers.

The Active Server Object, like any other Automation object, implements a **dual interface**, which supports both early (compile-time) binding through the VTable and late (runtime) binding through the *IDispatch* interface. For more information on dual interfaces, see “Dual interfaces” on page 36-13.

Using the ASP intrinsics

The ASP intrinsics are a set of COM objects supplied by ASP to the objects running in an Active Server Page. They let your Active Server Object access information that reflects the messages passing between your application and the Web browser, as well as a place to store information that is shared among Active Server Objects that belong to the same ASP application.

To make these objects easy to access, the base class for your Active Server Object surfaces them as properties. For a complete understanding of these objects, see the Microsoft documentation. However, the following topics provide a brief overview.

Application

The Application object is accessed through an *IApplicationObject* interface. It represents the entire ASP application, which is defined as the set of all .asp files in a virtual directory and its subdirectories. The Application object can be shared by multiple clients, so it includes locking support that you should use to prevent thread conflicts.

IApplicationObject includes the following:

Table 37.1 IApplicationObject interface members

Property, Method, or Event	Meaning
Contents property	Lists all the objects that were added to the application using script commands. This interface has two methods, *Remove* and *RemoveAll*, that you can use to delete one or all objects from the list.
StaticObjects property	Lists all the objects that were added to the application with the <OBJECT> tag.
Lock method	Prevents other clients from locking the Application object until you call Unlock. All clients should call Lock before accessing shared memory (such as the properties).
Unlock method	Releases the lock that was set using the Lock method.
Application_OnEnd event	Occurs when the application quits, after the Session_OnEnd event. The only intrinsics available are Application and Server. The event handler must be written in VBScript or JScript.
Application_OnStart event	Occurs before the new session is created (before Session_OnStart). The only intrinsics available are Application and Server. The event handler must be written in VBScript or JScript.

Request

The Request object is accessed through an *IRequest* interface. It provides information about the HTTP request message that caused the Active Server Page to be opened.

IRequest includes the following:

Table 37.2 IRequest interface members

Property, Method, or Event	Meaning
ClientCertificate property	Indicates the values of all fields in the client certificate that is sent with the HTTP message.
Cookies property	Indicates the values of all Cookie headers on the HTTP message.
Form property	Indicates the values of form elements in the HTTP body. These can be accessed by name.
QueryString property	Indicates the values of all variables in the query string from the HTTP header.
ServerVariables property	Indicates the values of various environment variables. These variables represent most of the common HTTP header variables.
TotalBytes property	Indicates the number of bytes in the request body. This is an upper limit on the number of bytes returned by the BinaryRead method.
BinaryRead method	Retrieves the content of a Post message. Call the method, specifying the maximum number of bytes to read. The resulting content is returns as a Variant array of bytes. After calling BinaryRead, you can't use the Form property.

Response

The Request object is accessed through an *IResponse* interface. It lets you specify information about the HTTP response message that is returned to the client browser.

IResponse includes the following:

Table 37.3 IResponse interface members

Property, Method, or Event	Meaning
Cookies property	Determines the values of all Cookie headers on the HTTP message.
Buffer property	Indicates whether page output is buffered When page output is buffered, the server does not send a response to the client until all of the server scripts on the current page are processed.
CacheControl property	Determines whether proxy servers can cache the output in the response.
Charset property	Adds the name of the character set to the content type header.
ContentType property	Specifies the HTTP content type of the response message's body.
Expires property	Specifies how long the response can be cached by a browser before it expires.
ExpiresAbsolute property	Specifies the date and time when the response expires.
IsClientConnected property	Indicates whether the client has disconnected from the server.
Pics property	Set the value for the pics-label field of the response header.
Status property	Indicates the status of the response. This is the value of an HTTP status header.
AddHeader method	Adds an HTTP header with a specified name and value.
AppendToLog method	Adds a string to the end of the Web server log entry for this request.
BinaryWrite method	Writes raw (uninterpreted) information to the body of the response message.
Clear method	Erases any buffered HTML output.
End method	Stops processing the .asp file and returns the current result.
Flush method	Sends any buffered output immediately.
Redirect method	Sends a redirect response message, redirecting the client browser to a different URL.
Write method	Writes a variable to the current HTTP output as a string.

Session

The Session object is accessed through the *ISessionObject* interface. It allows you to store variables that persist for the duration of a client's interaction with the ASP application. That is, these variables are not freed when the client moves from page to page within the ASP application, but only when the client exits the application altogether.

ISessionObject includes the following:

Table 37.4 ISessionObject interface members

Property, Method, or Event	Meaning
Contents property	Lists all the objects that were added to the session using the <OBJECT> tag. You can access any variable in the list by name, or call the Contents object's *Remove* or *RemoveAll* method to delete values.
StaticObjects property	Lists all the objects that were added to the session with the <OBJECT> tag.
CodePage property	Specifies the code page to use for symbol mapping. Different locales may use different code pages.
LCID property	Specifies the locale identifier to use for interpreting string content.
SessionID property	Indicates the session identifier for the current client.
Timeout property	Specifies the time, in minutes, that the session persists without a request (or refresh) from the client until the application terminates.
Abandon method	Destroys the session and releases its resources.
Session_OnEnd event	Occurs when the session is abandoned or times out. The only intrinsics available are Application, Server, and Session. The event handler must be written in VBScript or JScript.
Session_OnStart event	Occurs when the server creates a new session is created (after Application_OnStart but before running the script on the Active Server Page). All intrinsics are available. The event handler must be written in VBScript or JScript.

Server

The Server object is accessed through an *IServer* interface. It provides various utilities for writing your ASP application.

IServer includes the following:

Table 37.5 IServer interface members

Property, Method, or Event	Meaning
ScriptTimeout property	Same as the Timeout property on the Session object.
CreateObject method	Instantiates a specified Active Server Object.
Execute method	Executes the script in a specified .asp file.
GetLastError method	Returns an ASPError object that describes the error condition.
HTMLEncode method	Encodes a string for use in an HTML header, replacing reserved characters by the appropriate symbolic constants.
MapPath method	Maps a specified virtual path (an absolute path on the current server or a path relative to the current page) into a physical path.
Transfer method	Sends all of the current state information to another Active Server Page for processing.
URLEncode method	Applies URL encoding rules, including escape characters, to a specified string

Creating ASPs for in-process or out-of-process servers

You can use **Server.CreateObject** in an ASP page to launch either an in-process or out-of-process server, depending on your requirements. However, launching in-process servers is more common.

Unlike most in-process servers, an Active Server Object in an in-process server does not run in the client's process space. Instead, it runs in the IIS process space. This means that the client does not need to download your application (as, for example, it does when you use ActiveX objects). In-process component DLLs are faster and more secure than out-of-process servers, so they are better suited for server-side use.

Because out-of-process servers are less secure, it is common for IIS to be configured to *not* allow out-of-process executables. In this case, creating an out-of-process server for your Active Server Object would result in an error similar to the following:

```
Server object error 'ASP 0196'
Cannot launch out of process component
/path/outofprocess_exe.asp, line 11
```

Also, out-of-process components often create individual server processes for each object instance, so they are slower than CGI applications. They do not scale as well as component DLLs.

If performance and scalability are priorities for your site, in-process servers are highly recommended. However, Intranet sites that receive moderate to low traffic may use an out-of-process component without adversely affecting the site's overall performance.

For general information on in-process and out-of-process servers, see, "In-process, out-of-process, and remote servers," on page 33-6.

Registering an Active Server Object

You can register the Active Server Page as an in-process or an out-of-process server. However, in-process servers are more common.

Note When you want to remove the Active Server Page object from your system, you should first unregister it, removing its entries from the Windows registry.

Registering an in-process server

To register an in-process server (DLL or OCX),

- Choose Run | Register ActiveX Server.

To unregister an in-process server,

- Choose Run | Unregister ActiveX Server.

Registering an out-of-process server

To register an out-of-process server,

- Run the server with the /regserver command-line option. (You can set command-line options with the Run|Parameters dialog box.)

  You can also register the server by running it.

To unregister an out-of-process server,

- Run the server with the /unregserver command-line option.

Testing and debugging the Active Server Page application

Debugging any in-process server such as an Active Server Object is much like debugging a DLL. You choose a host application that loads the DLL, and debug as usual. To test and debug an Active Server Object,

1. Turn on debugging information using the Compiler tab on the Project|Options dialog box, if necessary. Also, turn on Integrated Debugging in the Tools|Debugger Options dialog.
2. Choose Run|Parameters, type the name of your Web Server in the Host Application box, and choose OK.
3. Choose Run|Run.
4. Set breakpoints in the Active Server Object implementation.
5. Use the Web browser to interact with the Active Server Page.

The debugger pauses when the breakpoints are reached.

Chapter

38

Creating an ActiveX control

An ActiveX control is a software component that integrates into and extends the functionality of any host application that supports ActiveX controls, such as C++Builder, Delphi, Visual Basic, Internet Explorer, and (given a plug-in) Netscape Navigator. ActiveX controls implement a particular set of interfaces that allow this integration.

For example, Delphi comes with several ActiveX controls, including charting, spreadsheet, and graphics controls. You can add these controls to the component palette in the IDE, and then use them like any standard VCL component, dropping them on forms and setting their properties using the Object Inspector.

An ActiveX control can also be deployed on the Web, allowing it to be referenced in HTML documents and viewed with ActiveX-enabled Web browsers.

Delphi provides wizards that let you create two types of ActiveX controls:

- **ActiveX controls that wrap VCL classes.** By wrapping a VCL class, you can convert existing components into ActiveX controls or create new ones, test them out locally, and then convert them into ActiveX controls. ActiveX controls are typically intended to be embedded in a larger host application.
- **Active forms.** Active forms let you use the form designer to create a more elaborate control that acts like a dialog or like a complete application. You develop the Active form in much the same way that you develop a typical Delphi application. Active Forms are typically intended for deployment on the Web.

This chapter provides an overview of how to create an ActiveX control in the Delphi environment. It is not intended to provide complete implementation details of writing ActiveX control without using a wizard. For that information, refer to your Microsoft Developer's Network (MSDN) documentation or search the Microsoft Web site for ActiveX information.

Overview of ActiveX control creation

Creating ActiveX controls using Delphi is very similar to creating ordinary controls or forms. This differs markedly from creating other COM objects, where you first define the object's interface and then complete the implementation. To create ActiveX controls (other than Active Forms), you reverse this process, starting with the implementation of a VCL control, and then generating the interface and type library once the control is written. When creating Active Forms, the interface and type library are created at the same time as your form, and then you use the form designer to implement the form.

The completed ActiveX control consists of a VCL control that provides the underlying implementation, a COM object that wraps the VCL control, and a type library that lists the COM object's properties, methods, and events.

To create a new ActiveX control (other than an Active Form), perform the following steps:

1. Design and create the custom VCL control that forms the basis of your ActiveX control.
2. Use the ActiveX control wizard to create an ActiveX control from the VCL control you created in step 1.
3. Use the ActiveX property page wizard to create one or more property pages for the control (optional).
4. Associate the property page with the ActiveX control (optional).
5. Register the control.
6. Test the control with all potential target applications.
7. Deploy the ActiveX control on the Web. (optional)

To create a new Active Form, perform the following steps:

1. Use the ActiveForm wizard to create an Active Form, which appears as a blank form in the IDE, and an associated ActiveX wrapper for that form.
2. Use the form designer to add components to your Active Form and implement its behavior in the same way you create and implement an ordinary form using the form designer.
3. Follow steps 3-7 above to give your Active Form a property page, register it, and deploy it on the Web.

Elements of an ActiveX control

An ActiveX control involves many elements which each perform a specific function. The elements include a VCL control, a corresponding COM object wrapper that exposes properties, methods, and events, and one or more associated type libraries.

VCL control

The underlying implementation of an ActiveX control in Delphi is a VCL control. When you create an ActiveX control, you must first design or choose the VCL control from which you will make your ActiveX control.

The underlying VCL control must be a descendant of *TWinControl*, because it must have a window that can be parented by the host application. When you create an Active form, this object is a descendant of *TActiveForm*.

Note The ActiveX control wizard lists the available *TWinControl* descendants from which you can choose to make an ActiveX control. This list does not include all *TWinControl* descendants, however. Some controls, such as *THeaderControl*, are registered as incompatible with ActiveX (using the *RegisterNonActiveX* procedure) and do not appear in the list.

ActiveX wrapper

The actual COM object is an ActiveX wrapper object for the VCL control. For Active forms, this class is always *TActiveFormControl*. For other ActiveX controls, it has a name of the form *TVCLClass*X, where *TVCLClass* is the name of the VCL control class. Thus, for example, the ActiveX wrapper for *TButton* would be named *TButtonX*.

The wrapper class is a descendant of *TActiveXControl*, which provides support for the ActiveX interfaces. The ActiveX wrapper inherits this support, which allows it to forward Windows messages to the VCL control and parent its window in the host application.

The ActiveX wrapper exposes the VCL control's properties and methods to clients via its default interface. The wizard automatically implements most of the wrapper class's properties and methods, delegating method calls to the underlying VCL control. The wizard also provides the wrapper class with methods that fire the VCL control's events on clients and assigns these methods as event handlers on the VCL control.

Type library

The ActiveX control wizards automatically generate a type library that contains the type definitions for the wrapper class, its default interface, and any type definitions that these require. This type information provides a way for your control to advertise its services to host applications. You can view and edit this information using the Type Library editor. Although this information is stored in a separate, binary type library file (.TLB extension), it is also automatically compiled into the ActiveX control DLL as a resource.

Property page

You can optionally give your ActiveX control a property page. The property page allows the user of a host (client) application to view and edit your control's properties. You can group several properties on a page, or use a page to provide a dialog-like interface for a property. For information on how to create property pages, see "Creating a property page for an ActiveX control" on page 38-11.

Designing an ActiveX control

When designing an ActiveX control, you start by creating a custom VCL control. This forms the basis of your ActiveX control. For information on creating custom controls, see Part V, “Creating custom components.”

When designing the VCL control, keep in mind that it will be embedded in another application; this control is not an application in itself. For this reason, you probably do not want to use elaborate dialog boxes or other major user-interface components. Your goal is typically to make a simple control that works inside of, and follows the rules of the main application.

In addition, you should make sure that the types for all properties and methods you want your object to expose to clients are Automation-compatible, because the ActiveX control’s interface must support *IDispatch*. The wizard does not add any methods to the wrapper class’s interface that have parameters that are not Automation-compatible. For a list of Automation-compatible types, see “Valid types” on page 34-11.

The wizards implement all the necessary ActiveX interfaces required using the COM wrapper class. They also surface all Automation-compatible properties, methods, and events through the wrapper class’s default interface. Once the wizard has generated the COM wrapper class and its interface, you can use the Type Library editor to modify the default interface or augment the wrapper class by implementing additional interfaces.

Generating an ActiveX control from a VCL control

To generate an ActiveX control from a VCL control, use the ActiveX Control wizard. The properties, methods, and events of the VCL control become the properties, methods, and events of the ActiveX control.

Before using the ActiveX control wizard, you must decide what VCL control will provide the underlying implementation of the generated ActiveX control.

To bring up the ActiveX control wizard,

1. Choose File | New | Other to open the New Items dialog box.
2. Select the tab labeled ActiveX.
3. Double-click the ActiveX Control icon.

In the wizard, select the name of the VCL control that will be wrapped by the new ActiveX control. The dialog lists all available controls, which are descendants of *TWinControl* that are not registered as incompatible with ActiveX using the *RegisterNonActiveX* procedure.

Tip If you do not see the control you want in the drop-down list, check whether you have installed it in the IDE or added its unit to your project.

Once you have selected a VCL control, the wizard automatically generates a name for the CoClass, the implementation unit for the ActiveX wrapper, and the ActiveX library project. (If you currently have an ActiveX library project open, and it does not contain a COM+ event object, the current project is automatically used.) You can change any of these in the wizard (unless you have an ActiveX library project already open, in which case the project name is not editable).

The wizard always specifies Apartment as the threading model. This is not a problem if your ActiveX project usually contains only a single control. However, if you add additional objects to your project, you are responsible for providing thread support.

The wizard also lets you configure various options on your ActiveX control:

- **Enabling licensing:** You can make your control licensed to ensure that users of the control can't open it either for design purposes or at runtime unless they have a license key for the control.
- **Including Version information:** You can include version information, such as a copyright or a file description, in the ActiveX control. This information can be viewed in a browser. Some host clients, such as Visual Basic 4.0, require Version information or they will not host the ActiveX control. Specify version information by choosing Project | Options and selecting the Version Info page.
- **Including an About box:** You can tell the wizard to generate a separate form that implements an About box for your control. Users of the host application can display this About box in a development environment. By default, the About box includes the name of the ActiveX control, an image, copyright information, and an OK button. You can modify this default form, which the wizard adds to your project.

When you exit the wizard, it generates the following:

- An ActiveX Library project file, which contains the code required to start an ActiveX control. You usually don’t change this file.
- A type library, which defines and CoClass for your control, the interface it exposes to clients, and any type definitions that these require. For more information about the type library, refer to Chapter 34, “Working with type libraries.”
- An ActiveX implementation unit, which defines and implements the ActiveX control, a descendant of *TActiveXControl*. This ActiveX control is a fully-functioning implementation that requires no additional work on your part. However, you can modify this class if you want to customize the properties, methods, and events that the ActiveX control exposes to clients.
- An About box form and unit if you requested them.
- A .LIC file if you enabled licensing.

Generating an ActiveX control based on a VCL form

Unlike other ActiveX controls, Active Forms are not first designed and then wrapped by an ActiveX wrapper class. Instead, the ActiveForm wizard generates a blank form that you design later when the wizard leaves you in the Form Designer.

When an ActiveForm is deployed on the Web, Delphi creates an HTML page to contain the reference to the ActiveForm and specify its location on the page. The ActiveForm can then displayed and run from a Web browser. Inside the browser, the form behaves just like a stand-alone Delphi form. The form can contain any VCL components or ActiveX controls, including custom-built VCL controls.

To start the ActiveForm wizard,

1 Choose File | New | Other to open the New Items dialog box.

2 Select the tab labeled ActiveX.

3 Double-click the ActiveForm icon.

The Active Form wizard looks just like the ActiveX control wizard, except that you can't specify the name of the VCL class to wrap. This is because Active forms are always based on *TActiveForm*.

As in the ActiveX control wizard, you can change the default names for the CoClass, implementation unit, and ActiveX library project. Similarly, this wizard lets you indicate whether you want your Active Form to require a license, whether it should include version information, and whether you want an About box form.

When you exit the wizard, it generates the following:

- An ActiveX Library project file, which contains the code required to start an ActiveX control. You usually don't change this file.
- A type library, which defines and CoClass for your control, the interface it exposes to clients, and any type definitions that these require. For more information about the type library, refer to Chapter 34, "Working with type libraries."
- A form that descends from *TActiveForm*. This form appears in the form designer, where you can use it to visually design the Active Form that appears to clients. Its implementation appears in the generated implementation unit. In the initialization section of the implementation unit, a class factory is created, setting up *TActiveFormControl* as the ActiveX wrapper for this form.
- An About box form and unit if you requested them.
- A .LIC file if you enabled licensing.

At this point, you can add controls and design the form as you like.

After you have designed and compiled the ActiveForm project into an ActiveX library (which has the OCX extension), you can deploy the project to your Web server and Delphi creates a test HTML page with a reference to the ActiveForm.

Licensing ActiveX controls

Licensing an ActiveX control consists of providing a license key at design-time and supporting the creation of licenses dynamically for controls created at runtime.

To provide design-time licenses, the ActiveX wizard creates a key for the control, which it stores in a file with the same name as the project with the LIC extension. This .LIC file is added to the project. The user of the control must have a copy of the .LIC file to open the control in a development environment. Each control in the project that has Make Control Licensed checked has a separate key entry in the LIC file.

To support runtime licenses, the wrapper class implements two methods, *GetLicenseString* and *GetLicenseFilename*. These return the license string for the control and the name of the .LIC file, respectively. When a host application tries to create the ActiveX control, the class factory for the control calls these methods and compares the string returned by *GetLicenseString* with the string stored in the .LIC file.

Runtime licenses for the Internet Explorer require an extra level of indirection because users can view HTML source code for any Web page, and because an ActiveX control is copied to the user's computer before it is displayed. To create runtime licenses for controls used in Internet Explorer, you must first generate a license package file (LPK file) and embed this file in the HTML page that contains the control. The LPK file is essentially an array of ActiveX control CLSIDs and license keys.

Note To generate the LPK file, use the utility, LPK_TOOL.EXE, which you can download from the Microsoft Web site (www.microsoft.com).

To embed the LPK file in a Web page, use the HTML objects, <OBJECT> and <PARAM> as follows:

```
<OBJECT CLASSID="clsid:6980CB99-f75D-84cf-B254-55CA55A69452">
    <PARAM NAME="LPKPath" VALUE="ctrllic.lpk">
</OBJECT>
```

The CLSID identifies the object as a license package and PARAM specifies the relative location of the license package file with respect to the HTML page.

When Internet Explorer tries to display the Web page containing the control, it parses the LPK file, extracts the license key, and if the license key matches the control's license (returned by *GetLicenseString*), it renders the control on the page. If more than one LPK is included in a Web page, Internet Explorer ignores all but the first.

For more information, look for Licensing ActiveX Controls on the Microsoft Web site.

Customizing the ActiveX control's interface

The ActiveX Control and ActiveForm wizards generate a default interface for the ActiveX wrapper class. This default interface simply exposes the properties, methods, and events of the original VCL control or form, with the following exceptions:

- Data-aware properties do not appear. Because ActiveX controls have a different mechanism for making controls data-aware than VCL controls, the wizards do not convert properties related to data. See "Enabling simple data binding with the type library" on page 38-10 for information on how to make your ActiveX control data-aware.
- Any property, method, or event that type that is not Automation-compatible does not appear. You may want to add these to the ActiveX control's interface after the wizard has finished.

You can add, edit, and remove the properties, methods, and events in an ActiveX control by editing the type library. You can use the Type Library editor as described in Chapter 34, "Working with type libraries."Remember that when you add events, they should be added to the Events interface, not the ActiveX control's default interface.

Note You can add unpublished properties to your ActiveX control's interface. Such properties can be set at runtime and will appear in a development environment, but changes made to them will not persist. That is, when the user of the control changes the value of a property at design time, the changes are not reflected when the control is run. If the source is a VCL object and the property is not already published, you can make properties persistent by creating a descendant of the VCL object and publishing the property in the descendant.

You may also choose not to expose all of the VCL control's properties, methods, and events to host applications. You can use the Type Library editor to remove these from the interfaces that the wizard generated. When you remove properties and methods from an interface using the Type Library editor, the Type Library editor does not remove them from the corresponding implementation class. Edit the ActiveX wrapper class in the implementation unit to remove these after you have changed the interface in the Type Library editor.

Warning Any changes you make to the type library will be lost if you regenerate the ActiveX control from the original VCL control or form.

Tip It is a good idea to check the methods that the wizard adds to your ActiveX wrapper class. Not only does this give you a chance to note where the wizard omitted any data-aware properties or methods that were not Automation-compatible, it also lets you detect methods for which the wizard could not generate an implementation. Such methods appear with a comment in the implementation that indicates the problem.

Adding additional properties, methods, and events

You can add additional properties, methods, and events to the control using the type library editor. The declaration is automatically added to the control's implementation unit, type library (TLB) file, and type library unit. The specifics of what Delphi supplies depends on whether you have added a property or method or whether you have added an event.

Adding properties and methods

The ActiveX wrapper class implements properties in its interface using read and write access methods. That is, the wrapper class has COM properties, which appear on an interface as getter and/or setter methods. Unlike VCL properties, you do not see a "property" declaration on the interface for COM properties. Rather, you see methods that are flagged as property access methods. When you add a property to the ActiveX control's default interface, the wrapper class definition (which appears in the _TLB unit that is updated by the Type Library editor) gains one or two new methods (a getter and/or setter) that you must implement, just as when you add a method to the interface, the wrapper class gains a corresponding method for you to implement. Thus, adding properties to the wrapper class's interface is essentially the same as adding methods: the wrapper class definition gains new skeletal method implementations for you to complete.

Note For details on what appears in the generated _TLB unit, see "Code generated when you import type library information" on page 35-5.

For example, consider a *Caption* property, of type *TCaption* in the underlying VCL object. To Add this property to the object's interface, you enter the following when you add a property to the interface via the type library editor:

```
property Caption: TCaption read Get_Caption write Set_Caption;
```

Delphi adds the following declarations to the wrapper class:

```
function Get_Caption: WideString; safecall;
procedure Set_Caption(const Value: WideString); safecall;
```

In addition, it adds skeletal method implementations for you to complete:

```
function TButtonX.Get_Caption: WideString;
begin
end;

procedure TButtonX.Set_Caption(Value: WideString);
begin
end;
```

Typically, you can implement these methods by simply delegating to the associated VCL control, which can be accessed using the *FDelphiControl* member of the wrapper class:

```
function TButtonX.Get_Caption: WideString;
begin
  Result := WideString(FDelphiControl.Caption);
end;

procedure TButtonX.Set_Caption(const Value: WideString);
begin
  FDelphiControl.Caption := TCaption(Value);
end;
```

In some cases, you may need to add code to convert the COM data types to native Object Pascal types. The preceding example manages this with typecasting.

Note Because the Automation interface methods are declared **safecall**, you do not have to implement COM exception code for these methods—the Delphi compiler handles this for you by generating code around the body of **safecall** methods to catch Delphi exceptions and to convert them into COM error info structures and return codes.

Adding events

The ActiveX control can fire events to its container in the same way that an automation object fires events to clients. This mechanism is described in "Exposing events to clients" on page 36-10.

If the VCL control you are using as the basis of your ActiveX control has any published events, the wizards automatically add the necessary support for managing a list of client event sinks to your ActiveX wrapper class and define the outgoing dispinterface that clients must implement to respond to events.

You add events to this outgoing dispinterface. To add an event in the type library editor, select the event interface and click on the method icon. Then manually add the list of parameters you want include using the parameter page.

Next, you must declare a method in your wrapper class that is of the same type as the event handler for the event in the underlying VCL control. This is not generated automatically, because Delphi does not know which event handler you are using:

```
  procedure KeyPressEvent(Sender: TObject; var Key: Char);
```

Implement this method to use the host application's event sink, which is stored in the wrapper class's *FEvents* member:

```
procedure TButtonX.KeyPressEvent(Sender: TObject; var Key: Char);
var
  TempKey: Smallint;
begin
    TempKey := Smallint(Key); {cast to an OleAutomation compatible type }
    if FEvents <> nil then
      FEvents.OnKeyPress(TempKey)
    Key := Char(TempKey);
  end;
```

Note When firing events in an ActiveX control, you do not need to iterate through a list of event sinks because the control only has a single host application. This is simpler than the process for most Automation servers.

Finally, you must assign this event handler to the underlying VCL control, so that it is called when the event occurs. You make this assignment in the *InitializeControl* method:

```
procedure TButtonX.InitializeControl;
begin
  FDelphiControl := Control as TButton;
  FDelphiControl.OnClick := ClickEvent;
  FDelphiControl.OnKeyPress := KeyPressEvent;
end;
```

Enabling simple data binding with the type library

With simple data binding, you can bind a property of your ActiveX control to a field in a database. To do this, the ActiveX control must communicate with its host application about what value represents field data and when it changes. You enable this communication by setting the property's binding flags using the Type Library editor.

By marking a property bindable, when a user modifies the property (such as a field in a database), the control notifies its container (the client host application) that the value has changed and requests that the database record be updated. The container interacts with the database and then notifies the control whether it succeeded or failed to update the record.

Note The container application that hosts your ActiveX control is responsible for connecting the data-aware properties you enable in the type library to the database. See "Using data-aware ActiveX controls" on page 35-8 for information on how to write such a container using Delphi.

Use the type library to enable simple data binding,

1. On the toolbar, click the property that you want to bind.
2. Choose the flags page.
3. Select the following binding attributes:

Binding attribute	Description
Bindable	Indicates that the property supports data binding. If marked bindable, the property notifies its container when the property value has changed.
Request Edit	Indicates that the property supports the OnRequestEdit notification. This allows the control to ask the container if its value can be edited by the user.
Display Bindable	Indicates that the container can show users that this property is bindable.
Default Bindable	Indicates the single, bindable property that best represents the object. Properties that have the default bind attribute must also have the bindable attribute. Cannot be specified on more than one property in a dispinterface.
Immediate Bindable	Allows individual bindable properties on a form to specify this behavior. When this bit is set, all changes will be notified. The bindable and request edit attribute bits need to be set for this new bit to have an effect.

4. Click the Refresh button on the toolbar to update the type library.

To test a data-binding control, you must register it first.

For example, to convert a *TEdit* control into a data-bound ActiveX control, create the ActiveX control from a *TEdit* and then change the Text property flags to Bindable, Display Bindable, Default Bindable, and Immediate Bindable. After the control is registered and imported, it can be used to display data.

Creating a property page for an ActiveX control

A property page is a dialog box similar to the Delphi Object Inspector in which users can change the properties of an ActiveX control. A property page dialog allows you to group many properties for a control together to be edited at once. Or, you can provide a dialog box for more complex properties.

Typically, users access the property page by right-clicking the ActiveX control and choosing Properties.

The process of creating a property page is similar to creating a form, you

1. Create a new property page.
2. Add controls to the property page.
3. Associate the controls on the property page with the properties of an ActiveX control.
4. Connect the property page to the ActiveX control.

Note When adding properties to an ActiveX control or ActiveForm, you must publish the properties that you want to persist. If they are not published in the underlying VCL control, you must make a custom descendant of the VCL control that redeclares the properties as published and then use the ActiveX control wizard to create an ActiveX control from the descendant class.

Creating a new property page

You use the Property Page wizard to create a new property page.

To create a new property page,

1. Choose File | New | Other.
2. Select the ActiveX tab.
3. Double-click the Property Page icon.

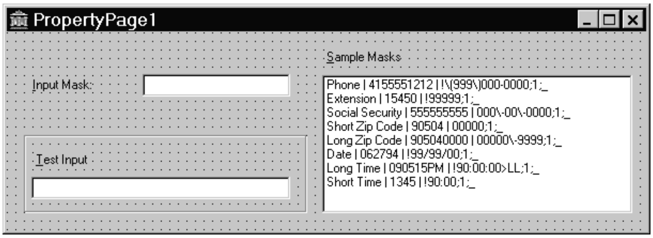
The wizard creates a new form and implementation unit for the property page. The form is a descendant of *TPropertyPage*, which lets you associate the form with the ActiveX control whose properties it edits.

Adding controls to a property page

You must add a control to the property page for each property of the ActiveX control that you want the user to access.

For example, the following illustration shows a property page for setting the MaskEdit property of an ActiveX control.

Figure 38.1 Mask Edit property page in design mode



```
Phone | 4155551212 | !\(999\)000-0000;1;_
Extension | 15450 | !99999;1;_
Social Security | 555555555 | 000\-00\-0000;1;_
Short Zip Code | 90504 | 00000;1;_
Long Zip Code | 905040000 | 00000\-9999;1;_
Date | 062794 | !99/99/00;1;_
Long Time | 090515PM | !90:00:00>LL;1;_
Short Time | 1345 | !90:00;1;_
```

The list box allows the user to select from a list of sample masks. The edit controls allow the user to test the mask before applying it to the ActiveX control. You add controls to the property page the same as you would to a form.

Associating property page controls with ActiveX control properties

After adding the controls you need to the property page, you must associate each control with its corresponding property. You make this association by adding code to the property page's *UpdatePropertyPage* and *UpdateObject* methods.

Updating the property page

Add code to the *UpdatePropertyPage* method to update the control on the property page when the properties of the ActiveX control change. You must add code to the *UpdatePropertyPage* method to update the property page with the current values of the ActiveX control's properties.

You can access the ActiveX control using the property page's *OleObject* property, which is an *OleVariant* that contains the ActiveX control's interface.

For example, the following code updates the property page's edit control (InputMask) with the current value of the ActiveX control's *EditMask* property:

```
procedure TPropertyPage1.UpdatePropertyPage;
begin
   { Update your controls from OleObject }
   InputMask.Text := OleObject.EditMask;
end;
```

Note It is also possible to write a property page that represents more than one ActiveX control. In this case, you don't use the *OleObject* property. Instead, you must iterate through a list of interfaces that is maintained by the *OleObjects* property.

Updating the object

Add code to the *UpdateObject* method to update the property when the user changes the controls on the property page. You must add code to the *UpdateObject* method in order to set the properties of the ActiveX control to their new values.

Once again you use the *OleObject* property to access the ActiveX control.

For example, the following code sets the *EditMask* property of the ActiveX control using the value in the property page's edit box control (InputMask):

```
procedure TPropertyPage1.UpdateObject;
begin
   {Update OleObject from your control }
   OleObject.EditMask := InputMask.Text;
end;
```

Connecting a property page to an ActiveX control

To connect a property page to an ActiveX control,

1 Add *DefinePropertyPage* with the GUID constant of the property page as the parameter to the *DefinePropertyPages* method implementation in the control's implementation for the unit. For example,

```
procedure TButtonX.DefinePropertyPages(DefinePropertyPage: TDefinePropertyPage);
begin
  DefinePropertyPage(Class_PropertyPage1);
end;
```

The GUID constant, Class_PropertyPage1, of the property page can be found in the property pages unit.

The GUID is defined in the property page's implementation unit; it is generated automatically by the Property Page wizard.

2 Add the property page unit to the **uses** clause of the controls implementation unit.

Registering an ActiveX control

After you have created your ActiveX control, you must register it so that other applications can find and use it.

To register an ActiveX control:

- Choose Run | Register ActiveX Server.

Note Before you remove an ActiveX control from your system, you should unregister it.

To unregister an ActiveX control:

- Choose Run | Unregister ActiveX Server.

As an alternative, you can use the **tregsvr** command from the command line or run the regsvr32.exe from the operating system.

Testing an ActiveX control

To test your control, add it to a package and import it as an ActiveX control. This procedure adds the ActiveX control to the Delphi component palette. You can drop the control on a form and test as needed.

Your control should also be tested in all target applications that will use the control.

To debug the ActiveX control, select Run | Parameters and type the client name in the Host Application edit box.

The parameters then apply to the host application. Selecting Run | Run will run the host or client application and allow you to set breakpoints in the control.

Deploying an ActiveX control on the Web

Before the ActiveX controls that you create can be used by Web clients, they must be deployed on your Web server. Every time you make a change to the ActiveX control, you must recompile and redeploy it so that client applications can see the changes.

Before you can deploy your ActiveX control, you must have a Web Server that will respond to client messages.

To deploy your ActiveX control, use the following steps:

1. Select Project | Web Deployment Options.
2. On the Project page, set the Target Dir to the location of the ActiveX control DLL as a path on the Web server. This can be a local path name or a UNC path, for example, C:\INETPUB\wwwroot.
3. Set the Target URL to the location as a Uniform Resource Locators (URL) of the ActiveX control DLL (without the file name) on your Web Server, for example, http://mymachine.inprise.com/. See the documentation for your Web Server for more information on how to do this.
4. Set the HTML Dir to the location (as a path) where the HTML file that contains a reference to the ActiveX control should be placed, for example, C:\INETPUB\wwwroot. This path can be a standard path name or a UNC path.
5. Set desired Web deployment options as described in “Setting options” on page 38-16.
6. Choose OK.
7. Choose Project | Web Deploy.

   This creates a deployment code base that contains the ActiveX control in an ActiveX library (with the OCX extension). Depending on the options you specify, this deployment code base can also contain a cabinet (with the CAB extension) or information (with the INF extension).

   The ActiveX library is placed in the Target Directory you specified in step 2. The HTML file has the same name as the project file but with the HTM extension. It is created in the HTML Directory specified in step 4. The HTML file contains a URL reference to the ActiveX library at the location specified in step 3.

Note If you want to put these files on your Web server, use an external utility such as ftp.

8. Invoke your ActiveX-enabled Web browser and view the created HTML page.

When this HTML page is viewed in the Web browser, your form or control is displayed and runs as an embedded application within the browser. That is, the library runs in the same process as the browser application.

Setting options

Before deploying an ActiveX control, specify the Web deployment options that should be followed when creating the ActiveX library.

Web deployment options include settings to allow you to set the following:

- **Including additional files:** If your ActiveX control depends on any packages or other additional files, you can indicate that these should be deployed with the project. By default, these files use the same options that you specify for the entire project, but you can override these settings using the Packages or Additional files tab. When you include packages or additional files, Delphi creates a file with the .INF extension (for INFormation). This file specifies the various files that need to be downloaded and set up for the ActiveX library to run. The syntax of the INF file allows URLs pointing to packages or additional files to download.
- **CAB file compression:** A cabinet is a single file, usually with a **CAB** file extension, that stores compressed files in a file library. Cabinet compression can dramatically decrease download time (up to 70%) of a file. During installation, the browser decompresses the files stored in a cabinet and copies them to the user's system. Each file that you deploy can be CAB file compressed. You can specify that the ActiveX library use CAB file compression on the Project tab of the Web Deployment options dialog.
- **Version information:** You can specify that you want version information included with your ActiveX control. This information is set in the VersionInfo page of the Project Options dialog. Part of this information is the release number, which you can have automatically updated every time you deploy your ActiveX control. If you include additional packages or files, their Version information resources can get added to the INF file as well.

Depending on whether you include additional files and whether you use CAB file compression, the resulting ActiveX library may be an OCX file, a CAB file containing an OCX file, or an INF file. The following table summarizes the results of choosing different combinations.

Packages and/or additional files	CAB file compression	Result
No	No	An ActiveX library (OCX) file.
No	Yes	A CAB file containing an ActiveX library file.
Yes	No	An INF file, an ActiveX library file, and any additional files and packages.
Yes	Yes	An INF file, a CAB file containing an ActiveX library, and a CAB file each for any additional files and packages.

Chapter

39

Creating MTS or COM+ objects

Delphi uses the term transactional objects to refer to objects that take advantage of the transaction services, security, and resource management supplied by Microsoft Transaction Server (MTS) (for versions of Windows prior to Windows 2000) or COM+ (for Windows 2000 and later). These objects are designed to work in a large, distributed environment. They are not available for use in cross-platform applications due to their dependence on Windows-specific technology.

Delphi provides a wizard that creates transactional objects so that you can take advantage of the benefits of COM+ attributes or the MTS environment. These features make creating COM clients and servers, particularly remote servers, easier to implement.

Note For database applications, Delphi also provides a Transactional Data Module. For more information, see Chapter 25, “Creating multi-tiered applications”.

Transactional objects make use of a number of low-level services, such as

- Managing system resources, including processes, threads, and database connections so that your server application can handle many simultaneous users
- Automatically initiating and controlling transactions so that your application is reliable.
- Creating, executing, and deleting server components when needed.
- Providing role-based security so that only authorized users can access your application.
- Managing events so that clients can respond to conditions that arise on the server (COM+ only).

By letting MTS or COM+ provide these underlying services, you can concentrate on developing the specifics for your particular distributed application. Which technology you choose (MTS or COM+) depends on the server on which you choose to run your application. To clients, the difference between the two (or, for that matter, the fact that the server object uses any of these services) is transparent (unless the client explicitly manipulates transactional services via a special interface).

Understanding transactional objects

Typically, transactional objects are small, and are used for discrete business functions. They can implement an application's business rules, providing views and transformations of the application state. Consider, for example, the case of a medical application. Medical records stored in various databases represent the persistent state of the application, such as a patient's health history. Transactional objects update that state to reflect such changes as new patients, test results, and X-ray files.

Transactional objects are distinguished from other COM objects in that they use a set of attributes supplied by MTS or COM+ for handling issues that arise in a distributed computing environment. Some of these attributes require the transactional object to implement the *IObjectControl* interface. *IObjectControl* defines methods that are called when the object is activated or deactivated, where you can manage resources such as database connections. It also is required for object pooling, which is described in "Object pooling" on page 39-8.

Note If you are using MTS, your transactional objects must implement *IObjectControl*. Under COM+, *IObjectControl* is not required, but is highly recommended. The Transactional Object wizard provides an object that derives from *IObjectControl*.

A client of a transactional object is called a **base client**. From a base client's perspective, a transactional object looks like any other COM object.

Under MTS, the transactional object must be built into a library (DLL), which is then installed in the MTS runtime environment (the MTS executive, mtxex.exe). That is, the server object runs in the MTS runtime process space. The MTS executive can be running in the same process as the base client, as a separate process on the same machine as the base client, or as a remote server process on a separate machine.

Under COM+, the server application need not be an in-process server. Because the various services are integrated into the COM libraries, there is no need for a separate MTS process to intercept calls to the server. Instead, COM itself (or, rather, COM+) provides the resource management, transaction support, and so on. However, the server application must still be installed, this time into a COM+ application.

The connection between the base client and the transactional object is handled by a proxy on the client and a stub on the server, just as with any out-of-process server. Connection information is maintained by the proxy. The connection between the base client and proxy remains open as long as the client requires a connection to the server, so it appears to the client that it has continued access to the server. In reality, though, the proxy may deactivate and reactivate the object, conserving resources so that other clients may use the connection. For details on activating and deactivating, see "Just-in-time activation" on page 39-4.

Requirements for a transactional object

In addition to the COM requirements, a transactional object must meet the following requirements:

- The object must have a standard class factory. This is automatically supplied by the wizard when you create the object.
- The server must expose its class object by exporting the standard *DllGetClassObject* method. Code to do this is supplied by the wizard.
- All object interfaces and CoClasses must be described by a type library, which is created automatically by the wizard. You can add methods and properties to interfaces in the type library by using the Type Library editor. The information in the type library is used by the MTS Explorer or COM+ Component Manager to extract information about the installed components at runtime.
- The server must only export interfaces that use standard COM marshaling. This is automatically supplied by the Transactional Object wizard. Delphi's support of transactional objects does not allow manual marshaling for custom interfaces. All interfaces must be implemented as dual interfaces that use COM's automatic marshaling support.
- The server must export the *DllRegisterServer* function and perform self-registration of its CLSID, ProgID, interfaces, and type library in this routine. This is provided by the Transactional Object wizard.

When using MTS rather than COM+, the following conditions apply as well:

- MTS requires that the server be a dynamic-link library (DLL). Servers that are implemented as executable files (.EXE files) cannot execute in the MTS runtime environment.
- The object must implement the *IObjectControl* interface. Support for this interface is automatically added by the Transactional Object wizard.
- A server running in the MTS process space cannot aggregate with COM objects not running in MTS.

Managing resources

Transactional objects can be administered to better manage the resources used by your application. These resources include everything from the memory for the object instances themselves to any resources they use (such as database connections).

In general, you configure how your application manages resources by the way you install and configure your object. You set your transactional object so that it takes advantage of the following:

- Just-in-time activation
- Resource pooling
- Object pooling (COM+ only)

If you want your object to take full advantage of these services, however, it must use the *IObjectContext* interface to indicate when resources can safely be released.

Accessing the object context

As with any COM object, a transactional object must be created before it is used. COM clients create an object by calling the COM library function, *CoCreateInstance*.

Each transactional object must have a corresponding context object. This context object is implemented automatically by MTS or COM+ and is used to manage the transactional object. The context object's interface is *IObjectContext*. To access most methods of the object context, you can use the *ObjectContext* property of the *TMtsAutoObject* object. For example, you can use the *ObjectContext* property as follows:

```
if ObjectContext.IsCallerInRole ('Manager') ...
```

Another way to access the Object context is to use methods in the *TMtsAutoObject* object:

```
if IsCallerInRole ('Manager') ...
```

You can use either of the above methods. However, there is a slight advantage of using the *TMtsAutoObject* methods rather than referencing the ObjectContext property when you are testing your application. For a discussion of the differences, see "Debugging and testing transactional objects" on page 39-21.

Just-in-time activation

The ability for an object to be deactivated and reactivated while clients hold references to it is called **just-in-time activation**. From the client's perspective, only a single instance of the object exists from the time the client creates it to the time it is finally released. Actually, it is possible that the object has been deactivated and reactivated many times. By having objects deactivated, clients can hold references to the object for an extended time without affecting system resources. When an object is deactivated, all its resources can be released. For example, when an object is deactivated, it can release its database connection so that other objects can use it.

A transactional object is created in a deactivated state and becomes active upon receiving a client request. When the transactional object is created, a corresponding context object is also created. This context object exists for the entire lifetime of the transactional object, across one or more reactivation cycles. The context object, accessed by the *IObjectContext* interface, keeps track of the object during deactivation and coordinates transactions.

Transactional objects are deactivated as soon as it is safe to do so. This is called **as-soon-as-possible deactivation**. A transactional object is deactivated when any of the following occurs:

- **The object requests deactivation with *SetComplete* or *SetAbort*:** An object calls the *IObjectContext SetComplete* method when it has successfully completed its work and it does not need to save the internal object state for the next call from the client. An object calls *SetAbort* to indicate that it cannot successfully complete its work and its object state does not need to be saved. That is, the object's state rolls back to the state prior to the current transaction. Often, objects can be designed to be **stateless**, which means that objects deactivate upon return from every method.

- **A transaction is committed or aborted:** When an object's transaction is committed or aborted, the object is deactivated. Of these deactivated objects, the only ones that continue to exist are the ones that have references from clients outside the transaction. Subsequent calls to these objects reactivate them and cause them to execute in a new transaction.
- **The last client releases the object:** Of course, when a client releases the object, the object is deactivated, and the object context is also released.

Note If you install the transactional object under COM+ from the IDE, you can specify whether object supports just-in-time activation using the COM+ page of the Type Library editor. Just select the object (CoClass) in the Type Library editor, go to the COM+ page, and check or uncheck the box for Just In Time Activation. Otherwise, a system administrator specifies this attribute using the COM+ Component Manager or MTS Explorer. (The system administrator can also override any settings you specify using the Type Library editor.)

Resource pooling

Since idle system resources are freed during a deactivation, the freed resources are available to other server objects. For example, a database connection that is no longer used by a server object can be reused by another client. This is called **resource pooling**. Pooled resources are managed by a resource dispenser.

A resource dispenser caches resources, so that transactional objects that are installed together can share them. The resource dispenser also manages nondurable shared state information. In this way, resource dispensers are similar to resource managers such as the SQL Server, but without the guarantee of durability.

When writing your transactional object, you can take advantage of two types of resource dispenser that are provided for you already:

- Database resource dispensers
- Shared Property Manager

Before other objects can use pooled resources, you must explicitly release them.

Database resource dispensers

Opening and closing connections to a database can be time-consuming. By using a resource dispenser to pool database connections, your object can reuse existing database connections rather than create new ones. For example, if you have a database lookup and a database update component running in a customer maintenance application, you can install those components together, and then they can share database connections. In this way, your application does not need as many connections and new object instances can access the data more quickly by using a connection that is already open but not in use.

- If you are using BDE components to connect to your data, the resource dispenser is the Borland Database Engine (BDE). This resource dispenser is only available when your transactional object is installed with MTS. To enable the resource dispenser, use the BDE administrator to turn on MTS POOLING in the System/ Init area of the configuration.

- If you are using the ADO database components to connect to your data, the resource dispenser is provided by ADO.

Note There is no built-in resource pooling if you are using InterbaseExpress components for your database access.

For remote transactional data modules, connections are automatically enlisted on an object's transactions, and the resource dispenser can automatically reclaim and reuse connections.

Shared property manager

The Shared Property Manager is a resource dispenser that you can use to share state among multiple objects within a server process. By using the Shared Property Manager, you avoid having to add a lot of code to your application for managing shared data: the Shared Property Manager handles it for you by implementing locks and semaphores to protect shared properties from simultaneous access. The Shared Property Manager eliminates name collisions by providing **shared property groups**, which establish unique name spaces for the shared properties they contain.

To use the Shared Property Manager resource, you first use the *CreateSharedPropertyGroup* helper function to create a shared property group. Then you can write all the properties to that group and read all the properties from that group. By using a shared property group, the state information is saved across all deactivations of a transactional object. In addition, state information can be shared among all transactional objects installed in the same MTS package or COM+ application. You can install transactional objects into a package as described in "Installing transactional objects" on page 39-22.

For objects to share state, they all must run in the same process. If you want instances of different components to share properties, you must install them in the same MTS package or COM+ application. Because there is a risk that administrators may move components from one package to another, it's safest to limit the use of a shared property group to instances of objects that are defined in the same DLL or EXE.

Objects sharing properties must have the same activation attribute. If two components in the same package have different activation attributes, they generally won't be able to share properties. For example, if one component is configured to run in a client's process and the other is configured to run in a server process, their objects will usually run in different processes, even though they're in the same MTS package or COM+ application.

The following example shows how to add code to support the Shared Property Manager in a transactional object:

Example: Sharing properties among transactional object instances

This example creates a property group called MyGroup to contain the properties to be shared among objects and object instances. In this example, there is a Counter property that is shared. It uses the *CreateSharedPropertyGroup* helper function to create the property group manager and property group, and then uses the *CreateProperty* method of the Group object to create a property called Counter.

To get the value of a property, you use the *PropertyByName* method of the Group object as shown below. You can also use the *PropertyByPosition* method.

```
unit Unit1;
interface
uses
  MtsObj, Mtx, ComObj, Project2_TLB;
type
  Tfoobar = class(TMtsAutoObject, Ifoobar)
  private
    Group: ISharedPropertyGroup;
  protected
    procedure OnActivate; override;
    procedure OnDeactivate; override;
    procedure IncCounter;
  end;
implementation
uses ComServ;
{ Tfoobar }
procedure Tfoobar.OnActivate;
var
  Exists: WordBool;
  Counter: ISharedProperty;
begin
  Group := CreateSharedPropertyGroup('MyGroup');
  Counter := Group.CreateProperty('Counter', Exists);
end;
procedure Tfoobar.IncCounter;
var
  Counter: ISharedProperty;
begin
  Counter := Group.PropertyByName['Counter'];
  Counter.Value := Counter.Value + 1;
end;
procedure Tfoobar.OnDeactivate;
begin
  Group := nil;
end;
initialization
  TAutoObjectFactory.Create(ComServer, Tfoobar, Class_foobar, ciMultiInstance, tmApartment);
end.
```

Releasing resources

You are responsible for releasing resources of an object. Typically, you do this by calling the *IObjectContext* methods *SetComplete* and *SetAbort* after servicing a client request. These methods release the resources allocated by the resource dispenser.

At this same time, you must release references to all other resources, including references to other objects (including transactional objects and context objects) and memory held by any instances of the component (freeing the component).

The only time you would not include these calls is if you want to maintain state between client calls. For details, see “Stateful and stateless objects” on page 39-11.

Object pooling

Just as you can pool resources, under COM+ you can also pool objects. When an object is deactivated, COM+ calls the *IObjectControl* interface method, *CanBePooled*, which indicates that the object can be pooled for reuse. If *CanBePooled* is returns *True*, then instead of being destroyed on deactivation, the object is moved to the object pool. It remains in the object pool for a specified timeout period, during which time it is available for use to any client requesting it. Only when the object pool is empty is a new instance of the object created. Objects that return *False* or that do not support the *IObjectControl* interface are destroyed when they are deactivated.

Object pooling is not available under MTS. MTS calls *CanBePooled* as described, but no pooling takes place. If your object will only run under COM+ and you want to allow object pooling, set the object’s *Pooled* property to *True*.

Even if an object’s *CanBePooled* method returns *True*, it can be configured so that COM+ does not move it to the object pool. If you install the transactional object under COM+ from the IDE, you can specify whether COM+ tries to pool the object using the COM+ page of the Type Library editor. Just select the object (CoClass) in the type library editor, go to the COM+ page, and check or uncheck the box for Object Pooling. Otherwise, a system administrator specifies this attribute using the COM+ Component Manager or MTS Explorer.

Similarly, you can configure the time a deactivated object remains in the object pool before it is freed If you are installing from the IDE, you can specify this duration using the Creation Timeout setting on the COM+ page of the type library editor. Otherwise, a system administrator specifies this attribute using the COM+ Component Manager.

MTS and COM+ transaction support

The transaction support that gives transactional objects their name lets you group actions into transactions. For example, in a medical records application, if you had a Transfer component to transfer records from one physician to another, you could include your Add and Delete methods in the same transaction. That way, either the entire Transfer works or it can be rolled back to its previous state. Transactions simplify error recovery for applications that must access *multiple* databases.

Transactions ensure that

- All updates in a single transaction are either committed or get aborted and rolled back to their previous state. This is referred to as **atomicity**.
- A transaction is a correct transformation of the system state, preserving the state invariants. This is referred to as **consistency**.
- Concurrent transactions do not see each other's partial and uncommitted results, which might create inconsistencies in the application state. This is referred to as **isolation**. Resource managers use transaction-based synchronization protocols to isolate the uncommitted work of active transactions.
- Committed updates to managed resources (such as database records) survive failures, including communication failures, process failures, and server system failures. This is referred to as **durability**. Transactional logging allows you to recover the durable state after disk media failures.

An object's associated context object indicates whether the object is executing within a transaction and, if so, the identity of the transaction. When an object is part of a transaction, the services that resource managers and resource dispensers perform on its behalf execute under the transaction as well. Resource dispensers use the context object to provide transaction-based services. For example, when an object executing within a transaction allocates a database connection by using the ADO or BDE resource dispenser, the connection is automatically enlisted on the transaction. All database updates using this connection become part of the transaction, and are either committed or aborted.

Work from multiple objects can be composed into a single transaction. Allowing an object to either live in its own transaction or be part of a larger group of objects that belong to a single transaction is a major advantage of MTS and COM+. It allows an object to be used in various ways, so that application developers can reuse application code in different applications without rewriting the application logic. In fact, developers can determine how objects are used in transactions when installing the transactional object. They can change the transaction behavior simply by adding an object to a different MTS package or COM+ application. For details about installing transactional objects, see “Installing transactional objects” on page 39-22.

Transaction attributes

Every transactional object has a transaction attribute that is recorded in the MTS catalog or that is registered with COM+.

Delphi lets you set the transaction attribute at design time using the Transactional Object wizard or the Type Library editor.

Each transaction attribute can be set to these settings:

Requires a transaction Objects must execute *within the scope of a transaction*. When a new object is created, its object context inherits the transaction from the context of the client. If the client does not have a transaction context, a new one is automatically created.

Requires a new transaction Objects must execute *within their own transactions*. When a new object is created, a new transaction is automatically created for the object, regardless of whether its client has a transaction. An object never runs inside the scope of its client's transaction. Instead, the system always creates independent transactions for the new objects.

Supports transactions Objects can execute *within the scope of their client's transactions*. When a new object is created, its object context inherits the transaction from the context of the client. This enables multiple objects to be composed in a single transaction. If the client does not have a transaction, the new context is also created without one.

Transactions Ignored Objects *do not run within the scope of transactions*. When a new object is created, its object context is created without a transaction, regardless of whether the client has a transaction. This setting is only available under COM+.

Does not support transactions The meaning of this setting varies, depending on whether you install the object under MTS or COM+. Under MTS, this setting has the same meaning as Transactions Ignored under COM+. Under COM+, not only is the object context created without a transaction, this setting prevents the object from being activated if the client has a transaction.

Setting the transaction attribute

You can set a transaction attribute when you first create a transactional object using the Transactional Object wizard.

You can also set (or change) the transaction attribute using the Type Library editor. To change the transaction attribute in the Type Library editor,

1 Choose View | Type Library to open the Type Library editor.

2 Select the class corresponding to the transactional object.

3 Click the COM+ tab and choose the desired transaction attribute.

Warning When you set the transaction attribute, Delphi inserts a special GUID for the specified attribute as custom data in the type library. This value is not recognized outside of Delphi. Therefore, it only has an effect if you install the transactional object from the IDE. Otherwise, a system administrator must set this value using the MTS Explorer or COM+ Component Manager.

Note: If the transactional object is already installed, you must first uninstall the object and reinstall it when changing the transaction attribute. Use Run | Install MTS objects or Run | Install COM+ objects to do so.

Stateful and stateless objects

Like any COM object, transactional objects can maintain internal state across multiple interactions with a client. For example, the client could set a property value in one call, and expect that property value to remain unchanged when it makes the next call. Such an object is said to be **stateful**. Transactional objects can also be **stateless**, which means the object does not hold any intermediate state while waiting for the next call from a client.

When a transaction is committed or aborted, all objects that are involved in the transaction are deactivated, causing them to lose any state they acquired during the course of the transaction. This helps ensure transaction isolation and database consistency; it also frees server resources for use in other transactions. Completing a transaction enables the resources held by an object to be reclaimed when the object is deactivated. See the following section for information on how to control when the object's state is released.

Maintaining state on an object requires the object to remain activated, holding potentially valuable resources such as database connections.

Influencing how transactions end

A transactional object uses the *IObjectContext* methods as shown in the following table to influence how a transaction completes. These methods, together with the object's transaction attribute, allow you to enlist one or more objects into a single transaction.

Table 39.1 IObjectContext methods for transaction support

Method	Description
SetComplete	Indicates that the object has successfully completed its work for the transaction. The object is deactivated upon return from the method that first entered the context. The object reactivates on the next call that requires object execution.
SetAbort	Indicates that the object's work can never be committed and the transaction should be rolled back. The object is deactivated upon return from the method that first entered the context. The object reactivates on the next call that requires object execution.

Table 39.1 IObjectContext methods for transaction support (continued)

Method	Description
EnableCommit	Indicates that the object's work is not necessarily done, but that its transactional updates can be committed in their current form. Use this to retain state across multiple calls from a client while still allowing transactions to complete. The object is not deactivated until it calls SetComplete or SetAbort. EnableCommit is the default state when an object is activated. This is why an object should *always call SetComplete or SetAbort before returning from a method,* unless you want the object to maintain its internal state for the next call from a client.
DisableCommit	Indicates that the object's work is inconsistent and that it cannot complete its work until it receives further method invocations from the client. Call this before returning control to the client to maintain state across multiple client calls while keeping the current transaction active. DisableCommit prevents the object from deactivating and releasing its resources on return from a method call. Once an object has called DisableCommit, if a client attempts to commit the transaction before the object has called EnableCommit or SetComplete, the transaction will abort.

Initiating transactions

Transactions can be controlled in three ways:

- They can be controlled by the client.

  Clients can have direct control over transactions by using a transaction context object (using the *ITransactionContext* interface).

- They can be controlled by the server.

  Servers can control transactions explicitly creating an object context for them. When the server creates an object this way, the created object is automatically enlisted in the current transaction.

- Transactions can occur automatically as a result of the object’s transaction attribute.

  Transactional objects can be declared so that their objects always execute within a transaction, regardless of how the objects are created. This way, objects do not need to include any logic to handle transactions. This feature also reduces the burden on client applications. Clients do not need to initiate a transaction simply because the component that they are using requires it.

Setting up a transaction object on the client side

A client-based application can control transaction context through the *ITransactionContextEx* interface. The following code example shows how a client application uses *CreateTransactionContextEx* to create the transaction context. This method returns an interface to this object.

This example wraps the call to the transaction context in a call to OleCheck which is necessary because the methods of *IObjectContext* are exposed by Windows directly and are therefore not declared as **safecall**.

```
procedure TForm1.MoveMoneyClick(Sender: TObject);
begin
  Transfer(CLASS_AccountA, CLASS_AccountB, 100);
end;
procedure TForm1.Transfer(DebitAccountId, CreditAccountId: TGuid; Amount: Currency);
var
  TransactionContextEx: ITransactionContextEx;
  CreditAccountIntf, DebitAccountIntf: IAccount;
begin
  TransactionContextEx := CreateTransactionContextEx;
  try
    OleCheck(TransactionContextEx.CreateInstance(DebitAccountId,
      IAccount, DebitAccountIntf));
    OleCheck(TransactionContextEx.CreateInstance(CreditAccountId,
      IAccount, CreditAccountIntf));
    DebitAccountIntf.Debit(Amount);
    CreditAccountIntf.Credit(Amount);
  except
    TransactionContextEx.Abort;
    raise;
  end;
  TransactionContextEx.Commit;
end;
```

Setting up a transaction object on the server side

To control transaction context from the server side, you create an instance of *ObjectContext*. In the following example, the Transfer method is in the transactional object. In using ObjectContext this way, the instance of the object we are creating will inherit all the transaction attributes of the object that creates it. We wrap the call in a call to OleCheck because the methods of *IObjectContext* are exposed by Windows directly and are therefore not declared as **safecall**.

```
procedure TAccountTransfer.Transfer(DebitAccountId, CreditAccountId: TGuid;
 Amount: Currency);
var
  CreditAccountIntf, DebitAccountIntf: IAccount;
begin
  try
    OleCheck(ObjectContext.CreateInstance(DebitAccountId,
      IAccount, DebitAccountIntf));
    OleCheck(ObjectContext.CreateInstance(CreditAccountId,
      IAccount, CreditAccountIntf));
    DebitAccountIntf.Debit(Amount);
    CreditAccountIntf.Credit(Amount);
  except
    DisableCommit;
    raise;
  end;
  EnableCommit;
end;
```

Transaction timeout

The transaction timeout sets how long (in seconds) a transaction can remain active. The system automatically aborts transactions that are still alive after the timeout. By default, the timeout value is 60 seconds. You can disable transaction timeouts by specifying a value of 0, which is useful when debugging transactional objects.

To set the timeout value on your computer,

1. In the MTS Explorer or COM+ Component Manager, select Computer, My Computer.

   By default, My Computer corresponds to the local computer.
2. Right-click and choose Properties and then choose the Options tab.

   The Options tab is used to set the computer's transaction timeout property.
3. Change the timeout value to 0 to disable transaction timeouts.
4. Click OK to save the setting.

For more information on debugging MTS applications, see “Debugging and testing transactional objects” on page 39-21.

Role-based security

MTS and COM+ provide role-based security where you assign a role to a logical group of users. For example, a medical information application might define roles for Physician, X-ray technician, and Patient.

You define authorization for each object and interface by assigning roles. For example, in the physicians’ medical application, only the Physician may be authorized to view all medical records; the X-ray Technician may view only X-rays; and Patients may view only their own medical record.

Typically, you define roles during application development and assign roles for each MTS package or COM+ Application. These roles are then assigned to specific users when the application is deployed. Administrators can configure the roles using the MTS Explorer or COM+ Component Manager.

If you want to control access to blocks of code rather than entire objects, you can provide more fine-grained security by using the *IObjectContext* method, *IsCallerInRole*. This method only works if security is enabled, which can be checked by calling the *IObjectContext* method *IsSecurityEnabled*. These methods are automatically added as methods to your transactional object. For example,

```
if IsSecurityEnabled then {check if security is enabled }
begin
  if IsCallerInRole(‘Physician’) then { check caller’s role }
  begin
    { execute the call normally }
  end
  else
```

```
      { not a physician, do something appropriate }
    end
  end
  else
    { no security enabled, do something appropriate }
  end;
```

Note For applications that require stronger security, context objects implement the *ISecurityProperty* interface, whose methods allow retrieval of the Window's security identifier (SID) for the direct caller and creator of the object, as well as the SID for the clients which are using the object.

Overview of creating transactional objects

The process of creating transactional object is as follows:

1. Use the Transactional Object wizard to create the transactional object.
2. Add methods and properties to the object's interface using the Type Library editor. For details on adding methods and properties using the Type Library editor, see Chapter 34, "Working with type libraries."
3. When implementing your object's methods, you can use the *IObjectContext* interface to manage transactions, persistent state, and security. In addition, if you are passing object references, you will need to use extra care so that they are correctly handled. (See "Passing object references" on page 20.)
4. Debug and test the transactional object.
5. Install the transactional object into an MTS package or COM+ application.
6. Administer your objects using the MTS Explorer or COM+ Component Manager.

Using the Transactional Object wizard

Use the Transactional Object wizard to create a COM object that can take advantage of the resource management, transaction processing, and role-based security provided by MTS or COM+.

To bring up the Transactional Object wizard,

1. Choose File | New | Other.
2. Select the tab labeled Multitier.
3. Double-click the Transactional Object icon.

In the wizard, you must specify the following:

- A threading model that indicates how client applications can call your object's interface. The threading model determines how the object is registered. You are responsible for ensuring that the object's implementation adheres to the selected model. For more information on threading models, see "Choosing a threading model for a transactional object" on page 39-16.

- A transaction model
- An indication of whether your object notifies clients of events. Event support is only provided for traditional events, not COM+ events.

When you complete this procedure, a new unit is added to the current project that contains the definition for the transactional object. In addition, the wizard adds a type library to the project and opens it in the Type Library editor. Now you can expose the properties and methods of the interface through the type library. You define the interface as you would define any COM object as described in “Defining a COM object’s interface” on page 36-9.

The transactional object implements a **dual interface**, which supports both early (compile-time) binding through the vtable and late (runtime) binding through the *IDispatch* interface.

The generated transactional object implements the *IObjectControl* interface methods, *Activate*, *Deactivate*, and *CanBePooled*.

It is not strictly necessary to use the transactional object wizard. You can convert any Automation object into a COM+ transactional object (and any in-process Automation object into an MTS transactional object) by using the COM+ page of the Type Library editor and then installing the object into an MTS package or COM+ application. However, the transactional object wizard provides certain benefits:

- It automatically implements the *IObjectControl* interface, adding *OnActivate* and *OnDeactivate* events to the object so that you can create event handlers that respond when the object is activated or deactivated.
- It automatically generates an ObjectContext property so that it is easy for your object to access the *IObjectContext* methods to control activation and transactions.

Choosing a threading model for a transactional object

The MTS runtime environment or COM+ manages threads for you. Transactional objects should not create threads. They must also never terminate a thread that calls into a DLL.

When you specify the threading model using the Transactional object wizard, you specify how objects are assigned to threads for method execution.

Table 39.2 Threading models for transactional objects

Threading model	Description	Implementation pros and cons
Single	No thread support. Client requests are serialized by the calling mechanism. All objects of a single-threaded component execute on the main thread. This is compatible with the default COM threading model, which is used for components that do not have a Threading Model Registry attribute or for COM components that are not reentrant. Method execution is serialized across all objects in the component and across all components in a process.	Allows components to use libraries that are not reentrant. Very limited scalability. Single-threaded, stateful components are prone to deadlocks. You can eliminate this problem by using stateless objects and calling SetComplete before returning from any method.
Apartment (or Single-threaded apartment)	Each object is assigned to a thread apartment, which lasts for the life of the object; however, multiple threads can be used for multiple objects. This is a standard COM concurrency model. Each apartment is tied to a specific thread and has a Windows message pump.	Provides significant concurrency improvements over the single threading model. Two objects can execute concurrently as long as they are not in the same activity. Similar to a COM apartment, except that the objects can be distributed across multiple processes.

Note These threading models are similar to those defined by COM objects. However, because the MTS and COM+ provide more underlying support for threads, the meaning of each threading model differs here. Also, the free threading model does not apply to transactional objects due to the built-in support for activities.

Activities

In addition to the threading model, transactional objects achieve concurrency through **activities**. Activities are recorded in an object's context, and the association between an object and an activity cannot be changed. An activity includes the transactional object created by the base client, as well as any transactional objects created by that object and its descendants. These objects can be distributed across one or more processes, executing on one or more computers.

For example, a physician's medical application may have a transactional object to add updates and remove records to various medical databases, each represented by a different object. This record object may use other objects as well, such as a receipt object to record the transaction. This results in several transactional objects that are either directly or indirectly under the control of a base client. These objects all belong to the same activity.

MTS or COM+ tracks the flow of execution through each activity, preventing inadvertent parallelism from corrupting the application state. This feature results in a single logical thread of execution throughout a potentially distributed collection of objects. By having one logical thread, applications are significantly easier to write.

When a transactional object is created from an existing context, using either a transaction context object or an object context, the new object becomes a member of the same activity. In other words, the new context inherits the activity identifier of the context used to create it.

Only a single logical thread of execution is allowed within an activity. This is similar in behavior to a COM apartment threading model, except that the objects can be distributed across multiple processes. When a base client calls into an activity, all other requests for work in the activity (such as from another client thread) are blocked until after the initial thread of execution returns back to the client.

Under MTS, every transactional object belongs to one activity. Under COM+, you can configure the way the object participates in activities by setting the **call synchronization**. The following options are available:

Table 39.3 Call synchronization options

Option	Meaning
Disabled	COM+ does not assign activities to the object but it may inherit them with the caller's context. If the caller has no transaction or object context, the object is not assigned to an activity. The result is the same as if the object was not installed in a COM+ application. This option should not be used if any object in the application uses a resource manager or if the object supports transactions or just-in-time activation.
Not Supported	COM+ never assigns the object to an activity, regardless of the status of its caller. This option should not be used if any object in the application uses a resource manager or if the object supports transactions or just-in-time activation.
Supported	COM+ assigns the object to the same activity as its caller. If the caller does not belong to an activity, the object does not either. This option should not be used if any object in the application uses a resource manager or if the object supports transactions or just-in-time activation.
Required	COM+ always assigns the object to an activity, creating one if necessary. This option must be used if the transaction attribute is Supported or Required.
Requires New	COM+ always assigns the object to a new activity, which is distinct from its caller's.

Generating events under COM+

Before COM+, Automation servers used a set of special interfaces for generating events. COM+, however, introduces a new system for managing events. Instead of the server object managing events, keeping track of clients that need to be notified and calling their interfaces when events occur, the underlying system (COM+) manages this process.

Note Transactional objects installed under COM+ can still use the old system for managing events. However, letting COM+ handle the process provides greater flexibility. For example, when COM+ manages events, the client can be an in-process server that is launched by COM+ when the event occurs.

When a COM+ object generates events, it does not do so directly. Rather, it makes use of an associated event object that is specifically created to generate events. The COM+ object calls its event object when it wants to fire an event. When that happens, COM+ calls all clients that have registered an interest in the particular event object.

Using the Event Object wizard

You can create event objects using the Event Object wizard. The wizard first checks whether the current project contains any implementation code, because projects containing COM+ event objects do not include an implementation. They can only contain event object definitions. (You can, however, include multiple COM+ event objects in a single project.)

To bring up the Event Object wizard,

1. Choose File | New.
2. Select the tab labeled ActiveX.
3. Double-click the COM+ Event Object icon.

In the Event Object wizard, specify the name of the event object, the name of the interface that defines the event handlers, and (optionally) a brief description of the events.

When you exit, the wizard creates a project containing a type library that defines your event object and its interface. Use the Type Library editor to define the methods of that interface. These methods are the event handlers that clients implement to respond to events.

The Event object project includes the project file, _ATL unit to import the ATL template classes, and the _TLB unit to define the type library information. It does not include an implementation unit, however, because COM+ event objects have no implementation. The implementation of the interface is the responsibility of the client. When your server object calls a COM+ event object, COM+ intercepts the call and dispatches it to registered clients. Because COM+ event objects require no implementation object, all you need to do after defining the object's interface in the Type Library editor is compile the project and install it with COM+

COM+ places certain restrictions on the interfaces of event objects. The interface you define in the Type Library editor for your event object must obey the following rules:

- The event object's interface must derive from IDispatch.
- All method names must be unique across all interfaces of the event object.
- All methods on the event object's interface must return an HRESULT value.
- The modifier for all parameters of methods must be blank.

Firing events using a COM+ event object

When an event occurs, your COM+ object must call the event object and tell it to fire the event on registered clients. It does this by creating an instance of the event object and calling the method that corresponds to the event:

Note Objects that fire COM+ events, like the event objects themselves, must be installed in a COM+ application.

Passing object references

Note Information on passing object references applies only to MTS, not COM+. This mechanism is needed under MTS because it is necessary to ensure that all pointers to objects running under MTS are routed through interceptors. Because interceptors are built into COM+, you do not need to pass object references.

Under MTS, you can pass object references, (for example, for use as a callback) only in the following ways:

- Through return from an object creation interface, such as *CoCreateInstance* (or its equivalent), *ITransactionContext.CreateInstance*, or *IObjectContext.CreateInstance.*
- Through a call to *QueryInterface*.
- Through a method that has called *SafeRef* to obtain the object reference.

An object reference that is obtained in the above ways is called a **safe reference**. Methods invoked using safe references are guaranteed execute within the correct context.

The MTS runtime environment requires calls to use safe references so that it can manage context switches and allows transactional objects to have lifetimes that are independent of client references. Safe references are not necessary under COM+.

Using the SafeRef method

An object can use the *SafeRef* function to obtain a reference to itself that is safe to pass outside its context. The unit that defines the *SafeRef* function is Mtx.

SafeRef takes as input

- A reference to the interface ID (RIID) of the interface that the current object wants to pass to another object or client.
- A reference to the current object's IUnknown interface.

SafeRef returns a pointer to the interface specified in the RIID parameter that is safe to pass outside the current object's context. It returns **nil** if the object is requesting a safe reference on an object other than itself, or the interface requested in the RIID parameter is not implemented.

When an MTS object wants to pass a self-reference to a client or another object (for example, for use as a callback), it should always call *SafeRef* first and then pass the reference returned by this call. An object should never pass a **self** pointer, or a self-reference obtained through an internal call to QueryInterface, to a client or to any other object. Once such a reference is passed outside the object's context, it is no longer a valid reference.

Calling *SafeRef* on a reference that is already safe returns the safe reference unchanged, except that the reference count on the interface is incremented.

When a client calls QueryInterface on a reference that is safe, the reference returned to the client is also a safe reference.

An object that obtains a safe reference must release the safe reference when finished with it.

For details on *SafeRef* see the SafeRef topic in the Microsoft documentation.

Callbacks

Objects can make callbacks to clients and to other transactional objects. For example, you can have an object that creates another object. The creating object can pass a reference of itself to the created object; the created object can then use this reference to call the creating object.

If you choose to use callbacks, note the following restrictions:

- Calling back to the base client or another package requires access-level security on the client. Additionally, the client must be a DCOM server.
- Intervening firewalls may block calls back to the client.
- Work done on the callback executes in the environment of the object being called. It may be part of the same transaction, a different transaction, or no transaction.
- Under MTS, the creating object must call *SafeRef* and pass the returned reference to the created object in order to call back to itself.

Debugging and testing transactional objects

You can debug local and remote transactional objects. When debugging transactional objects, you may want to turn off transaction timeouts.

The transaction timeout sets how long (in seconds) a transaction can remain active. Transactions that are still alive after the timeout are automatically aborted by the system. By default, the timeout value is 60 seconds. You can disable transaction timeouts by specifying a value of 0, which is useful when debugging.

For information on remote debugging, see the Remote Debugging topic in Online help.

When testing a transactional object that you intend to run under MTS, you may first want to test your object outside the MTS environment to simplify your test environment.

While developing your server, you cannot rebuild the server when it is still in memory. You may get a compiler error like, “Cannot write to DLL while executable is loaded." To avoid this, you can set the MTS package or COM+ application properties to shut down the server when it is idle.

To shut down the server when idle,

1 In the MTS Explorer or COM+ Component Manager, right-click the MTS package or COM+ application in which your transactional object is installed and choose Properties.

2 Select the Advanced tab.

The Advanced tab determines whether the server process associated with a package always runs, or whether it shuts down after a certain period of time.

3 Change the timeout value to 0, which shuts down the server as soon as no longer has a client to service.

4 Click OK to save the setting.

Note When testing outside the MTS environment, you do not reference the *ObjectProperty* of *TMtsObject* directly. The *TMtsObject* implements methods such as *SetComplete* and *SetAbort* that are safe to call when the object context is **nil**.

Installing transactional objects

MTS applications consist of a group of in-process MTS objects running in a single instance of the MTS executive (EXE). A group of COM objects that all run in the same process is called a **package**. A single machine can be running several different packages, where each package is running within a separate MTS EXE.

Under COM+, you work with a similar group, called a COM+ application. In a **COM+ application**, the objects need not be in-process, and there is no separate runtime environment.

You can group your application components into a single MTS package or COM+ application to be managed by a single process. You might want to distribute your components into different MTS packages or COM+ applications to partition your application across multiple processes or machines.

To install transactional objects into an MTS package or COM+ application,

1 If your system supports COM+, choose Run | Install COM+ objects. If your system does not support COM+ but you have MTS installed on your system, choose Run | Install MTS objects. If your system supports neither MTS nor COM+, you will not see a menu item for installing transactional objects.

2 In the Install Object dialog box, check the objects to be installed.

3 If you are installing MTS objects, click the Package button to get a list of MTS packages on your system. If you are installing COM+ objects, click the Application button. Indicate the MTS package or COM+ application into which you are installing your objects. You can choose Into New Package or Into New Application to create a new MTS package or COM+ application in which to install the object. You can choose Into Existing Package or Into Existing Application to install the object into an existing listed MTS package or COM+ application.

4 Choose OK to refresh the catalog, which makes the objects available at runtime.

MTS packages can contain components from multiple DLLs, and components from a single DLL can be installed into different packages. However, a single component cannot be distributed among multiple packages.

Similarly, COM+ applications can contain components from multiple executables and different components from a single executable can be installed into different COM+ applications.

Note You can also install your transactional object using the COM+ Component Manager or MTS Explorer. Be sure when installing the object with one of these tools that you apply the settings for the object that appear on the COM+ page of the Type Library editor. These settings are not applied automatically when you do not install from the IDE.

Administering transactional objects

Once you have installed transactional objects, you can administer these runtime objects using the MTS Explorer (if they are installed into an MTS package) or the COM+ Component Manager (if they are installed into a COM+ application). Both tools are identical, except that the MTS Explorer operates on the MTS runtime environment and the COM+ Component Manager operates on COM+ objects.

The COM+ Component Manager and MTS Explorer have a graphical user interface for managing and deploying transactional objects. Using one of these tools, you can

- Configure transactional objects, MTS packages or COM+ applications, and roles
- View properties of components in an package or COM+ application and view the MTS packages or COM+ applications installed on a computer
- Monitor and manage transactions for objects that comprise transactions
- Move MTS packages or COM+ applications between computers
- Make a remote transactional object available to a local client

For more details on these tools, see the appropriate *Administrator's Guide* from Microsoft.

Part

V

Creating custom components

The chapters in “Creating custom components” present concepts necessary for designing and implementing custom components in Delphi.

Chapter

40

Overview of component creation

This chapter provides an overview of component design and the process of writing components for Delphi applications. The material here assumes that you are familiar with Delphi and its standard components.

- VCL and CLX
- Components and classes
- How do you create components?
- What goes into a component?
- Creating a new component
- Testing uninstalled components
- Testing installed components

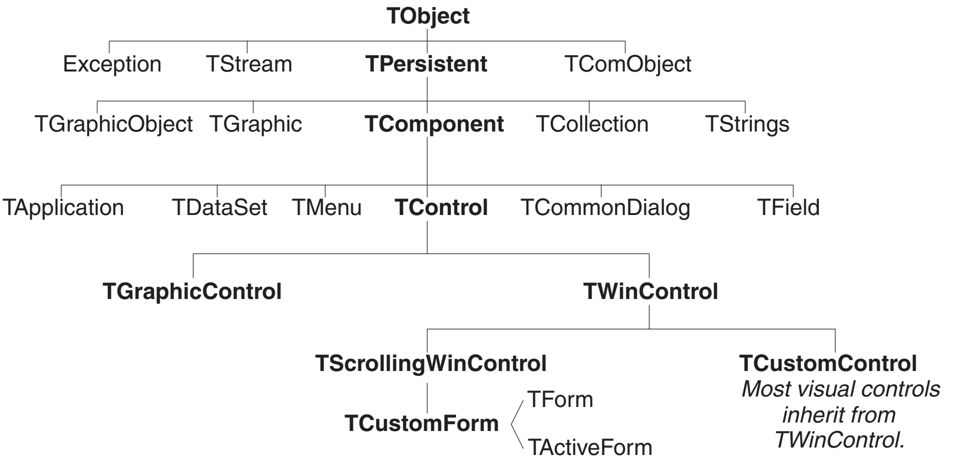
For information on installing new components, see “Installing component packages” on page 11-5.

VCL and CLX

Delphi’s components reside in two class hierarchies called the Visual Component Library (VCL) and the Component Library for Cross Platform (CLX). Figure 40.1 shows the relationship of selected classes that make up the VCL. The CLX hierarchy is similar to the VCL but Windows controls are called widgets (therefore *TWinControl* is called *TWidgetControl*, for example), and there are other differences. For a more detailed discussion of class hierarchies and the inheritance relationships among classes, see Chapter 41, “Object-oriented programming for component writers.” For an overview of how CLX differs from the VCL, see “CLX versus VCL” on page 10-5 and refer to the CLX online reference for details on the components.

The *TComponent* class is the shared ancestor of every component in the VCL and CLX. *TComponent* provides the minimal properties and events necessary for a component to work in Delphi. The various branches of the library provide other, more specialized capabilities.

Figure 40.1 Visual Component Library class hierarchy



When you create a component, you add to the VCL or CLX by deriving a new class from one of the existing class types in the hierarchy.

Components and classes

Because components are classes, component writers work with objects at a different level from application developers. Creating new components requires that you derive new classes.

Briefly, there are two main differences between creating components and using them in applications. When creating components,

- You access parts of the class that are inaccessible to application programmers.
- You add new parts (such as properties) to your components.

Because of these differences, you need to be aware of more conventions and think about how application developers will use the components you write.

How do you create components?

A component can be almost any program element that you want to manipulate at design time. Creating a component means deriving a new class from an existing one. You can derive a new component from any existing component, but the following are the most common ways to create components:

- Modifying existing controls
- Creating windowed controls
- Creating graphic controls
- Subclassing Windows controls
- Creating nonvisual components

Table 40.1 summarizes the different kinds of components and the classes you use as starting points for each.

Table 40.1 Component creation starting points

To do this	Start with this type
Modify an existing component	Any existing component, such as *TButton* or *TListBox*, or an abstract component type, such as *TCustomListBox*
Create a windowed (or widget-based in CLX) control	*TWinControl* (*TWidgetControl* in CLX)
Create a graphic control	*TGraphicControl*
Subclassing a control	Any Windows (VCL) or widget-based (CLX) control
Create a nonvisual component	*TComponent*

You can also derive classes that are not components and cannot be manipulated on a form. Delphi includes many such classes, like *TRegIniFile* and *TFont*.

Modifying existing controls

The simplest way to create a component is to customize an existing one. You can derive a new component from any of the components provided with Delphi.

Some controls, such as list boxes and grids, come in several variations on a basic theme. In these cases, the VCL and CLX includes an abstract class (with the word “custom” in its name, such as *TCustomGrid*) from which to derive customized versions.

For example, you might want to create a special list box that does not have some of the properties of the standard *TListBox* class. You cannot remove (hide) a property inherited from an ancestor class, so you need to derive your component from something above *TListBox* in the hierarchy. Rather than force you to start from the abstract *TWinControl* (or *TWidgetControl* in CLX) class and reinvent all the list box functions, the VCL or CLX provides *TCustomListBox*, which implements the properties of a list box but does not publish all of them. When you derive a component from an abstract class like *TCustomListBox*, you publish only the properties you want to make available in your component and leave the rest protected.

Chapter 42, “Creating properties,” explains publishing inherited properties. Chapter 48, “Modifying an existing component,” and Chapter 50, “Customizing a grid,” show examples of modifying existing controls.

Creating windowed controls

Windowed controls in the VCL and CLX are objects that appear at runtime and that the user can interact with. Each windowed control has a window handle, accessed through its *Handle* property, that lets the operating system identify and operate on the control. If using VCL controls, the handle allows the control to receive input focus and can be passed to Windows API functions. In CLX, these controls are widget-based controls. Each widget-based control has a handle, accessed through its *Handle* property, that identifies the underlying widget.

All windowed controls descend from the *TWinControl* (*TWidgetControl* in CLX) class. These include most standard windowed controls, such as pushbuttons, list boxes, and edit boxes. While you could derive an original control (one that's not related to any existing control) directly from *TWinControl* (*TWidgetControl* in CLX), Delphi provides the *TCustomControl* component for this purpose. *TCustomControl* is a specialized windowed control that makes it easier to draw complex visual images.

Chapter 50, "Customizing a grid," presents an example of creating a windowed control.

Creating graphic controls

If your control does not need to receive input focus, you can make it a graphic control. Graphic controls are similar to windowed controls, but have no window handles, and therefore consume fewer system resources. Components like *TLabel*, which never receive input focus, are graphic controls. Although these controls cannot receive focus, you can design them to react to mouse messages.

Delphi supports the creation of custom controls through the *TGraphicControl* component. *TGraphicControl* is an abstract class derived from *TControl*. Although you can derive controls directly from *TControl*, it is better to start from *TGraphicControl*, which provides a canvas to paint on and on Windows, handles *WM_PAINT* messages; all you need to do is override the *Paint* method.

Chapter 49, "Creating a graphic component," presents an example of creating a graphic control.

Subclassing Windows controls

In traditional Windows programming, you create custom controls by defining a new *window class* and registering it with Windows. The window class (which is similar to the *objects* or *classes* in object-oriented programming) contains information shared among instances of the same sort of control; you can base a new window class on an existing class, which is called *subclassing*. You then put your control in a dynamic-link library (DLL), much like the standard Windows controls, and provide an interface to it.

Using Delphi, you can create a component "wrapper" around any existing window class. So if you already have a library of custom controls that you want to use in Delphi applications, you can create Delphi components that behave like your controls, and derive new controls from them just as you would with any other component.

For examples of the techniques used in subclassing Windows controls, see the components in the StdCtls unit that represent standard Windows controls, such as *TEdit*. For CLX examples, see QStdCtls.

Creating nonvisual components

Nonvisual components are used as interfaces for elements like databases (*TDataSet* or *TSQLConnection*) and system clocks (*TTimer*), and as placeholders for dialog boxes (*TCommonDialog* (VCL) or *TDialog* (CLX) and its descendants). Most of the components you write are likely to be visual controls. Nonvisual components can be derived directly from *TComponent*, the abstract base class for all components.

What goes into a component?

To make your components reliable parts of the Delphi environment, you need to follow certain conventions in their design. This section discusses the following topics:

- Removing dependencies
- Properties, methods, and events
- Graphics encapsulation
- Registration

Removing dependencies

One quality that makes components usable is the absence of restrictions on what they can do at any point in their code. By their nature, components are incorporated into applications in varying combinations, orders, and contexts. You should design components that function in any situation, without preconditions.

An excellent example of removing dependencies is the *Handle* property of *TWinControl*. If you have written Windows applications before, you know that one of the most difficult and error-prone aspects of getting a program running is making sure that you do not try to access a window or control until you have created it by calling the *CreateWindow* API function. Delphi windowed controls relieve users from this concern by ensuring that a valid window handle is always available when needed. By using a property to represent the window handle, the control can check whether the window has been created; if the handle is not valid, the control creates a window and returns the handle. Thus, whenever an application's code accesses the *Handle* property, it is assured of getting a valid handle.

By removing background tasks like creating the window, Delphi components allow developers to focus on what they really want to do. Before passing a window handle to an API function, there is no need to verify that the handle exists or to create the window. The application developer can assume that things will work, instead of constantly checking for things that might go wrong.

Although it can take time to create components that are free of dependencies, it is generally time well spent. It not only spares application developers from repetition and drudgery, but it reduces your documentation and support burdens.

Properties, methods, and events

Aside from the visible image manipulated in the Form designer, the most obvious attributes of a component are its properties, events, and methods. Each of these has a chapter devoted to it in this book, but the discussion that follows explains some of the motivation for their use.

Properties

Properties give the application developer the illusion of setting or reading the value of a variable, while allowing the component writer to hide the underlying data structure or to implement special processing when the value is accessed.

There are several advantages to using properties:

- Properties are available at design time. The application developer can set or change initial values of properties without having to write code.
- Properties can check values or formats as the application developer assigns them. Validating input at design time prevents errors.
- The component can construct appropriate values on demand. Perhaps the most common type of error programmers make is to reference a variable that has not been initialized. By representing data with a property, you can ensure that a value is always available on demand.
- Properties allow you to hide data under a simple, consistent interface. You can alter the way information is structured in a property without making the change visible to application developers.

Chapter 42, "Creating properties," explains how to add properties to your components.

Events

An event is a special property that invokes code in response to input or other activity at runtime. Events give the application developer a way to attach specific blocks of code to specific runtime occurrences, such as mouse actions and keystrokes. The code that executes when an event occurs is called an *event handler*.

Events allow application developers to specify responses to different kinds of input without defining new components.

Chapter 43, "Creating events," explains how to implement standard events and how to define new ones.

Methods

Class methods are procedures and functions that operate on a class rather than on specific instances of the class. For example, every component's constructor method (*Create*) is a class method. Component methods are procedures and functions that operate on the component instances themselves. Application developers use methods to direct a component to perform a specific action or return a value not contained by any property.

Because they require execution of code, methods can be called only at runtime. Methods are useful for several reasons:

- Methods encapsulate the functionality of a component in the same object where the data resides.
- Methods can hide complicated procedures under a simple, consistent interface. An application developer can call a component's *AlignControls* method without knowing how the method works or how it differs from the *AlignControls* method in another component.
- Methods allow updating of several properties with a single call.

Chapter 44, "Creating methods," explains how to add methods to your components.

Graphics encapsulation

Delphi simplifies Windows graphics by encapsulating various graphic tools into a canvas. The canvas represents the drawing surface of a window or control and contains other classes, such as a pen, a brush, and a font. A canvas is like a Windows device context, but it takes care of all the bookkeeping for you.

If you have written a graphical Windows application, you are familiar with the requirements imposed by Windows' graphics device interface (GDI). For example, GDI limits the number of device contexts available and requires that you restore graphic objects to their initial state before destroying them.

With Delphi, you do not have to worry about these things. To draw on a form or other component, you access the component's *Canvas* property. If you want to customize a pen or brush, you set its color or style. When you finish, Delphi disposes of the resources. Delphi caches resources to avoid recreating them if your application frequently uses the same kinds of resource.

You still have full access to the Windows GDI, but you will often find that your code is simpler and runs faster if you use the canvas built into Delphi components. Graphics features are detailed in Chapter 45, "Using graphics in components."

CLX graphics encapsulation works differently. A canvas is a painter instead. To draw on a form or other component, you access the component's *Canvas* property. *Canvas* is a property and it is also an object called *TCanvas*. *TCanvas* is a wrapper around a Qt painter that is accessible through the *Handle* property. You can use the handle to access low-level Qt graphics library functions.

If you want to customize a pen or brush, you set its color or style. When you finish, Kylix disposes of the resources. CLX also caches the resources.

You can use the canvas built into CLX components by descending from them. How graphics images work in the component depends on the canvas of the object from which your component descends.

Registration

Before you can install your components in the Delphi IDE, you have to register them. Registration tells Delphi where to place the component on the Component palette. You can also customize the way Delphi stores your components in the form file. For information on registering a component, see Chapter 47, “Making components available at design time.”

Creating a new component

You can create a new component two ways:

- Using the Component wizard
- Creating a component manually

You can use either of these methods to create a minimally functional component ready to install on the Component palette. After installing, you can add your new component to a form and test it at both design time and runtime. You can then add more features to the component, update the Component palette, and continue testing.

There are several basic steps that you perform whenever you create a new component. These steps are described below; other examples in this document assume that you know how to perform them.

1. Create a unit for the new component.
2. Derive your component from an existing component type.
3. Add properties, methods, and events.
4. Register your component with Delphi.
5. Create a Help file for your component and its properties, methods, and events.
6. Create a package (a special dynamic-link library) so that you can install your component in the Delphi IDE.

When you finish, the complete component includes the following files:

- A package (.BPL) or package collection (.DPC) file
- A compiled package (.DCP) file
- A compiled unit (.DCU) file
- A palette bitmap (.DCR) file
- A Help (.HLP) file

Creating a help file to instruct component users on how to use the component is optional.

The chapters in the rest of Part V explain all the aspects of building components and provide several complete examples of writing different kinds of components.

Using the Component wizard

The Component wizard simplifies the initial stages of creating a component. When you use the Component wizard, you need to specify only these things:

- The class from which it is derived
- The class name for the new component
- The Component palette page where you want it to appear
- The name of the unit in which the component is created
- The search path where the unit is found
- The name of the package in which you want to place the component

The Component wizard performs the same tasks you would when creating a component manually:

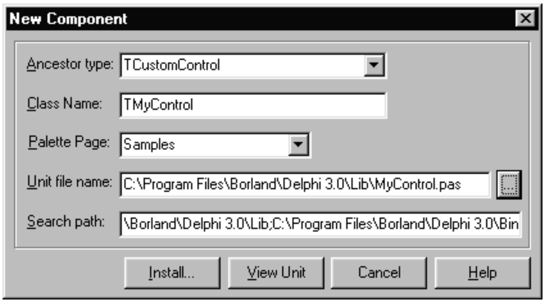
- Creating a unit
- Deriving the component
- Registering the component

The Component wizard cannot add components to an existing unit. You must add components to existing units manually.

To start the Component wizard, choose one of these two methods:

- Choose Component | New Component.
- Choose File | New | Other and double-click on Component

Figure 40.2 Component wizard



Ancestor type: TCustomControl

Class Name: TMyControl

Palette Page: Samples

Unit file name: C:\Program Files\Borland\Delphi 3.0\Lib\MyControl.pas

Search path: \Borland\Delphi 3.0\Lib;C:\Program Files\Borland\Delphi 3.0\Bin

Fill in the fields in the Component wizard:

1 In the Ancestor Type field, specify the class from which you are deriving your new component.

Note In the drop-down list, many components are listed twice with different unit names, one for VCL and one for CLX. The CLX-specific units begin with Q (such as QGraphics instead of Graphics). Be sure to descend from the correct component.

2 In the Class Name field, specify the name of your new component class.

3 In the Palette Page field, specify the page on the Component palette on which you want the new component to be installed.

4 In the Unit file name field, specify the name of the unit you want the component class declared in.

5 If the unit is not on the search path, edit the search path in the Search Path field as necessary.

To place the component in a new or existing package, click Component|Install and use the dialog box that appears to specify a package.

Warning If you derive a component from a VCL or CLX class whose name begins with "custom" (such as *TCustomControl*), do not try to place the new component on a form until you have overridden any abstract methods in the original component. Delphi cannot create instance objects of a class that has abstract properties or methods.

To see the source code for your unit, click View Unit. (If the Component wizard is already closed, open the unit file in the Code editor by selecting File|Open.) Delphi creates a new unit containing the class declaration and the *Register* procedure, and adds a **uses** clause that includes all the standard Delphi units.

The unit looks like this if descending from *TCustomControl* in the Controls unit:

```
unit MyControl;

interface

uses
  Windows, Messages, SysUtils, Classes, Controls;

type
  TMyControl = class(TCustomControl)
  private
  { Private declarations }
  protected
  { Protected declarations }
  public
  { Public declarations }
  published
  { Published declarations }
end;

procedure Register;

implementation

procedure Register;
begin
  RegisterComponents('Samples', [TMyControl]);
end;

end.
```

If descending from *TCustomControl* in the QControls unit, the only difference is the **uses** clause which looks like this:

```
uses
  Windows, Messages, SysUtils, Classes, QControls;
```

Where CLX uses separate units, they are replaced with units of the same name prefixed with a Q; Controls is replaced by QControls.

Creating a component manually

The easiest way to create a new component is to use the Component wizard. You can, however, perform the same steps manually.

To create a component manually, follow these steps:

1 Creating a unit file
2 Deriving the component
3 Registering the component

Creating a unit file

A unit is a separately compiled module of Object Pascal code. Delphi uses units for several purposes. Every form has its own unit, and most components (or groups of related components) have their own units as well

When you create a component, you either create a new unit for the component or add the new component to an existing unit.

To create a unit, choose File | New | Unit. Delphi creates a new unit file and opens it in the Code editor.

To open an existing unit, choose File | Open and select the source code unit that you want to add your component to.

Note When adding a component to an existing unit, make sure that the unit contains only component code. For example, adding component code to a unit that contains a form causes errors in the Component palette.

Once you have either a new or existing unit for your component, you can derive the component class.

Deriving the component

Every component is a class derived from *TComponent*, from one of its more specialized descendants (such as *TControl* or *TGraphicControl*), or from an existing component class. “How do you create components?” on page 40-2 describes which class to derive different kinds of components from.

Deriving classes is explained in more detail in the section “Defining new classes” on page 41-1.

To derive a component, add an object type declaration to the **interface** part of the unit that will contain the component.

A simple component class is a nonvisual component descended directly from *TComponent*.

To create a simple component class, add the following class declaration to the **interface** part of your component unit:

```
type
  TNewComponent = class(TComponent)
  end;
```

So far the new component does nothing different from *TComponent*. You have created a framework on which to build your new component.

Registering the component

Registration is a simple process that tells Delphi which components to add to its component library, and on which pages of the Component palette they should appear. For a more detailed discussion of the registration process, see Chapter 47, "Making components available at design time."

To register a component,

1 Add a procedure named *Register* to the **interface** part of the component's unit. *Register* takes no parameters, so the declaration is very simple:

```
procedure Register;
```

If you are adding a component to a unit that already contains components, it should already have a *Register* procedure declared, so you do not need to change the declaration.

2 Write the *Register* procedure in the **implementation** part of the unit, calling *RegisterComponents* for each component you want to register. *RegisterComponents* is a procedure that takes two parameters: the name of a Component palette page and a set of component types. If you are adding a component to an existing registration, you can either add the new component to the set in the existing statement, or add a new statement that calls *RegisterComponents*.

To register a component named *TMyControl* and place it on the Samples page of the palette, you would add the following *Register* procedure to the unit that contains *TMyControl*'s declaration:

```
procedure Register;
begin
  RegisterComponents('Samples', [TNewControl]);
end;
```

This *Register* procedure places *TMyControl* on the Samples page of the Component palette.

Once you register a component, you can compile it into a package (see Chapter 47, "Making components available at design time") and install it on the Component palette.

Testing uninstalled components

You can test the runtime behavior of a component before you install it on the Component palette. This is particularly useful for debugging newly created components, but the same technique works with any component, whether or not it is on the Component palette. For information on testing already installed components, see "Testing installed components" on page 40-14.

You test an uninstalled component by emulating the actions performed by Delphi when the component is selected from the palette and placed on a form.

To test an uninstalled component,

1 Add the name of component's unit to the form unit's **uses** clause.

2 Add an object field to the form to represent the component.

This is one of the main differences between the way you add components and the way Delphi does it. You add the object field to the public part at the bottom of the form's type declaration. Delphi would add it above, in the part of the type declaration that it manages.

Never add fields to the Delphi-managed part of the form's type declaration. The items in that part of the type declaration correspond to the items stored in the form file. Adding the names of components that do not exist on the form can render your form file invalid.

3 Attach a handler to the form's *OnCreate* event.

4 Construct the component in the form's *OnCreate* handler.

When you call the component's constructor, you must pass a parameter specifying the owner of the component (the component responsible for destroying the component when the time comes). You will nearly always pass *Self* as the owner. In a method, *Self* is a reference to the object that contains the method. In this case, in the form's *OnCreate* handler, *Self* refers to the form.

5 Assign the *Parent* property.

Setting the *Parent* property is always the first thing to do after constructing a control. The parent is the component that contains the control visually; usually it is the form on which the control appears, but it might be a group box or panel. Normally, you'll set *Parent* to *Self*, that is, the form. Always set *Parent* before setting other properties of the control.

Warning If your component is not a control (that is, if *TControl* is not one of its ancestors), skip this step. If you accidentally set the form's *Parent* property (instead of the component's) to *Self*, you can cause an operating-system problem.

6 Set any other component properties as desired.

Suppose you want to test a new component of type *TMyControl* in a unit named *MyControl*. Create a new project, then follow the steps to end up with a form unit that looks like this:

```
unit Unit1;
interface

uses
  SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls,
  Forms, Dialogs, MyControl;                               { 1. Add NewTest to uses clause }

type
  TForm1 = class(TForm)
    procedure FormCreate(Sender: TObject);               { 3. Attach a handler to OnCreate
}
  private
    { Private declarations }
  public
```

```
    { Public Declarations }
    MyControl1: TMyControl1;                                      { 2. Add an object field }
  end;

var
  Form1: TForm1;

implementation
{$R *.DFM}

procedure TForm1.FormCreate(Sender: TObject);
begin
  MyControl1 := TMyControl.Create(Self);                    { 4. Construct the component }
  MyControl1.Parent := Self;          { 5. Set Parent property if component is a control }
  MyControl1.Left := 12;                                    { 6. Set other properties... )
  ⋮                                                                  ...continue as needed }
end;
end.
```

Testing installed components

You can test the design-time behavior of a component after you install it on the Component palette. This is particularly useful for debugging newly created components, but the same technique works with any component, whether or not it is on the Component palette. For information on testing components that have not yet been installed, see “Testing uninstalled components” on page 40-12.

Testing your components after installing allows you to debug the component that only generates design-time exceptions when dropped on a form.

Test an installed component using a second running instance of Delphi:

1 From the Delphi IDE menu select Project|Options|and on the Directories/ Conditionals page, set the Debug Source Path to the component’s source file.

2 Then select Tools|Debugger Options. On the Language Exceptions, page enable the exceptions you want to track.

3 Open the component source file and set breakpoints.

4 Select Run|Parameters and set the Host Application field to the name and location of the Delphi executable file.

5 In the Run Parameters dialog, click the Load button to start a second instance of Delphi.

6 Then drop the components to be tested on the form, which should break on your breakpoints in the source.

Chapter

41

Object-oriented programming for component writers

If you have written applications with Delphi, you know that a class contains both data and code, and that you can manipulate classes at design time and at runtime. In that sense, you've become a component user.

When you create new components, you deal with classes in ways that application developers never need to. You also try to hide the inner workings of the component from the developers who will use it. By choosing appropriate ancestors for your components, designing interfaces that expose only the properties and methods that developers need, and following the other guidelines in this chapter, you can create versatile, reusable components.

Before you start creating components, you should be familiar with these topics, which are related to object-oriented programming (OOP):

- Defining new classes
- Ancestors, descendants, and class hierarchies
- Controlling access
- Dispatching methods
- Abstract class members
- Classes and pointers

Defining new classes

The difference between component writers and application developers is that component writers create new classes while application developers manipulate instances of classes.

A class is essentially a type. As a programmer, you are always working with types and instances, even if you do not use that terminology. For example, you create variables of a type, such as *Integer*. Classes are usually more complex than simple data types, but they work the same way: By assigning different values to instances of the same type, you can perform different tasks.

For example, it is quite common to create a form containing two buttons, one labeled OK and one labeled Cancel. Each is an instance of the class *TButton*, but by assigning different values to their *Caption* properties and different handlers to their *OnClick* events, you make the two instances behave differently.

Deriving new classes

There are two reasons to derive a new class:

- To change class defaults to avoid repetition
- To add new capabilities to a class

In either case, the goal is to create reusable objects. If you design components with reuse in mind, you can save work later on. Give your classes usable default values, but allow them to be customized.

To change class defaults to avoid repetition

Most programmers try to avoid repetition. Thus, if you find yourself rewriting the same lines of code over and over, you place the code in a subroutine or function, or build a library of routines that you can use in many programs. The same reasoning holds for components. If you find yourself changing the same properties or making the same method calls, you can create a new component that does these things by default.

For example, suppose that each time you create an application, you add a dialog box to perform a particular operation. Although it is not difficult to recreate the dialog each time, it is also not necessary. You can design the dialog once, set its properties, and install a wrapper component associated with it onto the Component palette. By making the dialog into a reusable component, you not only eliminate a repetitive task, but you encourage standardization and reduce the likelihood of errors each time the dialog is recreated.

Chapter 48, “Modifying an existing component,” shows an example of changing a component’s default properties.

Note If you want to modify only the published properties of an existing component, or to save specific event handlers for a component or group of components, you may be able to accomplish this more easily by creating a *component template*.

To add new capabilities to a class

A common reason for creating new components is to add capabilities not found in existing components. When you do this, you derive the new component from either an existing component or an abstract base class, such as *TComponent* or *TControl*.

Derive your new component from the class that contains the closest subset of the features you want. You can add capabilities to a class, but you cannot take them away; so if an existing component class contains properties that you do *not* want to include in yours, you should derive from that component’s ancestor.

For example, if you want to add features to a list box, you could derive your component from *TListBox*. However, if you want to add new features but exclude some capabilities of the standard list box, you need to derive your component from *TCustomListBox*, the ancestor of *TListBox*. Then you can recreate (or make visible) only the list-box capabilities you want, and add your new features.

Chapter 50, "Customizing a grid," shows an example of customizing an abstract component class.

Declaring a new component class

In addition to standard components, Delphi provides many abstract classes designed as bases for deriving new components. Table 40.1 on page 40-3 shows the classes you can start from when you create your own components.

To declare a new component class, add a class declaration to the component's unit file.

Here is the declaration of a simple graphical component:

```
type
  TSampleShape = class(TGraphicControl)
  end;
```

A finished component declaration usually includes property, event, and method declarations before the **end**. But a declaration like the one above is also valid, and provides a starting point for the addition of component features.

Ancestors, descendants, and class hierarchies

Application developers take for granted that every control has properties named *Top* and *Left* that determine its position on the form. To them, it may not matter that all controls inherit these properties from a common ancestor, *TControl*. When you create a component, however, you must know which class to derive it from so that it inherits the appropriate features. And you must know everything that your control inherits, so you can take advantage of inherited features without recreating them.

The class from which you derive a component is called its *immediate ancestor*. Each component inherits from its immediate ancestor, and from the immediate ancestor of its immediate ancestor, and so forth. All of the classes from which a component inherits are called its *ancestors*; the component is a *descendant* of its ancestors.

Together, all the ancestor-descendant relationships in an application constitute a hierarchy of classes. Each generation in the hierarchy contains more than its ancestors, since a class inherits everything from its ancestors, then adds new properties and methods or redefines existing ones.

If you do not specify an immediate ancestor, Delphi derives your component from the default ancestor, *TObject*. *TObject* is the ultimate ancestor of all classes in the object hierarchy.

The general rule for choosing which object to derive from is simple: Pick the object that contains as much as possible of what you want to include in your new object, but which does not include anything you do not want in the new object. You can always add things to your objects, but you cannot take things out.

Controlling access

There are five levels of *access control*—also called *visibility*—on properties, methods, and fields. Visibility determines which code can access which parts of the class. By specifying visibility, you define the *interface* to your components.

Table 41.1 shows the levels of visibility, from most restrictive to most accessible:

Table 41.1 Levels of visibility within an object

Visibility	Meaning	Used for
private	Accessible only to code in the unit where the class is defined.	Hiding implementation details.
protected	Accessible to code in the unit(s) where the class and its descendants are defined.	Defining the component writer's interface.
public	Accessible to all code.	Defining the runtime interface.
automated	Accessible to all code. Automation type information is generated.	OLE automation only.
published	Accessible to all code and from the Object Inspector.	Defining the design-time interface.

Declare members as **private** if you want them to be available only within the class where they are defined; declare them as **protected** if you want them to be available only within that class and its descendants. Remember, though, that if a member is available anywhere within a unit file, it is available *everywhere* in that file. Thus, if you define two classes in the same unit, the classes will be able to access each other's private methods. And if you derive a class in a different unit from its ancestor, all the classes in the new unit will be able to access the ancestor's protected methods.

Hiding implementation details

Declaring part of a class as **private** makes that part invisible to code outside the class's unit file. Within the unit that contains the declaration, code can access the part as if it were public.

Here is an example that shows how declaring a field as **private** hides it from application developers. The listing shows two VCL form units. Each form has a handler for its *OnCreate* event which assigns a value to a private field. The compiler allows assignment to the field only in the form where it is declared.

```
unit HideInfo;
interface

uses SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls, Forms, Dialogs;

type
  TSecretForm = class(TForm)                                      { declare new form }
    procedure FormCreate(Sender: TObject);
  private                                                      { declare private part }
    FSecretCode: Integer;                                    { declare a private field }
  end;

var
  SecretForm: TSecretForm;

implementation
procedure TSecretForm.FormCreate(Sender: TObject);
begin
  FSecretCode := 42;                                         { this compiles correctly }
end;
end.                                                                   { end of unit }

unit TestHide;                                           { this is the main form file }

interface
uses SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls, Forms, Dialogs,
  HideInfo;                                           { use the unit with TSecretForm }

type
  TTestForm = class(TForm)
    procedure FormCreate(Sender: TObject);
  end;
var
  TestForm: TTestForm;

implementation
procedure TTestForm.FormCreate(Sender: TObject);
begin
  SecretForm.FSecretCode := 13;        { compiler stops with "Field identifier expected" }
end;
end.                                                                   { end of unit }
```

Although a program using the *HideInfo* unit can use objects of type *TSecretForm*, it cannot access the *FSecretCode* field in any of those objects.

Defining the component writer’s interface

Declaring part of a class as **protected** makes that part visible only to the class itself and its descendants (and to other classes that share their unit files).

You can use **protected** declarations to define a *component writer’s interface* to the class. Application units do not have access to the protected parts, but derived classes do. This means that component writers can change the way a class works without making the details visible to application developers.

Note A common mistake is trying to access protected methods from an event handler. Event handlers are typically methods of the form, not the component that receives the event. As a result, they do not have access to the component’s protected methods (unless the component is declared in the same unit as the form).

Defining the runtime interface

Declaring part of a class as **public** makes that part visible to any code that has access to the class as a whole.

Public parts are available at runtime to all code, so the public parts of a class define its *runtime interface*. The runtime interface is useful for items that are not meaningful or appropriate at design time, such as properties that depend on runtime input or which are read-only. Methods that you intend for application developers to call must also be public.

Here is an example that shows two read-only properties declared as part of a component's runtime interface:

```
type
  TSampleComponent = class(TComponent)
  private
    FTempCelsius: Integer;                           { implementation details are private }
    function GetTempFahrenheit: Integer;
  public
    property TempCelsius: Integer read FTempCelsius;              { properties are public }
    property TempFahrenheit: Integer read GetTempFahrenheit;
  end;
⋮
function TSampleComponent.GetTempFahrenheit: Integer;
begin
  Result := FTempCelsius * 9 div 5 + 32;
end;
```

Defining the design-time interface

Declaring part of a class as **published** makes that part public and also generates runtime type information. Among other things, runtime type information allows the Object Inspector to access properties and events.

Because they show up in the Object Inspector, the published parts of a class define that class's *design-time interface*. The design-time interface should include any aspects of the class that an application developer might want to customize at design time, but must exclude any properties that depend on specific information about the runtime environment.

Read-only properties cannot be part of the design-time interface because the application developer cannot assign values to them directly. Read-only properties should therefore be public, rather than published.

Here is an example of a published property called *Temperature*. Because it is published, it appears in the Object Inspector at design time.

```
type
  TSampleComponent = class(TComponent)
  private
    FTemperature: Integer;                           { implementation details are private }
  published
    property Temperature: Integer read FTemperature write FTemperature;       { writable! }
  end;
```

Dispatching methods

Dispatch refers to the way a program determines where a method should be invoked when it encounters a method call. The code that calls a method looks like any other procedure or function call. But classes have different ways of dispatching methods.

The three types of method dispatch are

- Static
- Virtual
- Dynamic

Static methods

All methods are static unless you specify otherwise when you declare them. Static methods work like regular procedures or functions. The compiler determines the exact address of the method and links the method at compile time.

The primary advantage of static methods is that dispatching them is very quick. Because the compiler can determine the exact address of the method, it links the method directly. Virtual and dynamic methods, by contrast, use indirect means to look up the address of their methods at runtime, which takes somewhat longer.

A static method does not change when inherited by a descendant class. If you declare a class that includes a static method, then derive a new class from it, the derived class shares exactly the same method at the same address. This means that you cannot override static methods; a static method always does exactly the same thing no matter what class it is called in. If you declare a method in a derived class with the same name as a static method in the ancestor class, the new method simply replaces the inherited one in the derived class.

An example of static methods

In the following code, the first component declares two static methods. The second declares two static methods with the same names that replace the methods inherited from the first component.

```
type
  TFirstComponent = class(TComponent)
    procedure Move;
    procedure Flash;
  end;

  TSecondComponent = class(TFirstComponent)
    procedure Move;      { different from the inherited method, despite same declaration }
    function Flash(HowOften: Integer): Integer;               { this is also different }
  end;
```

Virtual methods

Virtual methods employ a more complicated, and more flexible, dispatch mechanism than static methods. A virtual method can be redefined in descendant classes, but still be called in the ancestor class. The address of a virtual method isn't determined at compile time; instead, the object where the method is defined looks up the address at runtime.

To make a method virtual, add the directive **virtual** after the method declaration. The **virtual** directive creates an entry in the object's *virtual method table*, or VMT, which holds the addresses of all the virtual methods in an object type.

When you derive a new class from an existing one, the new class gets its own VMT, which includes all the entries from the ancestor's VMT plus any additional virtual methods declared in the new class.

Overriding methods

Overriding a method means extending or refining it, rather than replacing it. A descendant class can override any of its inherited virtual methods.

To override a method in a descendant class, add the directive **override** to the end of the method declaration.

Overriding a method causes a compilation error if

- The method does not exist in the ancestor class.
- The ancestor's method of that name is static.
- The declarations are not otherwise identical (number and type of arguments parameters differ).

The following code shows the declaration of two simple components. The first declares three methods, each with a different kind of dispatching. The other, derived from the first, replaces the static method and overrides the virtual methods.

```
type
  TFirstComponent = class(TCustomControl)
    procedure Move;               { static method }
    procedure Flash; virtual;     { virtual method }
    procedure Beep; dynamic;      { dynamic virtual method }
  end;

  TSecondComponent = class(TFirstComponent)
    procedure Move;               { declares new method }
    procedure Flash; override;    { overrides inherited method }
    procedure Beep; override;     { overrides inherited method }
  end;
```

Dynamic methods

Dynamic methods are virtual methods with a slightly different dispatch mechanism. Because dynamic methods don't have entries in the object's virtual method table, they can reduce the amount of memory that objects consume. However, dispatching dynamic methods is somewhat slower than dispatching regular virtual methods. If a method is called frequently, or if its execution is time-critical, you should probably declare it as virtual rather than dynamic.

Objects must store the addresses of their dynamic methods. But instead of receiving entries in the virtual method table, dynamic methods are listed separately. The dynamic method list contains entries only for methods introduced or overridden by a particular class. (The virtual method table, in contrast, includes all of the object's virtual methods, both inherited and introduced.) Inherited dynamic methods are dispatched by searching each ancestor's dynamic method list, working backwards through the inheritance tree.

To make a method dynamic, add the directive **dynamic** after the method declaration.

Abstract class members

When a method is declared as **abstract** in an ancestor class, you must surface it (by redeclaring and implementing it) in any descendant component before you can use the new component in applications. Delphi cannot create instances of a class that contains abstract members. For more information about surfacing inherited parts of classes, see Chapter 42, "Creating properties," and Chapter 44, "Creating methods."

Classes and pointers

Every class (and therefore every component) is really a pointer. The compiler automatically dereferences class pointers for you, so most of the time you do not need to think about this. The status of classes as pointers becomes important when you pass a class as a parameter. In general, you should pass classes by value rather than by reference. The reason is that classes are already pointers, which are references; passing a class by reference amounts to passing a reference to a reference.

Chapter

42

Creating properties

Properties are the most visible parts of components. The application developer can see and manipulate them at design time and get immediate feedback as the components react in the Form designer. Well-designed properties make your components easier for others to use and easier for you to maintain.

To make the best use of properties in your components, you should understand the following:

- Why create properties?
- Types of properties
- Publishing inherited properties
- Defining properties
- Creating array properties
- Storing and loading properties

Why create properties?

From the application developer's standpoint, properties look like variables. Developers can set or read the values of properties as if they were fields. (About the only thing you can do with a variable that you cannot do with a property is pass it as a **var** parameter.)

Properties provide more power than simple fields because

- Application developers can set properties at design time. Unlike methods, which are available only at runtime, properties let the developer customize components before running an application. Properties can appear in the Object Inspector, which simplifies the programmer's job; instead of handling several parameters to construct an object, you let Delphi read the values from the Object Inspector. The Object Inspector also validates property assignments as soon as they are made.

- Properties can hide implementation details. For example, data stored internally in an encrypted form can appear unencrypted as the value of a property; although the value is a simple number, the component may look up the value in a database or perform complex calculations to arrive at it. Properties let you attach complex effects to outwardly simple assignments; what looks like an assignment to a field can be a call to a method which implements elaborate processing.
- Properties can be virtual. Hence, what looks like a single property to an application developer may be implemented differently in different components.

A simple example is the *Top* property of all controls. Assigning a new value to *Top* does not just change a stored value; it repositions and repaints the control. And the effects of setting a property need not be limited to an individual component; for example, setting the *Down* property of a speed button to *True* sets *Down* property of all other speed buttons in its group to *False*.

Types of properties

A property can be of any type. Different types are displayed differently in the Object Inspector, which validates property assignments as they are made at design time.

Table 42.1 How properties appear in the Object Inspector

Property type	Object Inspector treatment
Simple	Numeric, character, and string properties appear as numbers, characters, and strings. The application developer can edit the value of the property directly.
Enumerated	Properties of enumerated types (including Boolean) appear as editable strings. The developer can also cycle through the possible values by double-clicking the value column, and there is a drop-down list that shows all possible values.
Set	Properties of set types appear as sets. By double-clicking on the property, the developer can expand the set and treat each element as a Boolean value (**true** if it is included in the set).
Object	Properties that are themselves classes often have their own property editors, specified in the component's registration procedure. If the class held by a property has its own published properties, the Object Inspector lets the developer to expand the list (by double-clicking) to include these properties and edit them individually. Object properties must descend from *TPersistent*.
Interface	Properties that are interfaces can appear in the Object Inspector as long as the value is an interface that is implemented by a component (a descendant of *TComponent*). Interface properties often have their own property editors.
Array	Array properties must have their own property editors; the Object Inspector has no built-in support for editing them. You can specify a property editor when you register your components.

Publishing inherited properties

All components inherit properties from their ancestor classes. When you derive a new component from an existing one, your new component inherits all the properties of its immediate ancestor. If you derive from one of the abstract classes, many of the inherited properties are either protected or public, but not published.

To make a protected or public property available at design time in the Object Inspector, you must redeclare the property as published. Redeclaring means adding a declaration for the inherited property to the declaration of the descendant class.

If you derive a VCL component from *TWinControl*, for example, it inherits the protected *DockSite* property. By redeclaring *DockSite* in your new component, you can change the level of protection to either public or published.

The following code shows a redeclaration of *DockSite* as published, making it available at design time.

```
type
  TSampleComponent = class(TWinControl)
  published
    property DockSite;
  end;
```

When you redeclare a property, you specify only the property name, not the type and other information described below in “Defining properties”. You can also declare new default values and specify whether to store the property.

Redeclarations can make a property less restricted, but not more restricted. Thus you can make a protected property public, but you cannot hide a public property by redeclaring it as protected.

Defining properties

This section shows how to declare new properties and explains some of the conventions followed in the standard components. Topics include

- The property declaration
- Internal data storage
- Direct access
- Access methods
- Default property values

The property declaration

A property is declared in the declaration of its component class. To declare a property, you specify three things:

- The name of the property.
- The type of the property.
- The methods used to read and write the value of the property. If no write method is declared, the property is read-only.

Properties declared in a **published** section of the component’s class declaration are editable in the Object Inspector at design time. The value of a published property is saved with the component in the form file. Properties declared in a **public** section are available at runtime and can be read or set in program code.

Here is a typical declaration for a property called *Count*.

```
type
  TYourComponent = class(TComponent)
  private
    FCount: Integer;                        { used for internal storage }
    procedure SetCount (Value: Integer);    { write method }
  public
    property Count: Integer read FCount write SetCount;
  end;
```

Internal data storage

There are no restrictions on how you store the data for a property. In general, however, Delphi components follow these conventions:

- Property data is stored in class fields.
- The fields used to store property data are private and should be accessed only from within the component itself. Derived components should use the inherited property; they do not need direct access to the property's internal data storage.
- Identifiers for these fields consist of the letter *F* followed by the name of the property. For example, the raw data for the *Width* property defined in *TControl* is stored in a field called *FWidth*.

The principle that underlies these conventions is that only the implementation methods for a property should access the data behind it. If a method or another property needs to change that data, it should do so through the property, not by direct access to the stored data. This ensures that the implementation of an inherited property can change without invalidating derived components.

Direct access

The simplest way to make property data available is *direct access*. That is, the **read** and **write** parts of the property declaration specify that assigning or reading the property value goes directly to the internal-storage field without calling an access method. Direct access is useful when you want to make a property available in the Object Inspector but changes to its value trigger no immediate processing.

It is common to have direct access for the **read** part of a property declaration but use an access method for the **write** part. This allows the status of the component to be updated when the property value changes.

The following component-type declaration shows a property that uses direct access for both the **read** and the **write** parts.

```
type
  TSampleComponent = class(TComponent)
  private                                                { internal storage is private}
    FMyProperty: Boolean;                          { declare field to hold property value }
  published                                        { make property available at design time }
    property MyProperty: Boolean read FMyProperty write FMyProperty;
  end;
```

Access methods

You can specify an access method instead of a field in the **read** and **write** parts of a property declaration. Access methods should be protected, and are usually declared as **virtual**; this allows descendant components to override the property's implementation.

Avoid making access methods public. Keeping them protected ensures that application developers do not inadvertently modify a property by calling one of these methods.

Here is a class that declares three properties using the index specifier, which allows all three properties to have the same read and write access methods:

```
type
  TSampleCalendar = class(TCustomGrid)
  public
    property Day: Integer index 3 read GetDateElement write SetDateElement;
    property Month: Integer index 2 read GetDateElement write SetDateElement;
    property Year: Integer index 1 read GetDateElement write SetDateElement;
  private
    function GetDateElement(Index: Integer): Integer; { note the Index parameter }
    procedure SetDateElement(Index: Integer; Value: Integer);
  ⋮
```

Because each element of the date (day, month, and year) is an int, and because setting each requires encoding the date when set, the code avoids duplication by sharing the read and write methods for all three properties. You need only one method to read a date element, and another to write the date element.

Here is the read method that obtains the date element:

```
function TSampleCalendar.GetDateElement(Index: Integer): Integer;
var
  AYear, AMonth, ADay: Word;
begin
  DecodeDate(FDate, AYear, AMonth, ADay);           { break encoded date into elements }
  case Index of
    1: Result := AYear;
    2: Result := AMonth;
    3: Result := ADay;
    else Result := -1;
  end;
end;
```

This is the write method that sets the appropriate date element:

```
procedure TSampleCalendar.SetDateElement(Index: Integer; Value: Integer);
var
  AYear, AMonth, ADay: Word;
begin
  if Value > 0 then                                { all elements must be positive }
  begin
    DecodeDate(FDate, AYear, AMonth, ADay);        { get current date elements }
    case Index of                                  { set new element depending on Index }
      1: AYear := Value;
      2: AMonth := Value;
      3: ADay := Value;
      else Exit;
    end;
    FDate := EncodeDate(AYear, AMonth, ADay);      { encode the modified date }
    Refresh;                                       { update the visible calendar }
  end;
end;
```

The read method

The read method for a property is a function that takes no parameters (except as noted below) and returns a value of the same type as the property. By convention, the function's name is *Get* followed by the name of the property. For example, the read method for a property called *Count* would be *GetCount*. The read method manipulates the internal storage data as needed to produce the value of the property in the appropriate type.

The only exceptions to the no-parameters rule are for array properties and properties that use index specifiers (see "Creating array properties" on page 42-8), both of which pass their index values as parameters. (Use index specifiers to create a single read method that is shared by several properties. For more information about index specifiers, see the *Object Pascal Language Guide*.)

If you do not declare a read method, the property is write-only. Write-only properties are seldom used.

The write method

The write method for a property is a procedure that takes a single parameter (except as noted below) of the same type as the property. The parameter can be passed by reference or by value, and can have any name you choose. By convention, the write method's name is *Set* followed by the name of the property. For example, the write method for a property called *Count* would be *SetCount*. The value passed in the parameter becomes the new value of the property; the write method must perform any manipulation needed to put the appropriate data in the property's internal storage.

The only exceptions to the single-parameter rule are for array properties and properties that use index specifiers, both of which pass their index values as a second parameter. (Use index specifiers to create a single write method that is shared by several properties. For more information about index specifiers, see the *Object Pascal Language Guide*.)

If you do not declare a write method, the property is read-only.

Write methods commonly test whether a new value differs from the current value before changing the property. For example, here is a simple write method for an integer property called *Count* that stores its current value in a field called *FCount*.

```
procedure TMyComponent.SetCount(Value: Integer);
begin
  if Value <> FCount then
  begin
```

```
      FCount := Value;
      Update;
    end;
  end;
```

Default property values

When you declare a property, you can specify a *default value* for it. Delphi uses the default value to determine whether to store the property in a form file. If you do not specify a default value for a property, Delphi always stores the property.

To specify a default value for a property, append the **default** directive to the property's declaration (or redeclaration), followed by the default value. For example,

```
property Cool Boolean read GetCool write SetCool default True;
```

Note Declaring a default value does not set the property to that value. The component's constructor method should initialize property values when appropriate. However, since objects always initialize their fields to 0, it is not strictly necessary for the constructor to set integer properties to 0, string properties to null, or Boolean properties to *False*.

Specifying no default value

When redeclaring a property, you can specify that the property has no default value, even if the inherited property specified one.

To designate a property as having no default value, append the **nodefault** directive to the property's declaration. For example,

```
property FavoriteFlavor string nodefault;
```

When you declare a property for the first time, there is no need to include **nodefault**. The absence of a declared default value means that there is no default.

Here is the declaration of a component that includes a single Boolean property called *IsTrue* with a default value of *True*. Below the declaration (in the **implementation** section of the unit) is the constructor that initializes the property.

```
type
  TSampleComponent = class(TComponent)
  private
    FIsTrue: Boolean;
  public
    constructor Create(AOwner: TComponent); override;
  published
    property IsTrue: Boolean read FIsTrue write FIsTrue default True;
  end;
⋮
constructor TSampleComponent.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);              { call the inherited constructor }
  FIsTrue := True;                       { set the default value }
end;
```

Creating array properties

Some properties lend themselves to being indexed like arrays. For example, the *Lines* property of *TMemo* is an indexed list of the strings that make up the text of the memo; you can treat it as an array of strings. *Lines* provides natural access to a particular element (a string) in a larger set of data (the memo text).

Array properties are declared like other properties, except that

- The declaration includes one or more indexes with specified types. The indexes can be of any type.
- The **read** and **write** parts of the property declaration, if specified, must be methods. They cannot be fields.

The read and write methods for an array property take additional parameters that correspond to the indexes. The parameters must be in the same order and of the same type as the indexes specified in the declaration.

There are a few important differences between array properties and arrays. Unlike the index of an array, the index of an array property does not have to be an integer type. You can index a property on a string, for example. In addition, you can reference only individual elements of an array property, not the entire range of the property.

The following example shows the declaration of a property that returns a string based on an integer index.

```
type
  TDemoComponent = class(TComponent)
  private
    function GetNumberName(Index: Integer): string;
  public
    property NumberName[Index: Integer]: string read GetNumberName;
  end;
⋮
function TDemoComponent.GetNumberName(Index: Integer): string;
begin
  Result := 'Unknown';
  case Index of
    -MaxInt..-1: Result := 'Negative';
    0: Result := 'Zero';
    1..100: Result := 'Small';
    101..MaxInt: Result := 'Large';
  end;
end;
```

Creating properties for subcomponents

By default, when a property’s value is another component, you assign a value to that property by adding an instance of the other component to the form or data module and then assigning that component as the value of the property. However, it is also possible for your component to create its own instance of the object that implements the property value. Such a dedicated component is called a subcomponent.

Subcomponents can be any persistent object (any descendant of *TPersistent*). Unlike separate components that happen to be assigned as the value of a property, the published properties of subcomponents are saved with the component that creates them. In order for this to work, however, the following conditions must be met:

- The *Owner* of the subcomponent must be the component that creates it and uses it as the value of a published property. For subcomponents that are descendants of *TComponent*, you can accomplish this by setting the *Owner* property of the subcomponent. For other subcomponents, you must override the *GetOwner* method of the persistent object so that it returns the creating component.
- If the subcomponent is a descendant of *TComponent*, it must indicate that it is a subcomponent by calling the *SetSubComponent* method. Typically, this call is made either by the owner when it creates the subcomponent or by the constructor of the subcomponent.

Typically, properties whose values are subcomponents are read-only. If you allow a property whose value is a subcomponent to be changed, the property setter must free the subcomponent when another component is assigned as the property value. In addition, the component often re-instantiates its subcomponent when the property is set to nil. Otherwise, once the property is changed to another component, the subcomponent can never be restored at design time. The following example illustrates such a property setter for a property whose value is a *TTimer*:

```
procedure TDemoComponent.SetTimerProp(Value: TTimer);
begin
  if Value <> FTimer then
  begin
    if Value <> nil then
    begin
      if (FTimer <> nil and FTimer.Owner = self then
        FTimer.Free;
      FTimer := Value;
      FTimer,FreeNotification(self);
    end
    else { nil value }
    begin
      if FTimer.Owner <> self then
      {
        FTimer := TTimer.Create(self);
        FTimer.SetSubComponent(True);
        FTimer.FreeNotification(self);
      }
    end;
  end;
end;
```

Note that the property setter above called the *FreeNotification* method of the component that is set as the property value. This call ensures that the component that is the value of the property sends a notification if it is about to be destroyed. It sends this notification by calling the *Notification* method. You handle this call by overriding the *Notification* method, as follows:

```
procedure TDemoComponent.Notification(AComponent: TComponent; Operation: TOperation);
begin
  inherited Notification(AComponent, Operation);
  if (Operation = opRemove) and (AComponent = FTimer) then
    FTimer := nil;
end;
```

Creating properties for interfaces

You can use an interface as the value of a published property, much as you can use an object. However, the mechanism by which your component receives notifications from the implementation of that interface differs. In the previous topic, the property setter called the *FreeNotification* method of the component that was assigned as the property value. This allowed the component to update itself when the component that was the value of the property was freed. When the value of the property is an interface, however, you don't have access to the component that implements that interface. As a result, you can't call its *FreeNotification* method.

To handle this situation, you can call your component's *ReferenceInterface* method:

```
procedure TDemoComponent.SetMyIntfProp(const Value: IMyInterface);
begin
  ReferenceInterface(FIntfField, opRemove);
  FIntfField := Value;
  ReferenceInterface(FIntfField, opInsert);
end;
```

Calling *ReferenceInterface* with a specified interface does the same thing as calling another component's *FreeNotification* method. Thus, after calling *ReferenceInterface* from the property setter, you can override the *Notification* method to handle the notifications from the implementor of the interface:

```
procedure TDemoComponent.Notification(AComponent: TComponent; Operation: TOperation);
begin
  inherited Notification(AComponent, Operation);
  if (Assigned(MyIntfProp)) and (AComponent.IsImplementorOf(MyInftProp)) then
    MyIntfProp := nil;
end;
```

Note that the *Notification* code assigns **nil** to the *MyIntfProp* property, not to the private field (*FIntfField*). This ensures that *Notification* calls the property setter, which calls *ReferenceInterface* to remove the notification request that was established when the property value was set previously. All assignments to the interface property must be made through the property setter.

Storing and loading properties

Delphi stores forms and their components in form (.dfm in VCL and .xfm in CLX) files. A form file stores the properties of a form and its components. When Delphi developers add the components you write to their forms, your components must have the ability to write their properties to the form file when saved. Similarly, when loaded into Delphi or executed as part of an application, the components must restore themselves from the form file.

Most of the time you will not need to do anything to make your components work with form files because the ability to store a representation and load from it are part of the inherited behavior of components. Sometimes, however, you might want to alter the way a component stores itself or the way it initializes when loaded; so you should understand the underlying mechanism.

These are the aspects of property storage you need to understand:

- Using the store-and-load mechanism
- Specifying default values
- Determining what to store
- Initializing after loading
- Storing and loading unpublished properties

Using the store-and-load mechanism

The description of a form consists of a list of the form's properties, along with similar descriptions of each component on the form. Each component, including the form itself, is responsible for storing and loading its own description.

By default, when storing itself, a component writes the values of all its public and published properties that differ from their default values, in the order of their declaration. When loading itself, a component first constructs itself, setting all properties to their default values, then reads the stored, non-default property values.

This default mechanism serves the needs of most components, and requires no action at all on the part of the component writer. There are several ways you can customize the storing and loading process to suit the needs of your particular components, however.

Specifying default values

Delphi components save their property values only if those values differ from the defaults. If you do not specify otherwise, Delphi assumes a property has no default value, meaning the component always stores the property, whatever its value.

To specify a default value for a property, add the **default** directive and the new default value to the end of the property declaration.

You can also specify a default value when redeclaring a property. In fact, one reason to redeclare a property is to designate a different default value.

Note Specifying the default value does not automatically assign that value to the property on creation of the object. You must make sure that the component's constructor assigns the necessary value. A property whose value is not set by a component's constructor assumes a zero value—that is, whatever value the property assumes when its storage memory is set to 0. Thus numeric values default to 0, Boolean values to *False*, pointers to **nil**, and so on. If there is any doubt, assign a value in the constructor method.

The following code shows a component declaration that specifies a default value for the *Align* property and the implementation of the component's constructor that sets the default value. In this case, the new component is a special case of the standard panel component that will be used for status bars in a window, so its default alignment should be to the bottom of its owner.

```
type
  TStatusBar = class(TPanel)
  public
    constructor Create(AOwner: TComponent); override;       { override to set new default }
  published
    property Align default alBottom;                     { redeclare with new default value }
  end;
⋮
constructor TStatusBar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                              { perform inherited initialization }
  Align := alBottom;                                   { assign new default value for Align }
end;
```

Determining what to store

You can control whether Delphi stores each of your components' properties. By default, all properties in the published part of the class declaration are stored. You can choose not to store a given property at all, or you can designate a function that determines dynamically whether to store the property.

To control whether Delphi stores a property, add the **stored** directive to the property declaration, followed by *True*, *False*, or the name of a Boolean function.

The following code shows a component that declares three new properties. One is always stored, one is never stored, and the third is stored depending on the value of a Boolean function:

```
type
  TSampleComponent = class(TComponent)
  protected
    function StoreIt: Boolean;
  public
  ⋮
  published
    property Important: Integer stored True;          { always stored }
    property Unimportant: Integer stored False;       { never stored }
    property Sometimes: Integer stored StoreIt;       { storage depends on function value }
  end;
```

Initializing after loading

After a component reads all its property values from its stored description, it calls a virtual method named *Loaded*, which performs any required initializations. The call to *Loaded* occurs before the form and its controls are shown, so you do not need to worry about initialization causing flicker on the screen.

To initialize a component after it loads its property values, override the *Loaded* method.

Note The first thing to do in any *Loaded* method is call the inherited *Loaded* method. This ensures that any inherited properties are correctly initialized before you initialize your own component.

The following code comes from the *TDatabase* component. After loading, the database tries to reestablish any connections that were open at the time it was stored, and specifies how to handle any exceptions that occur while connecting.

```
procedure TDatabase.Loaded;
begin
  inherited Loaded;                                    { call the inherited method first}
  try
    if FStreamedConnected then Open                          { reestablish connections }
    else CheckSessionName(False);
  except
    if csDesigning in ComponentState then                             { at design time... }
      Application.HandleException(Self)                { let Delphi handle the exception }
    else raise;                                                       { otherwise, reraise }
  end;
end;
```

Storing and loading unpublished properties

By default, only published properties are loaded and saved with a component. However, it is possible to load and save unpublished properties. This allows you to have persistent properties that do not appear in the Object Inspector. It also allows components to store and load property values that Delphi does not know how to read or write because the value of the property is too complex. For example, the *TStrings* object can't rely on Delphi's automatic behavior to store and load the strings it represents and must use the following mechanism.

You can save unpublished properties by adding code that tells Delphi how to load and save your property's value.

To write your own code to load and save properties, use the following steps:

1 Create methods to store and load the property value.

2 Override the *DefineProperties* method, passing those methods to a filer object.

Creating methods to store and load property values

To store and load unpublished properties, you must first create a method to store your property value and another to load your property value. You have two choices:

- Create a method of type *TWriterProc* to store your property value and a method of type *TReaderProc* to load your property value. This approach lets you take advantage of Delphi's built-in capabilities for saving and loading simple types. If your property value is built out of types that Delphi knows how to save and load, use this approach.
- Create two methods of type *TStreamProc*, one to store and one to load your property's value. *TStreamProc* takes a stream as an argument, and you can use the stream's methods to write and read your property values.

For example, consider a property that represents a component that is created at runtime. Delphi knows how to write this value, but does not do so automatically because the component is not created in the form designer. Because the streaming system can already load and save components, you can use the first approach. The following methods load and store the dynamically created component that is the value of a property named *MyCompProperty*:

```
procedure TSampleComponent.LoadCompProperty(Reader: TReader);
begin
  if Reader.ReadBoolean then
    MyCompProperty := Reader.ReadComponent(nil);
end;
procedure TSampleComponent.StoreCompProperty(Writer: TWriter);
begin
  Writer.WriteBoolean(MyCompProperty <> nil);
  if MyCompProperty <> nil then
    Writer.WriteComponent(MyCompProperty);
end;
```

Overriding the DefineProperties method

Once you have created methods to store and load your property value, you can override the component's *DefineProperties* method. Delphi calls this method when it loads or stores the component. In the *DefineProperties* method, you must call the *DefineProperty* method or the *DefineBinaryProperty* method of the current filer, passing it the method to use for loading or saving your property value. If your load and store methods are of type *TWriterProc* and type *TReaderProc*, then you call the filer's *DefineProperty* method. If you created methods of type *TStreamProc*, call *DefineBinaryProperty* instead.

No matter which method you use to define the property, you pass it the methods that store and load your property value as well as a boolean value indicating whether the property value needs to be written. If the value can be inherited or has a default value, you do not need to write it.

For example, given the *LoadCompProperty* method of type *TReaderProc* and the *StoreCompProperty* method of type *TWriterProc*, you would override *DefineProperties* as follows:

```
procedure TSampleComponent.DefineProperties(Filer: TFiler);
  function DoWrite: Boolean;
  begin
    if Filer.Ancestor <> nil then { check Ancestor for an inherited value }
    begin
      if TSampleComponent(Filer.Ancestor).MyCompProperty = nil then
        Result := MyCompProperty <> nil
      else if MyCompProperty = nil or
         TSampleComponent(Filer.Ancestor).MyCompProperty.Name <> MyCompProperty.Name then
        Result := True
      else Result := False;
    end
    else { no inherited value -- check for default (nil) value }
      Result := MyCompProperty <> nil;
  end;
begin
  inherited; { allow base classes to define properties }
  Filer.DefineProperty('MyCompProperty', LoadCompProperty, StoreCompProperty, DoWrite);
end;
```

Chapter

43

Creating events

An event is a link between an occurrence in the system (such as a user action or a change in focus) and a piece of code that responds to that occurrence. The responding code is an *event handler*, and is nearly always written by the application developer. Events let application developers customize the behavior of components without having to change the classes themselves. This is known as *delegation*.

Events for the most common user actions (such as mouse actions) are built into all the standard components, but you can also define new events. To create events in a component, you need to understand the following:

- What are events?
- Implementing the standard events
- Defining your own events

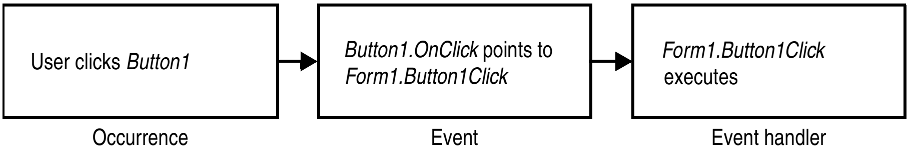
Events are implemented as properties, so you should already be familiar with the material in Chapter 42, “Creating properties,” before you attempt to create or change a component’s events.

What are events?

An event is a mechanism that links an occurrence to some code. More specifically, an event is a method pointer that points to a method in a specific class instance.

From the application developer’s perspective, an event is just a name related to a system occurrence, such as *OnClick*, to which specific code can be attached. For example, a push button called *Button1* has an *OnClick* method. By default, Delphi generates an event handler called *Button1Click* in the form that contains the button and assigns it to *OnClick*. When a click event occurs in the button, the button calls the method assigned to *OnClick*, in this case, *Button1Click*.

To write an event, you need to understand the following:



User clicks *Button1*
Button1.OnClick points to *Form1.Button1Click*
Form1.Button1Click executes
Occurrence
Event
Event handler

- Events are method pointers.
- Events are properties.
- Event types are method-pointer types
- Event-handler types are procedures
- Event handlers are optional.

Events are method pointers

Delphi uses method pointers to implement events. A method pointer is a special pointer type that points to a specific method in an instance object. As a component writer, you can treat the method pointer as a placeholder: When your code detects that an event occurs, you call the method (if any) specified by the user for that event.

Method pointers work just like any other procedural type, but they maintain a hidden pointer to an object. When the application developer assigns a handler to a component's event, the assignment is not just to a method with a particular name, but rather to a method in a specific instance object. That object is usually the form that contains the component, but it need not be.

All controls, for example, inherit a dynamic method called *Click* for handling click events:

```
procedure Click; dynamic;
```

The implementation of *Click* calls the user's click-event handler, if one exists. If the user has assigned a handler to a control's *OnClick* event, clicking the control results in that method being called. If no handler is assigned, nothing happens.

Events are properties

Components use properties to implement their events. Unlike most other properties, events do not use methods to implement their read and write parts. Instead, event properties use a private class field of the same type as the property.

By convention, the field's name is the name of the property preceded by the letter *F*. For example, the *OnClick* method's pointer is stored in a field called *FOnClick* of type *TNotifyEvent*, and the declaration of the *OnClick* event property looks like this:

```
type
  TControl = class(TComponent)
  private
    FOnClick: TNotifyEvent;                 { declare a field to hold the method pointer }
    ⋮
  protected
    property OnClick: TNotifyEvent read FOnClick write FOnClick;
  end;
```

To learn about *TNotifyEvent* and other event types, see the next section, "Event types are method-pointer types".

As with any other property, you can set or change the value of an event at runtime. The main advantage to having events be properties, however, is that component users can assign handlers to events at design time, using the Object Inspector.

Event types are method-pointer types

Because an event is a pointer to an event handler, the type of the event property must be a method-pointer type. Similarly, any code to be used as an event handler must be an appropriately typed method of an object.

All event-handler methods are procedures. To be compatible with an event of a given type, an event-handler method must have the same number and type of parameters, in the same order, passed in the same way.

Delphi defines method types for all its standard events. When you create your own events, you can use an existing type if that is appropriate, or define one of your own.

Event-handler types are procedures

Although the compiler allows you to declare method-pointer types that are functions, you should never do so for handling events. Because an empty function returns an undefined result, an empty event handler that was a function might not always be valid. For this reason, all your events and their associated event handlers should be procedures.

Although an event handler cannot be a function, you can still get information from the application developer's code using **var** parameters. When doing this, make sure you assign a valid value to the parameter before calling the handler so you don't require the user's code to change the value.

An example of passing **var** parameters to an event handler is the *OnKeyPress* event, of type *TKeyPressEvent*. *TKeyPressEvent* defines two parameters, one to indicate which object generated the event, and one to indicate which key was pressed:

```
type
  TKeyPressEvent = procedure(Sender: TObject; var Key: Char) of object;
```

Normally, the *Key* parameter contains the character pressed by the user. Under certain circumstances, however, the user of the component may want to change the character. One example might be to force all characters to uppercase in an editor. In that case, the user could define the following handler for keystrokes:

```
procedure TForm1.Edit1KeyPressed(Sender: TObject; var Key: Char);
begin
  Key := UpCase(Key);
end;
```

You can also use **var** parameters to let the user override the default handling.

Event handlers are optional

When creating events, remember that developers using your components may not attach handlers to them. This means that your component should not fail or generate errors simply because there is no handler attached to a particular event. (The mechanics of calling handlers and dealing with events that have no attached handler are explained in “Calling the event” on page 43-8.)

Events happen almost constantly in a GUI application. Just moving the mouse pointer across a visual component sends numerous mouse-move messages, which the component translates into *OnMouseMove* events. In most cases, developers do not want to handle the mouse-move events, and this should not cause a problem. So the components you create should not require handlers for their events.

Moreover, application developers can write any code they want in an event handler. The components in the VCL and CLX have events written in such a way as to minimize the chance of an event handler generating errors. Obviously, you cannot protect against logic errors in application code, but you can ensure that data structures are initialized before calling events so that application developers do not try to access invalid data.

Implementing the standard events

The controls that come with Delphi inherit events for the most common occurrences. These are called the *standard events*. Although all these events are built into the controls, they are often **protected**, meaning developers cannot attach handlers to them. When you create a control, you can choose to make events visible to users of your control.

There are three things you need to consider when incorporating the standard events into your controls:

- Identifying standard events
- Making events visible
- Changing the standard event handling

Identifying standard events

There are two categories of standard events: those defined for all controls and those defined only for the standard windowed controls.

Standard events for all controls

The most basic events are defined in the class *TControl*. All controls, whether windowed, graphical, or custom, inherit these events. The following events are available in all controls:

OnClick
OnDblClick
OnDragDrop
OnDragOver
OnEndDrag
OnMouseDown
OnMouseMove
OnMouseUp

The standard events have corresponding protected virtual methods declared in *TControl*, with names that correspond to the event names. For example, *OnClick* events call a method named *Click*, and *OnEndDrag* events call a method named *DoEndDrag*.

Standard events for standard controls

In addition to the events common to all controls, standard windowed controls (those that descend from *TWinControl* in the VCL and *TWidgetControl* in CLX) have the following events:

OnEnter *OnKeyDown* *OnKeyPress*
OnKeyUp *OnExit*

Like the standard events in *TControl*, the windowed-control events have corresponding methods. The standard key events listed above respond to all normal keystrokes.

VCL Note To respond to special keystrokes (such as the Alt key), however, you must respond to the WM_GETDLGCODE or CM_WANTSPECIALKEYS message from Windows. See Chapter 46, “Handling messages” for information on writing message handlers.

Making events visible

The declarations of the standard events in *TControl* and *TWinControl* (*TWidgetControl* in CLX) are protected, as are the methods that correspond to them. If you are inheriting from one of these abstract classes and want to make their events accessible at runtime or design time, you need to redeclare the events as either public or published.

Redeclaring a property without specifying its implementation keeps the same implementation methods, but changes the protection level. You can, therefore, take an event that is defined in *TControl* but not made visible, and surface it by declaring it as public or published.

For example, to create a component that surfaces the *OnClick* event at design time, you would add the following to the component’s class declaration.

```
type
  TMyControl = class(TCustomControl)
  ⋮
  published
    property OnClick;
  end;
```

Changing the standard event handling

If you want to change the way your component responds to a certain kind of event, you might be tempted to write some code and assign it to the event. As an application developer, that is exactly what you would do. But when you are creating a component, you must keep the event available for developers who use the component.

This is the reason for the protected implementation methods associated with each of the standard events. By overriding the implementation method, you can modify the internal event handling; and by calling the inherited method you can maintain the standard handling, including the event for the application developer's code.

The order in which you call the methods is significant. As a rule, call the inherited method first, allowing the application developer's event-handler to execute before your customizations (and in some cases, to keep the customizations from executing). There may be times when you want to execute your code before calling the inherited method, however. For example, if the inherited code is somehow dependent on the status of the component and your code changes that status, you should make the changes and then allow the user's code to respond to them.

Suppose you are writing a component and you want to modify the way it responds to mouse clicks. Instead of assigning a handler to the *OnClick* event as a application developer would, you override the protected method *Click*:

```
procedure click override       { forward declaration }
⋮

procedure TMyControl.Click;
begin
  inherited Click;             { perform standard handling, including calling handler }
...                           { your customizations go here }
end;
```

Defining your own events

Defining entirely new events is relatively unusual. There are times, however, when a component introduces behavior that is entirely different from that of any other component, so you will need to define an event for it.

There are the issues you will need to consider when defining an event:

- Triggering the event
- Defining the handler type
- Declaring the event
- Calling the event

Triggering the event

You need to know what triggers the event. For some events, the answer is obvious. For example, a mouse-down event occurs when the user presses the left button on the mouse and Windows sends a *WM_LBUTTONDOWN* message to the application. Upon receiving that message, a component calls its *MouseDown* method, which in turn calls any code the user has attached to the *OnMouseDown* event.

But some events are less clearly tied to specific external occurrences. For example, a scroll bar has an *OnChange* event, which is triggered by several kinds of occurrence, including keystrokes, mouse clicks, and changes in other controls. When defining your events, you must ensure that all the appropriate occurrences call the proper events.

Two kinds of events

There are two kinds of occurrence you might need to provide events for: user interactions and state changes. User-interaction events are nearly always triggered by a message from Windows, indicating that the user did something your component may need to respond to. State-change events may also be related to messages from Windows (focus changes or enabling, for example), but they can also occur through changes in properties or other code.

You have total control over the triggering of the events you define. Define the events with care so that developers are able to understand and use them.

Defining the handler type

Once you determine when the event occurs, you must define how you want the event handled. This means determining the type of the event handler. In most cases, handlers for events you define yourself are either simple notifications or event-specific types. It is also possible to get information back from the handler.

Simple notifications

A notification event is one that only tells you that the particular event happened, with no specific information about when or where. Notifications use the type *TNotifyEvent*, which carries only one parameter, the sender of the event. All a handler for a notification "knows" about the event is what kind of event it was, and what component the event happened to. For example, click events are notifications. When you write a handler for a click event, all you know is that a click occurred and which component was clicked.

Notification is a one-way process. There is no mechanism to provide feedback or prevent further handling of a notification.

Event-specific handlers

In some cases, it is not enough to know which event happened and what component it happened to. For example, if the event is a key-press event, it is likely that the handler will want to know which key the user pressed. In these cases, you need handler types that include parameters for additional information.

If your event was generated in response to a message, it is likely that the parameters you pass to the event handler come directly from the message parameters.

Returning information from the handler

Because all event handlers are procedures, the only way to pass information back from a handler is through a **var** parameter. Your components can use such information to determine how or whether to process an event after the user's handler executes.

For example, all the key events (*OnKeyDown*, *OnKeyUp*, and *OnKeyPress*) pass by reference the value of the key pressed in a parameter named *Key*. The event handler can change *Key* so that the application sees a different key as being involved in the event. This is a way to force typed characters to uppercase, for example.

Declaring the event

Once you have determined the type of your event handler, you are ready to declare the method pointer and the property for the event. Be sure to give the event a meaningful and descriptive name so that users can understand what the event does. Try to be consistent with names of similar properties in other components.

Event names start with "On"

The names of most events in Delphi begin with "On." This is just a convention; the compiler does not enforce it. The Object Inspector determines that a property is an event by looking at the type of the property: all method-pointer properties are assumed to be events and appear on the Events page.

Developers expect to find events in the alphabetical list of names starting with "On." Using other kinds of names is likely to confuse them.

Note The main exception to this rule is that many events that occur before and after some occurrence begin with "Before" and "After".

Calling the event

You should centralize calls to an event. That is, create a virtual method in your component that calls the application's event handler (if it assigns one) and provides any default handling.

Putting all the event calls in one place ensures that someone deriving a new component from yours can customize event handling by overriding a single method, rather than searching through your code for places where you call the event.

There are two other considerations when calling the event:

- Empty handlers must be valid.
- Users can override default handling.

Empty handlers must be valid

You should never create a situation in which an empty event handler causes an error, nor should the proper functioning of your component depend on a particular response from the application's event-handling code.

An empty handler should produce the same result as no handler at all. So the code for calling an application's event handler should look like this:

```
if Assigned(OnClick) then OnClick(Self);
...  { perform default handling }
```

You should *never* have something like this:

```
if Assigned(OnClick) then OnClick(Self)
else { perform default handling };
```

Users can override default handling

For some kinds of events, developers may want to replace the default handling or even suppress all responses. To allow this, you need to pass an argument by reference to the handler and check for a certain value when the handler returns.

This is in keeping with the rule that an empty handler should have the same effect as no handler at all. Because an empty handler will not change the values of arguments passed by reference, the default handling always takes place after calling the empty handler.

When handling key-press events, for example, application developers can suppress the component's default handling of the keystroke by setting the **var** parameter *Key* to a null character (#0). The logic for supporting this looks like

```
if Assigned(OnKeyPress) then OnKeyPress(Self, Key);
if Key <> #0 then ...  { perform default handling }
```

The actual code is a little different from this because it deals with Windows messages, but the logic is the same. By default, the component calls any user-assigned handler, then performs its standard handling. If the user's handler sets *Key* to a null character, the component skips the default handling.

Chapter

44

Creating methods

Component methods are procedures and functions built into the structure of a class. Although there are essentially no restrictions on what you can do with the methods of a component, Delphi does use some standards you should follow. These guidelines include

- Avoiding dependencies
- Naming methods
- Protecting methods
- Making methods virtual
- Declaring methods

In general, components should not contain many methods and you should minimize the number of methods that an application needs to call. The features you might be inclined to implement as methods are often better encapsulated into properties. Properties provide an interface that suits the Delphi environment and are accessible at design time.

Avoiding dependencies

At all times when writing components, minimize the preconditions imposed on the developer. To the greatest extent possible, developers should be able to do anything they want to a component, whenever they want to do it. There will be times when you cannot accommodate that, but your goal should be to come as close as possible.

This list gives you an idea of the kinds of dependencies to avoid:

- Methods that the user *must* call to use the component
- Methods that must execute in a particular order
- Methods that put the component into a state or mode where certain events or methods could be invalid

The best way to handle these situations is to ensure that you provide ways out of them. For example, if calling a method puts your component into a state where calling another method might be invalid, then write that second method so that if an application calls it when the component is in a bad state, the method corrects the state before executing its main code. At a minimum, you should raise an exception in cases when a user calls a method that is invalid.

In other words, if you create a situation where parts of your code depend on each other, the burden should be on *you* to be sure that using the code in incorrect ways does not cause problems. A warning message, for example, is preferable to a system failure if the user does not accommodate your dependencies.

Naming methods

Delphi imposes no restrictions on what you name methods or their parameters. There are a few conventions that make methods easier for application developers, however. Keep in mind that the nature of a component architecture dictates that many different kinds of people can use your components.

If you are accustomed to writing code that only you or a small group of programmers use, you might not think too much about how you name things. It is a good idea to make your method names clear because people unfamiliar with your code (and even unfamiliar with coding) might have to use your components.

Here are some suggestions for making clear method names:

- Make names descriptive. Use meaningful verbs.

  A name like *PasteFromClipboard* is much more informative than simply *Paste* or *PFC*.

- Function names should reflect the nature of what they return.

  Although it might be obvious to you as a programmer that a function named *X* returns the horizontal position of something, a name like *GetHorizontalPosition* is more universally understandable.

As a final consideration, make sure the method really needs to be a method. A good guideline is that method names have verbs in them. If you find that you create a lot of methods that do not have verbs in their names, consider whether those methods ought to be properties.

Protecting methods

All parts of classes, including fields, methods, and properties, have a level of protection or "visibility," as explained in "Controlling access" on page 41-4. Choosing the appropriate visibility for a method is simple.

Most methods you write in your components are **public** or **protected**. You rarely need to make a method **private**, unless it is truly specific to that type of component, to the point that even derived components should not have access to it.

Methods that should be public

Any method that application developers need to call must be declared as **public**. Keep in mind that most method calls occur in event handlers, so methods should avoid tying up system resources or putting the operating system in a state where it cannot respond to the user.

Note Constructors and destructors should always be **public**.

Methods that should be protected

Any implementation methods for the component should be **protected** so that applications cannot call them at the wrong time. If you have methods that application code should not call, but that are called in derived classes, declare them as **protected**.

For example, suppose you have a method that relies on having certain data set up for it beforehand. If you make that method **public**, there is a chance that applications will call it before setting up the data. On the other hand, by making it **protected**, you ensure that applications cannot call it directly. You can then set up other, **public** methods that ensure that data setup occurs before calling the **protected** method.

Property-implementation methods should be declared as virtual **protected** methods. Methods that are so declared allow the application developers to override the property implementation, either augmenting its functionality or replacing it completely. Such properties are fully polymorphic. Keeping access methods **protected** ensures that developers do not accidentally call them, inadvertently modifying a property.

Abstract methods

Sometimes a method is declared as **abstract** in a Delphi component. In the VCL and CLX, abstract methods usually occur in classes whose names begin with “custom,” such as *TCustomGrid*. Such classes are themselves abstract, in the sense that they are intended only for deriving descendant classes.

While you can create an instance object of a class that contains an abstract member, it is not recommended. Calling the abstract member leads to an *EAbstractError* exception.

The **abstract** directive is used to indicate parts of classes that should be surfaced and defined in descendant components; it forces Component writers to redeclare the abstract member in descendant classes before actual instances of the class can be created.

Making methods virtual

You make methods **virtual** when you want different types to be able to execute different code in response to the same method call.

If you create components intended to be used directly by application developers, you can probably make all your methods nonvirtual. On the other hand, if you create abstract components from which other components will be derived, consider making the added methods **virtual**. This way, derived components can override the inherited **virtual** methods.

Declaring methods

Declaring a method in a component is the same as declaring any class method.

To declare a new method in a component, you do two things:

- Add the declaration to the component's object-type declaration.
- Implement the method in the **implementation** part of the component's unit.

The following code shows a component that defines two new methods, one protected static method and one public virtual method.

```
type
  TSampleComponent = class(TControl)
  protected
    procedure MakeBigger;                               { declare protected static method }

  public
    function CalculateArea: Integer; virtual;             { declare public virtual method }
  end;
⋮
implementation
⋮
procedure TSampleComponent.MakeBigger;                           { implement first method }
begin
  Height := Height + 5;
  Width := Width + 5;
end;

function TSampleComponent.CalculateArea: Integer;               { implement second method }
begin
  Result := Width * Height;
end;
```

Chapter

45

Using graphics in components

Windows provides a powerful Graphics Device Interface (GDI) for drawing device-independent graphics. The GDI, however, imposes extra requirements on the programmer, such as managing graphic resources. Delphi takes care of all the GDI drudgery, allowing you to focus on productive work instead of searching for lost handles or unreleased resources.

As with any part of the Windows API, you can call GDI functions directly from your Delphi application. But you will probably find that using Delphi's encapsulation of the graphic functions is faster and easier.

The topics in this section include

- Overview of graphics
- Using the canvas
- Working with pictures
- Off-screen bitmaps
- Responding to changes

Overview of graphics

Delphi encapsulates the Windows GDI at several levels. The most important to you as a component writer is the way components display their images on the screen. When calling GDI functions directly, you need to have a handle to a device context, into which you have selected various drawing tools such as pens, brushes, and fonts. After rendering your graphic images, you must restore the device context to its original state before disposing of it.

CLX Note GDI functions are Windows-specific and do not apply to CLX or cross-platform applications.

Instead of forcing you to deal with graphics at a detailed level, Delphi provides a simple yet complete interface: your component's *Canvas* property. The canvas ensures that it has a valid device context, and releases the context when you are not using it. Similarly, the canvas has its own properties representing the current pen, brush, and font.

The canvas manages all these resources for you, so you need not concern yourself with creating, selecting, and releasing things like pen handles. You just tell the canvas what kind of pen it should use, and it takes care of the rest.

One of the benefits of letting Delphi manage graphic resources is that it can cache resources for later use, which can speed up repetitive operations. For example, if you have a program that repeatedly creates, uses, and disposes of a particular kind of pen tool, you need to repeat those steps each time you use it. Because Delphi caches graphic resources, chances are good that a tool you use repeatedly is still in the cache, so instead of having to recreate a tool, Delphi uses an existing one.

An example of this is an application that has dozens of forms open, with hundreds of controls. Each of these controls might have one or more *TFont* properties. Though this could result in hundreds or thousands of instances of *TFont* objects, most applications wind up using only two or three font handles thanks to a font cache.

Here are two examples of how simple Delphi's graphics code can be. The first uses standard GDI functions to draw a yellow ellipse outlined in blue on a window, the way you would using other development tools. The second uses a canvas to draw the same ellipse in an application written with Delphi.

```
procedure TMyWindow.Paint(PaintDC: HDC; var PaintInfo: TPaintStruct);
var
  PenHandle, OldPenHandle: HPEN;
  BrushHandle, OldBrushHandle: HBRUSH;
begin
  PenHandle := CreatePen(PS_SOLID, 1, RGB(0, 0, 255));                 { create blue pen }
  OldPenHandle := SelectObject(PaintDC, PenHandle);             { tell DC to use blue pen }
  BrushHandle := CreateSolidBrush(RGB(255, 255, 0));            { create a yellow brush }
  OldBrushHandle := SelectObject(PaintDC, BrushHandle);     { tell DC to use yellow brush }
  Ellipse(HDC, 10, 10, 50, 50);                                       { draw the ellipse }
  SelectObject(OldBrushHandle);                                 { restore original brush }
  DeleteObject(BrushHandle);                                       { delete yellow brush }
  SelectObject(OldPenHandle);                                     { restore original pen }
  DeleteObject(PenHandle);                                            { destroy blue pen }
end;

procedure TForm1.FormPaint(Sender: TObject);
begin
  with Canvas do
  begin
    Pen.Color := clBlue;                                               { make the pen blue }
    Brush.Color := clYellow;                                       { make the brush yellow }
    Ellipse(10, 10, 50, 50);                                            { draw the ellipse }
  end;
end;
```

Using the canvas

The canvas class encapsulates graphics controls at several levels, including high-level functions for drawing individual lines, shapes, and text; intermediate properties for manipulating the drawing capabilities of the canvas; and in the VCL, provides low-level access to the Windows GDI.

Table 45.1 summarizes the capabilities of the canvas.

Table 45.1 Canvas capability summary

Level	Operation	Tools
High	Drawing lines and shapes	Methods such as *MoveTo*, *LineTo*, *Rectangle*, and *Ellipse*
	Displaying and measuring text	*TextOut*, *TextHeight*, *TextWidth*, and *TextRect* methods
	Filling areas	*FillRect* and *FloodFill* methods
Intermediate	Customizing text and graphics	*Pen*, *Brush*, and *Font* properties
	Manipulating pixels	*Pixels* property.
	Copying and merging images	*Draw*, *StretchDraw*, *BrushCopy*, and *CopyRect* methods; *CopyMode* property
Low	Calling Windows GDI functions	*Handle* property

For detailed information on canvas classes and their methods and properties, see online Help.

Working with pictures

Most of the graphics work you do in Delphi is limited to drawing directly on the canvases of components and forms. Delphi also provides for handling stand-alone graphic images, such as bitmaps, metafiles, and icons, including automatic management of palettes.

There are three important aspects to working with pictures in Delphi:

- Using a picture, graphic, or canvas
- Loading and storing graphics
- Handling palettes

Using a picture, graphic, or canvas

There are three kinds of classes in Delphi that deal with graphics:

- A *canvas* represents a bitmapped drawing surface on a form, graphic control, printer, or bitmap. A canvas is always a property of something else, never a stand-alone class.

- A *graphic* represents a graphic image of the sort usually found in a file or resource, such as a bitmap, icon, or metafile. Delphi defines classes *TBitmap*, *TIcon*, and *TMetafile*, all descended from a generic *TGraphic*. You can also define your own graphic classes. By defining a minimal standard interface for all graphics, *TGraphic* provides a simple mechanism for applications to use different kinds of graphics easily.
- A *picture* is a container for a graphic, meaning it could contain any of the graphic classes. That is, an item of type *TPicture* can contain a bitmap, an icon, a metafile, or a user-defined graphic type, and an application can access them all in the same way through the picture class. For example, the image control has a property called *Picture*, of type *TPicture*, enabling the control to display images from many kinds of graphics.

Keep in mind that a picture class always has a graphic, and a graphic might have a canvas. (The only standard graphic that has a canvas is *TBitmap*.) Normally, when dealing with a picture, you work only with the parts of the graphic class exposed through *TPicture*. If you need access to the specifics of the graphic class itself, you can refer to the picture's *Graphic* property.

Loading and storing graphics

All pictures and graphics in Delphi can load their images from files and store them back again (or into different files). You can load or store the image of a picture at any time.

CLX Note You can also load images from and save them to a Qt MIME source, or a stream object if creating CLX components.

To load an image into a picture from a file, call the picture's *LoadFromFile* method. To save an image from a picture into a file, call the picture's *SaveToFile* method.

LoadFromFile and *SaveToFile* each take the name of a file as the only parameter. *LoadFromFile* uses the extension of the file name to determine what kind of graphic object it will create and load. *SaveToFile* saves whatever type of file is appropriate for the type of graphic object being saved.

To load a bitmap into an image control's picture, for example, pass the name of a bitmap file to the picture's *LoadFromFile* method:

```
procedure TForm1.LoadBitmapClick(Sender: TObject);
begin
  Image1.Picture.LoadFromFile('RANDOM.BMP');
end;
```

The picture recognizes .bmp as the standard extension for bitmap files, so it creates its graphic as a *TBitmap*, then calls that graphic's *LoadFromFile* method. Because the graphic is a bitmap, it loads the image from the file as a bitmap.

Handling palettes

For VCL components, when running on a palette-based device (typically, a 256-color video mode), Delphi controls automatically support palette realization. That is, if you have a control that has a palette, you can use two methods inherited from *TControl* to control how Windows accommodates that palette.

Palette support for controls has these two aspects:

- Specifying a palette for a control
- Responding to palette changes

Most controls have no need for a palette, but controls that contain “rich color” graphic images (such as the image control) might need to interact with Windows and the screen device driver to ensure the proper appearance of the control. Windows refers to this process as *realizing* palettes.

Realizing palettes is the process of ensuring that the foremost window uses its full palette, and that windows in the background use as much of their palettes as possible, then map any other colors to the closest available colors in the “real” palette. As windows move in front of one another, Windows continually realizes the palettes.

Note Delphi itself provides no specific support for creating or maintaining palettes, other than in bitmaps. If you have a palette handle, however, Delphi controls can manage it for you.

Specifying a palette for a control

To specify a palette for a VCL control, override the control’s *GetPalette* method to return the handle of the palette.

Specifying the palette for a control does these things for your application:

- It tells the application that your control’s palette needs to be realized.
- It designates the palette to use for realization.

Responding to palette changes

If your VCL control specifies a palette by overriding *GetPalette*, Delphi automatically takes care of responding to palette messages from Windows. The method that handles the palette messages is *PaletteChanged*.

The primary role of *PaletteChanged* is to determine whether to realize the control’s palette in the foreground or the background. Windows handles this realization of palettes by making the topmost window have a foreground palette, with other windows resolved in background palettes. Delphi goes one step further, in that it also realizes palettes for controls within a window in tab order. The only time you might need to override this default behavior is if you want a control that is not first in tab order to have the foreground palette.

Off-screen bitmaps

When drawing complex graphic images, a common technique in graphics programming is to create an off-screen bitmap, draw the image on the bitmap, and then copy the complete image from the bitmap to the final destination onscreen. Using an off-screen image reduces flicker caused by repeated drawing directly to the screen.

The bitmap class in Delphi, which represents bitmapped images in resources and files, can also work as an off-screen image.

There are two main aspects to working with off-screen bitmaps:

- Creating and managing off-screen bitmaps.
- Copying bitmapped images.

Creating and managing off-screen bitmaps

When creating complex graphic images, you should avoid drawing them directly on a canvas that appears onscreen. Instead of drawing on the canvas for a form or control, you can construct a bitmap object, draw on its canvas, and then copy its completed image to the onscreen canvas.

The most common use of an off-screen bitmap is in the *Paint* method of a graphic control. As with any temporary object, the bitmap should be protected with a **try**..**finally** block:

```
type
  TFancyControl = class(TGraphicControl)
  protected
    procedure Paint; override;                              { override the Paint method }
  end;

procedure TFancyControl.Paint;
var
  Bitmap: TBitmap;                         { temporary variable for the off-screen bitmap }
begin
  Bitmap := TBitmap.Create;                                { construct the bitmap object }
  try
    { draw on the bitmap }
    { copy the result into the control's canvas }
  finally
    Bitmap.Free;                                             { destroy the bitmap object }
  end;
end;
```

Copying bitmapped images

Delphi provides four different ways to copy images from one canvas to another. Depending on the effect you want to create, you call different methods.

Table 45.2 summarizes the image-copying methods in canvas objects.

Table 45.2 Image-copying methods

To create this effect	Call this method
Copy an entire graphic.	Draw
Copy and resize a graphic.	StretchDraw
Copy part of a canvas.	CopyRect
Copy a bitmap with raster operations.	BrushCopy (VCL)
Copy a graphic repeatedly to tile an area.	TiledDraw(CLX)

Responding to changes

All graphic objects, including canvases and their owned objects (pens, brushes, and fonts) have events built into them for responding to changes in the object. By using these events, you can make your components (or the applications that use them) respond to changes by redrawing their images.

Responding to changes in graphic objects is particularly important if you publish them as part of the design-time interface of your components. The only way to ensure that the design-time appearance of the component matches the properties set in the Object Inspector is to respond to changes in the objects.

To respond to changes in a graphic object, assign a method to the class's *OnChange* event.

The shape component publishes properties representing the pen and brush it uses to draw its shape. The component's constructor assigns a method to the *OnChange* event of each, causing the component to refresh its image if either the pen or brush changes:

```
type
  TShape = class(TGraphicControl)
  public
    procedure StyleChanged(Sender: TObject);
  end;
⋮
implementation
⋮
constructor TShape.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                    { always call the inherited constructor! }
  Width := 65;
  Height := 65;
  FPen := TPen.Create;                                                { construct the pen }
  FPen.OnChange := StyleChanged;                         { assign method to OnChange event }
  FBrush := TBrush.Create;                                          { construct the brush }
  FBrush.OnChange := StyleChanged;                       { assign method to OnChange event }
end;

procedure TShape.StyleChanged(Sender: TObject);
begin
  Invalidate();                                          { erase and repaint the component }
end;
```

Chapter

46

Handling messages

One of the keys to traditional Windows programming is handling the *messages* sent by Windows to applications. Delphi handles most of the common ones for you. It is possible, however, that you will need to handle messages that Delphi does not already handle or that you will create your own messages. CLX components do not handle Windows messages but you can create message handlers for your own messages.

There are three aspects to working with messages:

- Understanding the message-handling system
- Changing message handling
- Creating new message handlers

Understanding the message-handling system

All Delphi classes have a built-in mechanism for handling messages, called *message-handling methods* or *message handlers*. The basic idea of message handlers is that the class receives messages of some sort and dispatches them, calling one of a set of specified methods depending on the message received. If no specific method exists for a particular message, there is a default handler.

The following diagram shows the message-dispatch system:

The Visual Component Library defines a message-dispatching system that translates all Windows messages (including user-defined messages) directed to a particular class into method calls. (Note that for CLX, the dispatch system does not include MainWndProc and WndProc.) You should never need to alter this message-dispatch mechanism. All you will need to do is create message-handling methods. See the section “Declaring a new message-handling method” on page 46-7 for more on this subject.

What's in a Windows message?

Note This information is applicable when writing VCL components only.

A Windows message is a data record that contains several fields. The most important of these is an integer-size value that identifies the message. Windows defines many messages, and the *Messages* unit declares identifiers for all of them. Other useful information in a message comes in two parameter fields and a result field.

One parameter contains 16 bits, the other 32 bits. You often see Windows code that refers to those values as *wParam* and *lParam*, for "word parameter" and "long parameter." Often, each parameter will contain more than one piece of information, and you see references to names such as *lParamHi*, which refers to the high-order word in the long parameter.

Originally, Windows programmers had to remember or look up in the Windows API what each parameter contained. More recently, Microsoft has named the parameters. This so-called "message cracking" makes it much simpler to understand what information accompanies each message. For example, the parameters to the *WM_KEYDOWN* message are now called *nVirtKey* and *lKeyData*, which gives much more specific information than *wParam* and *lParam*.

For each type of message, Delphi defines a record type that gives a mnemonic name to each parameter. For example, mouse messages pass the x- and y-coordinates of the mouse event in the long parameter, one in the high-order word, and the other in the low-order word. Using the mouse-message structure, you do not have to worry about which word is which, because you refer to the parameters by the names *XPos* and *YPos* instead of *lParamLo* and *lParamHi*.

Dispatching messages

Note This information is applicable when writing VCL components only.

When an application creates a window, it registers a *window procedure* with the Windows kernel. The window procedure is the routine that handles messages for the window. Traditionally, the window procedure contains a huge **case** statement with entries for each message the window has to handle. Keep in mind that "window" in this sense means just about anything on the screen: each window, each control, and so on. Every time you create a new type of window, you have to create a complete window procedure.

Delphi simplifies message dispatching in several ways:

- Each component inherits a complete message-dispatching system.
- The dispatch system has default handling. You define handlers only for messages you need to respond to specially.
- You can modify small parts of the message handling and rely on inherited methods for most processing.

The greatest benefit of this message dispatch system is that you can safely send any message to any component at any time. If the component does not have a handler defined for the message, the default handling takes care of it, usually by ignoring the message.

Tracing the flow of messages

Delphi registers a method called *MainWndProc* as the window procedure for each type of component in an application. *MainWndProc* contains an exception-handling block, passing the message structure from Windows to a virtual method called *WndProc* and handling any exceptions by calling the application class's *HandleException* method.

MainWndProc is a nonvirtual method that contains no special handling for any particular messages. Customizations take place in *WndProc*, since each component type can override the method to suit its particular needs.

WndProc methods check for any special conditions that affect their processing so they can "trap" unwanted messages. For example, while being dragged, components ignore keyboard events, so the *WndProc* method of *TWinControl* passes along keyboard events only if the component is not being dragged. Ultimately, *WndProc* calls *Dispatch*, a nonvirtual method inherited from *TObject*, which determines which method to call to handle the message.

Dispatch uses the *Msg* field of the message structure to determine how to dispatch a particular message. If the component defines a handler for that particular message, *Dispatch* calls the method. If the component does not define a handler for that message, *Dispatch* calls *DefaultHandler*.

Changing message handling

Note This information is applicable when writing VCL components only.

Before changing the message handling of your components, make sure that is what you really want to do. Delphi translates most Windows messages into events that both the component writer and the component user can handle. Rather than changing the message-handling behavior, you should probably change the event-handling behavior.

To change message handling in VCL components, you override the message-handling method. You can also prevent a component from handling a message under certain circumstances by trapping the message.

Overriding the handler method

To change the way a component handles a particular message, you override the message-handling method for that message. If the component does not already handle the particular message, you need to declare a new message-handling method.

To override a message-handling method, you declare a new method in your component with the same message index as the method it overrides. Do *not* use the

override directive; you must use the **message** directive and a matching message index.

Note that the name of the method and the type of the single **var** parameter do not have to match the overridden method. Only the message index is significant. For clarity, however, it is best to follow the convention of naming message-handling methods after the messages they handle.

For example, to override a component's handling of the *WM_PAINT* message, you redeclare the *WMPaint* method:

```
type
  TMyComponent = class(...)
  ⋮
  procedure WMPaint(var Message: TWMPaint); message WM_PAINT;
end;
```

Using message parameters

Once inside a message-handling method, your component has access to all the parameters of the message structure. Because the parameter passed to the message handler is a **var** parameter, the handler can change the values of the parameters if necessary. The only parameter that changes frequently is the *Result* field for the message: the value returned by the *SendMessage* call that sends the message.

Note This information is applicable when writing VCL components only.

Because the type of the *Message* parameter in the message-handling method varies with the message being handled, you should refer to the documentation on Windows messages for the names and meanings of individual parameters. If for some reason you need to refer to the message parameters by their old-style names (*WParam*, *LParam*, and so on), you can typecast *Message* to the generic type *TMessage*, which uses those parameter names.

Trapping messages

Under some circumstances, you might want your components to ignore messages. That is, you want to keep the component from dispatching the message to its handler. To trap a message, you override the virtual method *WndProc*.

For VCL components, the *WndProc* method screens messages before passing them to the *Dispatch* method, which in turn determines which method gets to handle the message. By overriding *WndProc*, your component gets a chance to filter out messages before dispatching them. An override of *WndProc* for a control derived from *TWinControl* looks like this:

```
procedure TMyControl.WndProc(var Message: TMessage);
begin
  { tests to determine whether to continue processing }
  inherited WndProc(Message);
end;
```

The *TControl* component defines entire ranges of mouse messages that it filters when a user is dragging and dropping controls. Overriding *WndProc* helps this in two ways:

- It can filter ranges of messages instead of having to specify handlers for each one.
- It can preclude dispatching the message at all, so the handlers are never called.

For CLX, a control might be descended from *TWidgetControl* and you would override *EventFilter* instead of *WndProc*.

Here is part of the *WndProc* method for *TControl*, for example:

```
procedure TControl.WndProc(var Message: TMessage);
begin
  ⋮
  if (Message.Msg >= WM_MOUSEFIRST) and (Message.Msg <= WM_MOUSELAST) then
    if Dragging then                                      { handle dragging specially }
      DragMouseMsg(TWMMouse(Message))
    else
      ⋮                                                      { handle others normally }
    end;
⋮                                                       { otherwise process normally }
end;
```

Creating new message handlers

Because Delphi provides handlers for most common messages, the time you will most likely need to create new message handlers is when you define your own messages. Working with user-defined messages has two aspects:

- Defining your own messages
- Declaring a new message-handling method

CLX components do not handle Windows messages but you can create message handlers for your own messages. Note that you cannot create message handlers for Qt events because they are objects not message IDs.

Defining your own messages

A number of the standard components define messages for internal use. The most common reasons for defining messages are broadcasting information not covered by standard messages and notification of state changes. You can define your own messages in both VCL and CLX.

Defining a message is a two-step process. The steps are

1. Declaring a message identifier.
2. Declaring a message-record type.

Declaring a message identifier

A message identifier is an integer-sized constant. Windows reserves the messages below 1,024 for its own use, so when you declare your own messages you should start above that level.

The constant *WM_APP* represents the starting number for user-defined messages. When defining message identifiers, you should base them on *WM_APP*.

Be aware that some standard Windows controls use messages in the user-defined range. These include list boxes, combo boxes, edit boxes, and command buttons. If you derive a component from one of these and want to define a new message for it, be sure to check the Messages unit to see which messages Windows already defines for that control.

The following code shows two user-defined messages.

```
const
  WM_MYFIRSTMESSAGE = WM_APP + 400;
  WM_MYSECONDMESSAGE = WM_APP + 401;
```

Declaring a message-record type

If you want to give useful names to the parameters of your message, you need to declare a message-record type for that message. The message-record is the type of the parameter passed to the message-handling method. If you do not use the message's parameters, or if you want to use the old-style parameter notation (*wParam*, *lParam*, and so on), you can use the default message-record, *TMessage*.

To declare a message-record type, follow these conventions:

1 Name the record type after the message, preceded by a *T*.

2 Call the first field in the record *Msg*, of type *TMsgParam*.

3 Define the next two bytes to correspond to the *Word* parameter, and the next two bytes as unused.

   Or

   Define the next four bytes to correspond to the *Longint* parameter.

4 Add a final field called *Result*, of type *Longint*.

For example, here is the message record for all mouse messages, *TWMMouse*, which uses a variant record to define two sets of names for the same parameters.

```
type
  TWMMouse = record
    Msg: TMsgParam;        ( first is the message ID )
    Keys: Word;            ( this is the wParam )
    case Integer of         ( two ways to look at the lParam )
      0: {
         XPos: Integer;    ( either as x- and y-coordinates...)
         YPos: Integer);
      1: {
         Pos: TPoint;      ( ... or as a single point )
         Result: Longint); ( and finally, the result field )
end;
```

Declaring a new message-handling method

There are two sets of circumstances that require you to declare new message-handling methods:

- Your component needs to handle a Windows message that is not already handled by the standard components.
- You have defined your own message for use by your components.

To declare a message-handling method, do the following:

1. Declare the method in a **protected** part of the component's class declaration.
2. Make the method a procedure.
3. Name the method after the message it handles, but without any underline characters.
4. Pass a single **var** parameter called *Message*, of the type of the message record.
5. Within the message method implementation, write code for any handling specific to the component.
6. Call the inherited message handler.

Here is the declaration, for example, of a message handler for a user-defined message called *CM_CHANGECOLOR*.

```
const
  CM_CHANGECOLOR = WM_APP + 400;

type
  TMyComponent = class(TControl)
  ⋮
protected
  procedure CMChangeColor(var Message: TMessage); message CM_CHANGECOLOR;
end;

procedure TMyComponent.CMChangeColor(var Message: TMessage);
begin
  Color := Message.lParam;
  inherited;
end;
```

Chapter

47

Making components available at design time

This chapter describes the steps for making the components you create available in the IDE. Making your components available at design time requires several steps:

- Registering components
- Adding palette bitmaps
- Providing Help for your component
- Adding property editors
- Adding component editors
- Compiling components into packages

Not all these steps apply to every component. For example, if you don't define any new properties or events, you don't need to provide Help for them. The only steps that are always necessary are registration and compilation.

Once your components have been registered and compiled into packages, they can be distributed to other developers and installed in the IDE. For information on installing packages in the IDE, see "Installing component packages" on page 11-5.

Registering components

Registration works on a compilation unit basis, so if you create several components in a single compilation unit, you can register them all at once.

To register a component, add a *Register* procedure to the unit. Within the *Register* procedure, you register the components and determine where to install them on the Component palette.

Note If you create your component by choosing Component | New Component in the IDE, the code required to register your component is added automatically.

The steps for manually registering a component are:

- Declaring the Register procedure
- Writing the Register procedure

Declaring the Register procedure

Registration involves writing a single procedure in the unit, which must have the name *Register*. The *Register* procedure must appear in the interface part of the unit, and (unlike the rest of Object Pascal) its name is case-sensitive.

The following code shows the outline of a simple unit that creates and registers new components:

```
unit MyBtns;
interface
type
  ...                                           { declare your component types here }
procedure Register;                     { this must appear in the interface section }
implementation
  ...                                          { component implementation goes here }
procedure Register;
begin
  ...                                                     { register the components }
end;
end.
```

Within the *Register* procedure, call *RegisterComponents* for each component you want to add to the Component palette. If the unit contains several components, you can register them all in one step.

Writing the Register procedure

Inside the *Register* procedure of a unit containing components, you must register each component you want to add to the Component palette. If the unit contains several components, you can register them at the same time.

To register a component, call the *RegisterComponents* procedure once for each page of the Component palette to which you want to add components. *RegisterComponents* involves three important things:

1. Specifying the components
2. Specifying the palette page
3. Using the RegisterComponents function

Specifying the components

Within the Register procedure, pass the component names in an open array, which you can construct inside the call to RegisterComponents.

```
RegisterComponents('Miscellaneous', [TMyComponent]);
```

You could also register several components on the same page at once, or register components on different pages, as shown in the following code:

```
procedure Register;
begin
  RegisterComponents('Miscellaneous', [TFirst, TSecond]);           { two on this page... }
  RegisterComponents('Assorted', [TThird]);                        { ...one on another... }
  RegisterComponents(LoadStr(srStandard), [TFourth]);    { ...and one on the Standard page }
end;
```

Specifying the palette page

The palette-page name is a string. If the name you give for the palette page does not already exist, Delphi creates a new page with that name. Delphi stores the names of the standard pages in string-list resources so that international versions of the product can name the pages in their native languages. If you want to install a component on one of the standard pages, you should obtain the string for the page name by calling the *LoadStr* function, passing the constant representing the string resource for that page, such as *srSystem* for the System page.

Using the RegisterComponents function

Within the *Register* procedure, call *RegisterComponents* to register the components in the classes array. *RegisterComponents* is a function that takes two parameters: the name of a Component palette page and the array of component classes.

Set the Page parameter to the name of the page on the component palette where the components should appear. If the named page already exists, the components are added to that page. If the named page does not exist, Delphi creates a new palette page with that name.

Call RegisterComponents from the implementation of the Register procedure in one of the units that defines the custom components. The units that define the components must then be compiled into a package and the package must be installed before the custom components are added to the component palette.

```
procedure Register;
begin
  RegisterComponents('System', [TSystem1, TSystem2]);                 {add to system page}
  RegisterComponents('MyCustomPage',[TCustom1, TCustom2]);                     { new page}
end;
```

Adding palette bitmaps

Every component needs a bitmap to represent the component on the Component palette. If you don't specify your own bitmap, Delphi uses a default bitmap.

Because the palette bitmaps are needed only at design time, you don't compile them into the component's compilation unit. Instead, you supply them in a Windows resource file with the same name as the unit, but with the extension .DCR (dynamic component resource). You can create this resource file using the Image editor in Delphi. Each bitmap should be 24 pixels square.

For each component you want to install, supply a palette bitmap file, and within each palette bitmap file, supply a bitmap for each component you register. The bitmap image has the same name as the component. Keep the palette bitmap file in the same directory with the compiled files, so Delphi can find the bitmaps when it installs the components on the Component palette.

For example, if you create a component named *TMyControl* in a unit named ToolBox, you need to create a resource file called TOOLBOX.DCR that contains a bitmap called TMYCONTROL. The resource names are not case-sensitive, but by convention they are usually in uppercase letters.

Providing Help for your component

When you select a standard component on a form, or a property or event in the Object Inspector, you can press *F1* to get Help on that item. You can provide developers with the same kind of documentation for your components if you create the appropriate Help files.

You can provide a small Help file to describe your components, and your help file becomes part of the user's overall Delphi Help system.

See the section "Creating the Help file" on page 47-4 for information on how to compose the help file for use with a component.

Creating the Help file

You can use any tool you want to create the source file for a Windows Help file (in .rtf format). Delphi includes the Microsoft Help Workshop, which compiles your Help files and provides an online help authoring guide. You can find complete information about creating Help files in the online guide for Help Workshop.

Composing help files for components consists of the steps:

- Creating the entries
- Making component help context-sensitive Adding component help files

Creating the entries

To make your component's Help integrate seamlessly with the Help for the rest of the components in the library, observe the following conventions:

1 **Each component should have a help topic.**

   The component topic should show which unit the component is declared in and briefly describe the component. The component topic should link to secondary windows that describe the component's position in the object hierarchy and list all of its properties, events, and methods. Application developers access this topic by selecting the component on a form and pressing *F1*. For an example of a component topic, place any component on a form and press *F1*.

The component topic must have a # footnote with a value unique to the topic. The # footnote uniquely identifies each topic by the Help system.

The component topic should have a K footnote for keyword searching in the help system Index that includes the name of the component class. For example, the keyword footnote for the *TMemo* component is "TMemo."

The component topic should also have a $ footnote that provides the title of the topic. The title appears in the Topics Found dialog box, the Bookmark dialog box, and the History window.

2 **Each component should include the following secondary navigational topics:**

- A hierarchy topic with links to every ancestor of the component in the component hierarchy.
- A list of all properties available in the component, with links to entries describing those properties.
- A list of all events available in the component, with links to entries describing those events.
- A list of methods available in the component, with links to entries describing those methods.

Links to object classes, properties, methods, or events in the Delphi help system can be made using Alinks. When linking to an object class, the Alink uses the class name of the object, followed by an underscore and the string "object". For example, to link to the *TCustomPanel* object, use the following:

```
!AL(TCustomPanel_object,1)
```

When linking to a property, method, or event, precede the name of the property, method, or event by the name of the object that implements it and an underscore. For example, to link to the *Text* property which is implemented by *TControl*, use the following:

```
!AL(TControl_Text,1)
```

To see an example of the secondary navigation topics, display the help for any component and click on the links labeled hierarchy, properties, methods, or events.

3 **Each property, method, and event that is declared within the component should have a topic.**

A property, event, or method topic should show the declaration of the item and describe its use. Application developers see these topics either by highlighting the item in the Object Inspector and pressing *F1* or by placing the cursor in the Code editor on the name of the item and pressing *F1*. To see an example of a property topic, select any item in the Object Inspector and press *F1*.

The property, event, and method topics should include a K footnote that lists the name of the property, method, or event, and its name in combination with the name of the component. Thus, the *Text* property of *TControl* has the following K footnote:

```
Text,TControl;TControl,Text;Text,
```

The property, method, and event topics should also include a $ footnote that indicates the title of the topic, such as TControl.Text.

All of these topics should have a topic ID that is unique to the topic, entered as a # footnote.

Making component help context-sensitive

Each component, property, method, and event topic must have an A footnote. The A footnote is used to display the topic when the user selects a component and presses *F1*, or when a property or event is selected in the Object Inspector and the user presses *F1*. The A footnotes must follow certain naming conventions:

If the Help topic is for a component, the A footnote consists of two entries separated by a semicolon using this syntax:

```
ComponentClass_Object;ComponentClass
```

where *ComponentClass* is the name of the component class.

If the Help topic is for a property or event, the A footnote consists of three entries separated by semicolons using this syntax:

```
ComponentClass_Element;Element_Type;Element
```

where *ComponentClass* is the name of the component class, *Element* is the name of the property, method, or event, and *Type* is the either Property, Method, or Event

For example, for a property named *BackgroundColor* of a component named *TMyGrid*, the A footnote is

```
TMyGrid_BackgroundColor;BackgroundColor_Property;BackgroundColor
```

Adding component help files

To add your Help file to Delphi, use the OpenHelp utility (called oh.exe) located in the bin directory or accessed using Help|Customize in the IDE.

You will find information about using OpenHelp in the OpenHelp.hlp file, including adding your Help file to the Help system.

Adding property editors

The Object Inspector provides default editing for all types of properties. You can, however, provide an alternate editor for specific properties by writing and registering property editors. You can register property editors that apply only to the properties in the components you write, but you can also create editors that apply to all properties of a certain type.

At the simplest level, a property editor can operate in either or both of two ways: displaying and allowing the user to edit the current value as a text string, and displaying a dialog box that permits some other kind of editing. Depending on the property being edited, you might find it useful to provide either or both kinds.

Writing a property editor requires these five steps:

1 Deriving a property-editor class

2 Editing the property as text
3 Editing the property as a whole
4 Specifying editor attributes
5 Registering the property editor

Deriving a property-editor class

Both CLX and the VCL define several kinds of property editors, all of which descend from *TPropertyEditor*. When you create a property editor, your property-editor class can either descend directly from *TPropertyEditor* or indirectly through one of the property-editor classes described in Table 47.1. The classes in the DesignEditors unit can be used for both VCL and CLX applications. Some of the property-editor classes, however, supply specialized dialogs and so are specialized to either VCL or CLX. These can be found in the WinEditors and CLXEditors units, respectively.

Note All that is absolutely necessary for a property editor is that it descend from *TBasePropertyEditor* and that it support the *IProperty* interface. *TPropertyEditor*, however, provides a default implementation of the *IProperty* interface.

The list in Table 47.1 is not complete. The WinEditors and CLXEditors units also define some very specialized property editors used by unique properties such as the component name. The listed property editors are the ones that are the most useful for user-defined properties.

Table 47.1 Predefined property-editor types

Type	Properties edited
TOrdinalProperty	All ordinal-property editors (those for integer, character, and enumerated properties) descend from *TOrdinalProperty*.
TIntegerProperty	All integer types, including predefined and user-defined subranges.
TCharProperty	*Char*-type and subranges of *Char*, such as 'A'..'Z'.
TEnumProperty	Any enumerated type.
TFloatProperty	All floating-point numbers.
TStringProperty	Strings.
TSetElementProperty	Individual elements in sets, shown as Boolean values
TSetProperty	All sets. Sets are not directly editable, but can expand into a list of set-element properties.
TClassProperty	Classes. Displays the name of the class and allows expansion of the class's properties.
TMethodProperty	Method pointers, most notably events.
TComponentProperty	Components in the same form. The user cannot edit the component's properties, but can point to a specific component of a compatible type.
TColorProperty	Component colors. Shows color constants if applicable, otherwise displays hexadecimal value. Drop-down list contains the color constants. Double-click opens the color-selection dialog box.
TFontNameProperty	Font names. The drop-down list displays all currently installed fonts.
TFontProperty	Fonts. Allows expansion of individual font properties as well as access to the font dialog box.

The following example shows the declaration of a simple property editor named *TMyPropertyEditor*:

```
type
  TFloatProperty = class(TPropertyEditor)
  public
    function AllEqual: Boolean; override;
    function GetValue: string; override;
    procedure SetValue(const Value: string); override;
  end;
```

Editing the property as text

All properties need to provide a string representation of their values for the Object Inspector to display. Most properties also allow the user to type in a new value for the property. Property-editor classes provide virtual methods you can override to convert between the text representation and the actual value.

The methods you override are called *GetValue* and *SetValue*. Your property editor also inherits a set of methods used for assigning and reading different sorts of values, as shown in Table 47.2.

Table 47.2 Methods for reading and writing property values

Property type	Get method	Set method
Floating point	GetFloatValue	SetFloatValue
Method pointer (event)	GetMethodValue	SetMethodValue
Ordinal type	GetOrdValue	SetOrdValue
String	GetStrValue	SetStrValue

When you override a *GetValue* method, you will call one of the Get methods, and when you override *SetValue*, you will call one of the Set methods.

Displaying the property value

The property editor's *GetValue* method returns a string that represents the current value of the property. The Object Inspector uses this string in the value column for the property. By default, *GetValue* returns "unknown".

To provide a string representation of your property, override the property editor's *GetValue* method.

If the property is not a string value, *GetValue* must convert the value into a string representation.

Setting the property value

The property editor's *SetValue* method takes a string typed by the user in the Object Inspector, converts it into the appropriate type, and sets the value of the property. If the string does not represent a proper value for the property, *SetValue* should throw an exception and not use the improper value.

To read string values into properties, override the property editor's *SetValue* method.

SetValue should convert the string and validate the value before calling one of the Set methods.

Here are the *GetValue* and *SetValue* methods for *TIntegerProperty*. *Integer* is an ordinal type, so *GetValue* calls *GetOrdValue* and converts the result to a string. *SetValue* converts the string to an integer, performs some range checking, and calls *SetOrdValue*.

```
function TIntegerProperty.GetValue: string;
begin
  with GetTypeData(GetPropType)^ do
    if OrdType = otULong then // unsigned
      Result := IntToStr(Cardinal(GetOrdValue))
    else
      Result := IntToStr(GetOrdValue);
end;

procedure TIntegerProperty.SetValue(const Value: string);
  procedure Error(const Args: array of const);
  begin
    raise EPropertyError.CreateResFmt(@SOutOfRange, Args);
  end;
var
  L: Int64;
begin
  L := StrToInt64(Value);
  with GetTypeData(GetPropType)^ do
    if OrdType = otULong then
    begin   // unsigned compare and reporting needed
      if (L < Cardinal(MinValue)) or (L > Cardinal(MaxValue)) then
      // bump up to Int64 to get past the %d in the format string
        Error([Int64(Cardinal(MinValue)), Int64(Cardinal(MaxValue))]);
    end
    else if (L < MinValue) or (L > MaxValue) then
      Error([MinValue, MaxValue]);
  SetOrdValue(L);
end;
```

The specifics of the particular examples here are less important than the principle: *GetValue* converts the value to a string; *SetValue* converts the string and validates the value before calling one of the "Set" methods.

Editing the property as a whole

You can optionally provide a dialog box in which the user can visually edit a property. The most common use of property editors is for properties that are themselves classes. An example is the *Font* property, for which the user can open a font dialog box to choose all the attributes of the font at once.

To provide a whole-property editor dialog box, override the property-editor class's *Edit* method.

Edit methods use the same Get and Set methods used in writing *GetValue* and *SetValue* methods. In fact, an *Edit* method calls both a Get method and a Set method. Because the editor is type-specific, there is usually no need to convert the property values to strings. The editor generally deals with the value "as retrieved."

When the user clicks the '...' button next to the property or double-clicks the value column, the Object Inspector calls the property editor's *Edit* method.

Within your implementation of the *Edit* method, follow these steps:

1. Construct the editor you are using for the property.
2. Read the current value and assign it to the property using a Get method.
3. When the user selects a new value, assign that value to the property using a Set method.
4. Destroy the editor.

The *Color* properties found in most components use the standard Windows color dialog box as a property editor. Here is the *Edit* method from *TColorProperty*, which invokes the dialog box and uses the result:

```
procedure TColorProperty.Edit;
var
  ColorDialog: TColorDialog;
begin
  ColorDialog := TColorDialog.Create(Application);              { construct the editor }
  try
    ColorDialog.Color := GetOrdValue;                          { use the existing value }
    if ColorDialog.Execute then                          { if the user OKs the dialog... }
      SetOrdValue(ColorDialog.Color);                   { ...use the result to set value }
  finally
    ColorDialog.Free;                                              { destroy the editor }
  end;
end;
```

Specifying editor attributes

The property editor must provide information that the Object Inspector can use to determine what tools to display. For example, the Object Inspector needs to know whether the property has subproperties or can display a list of possible values.

To specify editor attributes, override the property editor's *GetAttributes* method.

GetAttributes is a method that returns a set of values of type *TPropertyAttributes* that can include any or all of the following values:

Table 47.3 Property-editor attribute flags

Flag	Related method	Meaning if included
paValueList	GetValues	The editor can give a list of enumerated values.
paSubProperties	GetProperties	The property has subproperties that can display.
paDialog	Edit	The editor can display a dialog box for editing the entire property.

Table 47.3 Property-editor attribute flags (continued)

Flag	Related method	Meaning if included
paMultiSelect	N/A	The property should display when the user selects more than one component.
paAutoUpdate	SetValue	Updates the component after every change instead of waiting for approval of the value.
paSortList	N/A	The Object Inspector should sort the value list.
paReadOnly	N/A	Users cannot modify the property value.
paRevertable	N/A	Enables the Revert to Inherited menu item on the Object Inspector's context menu. The menu item tells the property editor to discard the current property value and return to some previously established default or standard value.
paFullWidthName	N/A	The value does not need to be displayed. The Object Inspector uses its full width for the property name instead.
paVolatileSubProperties	GetProperties	The Object Inspector refetches the values of all subproperties any time the property value changes.
paReference	GetComponent Value	The value is a reference to something else. When used in conjunction with paSubProperties the referenced object should be displayed as sub properties to this property.

Color properties are more versatile than most, in that they allow several ways for users to choose them in the Object Inspector: typing, selection from a list, and customized editor. *TColorProperty*'s *GetAttributes* method, therefore, includes several attributes in its return value:

```
function TColorProperty.GetAttributes: TPropertyAttributes;
begin
  Result := [paMultiSelect, paDialog, paValueList, paRevertable];
end;
```

Registering the property editor

Once you create a property editor, you need to register it with Delphi. Registering a property editor associates a type of property with a specific property editor. You can register the editor with all properties of a given type or just with a particular property of a particular type of component.

To register a property editor, call the *RegisterPropertyEditor* procedure.

RegisterPropertyEditor takes four parameters:

- A type-information pointer for the type of property to edit.

  This is always a call to the built-in function *TypeInfo*, such as `TypeInfo(TMyComponent)`.

- The type of the component to which this editor applies. If this parameter is **nil**, the editor applies to all properties of the given type.

- The name of the property. This parameter only has meaning if the previous parameter specifies a particular type of component. In that case, you can specify the name of a particular property in that component type to which this editor applies.
- The type of property editor to use for editing the specified property.

Here is an excerpt from the procedure that registers the editors for the standard components on the Component palette:

```
procedure Register;
begin
  RegisterPropertyEditor(TypeInfo(TComponent), nil, '', TComponentProperty);
  RegisterPropertyEditor(TypeInfo(TComponentName), TComponent, 'Name',
    TComponentNameProperty);
  RegisterPropertyEditor(TypeInfo(TMenuItem), TMenu, '', TMenuItemProperty);
end;
```

The three statements in this procedure cover the different uses of *RegisterPropertyEditor*:

- The first statement is the most typical. It registers the property editor *TComponentProperty* for all properties of type *TComponent* (or descendants of *TComponent* that do not have their own editors registered). In general, when you register a property editor, you have created an editor for a particular type, and you want to use it for all properties of that type, so the second and third parameters are **nil** and an empty string, respectively.
- The second statement is the most specific kind of registration. It registers an editor for a specific property in a specific type of component. In this case, the editor is for the *Name* property (of type *TComponentName*) of all components.
- The third statement is more specific than the first, but not as limited as the second. It registers an editor for all properties of type *TMenuItem* in components of type *TMenu*.

Property categories

In the IDE, the Object Inspector lets you selectively hide and display properties based on property categories. The properties of new custom components can be fit into this scheme by registering properties in categories. Do this at the same time you register the component by calling *RegisterPropertyInCategory* or *RegisterPropertiesInCategory*. Use *RegisterPropertyInCategory* to register a single property. Use *RegisterPropertiesInCategory* to register multiple properties in a single function call. These functions are defined in the unit DesignIntf.

Note that it is not mandatory that you register properties or that you register all of the properties of a custom component when some are registered. Any property not explicitly associated with a category is included in the *TMiscellaneousCategory* category. Such properties are displayed or hidden in the Object Inspector based on that default categorization.

In addition to these two functions for registering properties, there is an *IsPropertyInCategory* function. This function is useful for creating localization utilities, in which you must determine whether a property is registered in a given property category.

Registering one property at a time

Register one property at a time and associate it with a property category using the *RegisterPropertyInCategory* function. *RegisterPropertyInCategory* comes in four overloaded variations, each providing a different set of criteria for identifying the property in the custom component to be associated with the property category.

The first variation lets you identify the property by the property's name. The line below registers a property related to visual display of the component, identifying the property by its name, "AutoSize".

```
RegisterPropertyInCategory('Visual', 'AutoSize');
```

The second variation is much like the first, except that it limits the category to only those properties of the given name that appear on components of a given type. The example below registers (into the 'Help and Hints' category) a property named "HelpContext" of a component of the custom class *TMyButton*.

```
RegisterPropertyInCategory('Help and Hints', TMyButton, 'HelpContext');
```

The third variation identifies the property using its type rather than its name. The example below registers a property based on its type, Integer.

```
RegisterPropertyInCategory('Visual', TypeInfo(Integer));
```

The final variation uses both the property's type and its name to identify the property. The example below registers a property based on a combination of its type, *TBitmap*, and its name, "Pattern".

```
RegisterPropertyInCategory('Visual', TypeInfo(TBitmap), 'Pattern');
```

See the section Specifying property categories for a list of the available property categories and a brief description of their uses.

Registering multiple properties at once

Register multiple properties at one time and associate them with a property category using the *RegisterPropertiesInCategory* function. *RegisterPropertiesInCategory* comes in three overloaded variations, each providing a different set of criteria for identifying the property in the custom component to be associated with property categories.

The first variation lets you identify properties based on property name or type. The list is passed as an array of constants. In the example below, any property that either has the name "Text" or belongs to a class of type *TEdit* is registered in the category 'Localizable'.

```
RegisterPropertiesInCategory('Localizable', ['Text', TEdit]);
```

The second variation lets you limit the registered properties to those that belong to a specific component. The list of properties to register include only names, not types. For example, the following code registers a number of properties into the 'Help and Hints' category for all components:

```
RegisterPropertiesInCategory('Help and Hints', TComponent, ['HelpContext', 'Hint',
'ParentShowHint', 'ShowHint']);
```

The third variation lets you limit the registered properties to those that have a specific type. As with the second variation, the list of properties to register can include only names:

```
RegisterPropertiesInCategory('Localizable', TypeInfo(String), ['Text', 'Caption']);
```

See the section Specifying property categories for a list of the available property categories and a brief description of their uses.

Specifying property categories

When you register properties in a category, you can use any string you want as the name of the category. If you use a string that has not been used before, the Object Inspector generates a new property category class with that name. You can also, however, register properties into one of the categories that are built-in. The built-in property categories are described in Table 47.4.:

Table 47.4 Property categories

Category	**Purpose**
Action	Properties related to runtime actions; the *Enabled* and *Hint* properties of *TEdit* are in this category.
Database	Properties related to database operations; the *DatabaseName* and *SQL* properties of *TQuery* are in this category.
Drag, Drop, and Docking	Properties related to drag-n-drop and docking operations; the *DragCursor* and *DragKind* properties of *TImage* are in this category.
Help and Hints	Properties related to using online help or hints; the *HelpContext* and *Hint* properties of *TMemo* are in this category.
Layout	Properties related to the visual display of a control at design-time; the *Top* and *Left* properties of *TDBEdit* are in this category.
Legacy	Properties related to obsolete operations; the *Ctl3D* and *ParentCtl3D* properties of *TComboBox* are in this category.
Linkage	Properties related to associating or linking one component to another; the *DataSet* property of *TDataSource* is in this category.
Locale	Properties related to international locales; the *BiDiMode* and *ParentBiDiMode* properties of *TMainMenu* are in this category.
Localizable	Properties that may require modification in localized versions of an application. Many string properties (such as *Caption*) are in this category, as are properties that determine the size and position of controls.
Visual	Properties related to the visual display of a control at runtime; the *Align* and *Visible* properties of *TScrollBox* are in this category.
Input	Properties related to the input of data (need not be related to database operations); the *Enabled* and *ReadOnly* properties of *TEdit* are in this category.
Miscellaneous	Properties that do not fit a category or do not need to be categorized (and properties not explicitly registered to a specific category); the AllowAllUp and Name properties of TSpeedButton are in this category.

Using the IsPropertyInCategory function

An application can query the existing registered properties to determine whether a given property is already registered in a specified category. This can be especially useful in situations like a localization utility that checks the categorization of properties preparatory to performing its localization operations. Two overloaded variations of the *IsPropertyInCategory* function are available, allowing for different criteria in determining whether a property is in a category.

The first variation lets you base the comparison criteria on a combination of the class type of the owning component and the property's name. In the command line below, for *IsPropertyInCategory* to return *True*, the property must belong to a *TCustomEdit* descendant, have the name "Text", and be in the property category `'Localizable'`.

```
IsItThere := IsPropertyInCategory('Localizable', TCustomEdit, 'Text');
```

The second variation lets you base the comparison criteria on a combination of the class name of the owning component and the property's name. In the command line below, for *IsPropertyInCategory* to return *True*, the property must be a *TCustomEdit* descendant, have the name "Text", and be in the property category `'Localizable'`.

```
IsItThere := IsPropertyInCategory('Localizable', ‘TCustomEdit’, 'Text');
```

Adding component editors

Component editors determine what happens when the component is double-clicked in the designer and add commands to the context menu that appears when the component is right-clicked. They can also copy your component to the Windows clipboard in custom formats.

If you do not give your components a component editor, Delphi uses the default component editor. The default component editor is implemented by the class *TDefaultEditor*. *TDefaultEditor* does not add any new items to a component's context menu. When the component is double-clicked, *TDefaultEditor* searches the properties of the component and generates (or navigates to) the first event handler it finds.

To add items to the context menu, change the behavior when the component is double-clicked, or add new clipboard formats, derive a new class from *TComponentEditor* and register its use with your component. In your overridden methods, you can use the *Component* property of *TComponentEditor* to access the component that is being edited.

Adding a custom component editor consists of the steps:

- Adding items to the context menu
- Changing the double-click behavior
- Adding clipboard formats
- Registering the component editor

Adding items to the context menu

When the user right-clicks the component, the *GetVerbCount* and *GetVerb* methods of the component editor are called to build context menu. You can override these methods to add commands (verbs) to the context menu.

Adding items to the context menu requires the steps:

- Specifying menu items
- Implementing commands

Specifying menu items

Override the *GetVerbCount* method to return the number of commands you are adding to the context menu. Override the *GetVerb* method to return the strings that should be added for each of these commands. When overriding *GetVerb*, add an ampersand (&) to a string to cause the following character to appear underlined in the context menu and act as a shortcut key for selecting the menu item. Be sure to add an ellipsis (...) to the end of a command if it brings up a dialog. *GetVerb* has a single parameter that indicates the index of the command.

The following code overrides the *GetVerbCount* and *GetVerb* methods to add two commands to the context menu.

```
function TMyEditor.GetVerbCount: Integer;
begin
  Result := 2;
end;

function TMyEditor.GetVerb(Index: Integer): String;
begin
  case Index of
    0: Result := '&DoThis ...';
    1: Result := 'Do&That';
  end;
end;
```

Note Be sure that your *GetVerb* method returns a value for every possible index indicated by *GetVerbCount*.

Implementing commands

When the command provided by *GetVerb* is selected in the designer, the *ExecuteVerb* method is called. For every command you provide in the *GetVerb* method, implement an action in the *ExecuteVerb* method. You can access the component that is being edited using the *Component* property of the editor.

For example, the following *ExecuteVerb* method implements the commands for the *GetVerb* method in the previous example.

```
procedure TMyEditor.ExecuteVerb(Index: Integer);
var
  MySpecialDialog: TMyDialog;
begin
  case Index of
```

```
      0: begin
           MyDialog := TMySpecialDialog.Create(Application);       { instantiate the editor }
           if MySpecialDialog.Execute then;                 { if the user OKs the dialog... }
             MyComponent.FThisProperty := MySpecialDialog.ReturnValue;   { ...use the value }
           MySpecialDialog.Free;                                         { destroy the editor }
         end;
      1: That;                                                         { call the That method }
    end;
  end;
```

Changing the double-click behavior

When the component is double-clicked, the *Edit* method of the component editor is called. By default, the *Edit* method executes the first command added to the context menu. Thus, in the previous example, double-clicking the component executes the *DoThis* command.

While executing the first command is usually a good idea, you may want to change this default behavior. For example, you can provide an alternate behavior if

- you are not adding any commands to the context menu.
- you want to display a dialog that combines several commands when the component is double-clicked.

Override the *Edit* method to specify a new behavior when the component is double-clicked. For example, the following *Edit* method brings up a font dialog when the user double-clicks the component:

```
procedure TMyEditor.Edit;
var
  FontDlg: TFontDialog;
begin
  FontDlg := TFontDialog.Create(Application);
  try
    if FontDlg.Execute then
      MyComponent.FFont.Assign(FontDlg.Font);
  finally
    FontDlg.Free
  end;
end;
```

Note If you want a double-click on the component to display the Code editor for an event handler, use *TDefaultEditor* as a base class for your component editor instead of *TComponentEditor*. Then, instead of overriding the *Edit* method, override the protected *TDefaultEditor.EditProperty* method instead. *EditProperty* scans through the event handlers of the component, and brings up the first one it finds. You can change this to look a particular event instead. For example:

```
procedure TMyEditor.EditProperty(PropertyEditor: TPropertyEditor;
  Continue, FreeEditor: Boolean)
begin
  if (PropertyEditor.ClassName = 'TMethodProperty') and
    (PropertyEditor.GetName = 'OnSpecialEvent') then
    // DefaultEditor.EditProperty(PropertyEditor, Continue, FreeEditor);
end;
```

Adding clipboard formats

By default, when a user chooses Copy while a component is selected in the IDE, the component is copied in Delphi's internal format. It can then be pasted into another form or data module. Your component can copy additional formats to the Clipboard by overriding the *Copy* method.

For example, the following *Copy* method allows a *TImage* component to copy its picture to the Clipboard. This picture is ignored by the Delphi IDE, but can be pasted into other applications.

```
procedure TMyComponent.Copy;
var
  MyFormat : Word;
  AData,APalette : THandle;
begin
  TImage(Component).Picture.Bitmap.SaveToClipBoardFormat(MyFormat, AData, APalette);
  ClipBoard.SetAsHandle(MyFormat, AData);
end;
```

Registering the component editor

Once the component editor is defined, it can be registered to work with a particular component class. A registered component editor is created for each component of that class when it is selected in the form designer.

To create the association between a component editor and a component class, call *RegisterComponentEditor*. *RegisterComponentEditor* takes the name of the component class that uses the editor, and the name of the component editor class that you have defined. For example, the following statement registers a component editor class named *TMyEditor* to work with all components of type *TMyComponent*:

```
RegisterComponentEditor(TMyComponent, TMyEditor);
```

Place the call to *RegisterComponentEditor* in the *Register* procedure where you register your component. For example, if a new component named *TMyComponent* and its component editor *TMyEditor* are both implemented in the same unit, the following code registers the component and its association with the component editor.

```
procedure Register;
begin
  RegisterComponents('Miscellaneous', [TMyComponent);
  RegisterComponentEditor(classes[0], TMyEditor);
end;
```

Compiling components into packages

Once your components are registered, you must compile them as packages before they can be installed in the IDE. A package can contain one or several components as well as custom property editors. For more information about packages, see Chapter 11, “Working with packages and components”.

To create and compile a package, see “Creating and editing packages” on page 11-6. Put the source-code units for your custom components in the package’s Contains list. If your components depend on other packages, include those packages in the Requires list.

To install your components in the IDE, see “Installing component packages” on page 11-5.

Chapter

48

Modifying an existing component

The easiest way to create a component is to derive it from a component that does nearly everything you want, then make whatever changes you need. What follows is a simple example that modifies the standard memo component to create a memo that does not wrap words by default.

The value of the memo component's *WordWrap* property is initialized to *True*. If you frequently use non-wrapping memos, you can create a new memo component that does not wrap words by default.

Note To modify published properties or save specific event handlers for an existing component, it is often easier to use a *component template* rather than create a new class.

Modifying an existing component takes only two steps:

- Creating and registering the component
- Modifying the component class

Creating and registering the component

Creation of every component begins the same way: you create a unit, derive a component class, register it, and install it on the Component palette. This process is outlined in "Creating a new component" on page 40-8.

For this example, follow the general procedure for creating a component, with these specifics:

- Call the component's unit *Memos*.
- Derive a new component type called *TWrapMemo*, descended from *TMemo*.
- Register *TWrapMemo* on the Samples page of the Component palette.

The resulting unit should look like this:

```
unit Memos;
interface
uses
  SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls,
  Forms, StdCtrls;
type
  TWrapMemo = class(TMemo)
  end;
procedure Register;
implementation
procedure Register;
begin
  RegisterComponents('Samples', [TWrapMemo]);
end;
end.
```

If you compile and install the new component now, it behaves exactly like its ancestor, *TMemo*. In the next section, you will make a simple change to your component.

Modifying the component class

Once you have created a new component class, you can modify it in almost any way. In this case, you will change only the initial value of one property in the memo component. This involves two small changes to the component class:

- Overriding the constructor.
- Specifying the new default property value.

The constructor actually sets the value of the property. The default tells Delphi what values to store in the form (.dfm for VCL and .xfm for CLX) file. Delphi stores only values that differ from the default, so it is important to perform both steps.

Overriding the constructor

When a component is placed on a form at design time, or when an application constructs a component at runtime, the component's constructor sets the property values. When a component is loaded from a form file, the application sets any properties changed at design time.

Note When you override a constructor, the new constructor must call the inherited constructor before doing anything else. For more information, see "Overriding methods" on page 41-8.

For this example, your new component needs to override the constructor inherited from *TMemo* to set the *WordWrap* property to *False*. To achieve this, add the constructor override to the forward declaration, then write the new constructor in the **implementation** part of the unit:

```
type
  TWrapMemo = class(TMemo)
  public                                             { constructors are always public }
    constructor Create(AOwner: TComponent); override; { this syntax is always the same }
  end;
⋮
constructor TWrapMemo.Create(AOwner: TComponent);     { this goes after implementation }
begin
  inherited Create(AOwner);                          { ALWAYS do this first! }
  WordWrap := False;                                 { set the new desired value }
end;
```

Now you can install the new component on the Component palette and add it to a form. Note that the *WordWrap* property is now initialized to *False*.

If you change an initial property value, you should also designate that value as the default. If you fail to match the value set by the constructor to the specified default value, Delphi cannot store and restore the proper value.

Specifying the new default property value

When Delphi stores a description of a form in a form file, it stores the values only of properties that differ from their defaults. Storing only the differing values keeps the form files small and makes loading the form faster. If you create a property or change the default value, it is a good idea to update the property declaration to include the new default. Form files, loading, and default values are explained in more detail in Chapter 47, “Making components available at design time.”

To change the default value of a property, redeclare the property name, followed by the directive **default** and the new default value. You don’t need to redeclare the entire property, just the name and the default value.

For the word-wrapping memo component, you redeclare the *WordWrap* property in the **published** part of the object declaration, with a default value of *False*:

```
type
  TWrapMemo = class(TMemo)
  ⋮
  published
    property WordWrap default False;
  end;
```

Specifying the default property value does not affect the workings of the component. You must still initialize the value in the component’s constructor. Redeclaring the default ensures that Delphi knows when to write *WordWrap* to the form file.

Chapter 49

Creating a graphic component

A graphic control is a simple kind of component. Because a purely graphic control never receives focus, it does not have or need a window handle. Users can still manipulate the control with the mouse, but there is no keyboard interface.

The graphic component presented in this chapter is *TShape*, the shape component on the Additional page of the Component palette. Although the component created is identical to the standard shape component, you need to call it something different to avoid duplicate identifiers. This chapter calls its shape component *TSampleShape* and shows you all the steps involved in creating the shape component:

- Creating and registering the component
- Publishing inherited properties
- Adding graphic capabilities

Creating and registering the component

Creation of every component begins the same way: create a unit, derive a component class, register it, compile it, and install it on the Component palette. This process is outlined in “Creating a new component” on page 40-8.

For this example, follow the general procedure for creating a component, with these specifics:

- Call the component’s unit *Shapes*.
- Derive a new component type called *TSampleShape*, descended from *TGraphicControl*.
- Register *TSampleShape* on the Samples page of the Component palette.

The resulting unit should look like this:

```
unit Shapes;
interface
uses SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls, Forms;
type
  TSampleShape = class(TGraphicControl)
  end;
procedure Register;
implementation
procedure Register;
begin
  RegisterComponent('Samples', [TSampleShape]);
end;
end.
```

Publishing inherited properties

Once you derive a component type, you can decide which of the properties and events declared in the protected parts of the ancestor class you want to surface in the new component. *TGraphicControl* already publishes all the properties that enable the component to function as a control, so all you need to publish is the ability to respond to mouse events and handle drag-and-drop.

Publishing inherited properties and events is explained in “Publishing inherited properties” on page 42-2 and “Making events visible” on page 43-5. Both processes involve redeclaring just the name of the properties in the published part of the class declaration.

For the shape control, you can publish the three mouse events, the three drag-and-drop events, and the two drag-and-drop properties:

```
type
  TSampleShape = class(TGraphicControl)
  published
    property DragCursor;       { drag-and-drop properties }
    property DragMode;
    property OnDragDrop;       { drag-and-drop events }
    property OnDragOver;
    property OnEndDrag;
    property OnMouseDown;      { mouse events }
    property OnMouseMove;
    property OnMouseUp;
  end;
```

The sample shape control now makes mouse and drag-and-drop interactions available to its users.

Adding graphic capabilities

Once you have declared your graphic component and published any inherited properties you want to make available, you can add the graphic capabilities that distinguish your component. You have two tasks to perform when creating a graphic control:

1 Determining what to draw.
2 Drawing the component image.

In addition, for the shape control example, you will add some properties that enable application developers to customize the appearance of the shape at design time.

Determining what to draw

A graphic control can change its appearance to reflect a dynamic condition, including user input. A graphic control that always looks the same should probably not be a component at all. If you want a static image, you can import the image instead of using a control.

In general, the appearance of a graphic control depends on some combination of its properties. The gauge control, for example, has properties that determine its shape and orientation and whether it shows its progress numerically as well as graphically. Similarly, the shape control has a property that determines what kind of shape it should draw.

To give your control a property that determines the shape it draws, add a property called *Shape*. This requires

1 Declaring the property type.
2 Declaring the property.
3 Writing the implementation method.

Creating properties is explained in more detail in Chapter 42, "Creating properties."

Declaring the property type

When you declare a property of a user-defined type, you must declare the type first, before the class that includes the property. The most common sort of user-defined type for properties is enumerated.

For the shape control, you need an enumerated type with an element for each kind of shape the control can draw.

Add the following type definition above the shape control class's declaration.

```
type
  TSampleShapeType = (sstRectangle, sstSquare, sstRoundRect, sstRoundSquare,
    sstEllipse, sstCircle);
  TSampleShape = class(TGraphicControl) { this is already there }
```

You can now use this type to declare a new property in the class.

Declaring the property

When you declare a property, you usually need to declare a private field to store the data for the property, then specify methods for reading and writing the property value. Often, you don't need to use a method to read the value, but can just point to the stored data instead.

For the shape control, you will declare a field that holds the current shape, then declare a property that reads that field and writes to it through a method call.

Add the following declarations to *TSampleShape*:

```
type
  TSampleShape = class(TGraphicControl)
  private
    FShape: TSampleShapeType;  { field to hold property value }
    procedure SetShape(Value: TSampleShapeType);
  published
    property Shape: TSampleShapeType read FShape write SetShape;
  end;
```

Now all that remains is to add the implementation of *SetShape*.

Writing the implementation method

When the **read** or **write** part of a property definition uses a method instead of directly accessing the stored property data, you need to implement the method.

Add the implementation of the *SetShape* method to the **implementation** part of the unit:

```
procedure TSampleShape.SetShape(Value: TSampleShapeType);
begin
  if FShape <> Value then                         { ignore if this isn't a change }
  begin
    FShape := Value;                              { store the new value }
    Invalidate;                                   { force a repaint with the new shape }
  end;
end;
```

Overriding the constructor and destructor

To change default property values and initialize owned classes for your component, you must override the inherited constructor and destructor. In both cases, remember always to call the inherited method in your new constructor or destructor.

Changing default property values

The default size of a graphic control is fairly small, so you can change the width and height in the constructor. Changing default property values is explained in more detail in Chapter 48, “Modifying an existing component.”

In this example, the shape control sets its size to a square 65 pixels on each side.

Add the overridden constructor to the declaration of the component class:

```
type
  TSampleShape = class(TGraphicControl)
  public                                                  { constructors are always public }
    constructor Create(AOwner: TComponent); override        { remember override directive }
  end;
```

1 Redeclare the *Height* and *Width* properties with their new default values:

```
type
  TSampleShape = class(TGraphicControl)
  ⋮
  published
    property Height default 65;
    property Width default 65;
  end;
```

2 Write the new constructor in the **implementation** part of the unit:

```
constructor TSampleShape.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);  { always call the inherited constructor }
  Width := 65;
  Height := 65;
end;
```

Publishing the pen and brush

By default, a canvas has a thin black pen and a solid white brush. To let developers change the pen and brush, you must provide classes for them to manipulate at design time, then copy the classes into the canvas during painting. Classes such as an auxiliary pen or brush are called *owned classes* because the component owns them and is responsible for creating and destroying them.

Managing owned classes requires

1 Declaring the class fields.

2 Declaring the access properties.

3 Initializing owned classes.

4 Setting owned classes' properties.

Declaring the class fields

Each class a component owns must have a class field declared for it in the component. The class field ensures that the component always has a pointer to the owned object so that it can destroy the class before destroying itself. In general, a component initializes owned objects in its constructor and destroys them in its destructor.

Fields for owned objects are nearly always declared as private. If applications (or other components) need access to the owned objects, you can declare **published** or **public** properties for this purpose.

Add fields for a pen and brush to the shape control:

```
type
  TSampleShape = class(TGraphicControl)
  private           { fields are nearly always private }
    FPen: TPen;      { a field for the pen object }
    FBrush: TBrush;  { a field for the brush object }
    ⋮
  end;
```

Declaring the access properties

You can provide access to the owned objects of a component by declaring properties of the type of the objects. That gives developers a way to access the objects at design time or runtime. Usually, the read part of the property just references the class field, but the write part calls a method that enables the component to react to changes in the owned object.

To the shape control, add properties that provide access to the pen and brush fields. You will also declare methods for reacting to changes to the pen or brush.

```
type
  TSampleShape = class(TGraphicControl)
  ⋮
  private                                        { these methods should be private }
    procedure SetBrush(Value: TBrush);
    procedure SetPen(Value: TPen);
  published                                    { make these available at design time }
    property Brush: TBrush read FBrush write SetBrush;
    property Pen: TPen read FPen write SetPen;
  end;
```

Then, write the *SetBrush* and *SetPen* methods in the implementation part of the unit:

```
procedure TSampleShape.SetBrush(Value: TBrush);
begin
  FBrush.Assign(Value);                       { replace existing brush with parameter }
end;

procedure TSampleShape.SetPen(Value: TPen);
begin
  FPen.Assign(Value);                           { replace existing pen with parameter }
end;
```

To directly assign the contents of *Value* to *FBrush*...

```
  FBrush := Value;
```

...would overwrite the internal pointer for *FBrush*, lose memory, and create a number of ownership problems.

Initializing owned classes

If you add classes to your component, the component’s constructor must initialize them so that the user can interact with the objects at runtime. Similarly, the component’s destructor must also destroy the owned objects before destroying the component itself.

Because you have added a pen and a brush to the shape control, you need to initialize them in the shape control's constructor and destroy them in the control's destructor:

1 Construct the pen and brush in the shape control constructor:

```
constructor TSampleShape.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                     { always call the inherited constructor }
  Width := 65;
  Height := 65;
  FPen := TPen.Create;                                               { construct the pen }
  FBrush := TBrush.Create;                                         { construct the brush }
end;
```

2 Add the overridden destructor to the declaration of the component class:

```
type
  TSampleShape = class(TGraphicControl)
  public                                               { destructors are always public}
    constructor Create(AOwner: TComponent); override;
    destructor Destroy; override;                        { remember override directive }
  end;
```

3 Write the new destructor in the **implementation** part of the unit:

```
destructor TSampleShape.Destroy;
begin
  FPen.Free;                                                  { destroy the pen object }
  FBrush.Free;                                              { destroy the brush object }
  inherited Destroy;                        { always call the inherited destructor, too }
end;
```

Setting owned classes' properties

As the final step in handling the pen and brush classes, you need to make sure that changes in the pen and brush cause the shape control to repaint itself. Both pen and brush classes have *OnChange* events, so you can create a method in the shape control and point both *OnChange* events to it.

Add the following method to the shape control, and update the component's constructor to set the pen and brush events to the new method:

```
type
  TSampleShape = class(TGraphicControl)
  published
    procedure StyleChanged(Sender: TObject);
  end;
⋮
implementation
⋮
constructor TSampleShape.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                     { always call the inherited constructor }
  Width := 65;
  Height := 65;
  FPen := TPen.Create;                                               { construct the pen }
  FPen.OnChange := StyleChanged;                       { assign method to OnChange event }
  FBrush := TBrush.Create;                                        { construct the brush }
  FBrush.OnChange := StyleChanged;                      { assign method to OnChange event }
end;

procedure TSampleShape.StyleChanged(Sender: TObject);
begin
  Invalidate;                                   { erase and repaint the component }
end;
```

With these changes, the component redraws to reflect changes to either the pen or the brush.

Drawing the component image

The essential element of a graphic control is the way it paints its image on the screen. The abstract type *TGraphicControl* defines a method called *Paint* that you override to paint the image you want on your control.

The *Paint* method for the shape control needs to do several things:

- Use the pen and brush selected by the user.
- Use the selected shape.
- Adjust coordinates so that squares and circles use the same width and height.

Overriding the *Paint* method requires two steps:

1 Add *Paint* to the component's declaration.
2 Write the *Paint* method in the **implementation** part of the unit.

For the shape control, add the following declaration to the class declaration:

```
type
  TSampleShape = class(TGraphicControl)
  ⋮
  protected
    procedure Paint; override;
  ⋮
  end;
```

Then write the method in the **implementation** part of the unit:

```
procedure TSampleShape.Paint;
begin
  with Canvas do
  begin
    Pen := FPen;                                              { copy the component's pen }
    Brush := FBrush;                                        { copy the component's brush }
    case FShape of
      sstRectangle, sstSquare:
        Rectangle(0, 0, Width, Height);                 { draw rectangles and squares }
      sstRoundRect, sstRoundSquare:
        RoundRect(0, 0, Width, Height, Width div 4, Height div 4); { draw rounded shapes }
      sstCircle, sstEllipse:
        Ellipse(0, 0, Width, Height);                                 { draw round shapes }
    end;
  end;
end;
```

Paint is called whenever the control needs to update its image. Controls are painted when they first appear or when a window in front of them goes away. In addition, you can force repainting by calling *Invalidate*, as the *StyleChanged* method does.

Refining the shape drawing

The standard shape control does one more thing that your sample shape control does not yet do: it handles squares and circles as well as rectangles and ellipses. To do that, you need to write code that finds the shortest side and centers the image.

Here is a refined *Paint* method that adjusts for squares and ellipses:

```
procedure TSampleShape.Paint;
var
  X, Y, W, H, S: Integer;
begin
  with Canvas do
  begin
    Pen := FPen;                                          { copy the component's pen }
    Brush := FBrush;                                    { copy the component's brush }
    W := Width;                                           { use the component width }
    H := Height;                                         { use the component height }
    if W < H then S := W else S := H;            { save smallest for circles/squares }

    case FShape of                                { adjust height, width and position }
      sstRectangle, sstRoundRect, sstEllipse:
        begin
          X := 0;                                { origin is top-left for these shapes }
          Y := 0;
        end;
      sstSquare, sstRoundSquare, sstCircle:
        begin
          X := (W - S) div 2;                          { center these horizontally... }
          Y := (H - S) div 2;                                       { ...and vertically }
          W := S;                                { use shortest dimension for width... }
          H := S;                                                   { ...and for height }
        end;
    end;

    case FShape of
      sstRectangle, sstSquare:
        Rectangle(X, Y, X + W, Y + H);                   { draw rectangles and squares }
      sstRoundRect, sstRoundSquare:
        RoundRect(X, Y, X + W, Y + H, S div 4, S div 4);          { draw rounded shapes }
      sstCircle, sstEllipse:
        Ellipse(X, Y, X + W, Y + H);                                 { draw round shapes }
    end;
  end;
end;
```

Chapter

50

Customizing a grid

Delphi provides abstract components you can use as the basis for customized components. The most important of these are grids and list boxes. In this chapter, you will see how to create a small one-month calendar from the basic grid component, *TCustomGrid*.

Creating the calendar involves these tasks:

- Creating and registering the component
- Publishing inherited properties
- Changing initial values
- Resizing the cells
- Filling in the cells
- Navigating months and years
- Navigating days

The resulting component is similar to the *TCalendar* component on the Samples page of the Component palette.

Creating and registering the component

Creation of every component begins the same way: create a unit, derive a component class, register it, compile it, and install it on the Component palette. This process is outlined in “Creating a new component” on page 40-8.

For this example, follow the general procedure for creating a component, with these specifics:

- Call the component’s unit *CalSamp*.
- Derive a new component type called *TSampleCalendar*, descended from *TCustomGrid*.
- Register *TSampleCalendar* on the Samples page of the Component palette.

The resulting unit descending from *TCustomGrid* in the VCL should look like this:

```
unit CalSamp;

interface

uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs, Grids;

type
  TSampleCalendar = class(TCustomGrid)
  end;

procedure Register;

implementation

procedure Register;
begin
  RegisterComponents('Samples', [TSampleCalendar]);
end;

end.
```

If descending from the CLX version of *TCustomGrid*, only the **uses** clause would differ showing CLX units instead.

If you install the calendar component now, you will find that it appears on the Samples page. The only properties available are the most basic control properties. The next step is to make some of the more specialized properties available to users of the calendar.

Note While you can install the sample calendar component you have just compiled, do not try to place it on a form yet. The *TCustomGrid* component has an abstract *DrawCell* method that must be redeclared before instance objects can be created. Overriding the *DrawCell* method is described in “Filling in the cells” below.

Publishing inherited properties

The abstract grid component, *TCustomGrid*, provides a large number of **protected** properties. You can choose which of those properties you want to make available to users of the calendar control.

To make inherited protected properties available to users of your components, redeclare the properties in the **published** part of your component’s declaration.

For the calendar control, publish the following properties and events, as shown here:

```
type
  TSampleCalendar = class(TCustomGrid)
  published
    property Align;  { publish properties }
    property BorderStyle;
    property Color;
    property Font;
    property GridLineWidth;
    property ParentColor;
    property ParentFont;
    property OnClick;  { publish events }
    property OnDblClick;
    property OnDragDrop;
    property OnDragOver;
    property OnEndDrag;
    property OnKeyDown;
    property OnKeyPress;
    property OnKeyUp;
  end;
```

There are a number of other properties you could also publish, but which do not apply to a calendar, such as the *Options* property that would enable the user to choose which grid lines to draw.

If you install the modified calendar component to the Component palette and use it in an application, you will find many more properties and events available in the calendar, all fully functional. You can now start adding new capabilities of your own design.

Changing initial values

A calendar is essentially a grid with a fixed number of rows and columns, although not all the rows always contain dates. For this reason, you have not published the grid properties *ColCount* and *RowCount*, because it is highly unlikely that users of the calendar will want to display anything other than seven days per week. You still must set the initial values of those properties so that the week always has seven days, however.

To change the initial values of the component's properties, override the constructor to set the desired values. The constructor must be virtual.

Remember that you need to add the constructor to the **public** part of the component's object declaration, then write the new constructor in the **implementation** part of the component's unit. The first statement in the new constructor should always be a call to the inherited constructor.

```
type
  TSampleCalendar = class(TCustomGrid
  public
    constructor Create(AOwner: TComponent); override;
  ⋮
  end;
⋮
constructor TSampleCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                                { call inherited constructor }
  ColCount := 7;                                             { always seven days/week }
  RowCount := 7;                                { always six weeks plus the headings }
  FixedCols := 0;                                                    { no row labels }
  FixedRows := 1;                                              { one row for day names }
  ScrollBars := ssNone;                                            { no need to scroll }
  Options := Options - [goRangeSelect] + [goDrawFocusSelected];  {disable range selection}
end;
```

The calendar now has seven columns and seven rows, with the top row fixed, or nonscrolling.

Resizing the cells

VCL When a user or application changes the size of a window or control, Windows sends a message called *WM_SIZE* to the affected window or control so it can adjust any settings needed to later paint its image in the new size. Your VCL component can respond to that message by altering the size of the cells so they all fit inside the boundaries of the control. To respond to the *WM_SIZE* message, you will add a message-handling method to the component.

Creating a message-handling method is described in detail in "Creating new message handlers" on page 46-5.

In this case, the calendar control needs a response to *WM_SIZE*, so add a protected method called *WMSize* to the control indexed to the *WM_SIZE* message, then write the method so that it calculates the proper cell size to allow all cells to be visible in the new size:

```
type
  TSampleCalendar = class(TCustomGrid)
  protected
    procedure WMSize(var Message: TWMSize); message WM_SIZE;
  ⋮
  end;
⋮
procedure TSampleCalendar.WMSize(var Message: TWMSize);
var
  GridLines: Integer;                                        { temporary local variable }
begin
  GridLines := 6 * GridLineWidth;                 { calculate combined size of all lines }
  DefaultColWidth := (Message.Width - GridLines) div 7;     { set new default cell width }
  DefaultRowHeight := (Message.Height - GridLines) div 7;             { and cell height }
end;
```

Now when the calendar is resized, it displays all the cells in the largest size that will fit in the control.

CLX In CLX, changes to the size of a window or control are automatically notified by a call to the protected *BoundsChanged* method. Your CLX component can respond to this notification by altering the size of the cells so they all fit inside the boundaries of the control.

In this case, the calendar control needs to override *BoundsChanged* so that it calculates the proper cell size to allow all cells to be visible in the new size:

```
type
  TSampleCalendar = class(TCustomGrid)
  protected
    procedure BoundsChanged; override;
  ⋮
  end;
```

```
⋮
procedure TSampleCalendar.BoundsChanged;
var
  GridLines: Integer;                                    { temporary local variable }
begin
  GridLines := 6 * GridLineWidth;                  { calculate combined size of all lines }
  DefaultColWidth := (Width - GridLines) div 7;     { set new default cell width }
  DefaultRowHeight := (Height - GridLines) div 7;            { and cell height }
  inherited; {now call the inherited method }
end;
```

Filling in the cells

A grid control fills in its contents cell-by-cell. In the case of the calendar, that means calculating which date, if any, belongs in each cell. The default drawing for grid cells takes place in a virtual method called *DrawCell*.

To fill in the contents of grid cells, override the *DrawCell* method.

The easiest part to fill in is the heading cells in the fixed row. The runtime library contains an array with short day names, so for the calendar, use the appropriate one for each column:

```
type
  TSampleCalendar = class(TCustomGrid)
  protected
    procedure DrawCell(ACol, ARow: Longint; ARect: TRect; AState: TGridDrawState);
      override;
  end;
⋮
procedure TSampleCalendar.DrawCell(ACol, ARow: Longint; ARect: TRect;
  AState: TGridDrawState);
begin
  if ARow = 0 then
    Canvas.TextOut(ARect.Left, ARect.Top, ShortDayNames[ACol + 1]);    { use RTL strings }
end;
```

Tracking the date

For the calendar control to be useful, users and applications must have a mechanism for setting the day, month, and year. Delphi stores dates and times in variables of type *TDateTime*. *TDateTime* is an encoded numeric representation of the date and time, which is useful for programmatic manipulation, but not convenient for human use.

You can therefore store the date in encoded form, providing runtime access to that value, but also provide *Day*, *Month*, and *Year* properties that users of the calendar component can set at design time.

Tracking the date in the calendar consists of the processes:

- Storing the internal date

- Accessing the day, month, and year
- Generating the day numbers
- Selecting the current day

Storing the internal date

To store the date for the calendar, you need a private field to hold the date and a runtime-only property that provides access to that date.

Adding the internal date to the calendar requires three steps:

1 Declare a private field to hold the date:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    FDate: TDateTime;
  ⋮
```

2 Initialize the date field in the constructor:

```
constructor TSampleCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);         { this is already here }
  ⋮                                 { other initializations here }
  FDate := Date;                    { get current date from RTL }
end;
```

3 Declare a runtime property to allow access to the encoded date.

You'll need a method for setting the date, because setting the date requires updating the onscreen image of the control:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    procedure SetCalendarDate(Value: TDateTime);
  public
    property CalendarDate: TDateTime read FDate write SetCalendarDate;
  ⋮
procedure TSampleCalendar.SetCalendarDate(Value: TDateTime);
begin
  FDate := Value;                 { set new date value }
  Refresh;                        { update the onscreen image }
end;
```

Accessing the day, month, and year

An encoded numeric date is fine for applications, but humans prefer to work with days, months, and years. You can provide alternate access to those elements of the stored, encoded date by creating properties.

Because each element of the date (day, month, and year) is an integer, and because setting each requires encoding the date when set, you can avoid duplicating the code each time by sharing the implementation methods for all three properties. That is, you can write two methods, one to read an element and one to write one, and use those methods to get and set all three properties.

To provide design-time access to the day, month, and year, you do the following:

1 Declare the three properties, assigning each a unique **index** number:

```
type
  TSampleCalendar = class(TCustomGrid)
  public
    property Day: Integer index 3 read GetDateElement write SetDateElement;
    property Month: Integer index 2 read GetDateElement write SetDateElement;
    property Year: Integer index 1 read GetDateElement write SetDateElement;
  ⋮
```

2 Declare and write the implementation methods, setting different elements for each index value:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    function GetDateElement(Index: Integer): Integer;        { note the Index parameter }
    procedure SetDateElement(Index: Integer; Value: Integer);
  ⋮
function TSampleCalendar.GetDateElement(Index: Integer): Integer;
var
  AYear, AMonth, ADay: Word;
begin
  DecodeDate(FDate, AYear, AMonth, ADay);             { break encoded date into elements }
  case Index of
    1: Result := AYear;
    2: Result := AMonth;
    3: Result := ADay;
    else Result := -1;
  end;
end;

procedure TSampleCalendar.SetDateElement(Index: Integer; Value: Integer);
var
  AYear, AMonth, ADay: Word;
begin
  if Value > 0 then                                     { all elements must be positive }
  begin
    DecodeDate(FDate, AYear, AMonth, ADay);                 { get current date elements }
    case Index of                                     { set new element depending on Index }
      1: AYear := Value;
      2: AMonth := Value;
      3: ADay := Value;
      else Exit;
    end;
    FDate := EncodeDate(AYear, AMonth, ADay);                 { encode the modified date }
    Refresh;                                                { update the visible calendar }
  end;
end;
```

Now you can set the calendar's day, month, and year at design time using the Object Inspector or at runtime using code. Of course, you have not yet added the code to paint the dates into the cells, but now you have the needed data.

Generating the day numbers

Putting numbers into the calendar involves several considerations. The number of days in the month depends on which month it is, and whether the given year is a leap year. In addition, months start on different days of the week, dependent on the month and year. Use the *IsLeapYear* function to determine whether the year is a leap year. Use the *MonthDays* array in the SysUtils unit to get the number of days in the month.

Once you have the information on leap years and days per month, you can calculate where in the grid the individual dates go. The calculation is based on the day of the week the month starts on.

Because you will need the month-offset number for each cell you fill in, the best practice is to calculate it once when you change the month or year, then refer to it each time. You can store the value in a class field, then update that field each time the date changes.

To fill in the days in the proper cells, you do the following:

1 Add a month-offset field to the object and a method that updates the field value:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    FMonthOffset: Integer;                                     { storage for the offset }
  ⋮
  protected
    procedure UpdateCalendar; virtual;                      { property for offset access }
  end;
⋮
procedure TSampleCalendar.UpdateCalendar;
var
  AYear, AMonth, ADay: Word;
  FirstDate: TDateTime;                                { date of the first day of the month }
begin
  if FDate <> 0 then                                 { only calculate offset if date is valid }
  begin
    DecodeDate(FDate, AYear, AMonth, ADay);                          { get elements of date }
    FirstDate := EncodeDate(AYear, AMonth, 1);                          { date of the first }
    FMonthOffset := 2 - DayOfWeek(FirstDate);           { generate the offset into the grid }
  end;
  Refresh;                                                        { always repaint the control }
end;
```

2 Add statements to the constructor and the *SetCalendarDate* and *SetDateElement* methods that call the new update method whenever the date changes:

```
constructor TSampleCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                                         { this is already here }
  ⋮                                                          { other initializations here }
  UpdateCalendar;                                                      { set proper offset }
end;

procedure TSampleCalendar.SetCalendarDate(Value: TDateTime);
```

```
begin
  FDate := Value;                                              { this was already here }
  UpdateCalendar;                                        { this previously called Refresh }
end;

procedure TSampleCalendar.SetDateElement(Index: Integer; Value: Integer);
begin
  ⋮
    FDate := EncodeDate(AYear, AMonth, ADay);                 { encode the modified date }
    UpdateCalendar;                                      { this previously called Refresh }
  end;
end;
```

3 Add a method to the calendar that returns the day number when passed the row and column coordinates of a cell:

```
function TSampleCalendar.DayNum(ACol, ARow: Integer): Integer;
begin
  Result := FMonthOffset + ACol + (ARow - 1) * 7;          { calculate day for this cell }
  if (Result < 1) or (Result > MonthDays[IsLeapYear(Year), Month]) then
    Result := -1;                                              { return -1 if invalid }
end;
```

Remember to add the declaration of *DayNum* to the component's type declaration.

4 Now that you can calculate where the dates go, you can update *DrawCell* to fill in the dates:

```
procedure TCalendar.DrawCell(ACol, ARow: Longint; ARect: TRect; AState: TGridDrawState);
var
  TheText: string;
  TempDay: Integer;
begin
  if ARow = 0 then                                        { if this is the header row ...}
    TheText := ShortDayNames[ACol + 1]                          { just use the day name }
  else begin
    TheText := '';                                          { blank cell is the default }
    TempDay := DayNum(ACol, ARow);                          { get number for this cell }
    if TempDay <> -1 then TheText := IntToStr(TempDay);       { use the number if valid }
  end;
  with ARect, Canvas do
    TextRect(ARect, Left + (Right - Left - TextWidth(TheText)) div 2,
      Top + (Bottom - Top - TextHeight(TheText)) div 2, TheText);
end;
```

Now if you reinstall the calendar component and place one on a form, you will see the proper information for the current month.

Selecting the current day

Now that you have numbers in the calendar cells, it makes sense to move the selection highlighting to the cell containing the current day. By default, the selection starts on the top left cell, so you need to set the *Row* and *Column* properties both when constructing the calendar initially and when the date changes.

To set the selection on the current day, change the *UpdateCalendar* method to set *Row* and *Column* before calling *Refresh*:

```
procedure TSampleCalendar.UpdateCalendar;
begin
  if FDate <> 0 then
  begin
    ⋮ { existing statements to set FMonthOffset }
    Row := (ADay - FMonthOffset) div 7 + 1;
    Col := (ADay - FMonthOffset) mod 7;
  end;
  Refresh; { this is already here }
end;
```

Note that you are now reusing the *ADay* variable previously set by decoding the date.

Navigating months and years

Properties are useful for manipulating components, especially at design time. But sometimes there are types of manipulations that are so common or natural, often involving more than one property, that it makes sense to provide methods to handle them. One example of such a natural manipulation is a “next month” feature for a calendar. Handling the wrapping around of months and incrementing of years is simple, but very convenient for the developer using the component.

The only drawback to encapsulating common manipulations into methods is that methods are only available at runtime. However, such manipulations are generally only cumbersome when performed repeatedly, and that is fairly rare at design time.

For the calendar, add the following four methods for next and previous month and year. Each of these methods uses the *IncMonth* function in a slightly different manner to increment or decrement *CalendarDate*, by increments of a month or a year. After incrementing or decrementing *CalendarDate*, decode the date value to fill the Year, Month, and Day properties with corresponding new values.

```
procedure TCalendar.NextMonth;
begin
  DecodeDate(IncMonth(CalendarDate, 1), Year, Month, Day);
end;

procedure TCalendar.PrevMonth;
begin
  DecodeDate(IncMonth(CalendarDate, -1), Year, Month, Day);
end;

procedure TCalendar.NextYear;
begin
  DecodeDate(IncMonth(CalendarDate, 12), Year, Month, Day);
end;

procedure TCalendar.PrevYear;
begin
  DecodeDate(IncMonth(CalendarDate, -12), Year, Month, Day);
end;
```

Be sure to add the declarations of the new methods to the class declaration.

Now when you create an application that uses the calendar component, you can easily implement browsing through months or years.

Navigating days

Within a given month, there are two obvious ways to navigate among the days. The first is to use the arrow keys, and the other is to respond to clicks of the mouse. The standard grid component handles both as if they were clicks. That is, an arrow movement is treated like a click on an adjacent cell.

The process of navigating days consists of

- Moving the selection
- Providing an OnChange event
- Excluding blank cells

Moving the selection

The inherited behavior of a grid handles moving the selection in response to either arrow keys or clicks, but if you want to change the selected day, you need to modify that default behavior.

To handle movements within the calendar, override the *Click* method of the grid.

When you override a method such as *Click* that is tied in with user interactions, you will nearly always include a call to the inherited method, so as not to lose the standard behavior.

The following is an overridden *Click* method for the calendar grid. Be sure to add the declaration of *Click* to *TSampleCalendar*, including the **override** directive afterward.

```
procedure TSampleCalendar.Click;
var
  TempDay: Integer;
begin
  inherited Click;                             { remember to call the inherited method! }
  TempDay := DayNum(Col, Row);                { get the day number for the clicked cell }
  if TempDay <> -1 then Day := TempDay;                            { change day if valid }
end;
```

Providing an OnChange event

Now that users of the calendar can change the date within the calendar, it makes sense to allow applications to respond to those changes.

Add an *OnChange* event to *TSampleCalendar*.

1 Declare the event, a field to store the event, and a dynamic method to call the event:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    FOnChange: TNotifyEvent;
  protected
    procedure Change; dynamic;
  ⋮
  published
    property OnChange: TNotifyEvent read FOnChange write FOnChange;
  ⋮
```

2 Write the *Change* method:

```
procedure TSampleCalendar.Change;
begin
  if Assigned(FOnChange) then FOnChange(Self);
end;
```

3 Add statements calling *Change* to the end of the *SetCalendarDate* and *SetDateElement* methods:

```
procedure TSampleCalendar.SetCalendarDate(Value: TDateTime);
begin
  FDate := Value;
  UpdateCalendar;
  Change;                                               { this is the only new statement }
end;

procedure TSampleCalendar.SetDateElement(Index: Integer; Value: Integer);
begin
    ⋮                                           { many statements setting element values }
    FDate := EncodeDate(AYear, AMonth, ADay);
    UpdateCalendar;
    Change;                                                                  { this is new }
  end;
end;
```

Applications using the calendar component can now respond to changes in the date of the component by attaching handlers to the *OnChange* event.

Excluding blank cells

As the calendar is written, the user can select a blank cell, but the date does not change. It makes sense, then, to disallow selection of the blank cells.

To control whether a given cell is selectable, override the *SelectCell* method of the grid.

SelectCell is a function that takes a column and row as parameters, and returns a Boolean value indicating whether the specified cell is selectable.

You can override *SelectCell* to return *False* if the cell does not contain a valid date:

```
function TSampleCalendar.SelectCell(ACol, ARow: Longint): Boolean;
begin
  if DayNum(ACol, ARow) = -1 then Result := False           { -1 indicates invalid date }
  else Result := inherited SelectCell(ACol, ARow);      { otherwise, use inherited value }
end;
```

Now if the user clicks a blank cell or tries to move to one with an arrow key, the calendar leaves the current cell selected.

Chapter

51

Making a control data aware

When working with database connections, it is often convenient to have controls that are *data aware*. That is, the application can establish a link between the control and some part of a database. Delphi includes data-aware labels, edit boxes, list boxes, combo boxes, lookup controls, and grids. You can also make your own controls data aware. For more information about using data-aware controls, see Chapter 15, “Using data controls”.

There are several degrees of data awareness. The simplest is read-only data awareness, or *data browsing*, the ability to reflect the current state of a database. More complicated is editable data awareness, or *data editing*, where the user can edit the values in the database by manipulating the control. Note also that the degree of involvement with the database can vary, from the simplest case, a link with a single field, to more complex cases, such as multiple-record controls.

This chapter first illustrates the simplest case, making a read-only control that links to a single field in a dataset. The specific control used will be the *TSampleCalendar* calendar created in Chapter 50, “Customizing a grid”. You can also use the standard calendar control on the Samples page of the Component palette, *TCalendar*.

The chapter then continues with an explanation of how to make the new data-browsing control a data-editing control.

Creating a data-browsing control

Creating a data-aware calendar control, whether it is a read-only control or one in which the user can change the underlying data in the dataset, involves the following steps:

- Creating and registering the component
- Adding the data link
- Responding to data changes

Creating and registering the component

Creation of every component begins the same way: create a unit, derive a component class, register it, compile it, and install it on the Component palette. This process is outlined in “Creating a new component” on page 40-8.

For this example, follow the general procedure for creating a component, with these specifics:

- Call the component’s unit *DBCal*.
- Derive a new component class called *TDBCalendar*, descended from the VCL component *TSampleCalendar*. Chapter 50, “Customizing a grid,” shows you how to create the *TSampleCalendar* component.
- Register *TDBCalendar* on the Samples page of the Component palette.

The resulting unit should look like this:

```
unit DBCal;

interface

uses SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls,
  Forms, Grids, Calendar;

type
  TDBCalendar = class(TSampleCalendar)
  end;

procedure Register;

implementation

procedure Register;
begin
  RegisterComponents('Samples', [TDBCalendar]);
end;

end.
```

You can now proceed with making the new calendar a data browser.

Making the control read-only

Because this data calendar will be read-only with respect to the data, it makes sense to make the control itself read-only, so users will not make changes within the control and expect them to be reflected in the database.

Making the calendar read-only involves,

- Adding the ReadOnly property.
- Allowing needed updates.

Note that if you started with the *TCalendar* component from Delphi’s Samples page instead of *TSampleCalendar*, it already has a *ReadOnly* property, so you can skip these steps.

Adding the ReadOnly property

By adding a *ReadOnly* property, you will provide a way to make the control read-only at design time. When that property is set to *True*, you can make all cells in the control unselectable.

1 Add the property declaration and a **private** field to hold the value:

```
type
  TDBCalendar = class(TSampleCalendar)
  private
    FReadOnly: Boolean;                                   { field for internal storage }
  public
    constructor Create(AOwner: TComponent); override;    { must override to set default }
  published
    property ReadOnly: Boolean read FReadOnly write FReadOnly default True;
  end;
⋮
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                       { always call the inherited constructor! }
  FReadOnly := True;                                                { set the default value }
end;
```

2 Override the *SelectCell* method to disallow selection if the control is read-only. Use of *SelectCell* is explained in “Excluding blank cells” on page 50-12.

```
function TDBCalendar.SelectCell(ACol, ARow: Longint): Boolean;
begin
  if FReadOnly then Result := False                       { cannot select if read only }
  else Result := inherited SelectCell(ACol, ARow);     { otherwise, use inherited method }
end;
```

Remember to add the declaration of *SelectCell* to the type declaration of *TDBCalendar*, and append the **override** directive.

If you now add the calendar to a form, you will find that the component ignores clicks and keystrokes. It also fails to update the selection position when you change the date.

Allowing needed updates

The read-only calendar uses the *SelectCell* method for all kinds of changes, including setting the *Row* and *Col* properties. The *UpdateCalendar* method sets *Row* and *Col* every time the date changes, but because *SelectCell* disallows changes, the selection remains in place, even though the date changes.

To get around this absolute prohibition on changes, you can add an internal Boolean flag to the calendar, and permit changes when that flag is set to *True*:

```
type
  TDBCalendar = class(TSampleCalendar)
  private
    FUpdating: Boolean;                                  { private flag for internal use }
  protected
    function SelectCell(ACol, ARow: Longint): Boolean; override;
  public
```

```
    procedure UpdateCalendar; override;              { remember the override directive }
  end;
  ⋮
function TDBCalendar.SelectCell(ACol, ARow: Longint): Boolean;
begin
  if (not FUpdating) and FReadOnly then Result := False      { allow select if updating }
  else Result := inherited SelectCell(ACol, ARow);     { otherwise, use inherited method }
end;

procedure TDBCalendar.UpdateCalendar;
begin
  FUpdating := True;                                         { set flag to allow updates }
  try
    inherited UpdateCalendar;                                          { update as usual }
  finally
    FUpdating := False;                                            { always clear the flag }
  end;
end;
```

The calendar still disallows user changes, but now correctly reflects changes made in the date by changing the date properties. Now that you have a true read-only calendar control, you are ready to add the data-browsing ability.

Adding the data link

The connection between a control and a database is handled by a class called a *data link*. The datalink class that connects a control with a single field in a database is *TFieldDataLink* (VCL or CLX). There are also data links for entire tables.

A data-aware control *owns* its datalink class. That is, the control has the responsibility for constructing and destroying the data link. For details on management of owned classes, see Chapter 49, “Creating a graphic component”.

Establishing a data link as an owned class requires these three steps:

1 Declaring the class field

2 Declaring the access properties

3 Initializing the data link

Declaring the class field

A component needs a field for each of its owned classes, as explained in “Declaring the class fields” on page 49-5. In this case, the calendar needs a field of type *TFieldDataLink* for its data link.

Declare a field for the data link in the calendar:

```
type
  TDBCalendar = class(TSampleCalendar)
  private
    FDataLink: TFieldDataLink;
  ⋮
  end;
```

Before you can compile the application, you need to add DB and DBCtrls to the unit's **uses** clause.

Declaring the access properties

Every data-aware control has a *DataSource* property that specifies which data-source class in the application provides the data to the control. In addition, a control that accesses a single field needs a *DataField* property to specify that field in the data source.

Unlike the access properties for the owned classes in the example in Chapter 49, "Creating a graphic component", these access properties do not provide access to the owned classes themselves, but rather to corresponding properties in the owned class. That is, you will create properties that enable the control and its data link to share the same data source and field.

Declare the *DataSource* and *DataField* properties and their implementation methods, then write the methods as "pass-through" methods to the corresponding properties of the datalink class:

An example of declaring access properties

```
type
  TDBCalendar = class(TSampleCalendar)
  private                                          { implementation methods are private }
    ...
    function GetDataField: string;                 { returns the name of the data field }
    function GetDataSource: TDataSource;         { returns reference to the data source }
    procedure SetDataField(const Value: string);           { assigns name of data field }
    procedure SetDataSource(Value: TDataSource);             { assigns new data source }
  published                                 { make properties available at design time }
    property DataField: string read GetDataField write SetDataField;
    property DataSource: TDataSource read GetDataSource write SetDataSource;
  end;
⋮
function TDBCalendar.GetDataField: string;
begin
  Result := FDataLink.FieldName;
end;

function TDBCalendar.GetDataSource: TDataSource;
begin
  Result := FDataLink.DataSource;
end;

procedure TDBCalendar.SetDataField(const Value: string);
begin
  FDataLink.FieldName := Value;
end;

procedure TDBCalendar.SetDataSource(Value: TDataSource);
begin
  FDataLink.DataSource := Value;
end;
```

Now that you have established the links between the calendar and its data link, there is one more important step. You must construct the data link class when the calendar control is constructed, and destroy the data link before destroying the calendar.

Initializing the data link

A data-aware control needs access to its data link throughout its existence, so it must construct the datalink object as part of its own constructor, and destroy the datalink object before it is itself destroyed.

Override the *Create* and *Destroy* methods of the calendar to construct and destroy the datalink object, respectively:

```
type
  TDBCalendar = class(TSampleCalendar)
  public                                 { constructors and destructors are always public }
    constructor Create(AOwner: TComponent); override;
    destructor Destroy; override;
    ⋮
  end;
⋮
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                 { always call the inherited constructor first
}
  FDataLink := TFieldDataLink.Create;                    { construct the datalink object }
  FDataLink.Control := self;               {let the datalink know about the calendar }
  FReadOnly := True;                                               { this is already here }
end;

destructor TDBCalendar.Destroy;
begin
  FDataLink.Free;                                 { always destroy owned objects first... }
  inherited Destroy;                                  { ...then call inherited destructor
}
end;
```

Now you have a complete data link, but you have not yet told the control what data it should read from the linked field. The next section explains how to do that.

Responding to data changes

Once a control has a data link and properties to specify the data source and data field, it needs to respond to changes in the data in that field, either because of a move to a different record or because of a change made to that field.

Datalink classes all have events named *OnDataChange*. When the data source indicates a change in its data, the datalink object calls any event handler attached to its *OnDataChange* event.

To update a control in response to data changes, attach a handler to the data link’s *OnDataChange* event.

In this case, you will add a method to the calendar, then designate it as the handler for the data link's *OnDataChange*.

Declare and implement the *DataChange* method, then assign it to the data link's *OnDataChange* event in the constructor. In the destructor, detach the *OnDataChange* handler before destroying the object.

```
type
  TDBCalendar = class(TSampleCalendar)
  private { this is an internal detail, so make it private }
    procedure DataChange(Sender: TObject);         { must have proper parameters for event
}
  end;
⋮
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                  { always call the inherited constructor first
}
  FReadOnly := True;                                               { this is already here }
  FDataLink := TFieldDataLink.Create;                    { construct the datalink object }
  FDataLink.OnDataChange := DataChange;                         { attach handler to event }
end;

destructor TDBCalendar.Destroy;
begin
  FDataLink.OnDataChange := nil;                 { detach handler before destroying object }
  FDataLink.Free;                                  { always destroy owned objects first... }
  inherited Destroy;                                   { ...then call inherited destructor
}
end;

procedure TDBCalendar.DataChange(Sender: TObject);
begin
  if FDataLink.Field = nil then                         { if there is no field assigned...
}
    CalendarDate := 0                                            { ...set to invalid date }
  else CalendarDate := FDataLink.Field.AsDateTime;   { otherwise, set calendar to the date }
end;
```

You now have a data-browsing control.

Creating a data-editing control

When you create a data-editing control, you create and register the component and add the data link just as you do for a data-browsing control. You also respond to data changes in the underlying field in a similar manner, but you must handle a few more issues.

For example, you probably want your control to respond to both key and mouse events. Your control must respond when the user changes the contents of the control. When the user exits the control, you want the changes made in the control to be reflected in the dataset.

The data-editing control described here is the same calendar control described in the first part of the chapter. The control is modified so that it can edit as well as view the data in its linked field.

Modifying the existing control to make it a data-editing control involves:

- Changing the default value of FReadOnly.
- Handling mouse-down and key-down messages.
- Updating the field datalink class.
- Modifying the Change method.
- Updating the dataset.

Changing the default value of FReadOnly

Because this is a data-editing control, the *ReadOnly* property should be set to *False* by default. To make the *ReadOnly* property *False*, change the value of *FReadOnly* in the constructor:

```
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  ⋮
  FReadOnly := False;  { set the default value }
  ⋮
end;
```

Handling mouse-down and key-down messages

When the user of the control begins interacting with it, the control receives either mouse-down messages (*WM_LBUTTONDOWN*, *WM_MBUTTONDOWN*, or *WM_RBUTTONDOWN*) or a key-down message (*WM_KEYDOWN*) from Windows. If using CLX, notification is from the operating system in the form of system events. To enable a control to respond to these messages, you must write handlers that respond to these messages.

- Responding to mouse-down messages
- Responding to key-down messages

Responding to mouse-down messages

A *MouseDown* method is a protected method for a control's *OnMouseDown* event. The control itself calls *MouseDown* in response to a Windows mouse-down message. When you override the inherited *MouseDown* method, you can include code that provides other responses in addition to calling the *OnMouseDown* event.

To override *MouseDown*, add the *MouseDown* method to the *TDBCalendar* class:

```
type
  TDBCalendar = class(TSampleCalendar);
   ⋮
  protected
    procedure MouseDown(Button: TButton, Shift: TShiftState, X: Integer, Y: Integer);
      override;
   ⋮
  end;
```

```
procedure TDBCalendar.MouseDown(Button: TButton; Shift: TShiftState; X, Y: Integer);
var
  MyMouseDown: TMouseEvent;
begin
  if not ReadOnly and FDataLink.Edit then
    inherited MouseDown(Button, Shift, X, Y)
  else
  begin
    MyMouseDown := OnMouseDown;
    if Assigned(MyMouseDown then MyMouseDown(Self, Button, Shift, X, Y);
  end;
end;
```

When *MouseDown* responds to a mouse-down message, the inherited *MouseDown* method is called only if the control's *ReadOnly* property is *False* and the datalink object is in edit mode, which means the field can be edited. If the field cannot be edited, the code the programmer put in the *OnMouseDown* event handler, if one exists, is executed.

Responding to key-down messages

A *KeyDown* method is a protected method for a control's *OnKeyDown* event. The control itself calls *KeyDown* in response to a Windows key-down message. When overriding the inherited *KeyDown* method, you can include code that provides other responses in addition to calling the *OnKeyDown* event.

To override *KeyDown*, follow these steps:

1 Add a *KeyDown* method to the *TDBCalendar* class:

```
type
  TDBCalendar = class(TSampleCalendar);
   ⋮
  protected
    procedure KeyDown(var Key: Word; Shift: TShiftState; X: Integer; Y: Integer);
      override;
   ⋮
  end;
```

2 Implement the *KeyDown* method:

```
procedure KeyDown(var Key: Word; Shift: TShiftState);
var
  MyKeyDown: TKeyEvent;
begin
  if not ReadOnly and (Key in [VK_UP, VK_DOWN, VK_LEFT, VK_RIGHT, VK_END,
    VK_HOME, VK_PRIOR, VK_NEXT]) and FDataLink.Edit then
    inherited KeyDown(Key, Shift)
  else
  begin
    MyKeyDown := OnKeyDown;
    if Assigned(MyKeyDown) then MyKeyDown(Self, Key, Shift);
  end;
end;
```

When *KeyDown* responds to a mouse-down message, the inherited *KeyDown* method is called only if the control's *ReadOnly* property is *False*, the key pressed is one of the cursor control keys, and the datalink object is in edit mode, which means the field can be edited. If the field cannot be edited or some other key is pressed, the code the programmer put in the *OnKeyDown* event handler, if one exists, is executed.

Updating the field datalink class

There are two types of data changes:

- A change in a field value that must be reflected in the data-aware control.
- A change in the data-aware control that must be reflected in the field value.

The *TDBCalendar* component already has a *DataChange* method that handles a change in the field's value in the dataset by assigning that value to the *CalendarDate* property. The *DataChange* method is the handler for the *OnDataChange* event. So the calendar component can handle the first type of data change.

Similarly, the field datalink class also has an *OnUpdateData* event that occurs as the user of the control modifies the contents of the data-aware control. The calendar control has a *UpdateData* method that becomes the event handler for the *OnUpdateData* event. *UpdateData* assigns the changed value in the data-aware control to the field data link.

1. To reflect a change made to the value in the calendar in the field value, add an *UpdateData* method to the private section of the calendar component:

```
type
  TDBCalendar = class(TSampleCalendar);
  private
    procedure UpdateData(Sender: TObject);
   ⋮
  end;
```

2. Implement the *UpdateData* method:

```
procedure UpdateData(Sender: TObject);
begin
  FDataLink.Field.AsDateTime := CalendarDate;        { set field link to calendar date }
end;
```

3. Within the constructor for *TDBCalendar*, assign the *UpdateData* method to the *OnUpdateData* event:

```
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);
  FReadOnly := True;
  FDataLink := TFieldDataLink.Create;
  FDataLink.OnDataChange := DataChange;
  FDataLink.OnUpdateData := UpdateData;
end;
```

Modifying the Change method

The *Change* method of the *TDBCalendar* is called whenever a new date value is set. *Change* calls the *OnChange* event handler, if one exists. The component user can write code in the *OnChange* event handler to respond to changes in the date.

When the calendar date changes, the underlying dataset should be notified that a change has occurred. You can do that by overriding the *Change* method and adding one more line of code. These are the steps to follow:

1 Add a new *Change* method to the *TDBCalendar* component:

```
type
  TDBCalendar = class(TSampleCalendar);
  private
    procedure Change; override;
   ⋮
  end;
```

2 Write the *Change* method, calling the *Modified* method that informs the dataset the data has changed, then call the inherited *Change* method:

```
procedure TDBCalendar.Change;
begin
  FDataLink.Modified;                  { call the Modified method }
  inherited Change;                    { call the inherited Change method }
end;
```

Updating the dataset

So far, a change within the data-aware control has changed values in the field datalink class. The final step in creating a data-editing control is to update the dataset with the new value. This should happen after the person changing the value in the data-aware control exits the control by clicking outside the control or pressing the *Tab* key. This process works differently in the VCL and CLX.

VCL VCL has defined message control IDs for operations on controls. For example, the *CM_EXIT* message is sent to the control when the user exits the control. You can write message handlers that respond to the message. In this case, when the user exits the control, the *CMExit* method, the message handler for *CM_EXIT*, responds by updating the record in the dataset with the changed values in the field datalink class. For more information about message handlers, see Chapter 46, “Handling messages.”

To update the dataset within a message handler, follow these steps:

1 Add the message handler to the *TDBCalendar* component:

```
type
  TDBCalendar = class(TSampleCalendar);
  private
    procedure CMExit(var Message: TWMNoParams); message CM_EXIT;
   ⋮
  end;
```

2 Implement the *CMExit* method so it looks like this:

```
procedure TDBCalendar.CMExit(var Message: TWMNoParams);
begin
  try
    FDataLink.UpdateRecord;                          { tell data link to update database }
  except
    on Exception do SetFocus;                      { if it failed, don't let focus leave }
 end;
  inherited;
end;
```

CLX In CLX, *TWidgetControl* has a protected *DoExit* method that is called when input focus shifts away from the control. This method calls the event handler for the *OnExit* event. You can override this method to update the record in the dataset before generating the *OnExit* event handler.

To update the dataset when the user exits the control, follow these steps:

1 Add an override for the *DoExit* method to the *TDBCalendar* component:

```
type
  TDBCalendar = class(TSampleCalendar);
  private
    procedure DoExit; override;
    ⋮
  end;
```

2 Implement the *DoExit* method so it looks like this:

```
procedure TDBCalendar.CMExit(var Message: TWMNoParams);
begin
  try
    FDataLink.UpdateRecord;                          { tell data link to update database }
  except
    on Exception do SetFocus;                      { if it failed, don't let focus leave }
 end;
  inherited;                        { let the inherited method generate an OnExit event }

end;
```

Chapter

52

Making a dialog box a component

You will find it convenient to make a frequently used dialog box into a component that you add to the Component palette. Your dialog box components will work just like the components that represent the standard common dialog boxes. The goal is to create a simple component that a user can add to a project and set properties for at design time.

Making a dialog box a component requires these steps:

1. Defining the component interface
2. Creating and registering the component
3. Creating the component interface
4. Testing the component

The Delphi "wrapper" component associated with the dialog box creates and executes the dialog box at runtime, passing along the data the user specified. The dialog-box component is therefore both reusable and customizable.

In this chapter, you will see how to create a wrapper component around the generic About Box form provided in the Delphi Object Repository.

Note Copy the files ABOUT.PAS and ABOUT.DFM into your working directory.

There are not many special considerations for designing a dialog box that will be wrapped into a component. Nearly any form can operate as a dialog box in this context.

Defining the component interface

Before you can create the component for your dialog box, you need to decide how you want developers to use it. You create an interface between your dialog box and applications that use it.

For example, look at the properties for the common dialog box components. They enable the developer to set the initial state of the dialog box, such as the caption and initial control settings, then read back any needed information after the dialog box closes. There is no direct interaction with the individual controls in the dialog box, just with the properties in the wrapper component.

The interface must therefore contain enough information that the dialog box form can appear in the way the developer specifies and return any information the application needs. You can think of the properties in the wrapper component as being persistent data for a transient dialog box.

In the case of the About box, you do not need to return any information, so the wrapper's properties only have to contain the information needed to display the About box properly. Because there are four separate fields in the About box that the application might affect, you will provide four string-type properties to provide for them.

Creating and registering the component

Creation of every component begins the same way: create a unit, derive a component class, register it, compile it, and install it on the component palette. This process is outlined in "Creating a new component" on page 40-8.

For this example, follow the general procedure for creating a component, with these specifics:

- Call the component's unit *AboutDlg*.
- Derive a new component type called *TAboutBoxDlg*, descended from *TComponent*.
- Register *TAboutBoxDlg* on the Samples page of the component palette.

The resulting unit should look like this:

```
unit AboutDlg;
interface
uses
  SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls, Forms;
type
  TAboutBoxDlg = class(TComponent)
  end;
procedure Register;
implementation
procedure Register;
begin
  RegisterComponents('Samples', [TAboutBoxDlg]);
end;
end.
```

The new component now has only the capabilities built into *TComponent*. It is the simplest nonvisual component. In the next section, you will create the interface between the component and the dialog box.

Creating the component interface

These are the steps to create the component interface:

1. Including the form unit
2. Adding interface properties
3. Adding the Execute method

Including the form unit

For your wrapper component to initialize and display the wrapped dialog box, you must add the form's unit to the **uses** clause of the wrapper component's unit.

Append *About* to the **uses** clause of the *AboutDlg* unit.

The **uses** clause now looks like this:

```
uses
  SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls, Forms,
  About;
```

The form unit always declares an instance of the form class. In the case of the About box, the form class is *TAboutBox*, and the *About* unit includes the following declaration:

```
var
  AboutBox: TAboutBox;
```

So by adding *About* to the **uses** clause, you make *AboutBox* available to the wrapper component.

Adding interface properties

Before proceeding, decide on the properties your wrapper needs to enable developers to use your dialog box as a component in their applications. Then, you can add declarations for those properties to the component's class declaration.

Properties in wrapper components are somewhat simpler than the properties you would create if you were writing a regular component. Remember that in this case, you are just creating some persistent data that the wrapper can pass back and forth to the dialog box. By putting that data in the form of properties, you enable developers to set data at design time so that the wrapper can pass it to the dialog box at runtime.

Declaring an interface property requires two additions to the component's class declaration:

- A private class field, which is a variable the wrapper uses to store the value of the property
- The published property declaration itself, which specifies the name of the property and tells it which field to use for storage

Interface properties of this sort do not need access methods. They use direct access to their stored data. By convention, the class field that stores the property's value has the same name as the property, but with the letter *F* in front. The field and the property *must* be of the same type.

For example, to declare an integer-type interface property called *Year*, you would declare it as follows:

```
type
  TMyWrapper = class(TComponent)
  private
    FYear: Integer;                                  { field to hold the Year-property data }
  published
    property Year: Integer read FYear write FYear;        { property matched with storage }
  end;
```

For this About box, you need four string-type properties—one each for the product name, the version information, the copyright information, and any comments.

```
type
  TAboutBoxDlg = class(TComponent)
  private
    FProductName, FVersion, FCopyright, FComments: string;               { declare fields }

  published
    property ProductName: string read FProductName write FProductName;
    property Version: string read FVersion write FVersion;
    property Copyright: string read FCopyright write FCopyright;
    property Comments: string read FComments write FComments;
  end;
```

When you install the component onto the component palette and place the component on a form, you will be able to set the properties, and those values will automatically stay with the form. The wrapper can then use those values when executing the wrapped dialog box.

Adding the Execute method

The final part of the component interface is a way to open the dialog box and return a result when it closes. As with the common-dialog-box components, you will use a boolean function called *Execute* that returns *True* if the user clicks OK, or *False* if the user cancels the dialog box.

The declaration for the *Execute* method always looks like this:

```
type
  TMyWrapper = class(TComponent)
  public
    function Execute: Boolean;
  end;
```

The minimum implementation for *Execute* needs to construct the dialog box form, show it as a modal dialog box, and return either *True* or *False*, depending on the return value from *ShowModal*.

Here is the minimal *Execute* method for a dialog-box form of type *TMyDialogBox*:

```
function TMyWrapper.Execute: Boolean;
begin
  DialogBox := TMyDialogBox.Create(Application);                    { construct the form }
  try
    Result := (DialogBox.ShowModal = IDOK);     { execute; set result based on how closed }
  finally
    DialogBox.Free;                                                  { dispose of the form }
  end;
end;
```

Note the use of a **try..finally** block to ensure that the application disposes of the dialog box object even if an exception occurs. In general, whenever you construct an object this way, you should use a **try..finally** block to protect the block of code and make certain the application frees any resources it allocates.

In practice, there will be more code inside the **try..finally** block. Specifically, before calling *ShowModal*, the wrapper will set some of the dialog box's properties based on the wrapper component's interface properties. After *ShowModal* returns, the wrapper will probably set some of its interface properties based on the outcome of the dialog box execution.

In the case of the About box, you need to use the wrapper component's four interface properties to set the contents of the labels in the About box form. Because the About box does not return any information to the application, there is no need to do anything after calling *ShowModal*. Write the About box wrapper's *Execute* method so that it looks like this:

Within the public part of the *TAboutDlg* class, add the declaration for the *Execute* method:

```
type
  TAboutDlg = class(TComponent)
public
  function Execute: Boolean;
end;

function TAboutBoxDlg.Execute: Boolean;
begin
  AboutBox := TAboutBox.Create(Application);                       { construct About box }
  try
    if ProductName = '' then                              { if product name's left blank... }
      ProductName := Application.Title;                  { ...use application title instead }
    AboutBox.ProductName.Caption := ProductName;                         { copy product name }
    AboutBox.Version.Caption := Version;                                 { copy version info }
    AboutBox.Copyright.Caption := Copyright;                           { copy copyright info }
    AboutBox.Comments.Caption := Comments;                                   { copy comments }
    AboutBox.Caption := 'About ' + ProductName;                      { set About-box caption }
    with AboutBox do begin
      ProgramIcon.Picture.Graphic := Application.Icon;                           { copy icon }
      Result := (ShowModal = IDOK);                                { execute and set result }
    end;
  finally
    AboutBox.Free;                                                    { dispose of About box }
  end;
end;
```

Testing the component

Once you have installed the dialog-box component, you can use it as you would any of the common dialog boxes, by placing one on a form and executing it. A quick way to test the About box is to add a command button to a form and execute the dialog box when the user clicks the button.

For example, if you created an About dialog box, made it a component, and added it to the Component palette, you can test it with the following steps:

1 Create a new project.

2 Place an About-box component on the main form.

3 Place a command button on the form.

4 Double-click the command button to create an empty click-event handler.

5 In the click-event handler, type the following line of code:

```
AboutBoxDlg1.Execute;
```

6 Run the application.

When the main form appears, click the command button. The About box appears with the default project icon and the name Project1. Choose OK to close the dialog box.

You can further test the component by setting the various properties of the About box component and again running the application.

1

Introduction

This manual describes the Object Pascal programming language as it is used in Borland development tools.

What's in this manual?

The first seven chapters describe most of the language elements used in ordinary programming. Chapter 8 summarizes standard routines for file I/O and string manipulation.

The next chapters describe language extensions and restrictions for dynamic-link libraries and packages (Chapter 9), and for object interfaces (Chapter 10). The final three chapters address advanced topics: memory management (Chapter 11), program control (Chapter 12), and assembly-language routines within Object Pascal programs (Chapter 13).

Using Object Pascal

The *Object Pascal Language Guide* is written to describe the Object Pascal language for use on either the Linux or Windows operating systems. Differences in the language relating to platform dependencies are noted where necessary.

Most Delphi/Kylix application developers write and compile their Object Pascal code in the integrated development environment (IDE). Working in the IDE allows the product to handle many details of setting up projects and source files, such as maintenance of dependency information among units. Borland products may enforce certain constraints on program organization that are not, strictly speaking, part of the Object Pascal language specification. For example, certain file- and program-naming conventions can be avoided if you write your programs outside of the IDE and compile them from the command prompt.

This manual generally assumes that you are working in the IDE and that you are building applications that use the Visual Component Library (VCL) and/or the Borland Component Library for Cross Platform (CLX). Occasionally, however, Borland-specific rules are distinguished from rules that apply to all Object Pascal programming.

Typographical conventions

Identifiers—that is, names of constants, variables, types, fields, properties, procedures, functions, programs, units, libraries, and packages—appear in *italics* in the text. Object Pascal operators, reserved words, and directives are in **boldface** type. Example code and text that you would type literally (into a file or at the command prompt) are in `monospaced` type.

In displayed program listings, reserved words and directives appear in **boldface**, just as they do in the text:

```
function Calculate(X, Y: Integer): Integer;
begin
  ⋮
end;
```

This is how the Code editor displays reserved words and directives, if you have the Syntax Highlight option turned on.

Some program listings, like the example above, contain ellipsis marks (... or ⋮). The ellipses represent additional code that would be included in an actual file. They are not meant to be copied literally.

In syntax descriptions, *italics* indicate placeholders for which, in real code, you would substitute syntactically valid constructions. For example, the heading of the function declaration above could be represented as

`function` *functionName*`(`*argumentList*`):` *returnType*`;`

Syntax descriptions can also contain ellipsis marks (...) and subscripts:

`function` *functionName*`(`arg_1`, ...,` arg_n`):` *ReturnType*`;`

Other sources of information

The online Help system for your development tool provides information about the IDE and user interface as well as the most up-to-date reference material for the VCL and/or CLX. Many programming topics, such as database development, are covered in depth in the *Developer's Guide*. For an overview of the documentation set, see the *Quick Start* manual that came with your software package.

Software registration and technical support

Borland Software Corporation offers a range of support plans to fit the needs of individual developers, consultants, and corporations. To receive help with this product, return the registration card and select the plan that best suits your needs. For additional information about technical support and other Borland services, contact your local sales representative or visit us online at http://www.borland.com/.

Part

I

Basic language description

The chapters in Part I present the essential language elements required for most programming tasks. These chapters include:

- Chapter 2, “Overview”
- Chapter 3, “Programs and units”
- Chapter 4, “Syntactic elements”
- Chapter 5, “Data types, variables, and constants”
- Chapter 6, “Procedures and functions”
- Chapter 7, “Classes and objects”
- Chapter 8, “Standard routines and I/O”

Chapter

2

Overview

Object Pascal is a high-level, compiled, strongly typed language that supports structured and object-oriented design. Its benefits include easy-to-read code, quick compilation, and the use of multiple unit files for modular programming.

Object Pascal has special features that support Borland's component framework and RAD environment. For the most part, descriptions and examples in this manual assume that you are using Object Pascal to develop applications using Borland development tools such as Delphi or Kylix.

Program organization

Programs are usually divided into source-code modules called *units*. Each program begins with a heading, which specifies a name for the program. The heading is followed by an optional **uses** clause, then a block of declarations and statements. The **uses** clause lists units that are linked into the program; these units, which can be shared by different programs, often have **uses** clauses of their own.

The **uses** clause provides the compiler with information about dependencies among modules. Because this information is stored in the modules themselves, Object Pascal programs do not require makefiles, header files, or preprocessor "include" directives. (The Project Manager generates a makefile each time a project is loaded in the IDE, but saves these files only for project groups that include more than one project.)

For further discussion of program structure and dependencies, see Chapter 3, "Programs and units".

Pascal source files

The compiler expects to find Pascal source code in files of three kinds:

- *unit* source files (which end with the .pas extension)

- *project* files (which end with the .dpr extension)
- *package* source files (which end with the .dpk extension)

Unit source files contain most of the code in an application. Each application has a single project file and several unit files; the project file—which corresponds to the "main" program file in traditional Pascal—organizes the unit files into an application. Borland development tools automatically maintain a project file for each application.

If you are compiling a program from the command line, you can put all your source code into unit (.pas) files. But if you use the IDE to build your application, you must have a project (.dpr) file.

Package source files are similar to project files, but they are used to construct special dynamically linkable libraries called *packages*. For more information about packages, see Chapter 9, "Libraries and packages".

Other files used to build applications

In addition to source-code modules, Borland products use several non-Pascal files to build applications. These files are maintained automatically and include

- *form* files, which end with the .dfm (Delphi) or .xfm (Kylix) extension,
- *resource* files, which end with the .res extension, and
- *project options* files, which end with the .dof (Delphi) or .kof (Kylix) extension.

A form file is either a text file or a compiled resource file that can contain bitmaps, strings, and so forth. Each form file represents a single form, which usually corresponds to a window or dialog box in an application. The IDE allows you to view and edit form files as text, and to save form files as either text or binary. Although the default behavior is to save form files as text, they are usually not edited manually; it is more common to use Borland's visual design tools for this purpose. Each project has at least one form, and each form has an associated unit (.pas) file that, by default, has the same name as the form file.

In addition to form files, each project uses a resource (.res) file to hold the bitmap for the application's icon. By default, this file has the same name as the project (.dpr) file. To change an application's icon, use the Project Options dialog.

A project options (.dof or .kof) file contains compiler and linker settings, search directories, version information, and so forth. Each project has an associated project options file with the same name as the project (.dpr) file. Usually, the options in this file are set from Project Options dialog.

Various tools in the IDE store data in files of other types. Desktop settings (.dsk or .desk) files contain information about the arrangement of windows and other configuration options; desktop settings can be project-specific or environment-wide. These files have no direct effect on compilation.

Compiler-generated files

The first time you build an application or a standard dynamic-link library, the compiler produces a compiled unit .dcu (Windows) .dcu/.dpu (Linux) file for each new unit used in your project; all the .dcu (Windows) .dcu/.dpu (Linux) files in your project are then linked to create a single executable or shared library file. The first time you build a package, the compiler produces a .dcu (Windows) .dpu (Linux) file for each new unit contained in the package, and then creates both a .dcp and a package file. (For more information about libraries and packages, see Chapter 9.) If you use the **–GD** switch, the linker generates a map file and a .drc file; the .drc file, which contains string resources, can be compiled into a resource file.

When you rebuild a project, individual units are not recompiled unless their source (.pas) files have changed since the last compilation, or their .dcu (Windows) .dcu/ .dpu (Linux) files cannot be found, or you explicitly tell the compiler to reprocess them. In fact, it is not necessary for a unit's source file to be present at all, as long as the compiler can find the compiled unit file.

Example programs

The examples that follow illustrate basic features of Object Pascal programming. The examples show simple Object Pascal applications that cannot be compiled from the IDE; but you can compile them from the command line.

A simple console application

The program below is a simple console application that you can compile and run from the command prompt.

```
program Greeting;

{$APPTYPE CONSOLE}

var MyMessage: string;

begin
  MyMessage := 'Hello world!';
  Writeln(MyMessage);
end.
```

The first line declares a program called *Greeting*. The `{$APPTYPE CONSOLE}` directive tells the compiler that this is a console application, to be run from the command line. The next line declares a variable called *MyMessage*, which holds a string. (Object Pascal has genuine string data types.) The program then assigns the string "Hello world!" to the variable *MyMessage*, and sends the contents of *MyMessage* to the standard output using the *Writeln* procedure. (*Writeln* is defined implicitly in the *System* unit, which the compiler automatically includes in every application.)

You can type this program into a file called Greeting.pas or Greeting.dpr and compile it by entering

```
On Delphi: DCC32 Greeting

On Kylix: dcc Greeting
```

on the command line. The resulting executable prints the message "Hello world!"

Aside from its simplicity, this example differs in several important ways from programs that you are likely to write with Borland development tools. First, it is a console application. Borland development tools are typically used to write applications with graphical interfaces; hence, you would not ordinarily call *Writeln*. Moreover, the entire example program (save for *Writeln*) is in a single file. In a typical application, the program heading—the first line of the example—would be placed in a separate project file that would not contain any of the actual application logic, other than a few calls to *methods* defined in unit files.

A more complicated example

The next example shows a program that is divided into two files: a *project* file and a *unit* file. The project file, which you can save as Greeting.dpr, looks like this:

```
program Greeting;

{$APPTYPE CONSOLE}

uses Unit1;

begin
  PrintMessage('Hello World!');
end.
```

The first line declares a program called *Greeting*, which, once again, is a console application. The `uses Unit1;` clause tells the compiler that *Greeting* includes a unit called *Unit1*. Finally, the program calls the *PrintMessage* procedure, passing to it the string "Hello World!" Where does the *PrintMessage* procedure come from? It's defined in *Unit1*. Here's the source code for *Unit1*, which you can save in a file called Unit1.pas:

```
unit Unit1;

interface

procedure PrintMessage(msg: string);

implementation

procedure PrintMessage(msg: string);
begin
  Writeln(msg);
end;

end.
```

Unit1 defines a procedure called *PrintMessage* that takes a single string as an argument and sends the string to the standard output. (In Pascal, routines that do not return a value are called *procedures*. Routines that return a value are called *functions*.) Notice that *PrintMessage* is declared twice in *Unit1*. The first declaration, under the reserved word **interface**, makes *PrintMessage* available to other modules (such as *Greeting*) that use *Unit1*. The second declaration, under the reserved word **implementation**, actually defines *PrintMessage*.

You can now compile *Greeting* from the command line by entering

```
On Delphi: DCC32 Greeting
```

```
On Kylix: dcc Greeting
```

There's no need to include *Unit1* as a command-line argument. When the compiler processes Greeting.dpr, it automatically looks for unit files that the *Greeting* program depends on. The resulting executable does the same thing as our first example: it prints the message "Hello world!"

A native application

Our next example is an application built using VCL or CLX components in the IDE. This program uses automatically generated form and resource files, so you won't be able to compile it from the source code alone. But it illustrates important features of Object Pascal. In addition to multiple units, the program uses classes and objects, which are discussed in Chapter 7, "Classes and objects".

The program includes a project file and two new unit files. First, the project file:

```
program Greeting;  { comments are enclosed in braces }

uses
  Forms, {change the unit name to QForms on Linux}
  Unit1 in 'Unit1.pas' { the unit for Form1 },
  Unit2 in 'Unit2.pas' { the unit for Form2 };

{$R *.res}  { this directive links the project's resource file }

begin
  { calls to Application }
  Application.Initialize;
  Application.CreateForm(TForm1, Form1);
  Application.CreateForm(TForm2, Form2);
  Application.Run;
end.
```

Once again, our program is called *Greeting*. It uses three units: *Forms*, which is part of VCL and CLX; *Unit1*, which is associated with the application's main form (*Form1*); and *Unit2*, which is associated with another form (*Form2*).

The program makes a series of calls to an object named *Application*, which is an instance of the *TApplication* class defined in the *Forms* unit. (Every project has an automatically generated *Application* object.) Two of these calls invoke a *TApplication* method named *CreateForm*. The first call to *CreateForm* creates *Form1,* an instance of the *TForm1* class defined in *Unit1*. The second call to *CreateForm* creates *Form2,* an instance of the *TForm2* class defined in *Unit2*.

Unit1 looks like this:

```
unit Unit1;

interface

uses  { these units are part of the Visual Component Library (VCL) }
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs, StdCtrls;

{
On Linux, the uses clause looks like this:
uses  { these units are part of CLX }
  SysUtils, Types, Classes, QGraphics, QControls, QForms, QDialogs;
}

type
  TForm1 = class(TForm)
    Button1: TButton;
    procedure Button1Click(Sender: TObject);
  end;

var
  Form1: TForm1;

implementation

uses Unit2;  { this is where Form2 is defined }

{$R *.dfm}  { this directive links Unit1's form file }

procedure TForm1.Button1Click(Sender: TObject);
begin
  Form2.ShowModal;
end;

end.
```

Unit1 creates a class named *TForm1* (derived from *TForm*) and an instance of this class*, Form1*. *TForm1* includes a button—*Button1,* an instance of *TButton*—and a procedure named *TForm1.Button1Click* that is called at runtime whenever the user presses *Button1*. *TForm1.Button1Click* hides *Form1* and it displays *Form2* (the call to *Form2.ShowModal*). *Form2* is defined in *Unit2*:

```
unit Unit2;

interface

uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
  StdCtrls;
```

```
{
On Linux, the uses clause looks like this:
uses  { these units are part of CLX }
  SysUtils, Types, Classes, QGraphics, QControls, QForms, QDialogs;
}
type
  TForm2 = class(TForm)
    Label1: TLabel;
    CancelButton: TButton;
    procedure CancelButtonClick(Sender: TObject);
    procedure FormClose(Sender: TObject; var Action: TCloseAction);
  end;

var
  Form2: TForm2;

implementation

uses Unit1;

{$R *.dfm}

procedure TForm2.CancelButtonClick(Sender: TObject);
begin
  Form2.Close;
end;

end.
```

Unit2 creates a class named *TForm2* and an instance of this class, *Form2*. *TForm2* includes a button (*CancelButton*, an instance of *TButton*) and a label (*Label1*, an instance of *TLabel*). You can't see this from the source code, but *Label1* displays a caption that reads "Hello world!" The caption is defined in *Form2*'s form file, Unit2.dfm.

Unit2 defines one procedure. *TForm2.CancelButtonClick* is called at runtime whenever the user presses *CancelButton*; it closes *Form2*. This procedure (along with *Unit1*'s *TForm1.Button1Click*) is known as an *event handler* because it responds to events that occur while the program is running. Event handlers are assigned to specific events by the form (.dfm on Windows .xfm on Linux) files for *Form1* and *Form2*.

When the *Greeting* program starts, *Form1* is displayed and *Form2* is invisible. (By default, only the first form created in the project file is visible at runtime. This is called the project's *main form*.) When the user presses the button on *Form1*, *Form1* disappears and is replaced by *Form2*, which displays the "Hello world!" greeting. When the user closes *Form2* (by pressing *CancelButton* or the Close button on the title bar), *Form1* reappears.

Chapter

3

Programs and units

A program is constructed from source-code modules called *units*. Each unit is stored in its own file and compiled separately; compiled units are linked to create an application. Units allow you to

- divide large programs into modules that can be edited separately.
- create libraries that you can share among programs.
- distribute libraries to other developers without making the source code available.

In traditional Pascal programming, all source code, including the main program, is stored in .pas files. Borland tools use a *project* (.dpr) file to store the "main" program, while most other source code resides in *unit* (.pas) files. Each application—or *project*—consists of a single project file and one or more unit files. (Strictly speaking, you needn't explicitly use any units in a project, but all programs automatically use the *System* unit.) To build a project, the compiler needs either a source file or a compiled unit file for each unit.

Program structure and syntax

A program contains

- a program heading,
- a **uses** clause (optional), and
- a block of declarations and statements.

The program heading specifies a name for the program. The **uses** clause lists units used by the program. The block contains declarations and statements that are executed when the program runs. The IDE expects to find these three elements in a single project (.dpr) file.

The example below shows the project file for a program called Editor.

```
 1    program Editor;
 2
 3    uses
 4      Forms, {change to QForms in Linux}
 5      REAbout in 'REAbout.pas' {AboutBox},
 6      REMain in 'REMain.pas' {MainForm};
 7
 8    {$R *.res}
 9
10    begin
11      Application.Title := 'Text Editor';
12      Application.CreateForm(TMainForm, MainForm);
13      Application.Run;
14    end.
```

Line 1 contains the program heading. The **uses** clause is on lines 3 through 6. Line 8 is a compiler directive that links the project's resource file into the program. Lines 10 through 14 contain the block of statements that are executed when the program runs. Finally, the project file, like all source files, ends with a period.

This is, in fact, a fairly typical project file. Project files are usually short, since most of a program's logic resides in its unit files. Project files are generated and maintained automatically, and it is seldom necessary to edit them manually.

The program heading

The program heading specifies the program's name. It consists of the reserved word **program**, followed by a valid identifier, followed by a semicolon. The identifier must match the project file name. In the example above, since the program is called Editor, the project file should be called EDITOR.dpr.

In standard Pascal, a program heading can include parameters after the program name:

```
program Calc(input, output);
```

Borland's Object Pascal compiler ignores these parameters.

The program uses clause

The **uses** clause lists units that are incorporated into the program. These units may in turn have **uses** clauses of their own. For more information about the **uses** clause, see "Unit references and the uses clause" on page 3-5.

The block

The block contains a simple or structured statement that is executed when the program runs. In most programs, the block consists of a compound statement—bracketed between the reserved words **begin** and **end**—whose component statements are simply method calls to the project's *Application* object. (Every project has an *Application* variable that holds an instance of *TApplication*, *TWebApplication*, or *TServiceApplication*.) The block can also contain declarations of constants, types, variables, procedures, and functions; these declarations must precede the statement part of the block.

Unit structure and syntax

A unit consists of types (including classes), constants, variables, and routines (functions and procedures). Each unit is defined in its own unit (.pas) file.

A unit file begins with a unit heading, which is followed by the *interface*, *implementation*, *initialization*, and *finalization* sections. The initialization and finalization sections are optional. A skeleton unit file looks like this:

```
unit Unit1;

interface

uses  { List of units goes here }

  { Interface section goes here }

implementation

uses  { List of units goes here }

  { Implementation section goes here }

initialization
  { Initialization section goes here }

finalization
  { Finalization section goes here }

end.
```

The unit must conclude with the word **end** followed by a period.

The unit heading

The unit heading specifies the unit's name. It consists of the reserved word **unit**, followed by a valid identifier, followed by a semicolon. For applications developed using Borland tools, the identifier must match the unit file name. Thus, the unit heading

```
unit MainForm;
```

would occur in a source file called MAINFORM.pas, and the file containing the compiled unit would be MAINFORM.dcu.

Unit names must be unique within a project. Even if their unit files are in different directories, two units with the same name cannot be used in a single program.

The interface section

The interface section of a unit begins with the reserved word **interface** and continues until the beginning of the implementation section. The interface section declares constants, types, variables, procedures, and functions that are available to *clients*—that is, to other units or programs that use the unit where they are declared. These entities are called *public* because a client can access them as if they were declared in the client itself.

The interface declaration of a procedure or function includes only the routine's heading. The block of the procedure or function follows in the implementation section. Thus procedure and function declarations in the interface section work like forward declarations, although the **forward** directive isn't used.

The interface declaration for a class must include declarations for all class members.

The interface section can include its own **uses** clause, which must appear immediately after the word **interface**. For information about the **uses** clause, see "Unit references and the uses clause" on page 3-5.

The implementation section

The implementation section of a unit begins with the reserved word **implementation** and continues until the beginning of the initialization section or, if there is no initialization section, until the end of the unit. The implementation section defines procedures and functions that are declared in the interface section. Within the implementation section, these procedures and functions may be defined and called in any order. You can omit parameter lists from public procedure and function headings when you define them in the implementation section; but if you include a parameter list, it must match the declaration in the interface section exactly.

In addition to definitions of public procedures and functions, the implementation section can declare constants, types (including classes), variables, procedures, and functions that are *private* to the unit—that is, inaccessible to clients.

The implementation section can include its own **uses** clause, which must appear immediately after the word **implementation**. For information about the **uses** clause, see "Unit references and the uses clause" on page 3-5.

The initialization section

The initialization section is optional. It begins with the reserved word **initialization** and continues until the beginning of the finalization section or, if there is no finalization section, until the end of the unit. The initialization section contains statements that are executed, in the order in which they appear, on program start-up.

So, for example, if you have defined data structures that need to be initialized, you can do this in the initialization section.

The initialization sections of units used by a client are executed in the order in which the units appear in the client's **uses** clause.

The finalization section

The finalization section is optional and can appear only in units that have an initialization section. The finalization section begins with the reserved word **finalization** and continues until the end of the unit. It contains statements that are executed when the main program terminates. Use the finalization section to free resources that are allocated in the initialization section.

Finalization sections are executed in the opposite order from initializations. For example, if your application initializes units *A*, *B*, and *C*, in that order, it will finalize them in the order *C*, *B*, and *A*.

Once a unit's initialization code starts to execute, the corresponding finalization section is guaranteed to execute when the application shuts down. The finalization section must therefore be able to handle incompletely initialized data, since, if a runtime error occurs, the initialization code might not execute completely.

Unit references and the uses clause

A **uses** clause lists units used by the program, library, or unit in which the clause appears. (For information about libraries, see Chapter 9, "Libraries and packages".) A **uses** clause can occur in

- the project file for a program or library,
- the interface section of a unit, and
- the implementation section of a unit.

Most project files contain a **uses** clause, as do the interface sections of most units. The implementation section of a unit can contain its own **uses** clause as well.

The *System* unit is used automatically by every application and cannot be listed explicitly in the **uses** clause. (*System* implements routines for file I/O, string handling, floating point operations, dynamic memory allocation, and so forth.) Other standard library units, such as *SysUtils*, must be included in the **uses** clause. In most cases, all necessary units are placed in the **uses** clause when your project generates and maintains a source file.

For more information about the placement and content of the **uses** clause, see "Multiple and indirect unit references" on page 3-6 and "Circular unit references" on page 3-7.

The syntax of a uses clause

A **uses** clause consists of the reserved word **uses**, followed by one or more comma-delimited unit names, followed by a semicolon. Examples:

```
uses Forms, Main;

uses Windows, Messages, SysUtils, Strings, Classes, Unit2, MyUnit;

uses SysUtils, Types, Classes, QGraphics, QControls, QForms, QDialogs;
```

In the **uses** clause of a program or library, any unit name may be followed by the reserved word **in** and the name of a source file, with or without a directory path, in single quotation marks; directory paths can be absolute or relative. Examples:

```
uses Windows, Messages, SysUtils, Strings in 'C:\Classes\Strings.pas', Classes;

uses
  QForms,
  Main,
  Extra in '../extra/extra.pas';
```

Include **in** ... after a unit name when you need to specify the unit's source file. Since the IDE expects unit names to match the names of the source files in which they reside, there is usually no reason to do this. Using **in** is necessary only when the location of the source file is unclear, for example when

- You have used a source file that is in a different directory from the project file, and that directory is not in the compiler's search path or the general Library search path.
- Different directories in the compiler's search path have identically named units.
- You are compiling a console application from the command line, and you have named a unit with an identifier that doesn't match the name of its source file.

The compiler also relies on the **in** ... construction to determine which units are part of a project. Only units that appear in a project (.dpr) file's **uses** clause followed by **in** and a file name are considered to be part of the project; other units in the **uses** clause are used by the project without belonging to it. This distinction has no effect on compilation, but it affects IDE tools like the Project Manager and Project Browser.

In the **uses** clause of a unit, you cannot use **in** to tell the compiler where to find a source file. Every unit must be in the compiler's search path, the general Library search path, or the same directory as the unit that uses it. Moreover, unit names must match the names of their source files.

Multiple and indirect unit references

The order in which units appear in the **uses** clause determines the order of their initialization (see "The initialization section" on page 3-4) and affects the way identifiers are located by the compiler. If two units declare a variable, constant, type, procedure, or function with the same name, the compiler uses the one from the unit listed last in the **uses** clause. (To access the identifier from the other unit, you would have to add a qualifier: *UnitName.Identifier*.)

A **uses** clause need include only units used directly by the program or unit in which the clause appears. That is, if unit *A* references constants, types, variables, procedures, or functions that are declared in unit *B*, then *A* must use *B* explicitly. If *B* in turn references identifiers from unit *C*, then *A* is indirectly dependent on *C*; in this case, *C* needn't be included in a **uses** clause in *A*, but the compiler must still be able to find both *B* and *C* in order to process *A*.

The example below illustrates indirect dependency.

```
program Prog;
uses Unit2;
const a = b;
⋮

unit Unit2;
interface
uses Unit1;
const b = c;
⋮

unit Unit1;
interface
const c = 1;
⋮
```

In this example, *Prog* depends directly on *Unit2*, which depends directly on *Unit1*. Hence *Prog* is indirectly dependent on *Unit1*. Because *Unit1* does not appear in *Prog*'s **uses** clause, identifiers declared in *Unit1* are not available to *Prog*.

To compile a client module, the compiler needs to locate all units that the client depends on, directly or indirectly. Unless the source code for these units has changed, however, the compiler needs only their .dcu (Windows) or .dcu/.dpu (Linux) files, not their source (.pas) files.

When changes are made in the interface section of a unit, other units that depend on it must be recompiled. But when changes are made only in the implementation or other sections of a unit, dependent units don't have to be recompiled. The compiler tracks these dependencies automatically and recompiles units only when necessary.

Circular unit references

When units reference each other directly or indirectly, the units are said to be mutually dependent. Mutual dependencies are allowed as long as there are no circular paths connecting the **uses** clause of one interface section to the **uses** clause of another. In other words, starting from the interface section of a unit, it must never be possible to return to that unit by following references through interface sections of other units. For a pattern of mutual dependencies to be valid, each circular reference path must lead through the **uses** clause of at least one implementation section.

In the simplest case of two mutually dependent units, this means that the units cannot list each other in their interface **uses** clauses. So the following example leads to a compilation error:

```
unit Unit1;
interface
uses Unit2;
⋮

unit Unit2;
interface
uses Unit1;
⋮
```

However, the two units can legally reference each other if one of the references is moved to the implementation section:

```
unit Unit1;
interface
uses Unit2;
⋮

unit Unit2;
interface
⋮
implementation
uses Unit1;
⋮
```

To reduce the chance of circular references, it's a good idea to list units in the implementation **uses** clause whenever possible. Only when identifiers from another unit are used in the interface section is it necessary to list that unit in the interface **uses** clause.

Chapter

4

Syntactic elements

Object Pascal uses the ASCII character set, including the letters *A* through *Z* and *a* through *z*, the digits *0* through *9*, and other standard characters. It is *not* case-sensitive. The space character (ASCII 32) and the control characters (ASCII 0 through 31—including ASCII 13, the return or end-of-line character) are called *blanks*.

Fundamental syntactic elements, called *tokens*, combine to form expressions, declarations, and statements. A *statement* describes an algorithmic action that can be executed within a program. An *expression* is a syntactic unit that occurs within a statement and denotes a value. A *declaration* defines an identifier (such as the name of a function or variable) that can be used in expressions and statements, and, where appropriate, allocates memory for the identifier.

Fundamental syntactic elements

On the simplest level, a program is a sequence of tokens delimited by separators. A *token* is the smallest meaningful unit of text in a program. A *separator* is either a blank or a comment. Strictly speaking, it is not always necessary to place a separator between two tokens; for example, the code fragment

```
Size:=20;Price:=10;
```

is perfectly legal. Convention and readability, however, dictate that we write this as

```
Size := 20;
Price := 10;
```

Tokens are categorized as *special symbols*, *identifiers*, *reserved words*, *directives*, *numerals*, *labels*, and *character strings*. A separator can be part of a token only if the token is a character string. Adjacent identifiers, reserved words, numerals, and labels must have one or more separators between them.

Special symbols

Special symbols are nonalphanumeric characters, or pairs of such characters, that have fixed meanings. The following single characters are special symbols.

# $ & ' ( ) * + , – . / : ; < = > @ [ ] ^ { }

The following character pairs are also special symbols.

(* (. *) .) .. // := <= >= <>

The left bracket—**[**—is equivalent to the character pair of left parenthesis and period—**(.**; the right bracket—**]**—is equivalent to the character pair of period and right parenthesis—**.)** . The left-parenthesis–plus–asterisk and asterisk–plus–right-parenthesis—**(* *)**—are equivalent to the left and right brace—**{ }**.

Notice that **!**, **"** (double quotation marks), **%**, **?**, ****, **_** (underscore), **|** (pipe), and **~** (tilde) are not special characters.

Identifiers

Identifiers denote constants, variables, fields, types, properties, procedures, functions, programs, units, libraries, and packages. An identifier can be of any length, but only the first 255 characters are significant. An identifier must begin with a letter or an underscore (_) and cannot contain spaces; letters, digits, and underscores are allowed after the first character. Reserved words cannot be used as identifiers.

Since Object Pascal is case-insensitive, an identifier like *CalculateValue* could be written in any of these ways:

```
CalculateValue
calculateValue
calculatevalue
CALCULATEVALUE
```

On Linux, the only identifiers for which case is important are unit names. Since unit names correspond to file names, inconsistencies in case can sometimes affect compilation.

Qualified identifiers

When you use an identifier that has been declared in more than one place, it is sometimes necessary to *qualify* the identifier. The syntax for a qualified identifier is

identifier$_1$.*identifier*$_2$

where *identifier*$_1$ qualifies *identifier*$_2$. For example, if two units each declare a variable called *CurrentValue*, you can specify that you want to access the *CurrentValue* in *Unit2* by writing

```
Unit2.CurrentValue
```

Qualifiers can be iterated. For example,

```
Form1.Button1.Click
```

calls the *Click* method in *Button1* of *Form1*.

If you don't qualify an identifier, its interpretation is determined by the rules of scope described in "Blocks and scope" on page 4-27.

Reserved words

The following reserved words cannot be redefined or used as identifiers.

Table 4.1 Reserved words

and	**downto**	**in**	**or**	**string**
array	**else**	**inherited**	**out**	**then**
as	**end**	**initialization**	**packed**	**threadvar**
asm	**except**	**inline**	**procedure**	**to**
begin	**exports**	**interface**	**program**	**try**
case	**file**	**is**	**property**	**type**
class	**finalization**	**label**	**raise**	**unit**
const	**finally**	**library**	**record**	**until**
constructor	**for**	**mod**	**repeat**	**uses**
destructor	**function**	**nil**	**resourcestring**	**var**
dispinterface	**goto**	**not**	**set**	**while**
div	**if**	**object**	**shl**	**with**
do	**implementation**	**of**	**shr**	**xor**

In addition to the words in Table 4.1, **private**, **protected**, **public**, **published**, and **automated** act as reserved words within object type declarations, but are otherwise treated as directives. The words **at** and **on** also have special meanings.

Directives

Directives are words that are sensitive in specific locations within source code. Directives have special meanings in Object Pascal, but, unlike reserved words, appear only in contexts where user-defined identifiers cannot occur. Hence—although it is inadvisable to do so—you can define an identifier that looks exactly like a directive.

Table 4.2 Directives

absolute	**dynamic**	**message**	**private**	**resident**

deprecated	**library**	**pascal**	**reintroduce**	**writeonly**
dispid	**local**	**platform**	**requires**	

Numerals

Integer and real constants can be represented in decimal notation as sequences of digits without commas or spaces, and prefixed with the **+** or **–** operator to indicate sign. Values default to positive (so that, for example, `67258` is equivalent to `+67258`) and must be within the range of the largest predefined real or integer type.

Numerals with decimal points or exponents denote reals, while other numerals denote integers. When the character *E* or *e* occurs within a real, it means “times ten to the power of”. For example, `7E-2` means 7×10^{-2}, and `12.25e+6` and `12.25e6` both mean 12.25×10^{6}.

The dollar-sign prefix indicates a hexadecimal numeral—for example, `$8F`. For the Integer type (16-bit integer), the sign of a hexadecimal is determined by the leftmost (most significant) bit of its binary representation. For all other types, you must use a prefixed + or - operator to indicate sign.

For more information about real and integer types, see Chapter 5, “Data types, variables, and constants”. For information about the data types of numerals, see “True constants” on page 5-39.

Labels

A label is a sequence of no more than four digits—that is, a numeral between 0 and 9999. Leading zeros are not significant. Identifiers can also function as labels.

Labels are used in **goto** statements. For more information about **goto** statements and labels, see “Goto statements” on page 4-18.

Character strings

A character string, also called a *string literal* or *string constant*, consists of a *quoted string*, a *control string*, or a combination of quoted and control strings. Separators can occur only within quoted strings.

A quoted string is a sequence of up to 255 characters from the extended ASCII character set, written on one line and enclosed by apostrophes. A quoted string with nothing between the apostrophes is a *null string*. Two sequential apostrophes in a quoted string denote a single character, namely an apostrophe. For example,

```
'BORLAND'          { BORLAND }
'You''ll see'      { You'll see }
''''               { ' }
''                 { null string }
' '                { a space }
```

A control string is a sequence of one or more *control characters*, each of which consists of the **#** symbol followed by an unsigned integer constant from 0 to 255 (decimal or hexadecimal) and denotes the corresponding ASCII character. The control string

```
#89#111#117
```

is equivalent to the quoted string

```
'You'
```

You can combine quoted strings with control strings to form larger character strings. For example, you could use

```
'Line 1'#13#10'Line 2'
```

to put a carriage-return–line-feed between “Line 1” and “Line 2”. However, you cannot concatenate two quoted strings in this way, since a pair of sequential apostrophes is interpreted as a single character. (To concatenate quoted strings, use the + operator described in “String operators” on page 4-9, or simply combine them into a single quoted string.)

A character string’s *length* is the number of characters in the string. A character string of any length is compatible with any string type and with the *PChar* type. A character string of length 1 is compatible with any character type, and, when extended syntax is enabled (**{$X+}**), a character string of length *n* ≥ 1 is compatible with zero-based arrays and packed arrays of *n* characters. For more information about string types, see Chapter 5, “Data types, variables, and constants”.

Comments and compiler directives

Comments are ignored by the compiler, except when they function as separators (delimiting adjacent tokens) or compiler directives.

There are several ways to construct comments:

```
{ Text between a left brace and a right brace constitutes a comment. }

(* Text between a left-parenthesis-plus-asterisk and an
   asterisk-plus-right-parenthesis also constitutes a comment. *)

// Any text between a double-slash and the end of the line constitutes a comment.
```

A comment that contains a dollar sign (**$**) immediately after the opening **{** or **(*** is a compiler directive. For example,

```
{$WARNINGS OFF}
```

tells the compiler not to generate warning messages.

Expressions

An *expression* is a construction that returns a value. For example,

```
X                    { variable }
@X                   { address of a variable }
15                   { integer constant }
InterestRate         { variable }
Calc(X,Y)            { function call }
X * Y                { product of X and Y }
Z / (1 - Z)          { quotient of Z and (1 - Z) }
X = 1.5              { Boolean }
C in Range1          { Boolean }
not Done             { negation of a Boolean }
```

```
['a','b','c']        { set }
Char(48)             { value typecast }
```

The simplest expressions are variables and constants (described in Chapter 5, "Data types, variables, and constants"). More complex expressions are built from simpler ones using *operators*, *function calls*, *set constructors*, *indexes*, and *typecasts*.

Operators

Operators behave like predefined functions that are part of the Object Pascal language. For example, the expression `(X + Y)` is built from the variables `X` and `Y`—called *operands*—with the **+** operator; when `X` and `Y` represent integers or reals, `(X + Y)` returns their sum. Operators include **@**, **not**, **^**, *****, **/**, **div**, **mod**, **and**, **shl**, **shr**, **as**, **+**, **–**, **or**, **xor**, **=**, **>**, **<**, **<>**, **<=**, **>=**, **in**, and **is**.

The operators **@**, **not**, and **^** are *unary* (taking one operand). All other operators are *binary* (taking two operands), except that **+** and **–** can function as either unary or binary. A unary operator always precedes its operand (for example, `-B`), except for **^**, which follows its operand (for example, `P^`). A binary operator is placed between its operands (for example, `A = 7`).

Some operators behave differently depending on the type of data passed to them. For example, **not** performs bitwise negation on an integer operand and logical negation on a Boolean operand. Such operators appear below under multiple categories.

Except for **^**, **is**, and **in**, all operators can take operands of type *Variant*. For details, see "Variant types" on page 5-30.

The sections that follow assume some familiarity with Object Pascal data types. For information about data types, see Chapter 5, "Data types, variables, and constants".

For information about operator precedence in complex expressions, see "Operator precedence rules" on page 4-12.

Arithmetic operators

Arithmetic operators, which take real or integer operands, include **+**, **–**, *****, **/**, **div**, and **mod**.

Table 4.3 Binary arithmetic operators

Operator	Operation	Operand types	Result type	Example
+	addition	integer, real	integer, real	`X + Y`
–	subtraction	integer, real	integer, real	`Result - 1`
*****	multiplication	integer, real	integer, real	`P * InterestRate`
/	real division	integer, real	real	`X / 2`
div	integer division	integer	integer	`Total` **div** `UnitSize`
mod	remainder	integer	integer	`Y` **mod** `6`

Table 4.4 Unary arithmetic operators

Operator	Operation	Operand type	Result type	Example
+	sign identity	integer, real	integer, real	`+7`
–	sign negation	integer, real	integer, real	`-X`

The following rules apply to arithmetic operators.

- The value of *x*/*y* is of type *Extended*, regardless of the types of *x* and *y*. For other arithmetic operators, the result is of type *Extended* whenever at least one operand is a real; otherwise, the result is of type *Int64* when at least one operand is of type *Int64*; otherwise, the result is of type *Integer*. If an operand's type is a subrange of an integer type, it is treated as if it were of the integer type.
- The value of *x* **div** *y* is the value of *x*/*y* rounded in the direction of zero to the nearest integer.
- The **mod** operator returns the remainder obtained by dividing its operands. In other words, *x* **mod** *y* = *x* – (*x* **div** *y*) * *y*.
- A runtime error occurs when *y* is zero in an expression of the form *x*/*y*, *x* **div** *y*, or *x* **mod** *y*.

Boolean operators

The Boolean operators **not**, **and**, **or**, and **xor** take operands of any Boolean type and return a value of type *Boolean*.

Table 4.5 Boolean operators

Operator	Operation	Operand types	Result type	Example
not	negation	Boolean	*Boolean*	**not** (C **in** MySet)
and	conjunction	Boolean	*Boolean*	Done **and** (Total > 0)
or	disjunction	Boolean	*Boolean*	A **or** B
xor	exclusive disjunction	Boolean	*Boolean*	A **xor** B

These operations are governed by standard rules of Boolean logic. For example, an expression of the form *x* **and** *y* is *True* if and only if both *x* and *y* are *True*.

Complete versus short-circuit Boolean evaluation

The compiler supports two modes of evaluation for the **and** and **or** operators: complete evaluation and short-circuit (partial) evaluation. *Complete evaluation* means that each conjunct or disjunct is evaluated, even when the result of the entire expression is already determined. *Short-circuit evaluation* means strict left-to-right evaluation that stops as soon as the result of the entire expression is determined. For example, if the expression `A and B` is evaluated under short-circuit mode when *A* is *False*, the compiler won't evaluate *B*; it knows that the entire expression is *False* as soon as it evaluates *A*.

Short-circuit evaluation is usually preferable because it guarantees minimum execution time and, in most cases, minimum code size. Complete evaluation is sometimes convenient when one operand is a function with side effects that alter the execution of the program.

Short-circuit evaluation also allows the use of constructions that might otherwise result in illegal runtime operations. For example, the following code iterates through the string *S*, up to the first comma.

```
while (I <= Length(S)) and (S[I] <> ',') do
begin
  ⋮
  Inc(I);
end;
```

In a case where *S* has no commas, the last iteration increments *I* to a value which is greater than the length of *S*. When the **while** condition is next tested, complete evaluation results in an attempt to read *S[I]*, which could cause a runtime error. Under short-circuit evaluation, in contrast, the second part of the **while** condition—`(S[I] <> ',')`—is not evaluated after the first part fails.

Use the **$B** compiler directive to control evaluation mode. The default state is **{$B–}**, which enables short-circuit evaluation. To enable complete evaluation locally, add the **{$B+}** directive to your code. You can also switch to complete evaluation on a project-wide basis by selecting Complete Boolean Evaluation in the Compiler Options dialog.

Note If either operand involves a variant, the compiler always performs complete evaluation (even in the **{$B–}** state).

Logical (bitwise) operators

The following logical operators perform bitwise manipulation on integer operands. For example, if the value stored in *X* (in binary) is 001101 and the value stored in *Y* is 100001, the statement

```
Z := X or Y;
```

assigns the value 101101 to *Z*.

Table 4.6 Logical (bitwise) operators

Operator	Operation	Operand types	Result type	Examples
not	bitwise negation	integer	integer	**not** X
and	bitwise and	integer	integer	X **and** Y
or	bitwise or	integer	integer	X **or** Y
xor	bitwise xor	integer	integer	X **xor** Y
shl	bitwise shift left	integer	integer	X **shl** 2
shr	bitwise shift right	integer	integer	Y **shr** I

The following rules apply to bitwise operators.

- The result of a **not** operation is of the same type as the operand.

- If the operands of an **and**, **or**, or **xor** operation are both integers, the result is of the predefined integer type with the smallest range that includes all possible values of both types.
- The operations *x* **shl** *y* and *x* **shr** *y* shift the value of *x* to the left or right by *y* bits, which is equivalent to multiplying or dividing *x* by 2^y; the result is of the same type as *x*. For example, if *N* stores the value 01101 (decimal 13), then `N shl 1` returns 11010 (decimal 26). Note that the value of y is interpreted modulo the size of the type of x. Thus for example, if x is an integer, x shl 40 is interpreted as x shl 8 because an integer is 32 bits and 40 mod 32 is 8.

String operators

The relational operators **=**, **<>**, **<**, **>**, **<=**, and **>=** all take string operands (see "Relational operators" on page 4-10). The **+** operator concatenates two strings.

Table 4.7 String operators

Operator	Operation	Operand types	Result type	Example
+	concatenation	string, packed string, character	string	`S + '. '`

The following rules apply to string concatenation.

- The operands for **+** can be strings, packed strings (packed arrays of type *Char*), or characters. However, if one operand is of type *WideChar*, the other operand must be a long string.
- The result of a **+** operation is compatible with any string type. However, if the operands are both short strings or characters, and their combined length is greater than 255, the result is truncated to the first 255 characters.

Pointer operators

The relational operators **<**, **>**, **<=**, and **>=** can take operands of type *PChar* (see "Relational operators" on page 4-10). The following operators also take pointers as operands. For more information about pointers, see "Pointers and pointer types" on page 5-25.

Table 4.8 Character-pointer operators

Operator	Operation	Operand types	Result type	Example
+	pointer addition	character pointer, integer	character pointer	`P + I`
-	pointer subtraction	character pointer, integer	character pointer, integer	`P - Q`
^	pointer dereference	pointer	base type of pointer	`P^`
=	equality	pointer	*Boolean*	`P = Q`
<>	inequality	pointer	*Boolean*	`P <> Q`

The **^** operator dereferences a pointer. Its operand can be a pointer of any type except the generic *Pointer*, which must be typecast before dereferencing.

P **=** *Q* is *True* just in case *P* and *Q* point to the same address; otherwise, *P* **<>** *Q* is *True*.

You can use the **+** and **–** operators to increment and decrement the offset of a character pointer. You can also use **–** to calculate the difference between the offsets of two character pointers. The following rules apply.

- If *I* is an integer and *P* is a character pointer, then *P* **+** *I* adds *I* to the address given by *P*; that is, it returns a pointer to the address *I* characters after *P*. (The expression *I* **+** *P* is equivalent to *P* **+** *I*.) *P* **–** *I* subtracts *I* from the address given by *P*; that is, it returns a pointer to the address *I* characters before *P*.
- If *P* and *Q* are both character pointers, then *P* **–** *Q* computes the difference between the address given by *P* (the higher address) and the address given by *Q* (the lower address); that is, it returns an integer denoting the number of characters between *P* and *Q*. *P* **+** *Q* is not defined.

Set operators

The following operators take sets as operands.

Table 4.9 Set operators

Operator	Operation	Operand types	Result type	Example
+	union	set	set	`Set1 + Set2`
–	difference	set	set	`S - T`
*	intersection	set	set	`S * T`
<=	subset	set	*Boolean*	`Q <= MySet`
>=	superset	set	*Boolean*	`S1 >= S2`
=	equality	set	*Boolean*	`S2 = MySet`
<>	inequality	set	*Boolean*	`MySet <> S1`
in	membership	ordinal, set	*Boolean*	`A` **in** `Set1`

The following rules apply to **+**, **–**, and *****.

- An ordinal *O* is in *X* **+** *Y* if and only if *O* is in *X* or *Y* (or both). *O* is in *X* **–** *Y* if and only if *O* is in *X* but not in *Y*. *O* is in *X* ***** *Y* if and only if *O* is in both *X* and *Y*.
- The result of a **+**, **–**, or ***** operation is of the type **set of** *A*..*B*, where *A* is the smallest ordinal value in the result set and *B* is the largest.

The following rules apply to **<=**, **>=**, **=**, **<>**, and **in**.

- *X* **<=** *Y* is *True* just in case every member of *X* is a member of *Y*; *Z* **>=** *W* is equivalent to *W* **<=** *Z*. *U* **=** *V* is *True* just in case *U* and *V* contain exactly the same members; otherwise, *U* **<>** *V* is *True*.
- For an ordinal *O* and a set *S*, *O* **in** *S* is *True* just in case *O* is a member of *S*.

Relational operators

Relational operators are used to compare two operands. The operators **=**, **<>**, **<=**, and **>=** also apply to sets (see “Set operators” on page 4-10); **=** and **<>** also apply to pointers (see “Pointer operators” on page 4-9).

Table 4.10 Relational operators

Operator	Operation	Operand types	Result type	Example
=	equality	simple, class, class reference, interface, string, packed string	*Boolean*	`I = Max`
<>	inequality	simple, class, class reference, interface, string, packed string	*Boolean*	`X <> Y`
<	less-than	simple, string, packed string, *PChar*	*Boolean*	`X < Y`
>	greater-than	simple, string, packed string, *PChar*	*Boolean*	`Len > 0`
<=	less-than-or-equal-to	simple, string, packed string, *PChar*	*Boolean*	`Cnt <= I`
>=	greater-than-or-equal-to	simple, string, packed string, *PChar*	*Boolean*	`I >= 1`

For most simple types, comparison is straightforward. For example, *I* = *J* is *True* just in case *I* and *J* have the same value, and *I* <> *J* is *True* otherwise. The following rules apply to relational operators.

- Operands must be of compatible types, except that a real and an integer can be compared.
- Strings are compared according to the ordering of the extended ASCII character set. Character types are treated as strings of length 1.
- Two packed strings must have the same number of components to be compared. When a packed string with *n* components is compared to a string, the packed string is treated as a string of length *n*.
- The operators <, >, <=, and >= apply to *PChar* operands only if the two pointers point within the same character array.
- The operators = and <> can take operands of class and class-reference types. With operands of a class type, = and <> are evaluated according the rules that apply to pointers: *C* = *D* is *True* just in case *C* and *D* point to the same instance object, and *C* <> *D* is *True* otherwise. With operands of a class-reference type, *C* = *D* is *True* just in case *C* and *D* denote the same class, and *C* <> *D* is *True* otherwise. For more information about classes, see Chapter 7, “Classes and objects”.

Class operators

The operators **as** and **is** take classes and instance objects as operands; **as** operates on interfaces as well. For more information, see Chapter 7, “Classes and objects” and Chapter 10, “Object interfaces”.

The relational operators = and <> also operate on classes. See “Relational operators” on page 4-10.

The @ operator

The @ operator returns the address of a variable, or of a function, procedure, or method; that is, @ constructs a pointer to its operand. For more information about pointers, see "Pointers and pointer types" on page 5-25. The following rules apply to @.

- If *X* is a variable, @*X* returns the address of *X*. (Special rules apply when *X* is a procedural variable; see "Procedural types in statements and expressions" on page 5-29.) The type of @*X* is *Pointer* if the default **{$T–}** compiler directive is in effect. In the **{$T+}** state, @*X* is of type **^***T*, where *T* is the type of *X*.
- If *F* is a routine (a function or procedure), @*F* returns *F*'s entry point. The type of @*F* is always *Pointer*.
- When @ is applied to a method defined in a class, the method identifier must be qualified with the class name. For example,

  ```
  @TMyClass.DoSomething
  ```

  points to the *DoSomething* method of *TMyClass*. For more information about classes and methods, see Chapter 7, "Classes and objects".

Operator precedence rules

In complex expressions, rules of precedence determine the order in which operations are performed.

Table 4.11 Precedence of operators

Operators	Precedence
@, **not**	first (highest)
*, /, **div**, **mod**, **and**, **shl**, **shr**, **as**	second
+, –, **or**, **xor**	third
=, <>, <, >, <=, >=, **in**, **is**	fourth (lowest)

An operator with higher precedence is evaluated before an operator with lower precedence, while operators of equal precedence associate to the left. Hence the expression

```
X + Y * Z
```

multiplies *Y* times *Z*, then adds *X* to the result; * is performed first, because is has a higher precedence than **+**. But

```
X - Y + Z
```

first subtracts *Y* from *X*, then adds *Z* to the result; **–** and **+** have the same precedence, so the operation on the left is performed first.

You can use parentheses to override these precedence rules. An expression within parentheses is evaluated first, then treated as a single operand. For example,

```
(X + Y) * Z
```

multiplies *Z* times the sum of *X* and *Y*.

Parentheses are sometimes needed in situations where, at first glance, they seem not to be. For example, consider the expression

```
X = Y or X = Z
```

The intended interpretation of this is obviously

```
(X = Y) or (X = Z)
```

Without parentheses, however, the compiler follows operator precedence rules and reads it as

```
(X = (Y or X)) = Z
```

—which results in a compilation error unless *Z* is Boolean.

Parentheses often make code easier to write and to read, even when they are, strictly speaking, superfluous. Thus the first example above could be written as

```
X + (Y * Z)
```

Here the parentheses are unnecessary (to the compiler), but they spare both programmer and reader from having to think about operator precedence.

Function calls

Because functions return a value, function calls are expressions. For example, if you've defined a function called *Calc* that takes two integer arguments and returns an integer, then the function call `Calc(24, 47)` is an integer expression. If *I* and *J* are integer variables, then `I + Calc(J, 8)` is also an integer expression. Examples of function calls include

```
Sum(A, 63)
Maximum(147, J)
Sin(X + Y)
Eof(F)
Volume(Radius, Height)
GetValue
TSomeObject.SomeMethod(I,J);
```

For more information about functions, see Chapter 6, "Procedures and functions".

Set constructors

A set constructor denotes a set-type value. For example,

```
[5, 6, 7, 8]
```

denotes the set whose members are 5, 6, 7, and 8. The set constructor

```
[ 5..8 ]
```

could also denote the same set.

The syntax for a set constructor is

[$item_1$, ..., $item_n$]

where each *item* is either an expression denoting an ordinal of the set's base type or a pair of such expressions with two dots (**..**) in between. When an *item* has the form *x*..*y*, it is shorthand for all the ordinals in the range from *x* to *y*, inclusive; but if *x* is greater than *y*, then *x*..*y* denotes nothing and **[***x*..*y***]** is the empty set. The set constructor `[ ]` denotes the empty set, while **[***x***]** denotes the set whose only member is the value of *x*.

Examples of set constructors:

```
[red, green, MyColor]
[1, 5, 10..K mod 12, 23]
['A'..'Z', 'a'..'z', Chr(Digit + 48)]
```

For more information about sets, see "Sets" on page 5-17.

Indexes

Strings, arrays, array properties, and pointers to strings or arrays can be indexed. For example, if *FileName* is a string variable, the expression `FileName[3]` returns the third character in the string denoted by *FileName*, while `FileName[I + 1]` returns the character immediately after the one indexed by *I*. For information about strings, see "String types" on page 5-10. For information about arrays and array properties, see "Arrays" on page 5-18 and "Array properties" on page 7-19.

Typecasts

It is sometimes useful to treat an expression as if it belonged to different type. A typecast allows you to do this by, in effect, temporarily changing an expression's type. For example, `Integer('A')` casts the character *A* as an integer.

The syntax for a typecast is

typeIdentifier(*expression*)

If the expression is a variable, the result is called a *variable typecast*; otherwise, the result is a *value typecast*. While their syntax is the same, different rules apply to the two kinds of typecast.

Value typecasts

In a value typecast, the type identifier and the cast expression must both be ordinal types or both be pointer types. Examples of value typecasts include

```
Integer('A')
Char(48)
Boolean(0)
Color(2)
Longint(@Buffer)
```

The resulting value is obtained by converting the expression in parentheses. This may involve truncation or extension if the size of the specified type differs from that of the expression. The expression's sign is always preserved.

The statement

```
I := Integer('A');
```

assigns the value of `Integer('A')`—that is, 65—to the variable *I*.

A value typecast cannot be followed by qualifiers and cannot appear on the left side of an assignment statement.

Variable typecasts

You can cast any variable to any type, provided their sizes are the same and you do not mix integers with reals. (To convert numeric types, rely on standard functions like *Int* and *Trunc*.) Examples of variable typecasts include

```
Char(I)
Boolean(Count)
TSomeDefinedType(MyVariable)
```

Variable typecasts can appear on either side of an assignment statement. Thus

```
var MyChar: char;
⋮
Shortint(MyChar) := 122;
```

assigns the character *z* (ASCII 122) to *MyChar*.

You can cast variables to a procedural type. For example, given the declarations

```
type Func = function(X: Integer): Integer;
var
  F: Func;
  P: Pointer;
  N: Integer;
```

you can make the following assignments.

```
F := Func(P);          { Assign procedural value in P to F }
Func(P) := F;          { Assign procedural value in F to P }
@F := P;               { Assign pointer value in P to F }
P := @F;               { Assign pointer value in F to P }
N := F(N);             { Call function via F }
N := Func(P)(N);       { Call function via P }
```

Variable typecasts can also be followed by qualifiers, as illustrated in the following example.

```
type
  TByteRec = record
    Lo, Hi: Byte;
  end;
  TWordRec = record
    Low, High: Word;
  end;
  PByte = ^Byte;
var
  B: Byte;
  W: Word;
  L: Longint;
  P: Pointer;
begin
  W := $1234;
  B := TByteRec(W).Lo;
  TByteRec(W).Hi := 0;
  L := $01234567;
  W := TWordRec(L).Low;
  B := TByteRec(TWordRec(L).Low).Hi;
  B := PByte(L)^;
end;
```

In this example, *TByteRec* is used to access the low- and high-order bytes of a word, and *TWordRec* to access the low- and high-order words of a long integer. You could call the predefined functions *Lo* and *Hi* for the same purpose, but a variable typecast has the advantage that it can be used on the left side of an assignment statement.

For information about typecasting pointers, see “Pointers and pointer types” on page 5-25. For information about casting class and interface types, see “The as operator” on page 7-25 and “Interface typecasts” on page 10-10.

Declarations and statements

Aside from the **uses** clause (and reserved words like **implementation** that demarcate parts of a unit), a program consists entirely of *declarations* and *statements*, which are organized into *blocks*.

Declarations

The names of variables, constants, types, fields, properties, procedures, functions, programs, units, libraries, and packages are called *identifiers*. (Numeric constants like `26057` are not identifiers.) Identifiers must be *declared* before you can use them; the only exceptions are a few predefined types, routines, and constants that the compiler understands automatically, the variable *Result* when it occurs inside a function block, and the variable *Self* when it occurs inside a method implementation.

A declaration defines an identifier and, where appropriate, allocates memory for it. For example,

```
var Size: Extended;
```

declares a variable called *Size* that holds an *Extended* (real) value, while

```
function DoThis(X, Y: string): Integer;
```

declares a function called *DoThis* that takes two strings as arguments and returns an integer. Each declaration ends with a semicolon. When you declare several variables, constants, types, or labels at the same time, you need only write the appropriate reserved word once:

```
var
  Size: Extended;
  Quantity: Integer;
  Description: string;
```

The syntax and placement of a declaration depend on the kind of identifier you are defining. In general, declarations can occur only at the beginning of a block or at the beginning of the interface or implementation section of a unit (after the **uses** clause). Specific conventions for declaring variables, constants, types, functions, and so forth are explained in the chapters on those topics.

The "hint" directives **platform**, **deprecated**, and **library** may be appended to any declaration, except that units cannot be declared with **deprecated**. In the case of a procedure or function declaration, the hint directive should be separated from the rest of the declaration with a semicolon. Examples:

```
procedure SomeOldRoutine; stdcall; deprecated;

var VersionNumber: Real library;

type AppError = class(Exception)
  ⋮
end platform;
```

When source code is compiled in the **{$HINTS ON} {$WARNINGS ON}** state, each reference to an identifier declared with one of these directives generates an appropriate hint or warning. Use **platform** to mark items that are specific to a particular operating environment (such as Windows or Linux), **deprecated** to indicate that an item is obsolete or supported only for backward compatibility, and **library** to flag dependencies on a particular library or component framework (such as VCL or CLX).

Statements

Statements define algorithmic actions within a program. Simple statements—like assignments and procedure calls—can combine to form loops, conditional statements, and other structured statements.

Multiple statements within a block, and in the initialization or finalization section of a unit, are separated by semicolons.

Simple statements

A simple statement doesn't contain any other statements. Simple statements include assignments, calls to procedures and functions, and **goto** jumps.

Assignment statements

An assignment statement has the form

variable := *expression*

where *variable* is any variable reference—including a variable, variable typecast, dereferenced pointer, or component of a structured variable—and *expression* is any assignment-compatible expression. (Within a function block, *variable* can be replaced with the name of the function being defined. See Chapter 6, "Procedures and functions".) The **:=** symbol is sometimes called the *assignment operator*.

An assignment statement replaces the current value of *variable* with the value of *expression*. For example,

```
I := 3;
```

assigns the value 3 to the variable *I*. The variable reference on the left side of the assignment can appear in the expression on the right. For example,

```
I := I + 1;
```

increments the value of *I*. Other assignment statements include

```
X := Y + Z;
Done := (I >= 1) and (I < 100);
Hue1 := [Blue, Succ(C)];
I := Sqr(J) - I  * K;
Shortint(MyChar) := 122;
TByteRec(W).Hi := 0;
MyString[I] := 'A';
SomeArray[I + 1] := P^;
TMyObject.SomeProperty := True;
```

Procedure and function calls

A procedure call consists of the name of a procedure (with or without qualifiers), followed by a parameter list (if required). Examples include

```
PrintHeading;
Transpose(A, N, M);
Find(Smith, William);
Writeln('Hello world!');
DoSomething();
Unit1.SomeProcedure;
TMyObject.SomeMethod(X,Y);
```

With extended syntax enabled (**{$X+}**), function calls, like calls to procedures, can be treated as statements in their own right:

```
MyFunction(X);
```

When you use a function call in this way, its return value is discarded.

For more information about procedures and functions, see Chapter 6, “Procedures and functions”.

Goto statements

A **goto** statement, which has the form

goto *label*

transfers program execution to the statement marked by the specified label. To mark a statement, you must first declare the label. Then precede the statement you want to mark with the label and a colon:

label: *statement*

Declare labels like this:

label *label*;

You can declare several labels at once:

```
label label1, ..., labeln;
```

A label can be any valid identifier or any numeral between 0 and 9999.

The label declaration, marked statement, and **goto** statement must belong to the same block. (See "Blocks and scope" on page 4-27.) Hence it is not possible to jump into or out of a procedure or function. Do not mark more than one statement in a block with the same label.

For example,

```
label StartHere;
⋮
StartHere: Beep;
goto StartHere;
```

creates an infinite loop that calls the *Beep* procedure repeatedly.

The **goto** statement is generally discouraged in structured programming. It is, however, sometimes used as a way of exiting from nested loops, as in the following example.

```
procedure FindFirstAnswer;
var X, Y, Z, Count: Integer;
label FoundAnAnswer;
begin
  Count := SomeConstant;
  for X := 1 to Count do
    for Y := 1 to Count do
      for Z := 1 to Count do
        if ... { some condition holds on X, Y, and Z } then
          goto FoundAnAnswer;

  ⋮ {code to execute if no answer is found }
  Exit;

  FoundAnAnswer:
    ⋮ { code to execute when an answer is found }
end;
```

Notice that we are using **goto** to jump *out* of a nested loop. Never jump *into* a loop or other structured statement, since this can have unpredictable effects.

Structured statements

Structured statements are built from other statements. Use a structured statement when you want to execute other statements sequentially, conditionally, or repeatedly.

- A compound or **with** statement simply executes a sequence of constituent statements.
- A conditional statement—that is, an **if** or **case** statement—executes at most one of its constituents, depending on specified criteria.

- Loop statements—including **repeat**, **while**, and **for** loops—execute a sequence of constituent statements repeatedly.
- A special group of statements—including **raise**, **try...except**, and **try...finally** constructions—create and handle *exceptions*. For information about exception generation and handling, see "Exceptions" on page 7-26.

Compound statements

A compound statement is a sequence of other (simple or structured) statements to be executed in the order in which they are written. The compound statement is bracketed by the reserved words **begin** and **end**, and its constituent statements are separated by semicolons. For example:

```
begin
  Z := X;
  X := Y;
  Y := Z;
end;
```

The last semicolon before **end** is optional. So we could have written this as

```
begin
  Z := X;
  X := Y;
  Y := Z
end;
```

Compound statements are essential in contexts where Object Pascal syntax requires a single statement. In addition to program, function, and procedure blocks, they occur within other structured statements, such as conditionals or loops. For example:

```
begin
  I := SomeConstant;
  while I > 0 do
  begin
    ⋮
    I := I - 1;
  end;
end;
```

You can write a compound statement that contains only a single constituent statement; like parentheses in a complex term, **begin** and **end** sometimes serve to disambiguate and to improve readability. You can also use an empty compound statement to create a block that does nothing:

```
begin
end;
```

With statements

A **with** statement is a shorthand for referencing the fields of a record or the fields, properties, and methods of an object. The syntax of a **with** statement is

with *obj* do *statement*

or

with obj_1, ..., obj_n do *statement* where *obj* is a variable reference denoting an object or record, and *statement* is any simple or structured statement. Within *statement*, you can refer to fields, properties, and methods of *obj* using their identifiers alone—without qualifiers.

For example, given the declarations

```
type TDate = record
  Day: Integer;
  Month: Integer;
  Year: Integer;
end;

var OrderDate: TDate;
```

you could write the following **with** statement.

```
with OrderDate do
  if Month = 12 then
  begin
    Month := 1;
    Year := Year + 1;
  end
  else
    Month := Month + 1;
```

This is equivalent to

```
if OrderDate.Month = 12 then
begin
  OrderDate.Month := 1;
  OrderDate.Year := OrderDate.Year + 1;
end
else
  OrderDate.Month := OrderDate.Month + 1;
```

If the interpretation of *obj* involves indexing arrays or dereferencing pointers, these actions are performed once, before *statement* is executed. This makes **with** statements efficient as well as concise. It also means that assignments to a variable within *statement* cannot affect the interpretation of *obj* during the current execution of the **with** statement.

Each variable reference or method name in a **with** statement is interpreted, if possible, as a member of the specified object or record. If there is another variable or method of the same name that you want to access from the **with** statement, you need to prepend it with a qualifier, as in the following example.

```
with OrderDate do
  begin
    Year := Unit1.Year
    ⋮
  end;
```

When multiple objects or records appear after **with**, the entire statement is treated like a series of nested **with** statements. Thus

with obj_1, obj_2, ..., obj_n do *statement* is equivalent to

```
with obj1 do
  with obj2 do
     ⋮
     with objn do
       statement
```

In this case, each variable reference or method name in *statement* is interpreted, if possible, as a member of obj_n; otherwise it is interpreted, if possible, as a member of obj_{n-1}; and so forth. The same rule applies to interpreting the *obj*s themselves, so that, for instance, if obj_n is a member of both obj_1 and obj_2, it is interpreted as $obj_2.obj_n$.

If statements

There are two forms of **if** statement: **if...then** and the **if...then...else**. The syntax of an **if...then** statement is

```
if expression then statement
```

where *expression* returns a Boolean value. If *expression* is *True*, then *statement* is executed; otherwise it is not. For example,

```
if J <> 0 then Result := I/J;
```

The syntax of an **if...then...else** statement is

```
if expression then statement1 else statement2
```

where *expression* returns a Boolean value. If *expression* is *True*, then $statement_1$ is executed; otherwise $statement_2$ is executed. For example,

```
if J = 0 then
  Exit
else
  Result := I/J;
```

The **then** and **else** clauses contain one statement each, but it can be a structured statement. For example,

```
if J <> 0 then
begin
  Result := I/J;
  Count := Count + 1;
end
else if Count = Last then
  Done := True
else
  Exit;
```

Notice that there is never a semicolon between the **then** clause and the word **else**. You can place a semicolon after an entire **if** statement to separate it from the next statement in its block, but the **then** and **else** clauses require nothing more than a space or carriage return between them. Placing a semicolon immediately before **else** (in an **if** statement) is a common programming error.

A special difficulty arises in connection with nested **if** statements. The problem arises because some **if** statements have **else** clauses while others do not, but the syntax for the two kinds of statement is otherwise the same. In a series of nested conditionals where there are fewer **else** clauses than **if** statements, it may not seem clear which **else** clauses are bound to which **if**s. Consider a statement of the form

if *expression*$_1$ then if *expression*$_2$ then *statement*$_1$ else *statement*$_2$;

There would appear to be two ways to parse this:

if *expression*$_1$ then [if *expression*$_2$ then *statement*$_1$ else *statement*$_2$];

if *expression*$_1$ then [if *expression*$_2$ then *statement*$_1$] else *statement*$_2$;

The compiler always parses in the first way. That is, in real code, the statement

```
if ... { expression1 } then
  if ... { expression2 } then
    ... { statement1 }
  else
    ... { statement2 } ;
```

is equivalent to

```
if ... { expression1 } then
begin
  if ... { expression2 } then
    ... { statement1 }
  else
    ... { statement2 }
end;
```

The rule is that nested conditionals are parsed starting from the innermost conditional, with each **else** bound to the nearest available **if** on its left. To force the compiler to read our example in the second way, you would have to write it explicitly as

```
if ... { expression1 } then
begin
  if ... { expression2 } then
    ... { statement1 }
end
else
  ... { statement2 } ;
```

Case statements

The **case** statement provides a readable alternative to complex nested **if** conditionals. A **case** statement has the form

case *selectorExpression* of

caseList$_1$: *statement*$_1$;

⋮

caseList$_n$: *statement*$_n$;

end

where *selectorExpression* is any expression of an ordinal type (string types are invalid) and each *caseList* is one of the following:

- A numeral, declared constant, or other expression that the compiler can evaluate without executing your program. It must be of an ordinal type compatible with *selectorExpression*. Thus `7`, `True`, `4 + 5 * 3`, `'A'`, and `Integer('A')` can all be used as *caseList*s, but variables and most function calls cannot. (A few built-in functions like *Hi* and *Lo* can occur in a *caseList*. See “Constant expressions” on page 5-41.)
- A subrange having the form *First..Last*, where *First* and *Last* both satisfy the criterion above and *First* is less than or equal to *Last*.
- A list having the form *item*$_1$, ..., *item*$_n$, where each *item* satisfies one of the criteria above.

Each value represented by a *caseList* must be unique in the **case** statement; subranges and lists cannot overlap. A **case** statement can have a final **else** clause:

```
case selectorExpression of
  caseList1: statement1;
  ⋮
  caseListn: statementn;
else
  statements;
end
```

where *statements* is a semicolon-delimited sequence of statements. When a **case** statement is executed, at most one of *statement*$_1$ ... *statement*$_n$ is executed. Whichever *caseList* has a value equal to that of *selectorExpression* determines the *statement* to be used. If none of the *caseList*s has the same value as *selectorExpression*, then the statements in the **else** clause (if there is one) are executed.

The **case** statement

```
case I of
  1..5: Caption := 'Low';
  6..9: Caption := 'High';
  0, 10..99: Caption := 'Out of range';
else
  Caption := '';
end;
```

is equivalent to the nested conditional

```
if I in [1..5] then
  Caption := 'Low'
  else if I in [6..10] then
    Caption := 'High'
    else if (I = 0) or (I in [10..99]) then
      Caption := 'Out of range'
      else
        Caption := '';
```

Other examples of **case** statements:

```
case MyColor of
  Red: X := 1;
  Green: X := 2;
  Blue: X := 3;
  Yellow, Orange, Black: X := 0;
```

```
end;

case Selection of
  Done: Form1.Close;
  Compute: CalculateTotal(UnitCost, Quantity);
else
  Beep;
end;
```

Control loops

Loops allow you to execute a sequence of statements repeatedly, using a control condition or variable to determine when the execution stops. Object Pascal has three kinds of control loop: **repeat** statements, **while** statements, and **for** statements.

You can use the standard *Break* and *Continue* procedures to control the flow of a **repeat**, **while**, or **for** statement. *Break* terminates the statement in which it occurs, while *Continue* begins executing the next iteration of the sequence. For more information about these procedures, see the online Help.

Repeat statements

The syntax of a **repeat** statement is

repeat *statement*$_1$; ...; *statement*$_n$; until *expression*

where *expression* returns a Boolean value. (The last semicolon before **until** is optional.) The **repeat** statement executes its sequence of constituent statements continually, testing *expression* after each iteration. When *expression* returns *True*, the **repeat** statement terminates. The sequence is always executed at least once because *expression* is not evaluated until after the first iteration.

Examples of **repeat** statements include

```
repeat
  K := I mod J;
  I := J;
  J := K;
until J = 0;

repeat
  Write('Enter a value (0..9): ');
  Readln(I);
until (I >= 0) and (I <= 9);
```

While statements

A **while** statement is similar to a **repeat** statement, except that the control condition is evaluated before the first execution of the statement sequence. Hence, if the condition is false, the statement sequence is never executed.

The syntax of a **while** statement is

while *expression* do *statement*

where *expression* returns a Boolean value and *statement* can be a compound statement. The **while** statement executes its constituent *statement* repeatedly, testing *expression* before each iteration. As long as *expression* returns *True*, execution continues.

Examples of **while** statements include

```
while Data[I] <> X do I := I + 1;

while I > 0 do
begin
  if Odd(I) then Z := Z * X;
  I := I div 2;
  X := Sqr(X);
end;

while not Eof(InputFile) do
begin
  Readln(InputFile, Line);
  Process(Line);
end;
```

For statements

A **for** statement, unlike a **repeat** or **while** statement, requires you to specify explicitly the number of iterations you want the loop to go through. The syntax of a **for** statement is

`for` *counter* `:=` *initialValue* `to` *finalValue* `do` *statement*

or

`for` *counter* `:=` *initialValue* `downto` *finalValue* `do` *statement*

where

- *counter* is a local variable (declared in the block containing the **for** statement) of ordinal type, without any qualifiers.
- *initialValue* and *finalValue* are expressions that are assignment-compatible with *counter*.
- *statement* is a simple or structured statement that does not change the value of *counter*.

The **for** statement assigns the value of *initialValue* to *counter*, then executes *statement* repeatedly, incrementing or decrementing *counter* after each iteration. (The **for...to** syntax increments *counter*, while the **for...downto** syntax decrements it.) When *counter* returns the same value as *finalValue*, *statement* is executed once more and the **for** statement terminates. In other words, *statement* is executed once for every value in the range from *initialValue* to *finalValue*. If *initialValue* is equal to *finalValue*, *statement* is executed exactly once. If *initialValue* is greater than *finalValue* in a **for...to** statement, or less than *finalValue* in a **for...downto** statement, then *statement* is never executed. After the **for** statement terminates, the value of *counter* is undefined.

For purposes of controlling execution of the loop, the expressions *initialValue* and *finalValue* are evaluated only once, before the loop begins. Hence the **for...to** statement is almost, but not quite, equivalent to this **while** construction:

```
begin
  counter := initialValue;
  while counter <= finalValue do
  begin
    statement;
    counter := Succ(counter);
  end;
end
```

The difference between this construction and the **for...to** statement is that the **while** loop re-evaluates *finalValue* before each iteration. This can result in noticeably slower performance if *finalValue* is a complex expression, and it also means that changes to the value of *finalValue* within *statement* can affect execution of the loop.

Examples of **for** statements:

```
for I := 2 to 63 do
  if Data[I] > Max then
    Max := Data[I];

for I := ListBox1.Items.Count - 1 downto 0 do
  ListBox1.Items[I] := UpperCase(ListBox1.Items[I]);

for I := 1 to 10 do
  for J := 1 to 10 do
  begin
    X := 0;
    for K := 1 to 10 do
      X := X + Mat1[I, K] * Mat2[K, J];
    Mat[I, J] := X;
  end;

for C := Red to Blue do Check(C);
```

Blocks and scope

Declarations and statements are organized into *blocks*, which define local namespaces (or *scopes*) for labels and identifiers. Blocks allow a single identifier, such as a variable name, to have different meanings in different parts of a program. Each block is part of the declaration of a program, function, or procedure; each program, function, or procedure declaration has one block.

Blocks

A block consists of a series of declarations followed by a compound statement. All declarations must occur together at the beginning of the block. So the form of a block is

```
declarations
begin
  statements
end
```

The *declarations* section can include, in any order, declarations for variables, constants (including resource strings), types, procedures, functions, and labels. In a program block, the *declarations* section can also include one or more **exports** clauses (see Chapter 9, "Libraries and packages").

For example, in a function declaration like

```
function UpperCase(const S: string): string;
var
  Ch: Char;
  L: Integer;
  Source, Dest: PChar;
begin
  ⋮
end;
```

the first line of the declaration is the function heading and all of the succeeding lines make up the block. *Ch*, *L*, *Source*, and *Dest* are local variables; their declarations apply only to the *UpperCase* function block and override—in this block only—any declarations of the same identifiers that may occur in the program block or in the interface or implementation section of a unit.

Scope

An identifier, such as a variable or function name, can be used only within the *scope* of its declaration. The location of a declaration determines its scope. An identifier declared within the declaration of a program, function, or procedure has a scope limited to the block in which it is declared. An identifier declared in the interface section of a unit has a scope that includes any other units or programs that use the unit where the declaration occurs. Identifiers with narrower scope—especially identifiers declared in functions and procedures—are sometimes called *local*, while identifiers with wider scope are called *global*.

The rules that determine identifier scope are summarized below.

If the identifier is declared in ...	its scope extends ...
the declaration of a program, function, or procedure	from the point where it is declared to the end of the current block, including all blocks enclosed within that scope.
the interface section of a unit	from the point where it is declared to the end of the unit, and to any other unit or program that uses that unit. (See Chapter 3, "Programs and units".)
the implementation section of a unit, but not within the block of any function or procedure	from the point where it is declared to the end of the unit. The identifier is available to any function or procedure in the unit, including the initialization and finalization sections, if present.
the definition of a record type (that is, the identifier is the name of a field in the record)	from the point of its declaration to the end of the record-type definition. (See "Records" on page 5-21.)
the definition of a class (that is, the identifier is the name of a data field property or method in the class)	from the point of its declaration to the end of the class-type definition, and also includes descendants of the class and the blocks of all methods in the class and its descendants. (See Chapter 7, "Classes and objects".)

Naming conflicts

When one block encloses another, the former is called the *outer block* and the latter the *inner block*. If an identifier declared in an outer block is redeclared in an inner block, the inner declaration overrides the outer one and determines the meaning of the identifier for the duration of the inner block. For example, if you declare a variable called *MaxValue* in the interface section of a unit, and then declare another variable with the same name in a function declaration within that unit, any unqualified occurrences of *MaxValue* in the function block are governed by the second, local declaration. Similarly, a function declared within another function creates a new, inner scope in which identifiers used by the outer function can be redeclared locally.

The use of multiple units further complicates the definition of scope. Each unit listed in a **uses** clause imposes a new scope that encloses the remaining units used and the program or unit containing the **uses** clause. The first unit in a **uses** clause represents the outermost scope and each succeeding unit represents a new scope inside the previous one. If two or more units declare the same identifier in their interface sections, an unqualified reference to the identifier selects the declaration in the innermost scope—that is, in the unit where the reference itself occurs, or, if that unit doesn't declare the identifier, in the last unit in the **uses** clause that does declare the identifier.

The *System* unit is used automatically by every program or unit. The declarations in *System*, along with the predefined types, routines, and constants that the compiler understands automatically, always have the outermost scope.

You can override these rules of scope and by-pass an inner declaration by using a qualified identifier (see "Qualified identifiers" on page 4-2) or a **with** statement (see "With statements" on page 4-20).

Chapter

Data types, variables, and constants

A *type* is essentially a name for a kind of data. When you declare a variable you must specify its type, which determines the set of values the variable can hold and the operations that can be performed on it. Every expression returns data of a particular type, as does every function. Most functions and procedures require parameters of specific types.

Object Pascal is a “strongly typed” language, which means that it distinguishes a variety of data types and does not always allow you to substitute one type for another. This is usually beneficial because it lets the compiler treat data intelligently and validate your code more thoroughly, preventing hard-to-diagnose runtime errors. When you need greater flexibility, however, there are mechanisms to circumvent strong typing. These include *typecasting* (see “Typecasts” on page 4-14), *pointers* (see “Pointers and pointer types” on page 5-25), *variants* (see “Variant types” on page 5-30), *variant parts* in records (see “Variant parts in records” on page 5-22), and *absolute addressing* of variables (see “Absolute addresses” on page 5-38).

About types

There are several ways to categorize Object Pascal data types:

- Some types are *predefined* (or *built-in*); the compiler recognizes these automatically, without the need for a declaration. Almost all of the types documented in this language reference are predefined. Other types are created by declaration; these include user-defined types and the types defined in the product libraries.
- Types can be classified as either *fundamental* or *generic*. The range and format of a fundamental type is the same in all implementations of Object Pascal, regardless of the underlying CPU and operating system. The range and format of a generic type is platform-specific and could vary across different implementations. Most predefined types are fundamental, but a handful of integer, character, string, and pointer types are generic. It’s a good idea to use generic types when possible, since they provide optimal performance and portability. However, changes in storage

format from one implementation of a generic type to the next could cause compatibility problems—for example, if you are streaming data to a file.

- Types can be classified as *simple*, *string*, *structured*, *pointer*, *procedural*, or *variant*. In addition, type identifiers themselves can be regarded as belonging to a special "type" because they can be passed as parameters to certain functions (such as *High*, *Low*, and *SizeOf*).

The outline below shows the taxonomy of Object Pascal data types.

- **simple**
  - ordinal
    - integer
    - character
    - Boolean
    - enumerated
    - subrange
  - real
- **string**
- **structured**
  - set
  - array
  - record
  - file
  - class
  - class reference
  - interface
- **pointer**
- **procedural**
- **variant**
- **type identifier**

The standard function *SizeOf* operates on all variables and type identifiers. It returns an integer representing the amount of memory (in bytes) used to store data of the specified type. For example, `SizeOf(Longint)` returns 4, since a *Longint* variable uses four bytes of memory.

Type declarations are illustrated in the sections that follow. For general information about type declarations, see "Declaring types" on page 5-36.

Simple types

Simple types, which include *ordinal* types and *real* types, define ordered sets of values.

Ordinal types

Ordinal types include *integer*, *character*, *Boolean*, *enumerated*, and *subrange* types. An ordinal type defines an ordered set of values in which each value except the first has a unique *predecessor* and each value except the last has a unique *successor*. Further, each value has an *ordinality* which determines the ordering of the type. In most cases, if a value has ordinality *n*, its predecessor has ordinality *n*–1 and its successor has ordinality *n*+1.

- For integer types, the ordinality of a value is the value itself.
- Subrange types maintain the ordinalities of their base types.
- For other ordinal types, by default the first value has ordinality 0, the next value has ordinality 1, and so forth. The declaration of an enumerated type can explicitly override this default.

Several predefined functions operate on ordinal values and type identifiers. The most important of them are summarized below.

Function	Parameter	Return value	Remarks
Ord	ordinal expression	ordinality of expression's value	Does not take *Int64* arguments.
Pred	ordinal expression	predecessor of expression's value	Do not use on properties that have a **write** procedure.
Succ	ordinal expression	successor of expression's value	Do not use on properties that have a **write** procedure.
High	ordinal type identifier or variable of ordinal type	highest value in type	Also operates on short-string types and arrays.
Low	ordinal type identifier or variable of ordinal type	lowest value in type	Also operates on short-string types and arrays.

For example, `High(Byte)` returns 255 because the highest value of type *Byte* is 255, and `Succ(2)` returns 3 because 3 is the successor of 2.

The standard procedures *Inc* and *Dec* increment and decrement the value of an ordinal variable. For example, `Inc(I)` is equivalent to `I := Succ(I)` and, if *I* is an integer variable, to `I := I + 1`.

Integer types

An integer type represents a subset of the whole numbers. The generic integer types are *Integer* and *Cardinal*; use these whenever possible, since they result in the best performance for the underlying CPU and operating system. The table below gives their ranges and storage formats for the current 32-bit Object Pascal compiler.

Table 5.1 Generic integer types for 32-bit implementations of Object Pascal

Type	Range	Format
Integer	–2147483648..2147483647	signed 32-bit
Cardinal	0..4294967295	unsigned 32-bit

Fundamental integer types include *Shortint*, *Smallint*, *Longint*, *Int64*, *Byte*, *Word*, and *Longword*.

Table 5.2 Fundamental integer types

Type	Range	Format
Shortint	–128..127	signed 8-bit
Smallint	–32768..32767	signed 16-bit
Longint	–2147483648..2147483647	signed 32-bit
Int64	$-2^{63}..2^{63}-1$	signed 64-bit
Byte	0..255	unsigned 8-bit
Word	0..65535	unsigned 16-bit
Longword	0..4294967295	unsigned 32-bit

In general, arithmetic operations on integers return a value of type *Integer*—which, in its current implementation, is equivalent to the 32-bit *Longint*. Operations return a value of type *Int64* only when performed on an *Int64* operand. Hence the following code produces incorrect results.

```
var
  I: Integer;
  J: Int64;
  ⋮
I := High(Integer);
J := I + 1;
```

To get an *Int64* return value in this situation, cast *I* as *Int64*:

```
 ⋮
J := Int64(I) + 1;
```

For more information, see “Arithmetic operators” on page 4-6.

Note Most standard routines that take integer arguments truncate *Int64* values to 32 bits. However, the *High*, *Low*, *Succ*, *Pred*, *Inc*, *Dec*, *IntToStr*, and *IntToHex* routines fully support *Int64* arguments. Also, the *Round*, *Trunc*, *StrToInt64*, and *StrToInt64Def* functions return *Int64* values. A few routines—including *Ord*—cannot take *Int64* values at all.

When you increment the last value or decrement the first value of an integer type, the result wraps around the beginning or end of the range. For example, the *Shortint* type has the range –128..127; hence, after execution of the code

```
var I: Shortint;
 ⋮
I := High(Shortint);
I := I + 1;
```

the value of *I* is –128. If compiler range-checking is enabled, however, this code generates a runtime error.

Character types

The fundamental character types are *AnsiChar* and *WideChar*. *AnsiChar* values are byte-sized (8-bit) characters ordered according to the locale character set which is possibly multibyte. *AnsiChar* was originally modeled after the ANSI character set (thus its name) but has now been broadened to refer to the current locale character set.

WideChar characters use more than one byte to represent every character. In the current implementations, *WideChar* is word-sized (16-bit) characters ordered according to the Unicode character set (note that it could be longer in future implementations). The first 256 Unicode characters correspond to the ANSI characters.

The generic character type is *Char*, which is equivalent to *AnsiChar*. Because the implementation of *Char* is subject to change, it's a good idea to use the standard function *SizeOf* rather than a hard-coded constant when writing programs that may need to handle characters of different sizes.

A string constant of length 1, such as `'A'`, can denote a character value. The predefined function *Chr* returns the character value for any integer in the range of *AnsiChar* or *WideChar*; for example, `Chr(65)` returns the letter *A*.

Character values, like integers, wrap around when decremented or incremented past the beginning or end of their range (unless range-checking is enabled). For example, after execution of the code

```
var
  Letter: Char;
  I: Integer;
begin
  Letter := High(Letter);
  for I := 1 to 66 do
    Inc(Letter);
end;
```

Letter has the value *A* (ASCII 65).

For more information about Unicode characters, see "About extended character sets" on page 5-13 and "Working with null-terminated strings" on page 5-13.

Boolean types

The four predefined Boolean types are *Boolean*, *ByteBool*, *WordBool*, and *LongBool*. *Boolean* is the preferred type. The others exist to provide compatibility with other languages and operating system libraries.

A *Boolean* variable occupies one byte of memory, a *ByteBool* variable also occupies one byte, a *WordBool* variable occupies two bytes (one word), and a *LongBool* variable occupies four bytes (two words).

Boolean values are denoted by the predefined constants *True* and *False*. The following relationships hold.

Boolean	**ByteBool, WordBool, LongBool**
False < *True*	*False* <> *True*
Ord(*False*) = 0	*Ord*(*False*) = 0
Ord(*True*) = 1	*Ord*(*True*) <> 0
Succ(*False*) = *True*	*Succ*(*False*) = *True*
Pred(*True*) = *False*	*Pred*(*False*) = *True*

A value of type *ByteBool*, *LongBool*, or *WordBool* is considered *True* when its ordinality is nonzero. If such a value appears in a context where a *Boolean* is expected, the compiler automatically converts any value of nonzero ordinality to *True*.

The remarks above refer to the ordinality of Boolean values—not to the values themselves. In Object Pascal, Boolean expressions cannot be equated with integers or reals. Hence, if *X* is an integer variable, the statement

```
if X then ...;
```

generates a compilation error. Casting the variable to a Boolean type is unreliable, but each of the following alternatives will work.

```
if X <> 0 then ...;       { use longer expression that returns Boolean value }

var OK: Boolean           { use Boolean variable }
 ⋮
if X <> 0 then OK := True;
if OK then ...;
```

Enumerated types

An enumerated type defines an ordered set of values by simply listing identifiers that denote these values. The values have no inherent meaning. To declare an enumerated type, use the syntax

type *typeName* = (*val*$_1$, ..., *val*$_n$)

where *typeName* and each *val* are valid identifiers. For example, the declaration

```
type Suit = (Club, Diamond, Heart, Spade);
```

defines an enumerated type called *Suit* whose possible values are *Club*, *Diamond*, *Heart*, and *Spade*, where `Ord(Club)` returns 0, `Ord(Diamond)` returns 1, and so forth.

When you declare an enumerated type, you are declaring each *val* to be a constant of type *typeName*. If the *val* identifiers are used for another purpose within the same scope, naming conflicts occur. For example, suppose you declare the type

```
type TSound = (Click, Clack, Clock);
```

Unfortunately, *Click* is also the name of a method defined for *TControl* and all of the objects in the VCL and/or CLX that descend from it. So if you're writing an application and you create an event handler like

```
procedure TForm1.DBGrid1Enter(Sender: TObject);
var Thing: TSound;
begin
  ⋮
  Thing := Click;
  ⋮
end;
```

you'll get a compilation error; the compiler interprets *Click* within the scope of the procedure as a reference to *TForm*'s *Click* method. You can work around this by qualifying the identifier; thus, if *TSound* is declared in *MyUnit*, you would use

```
Thing := MyUnit.Click;
```

A better solution, however, is to choose constant names that are not likely to conflict with other identifiers. Examples:

```
type
  TSound = (tsClick, tsClack, tsClock);
  TMyColor = (mcRed, mcBlue, mcGreen, mcYellow, mcOrange);
  Answer = (ansYes, ansNo, ansMaybe);
```

You can use the (*val*$_1$, ..., *val*$_n$) construction directly in variable declarations, as if it were a type name:

```
var MyCard: (Club, Diamond, Heart, Spade);
```

But if you declare *MyCard* this way, you can't declare another variable within the same scope using these constant identifiers. Thus

```
var Card1: (Club, Diamond, Heart, Spade);
var Card2: (Club, Diamond, Heart, Spade);
```

generates a compilation error. But

```
var Card1, Card2: (Club, Diamond, Heart, Spade);
```

compiles cleanly, as does

```
type Suit = (Club, Diamond, Heart, Spade);
var
  Card1: Suit;
  Card2: Suit;
```

Enumerated types with explicitly assigned ordinality

By default, the ordinalities of enumerated values start from 0 and follow the sequence in which their identifiers are listed in the type declaration. You can override this by explicitly assigning ordinalities to some or all of the values in the declaration. To assign an ordinality to a value, follow its identifier with = *constantExpression*, where *constantExpression* is a constant expression that evaluates to an integer. (See "Constant expressions" on page 5-41) For example,

```
type Size = (Small = 5, Medium = 10, Large = Small + Medium);
```

defines a type called *Size* whose possible values include *Small*, *Medium*, and *Large*, where `Ord(Small)` returns 5, `Ord(Medium)` returns 10, and `Ord(Large)` returns 15.

An enumerated type is, in effect, a subrange whose lowest and highest values correspond to the lowest and highest ordinalities of the constants in the declaration.

In the example above, the *Size* type has 11 possible values whose ordinalities range from 5 to 15. (Hence the type `array[Size] of Char` represents an array of 11 characters.) Only three of these values have names, but the others are accessible through typecasts and through routines such as *Pred*, *Succ*, *Inc*, and *Dec*. In the following example, “anonymous” values in the range of *Size* are assigned to the variable *X*.

```
var X: Size;
X := Small;    // Ord(X) = 5
X := Size(6);  // Ord(X) = 6
Inc(X);        // Ord(X) = 7
```

Any value that isn’t explicitly assigned an ordinality has ordinality one greater than that of the previous value in the list. If the first value isn’t assigned an ordinality, its ordinality is 0. Hence, given the declaration

```
type SomeEnum = (e1, e2, e3 = 1);
```

SomeEnum has only two possible values: `Ord(e1)` returns 0, `Ord(e2)` returns 1, and `Ord(e3)` also returns 1; because *e2* and *e3* have the same ordinality, they represent the same value.

Subrange types

A subrange type represents a subset of the values in another ordinal type (called the *base type*). Any construction of the form *Low..High*, where *Low* and *High* are constant expressions of the same ordinal type and *Low* is less than *High*, identifies a subrange type that includes all values between *Low* and *High*. For example, if you declare the enumerated type

```
type TColors = (Red, Blue, Green, Yellow, Orange, Purple, White, Black);
```

you can then define a subrange type like

```
type TMyColors = Green..White;
```

Here *TMyColors* includes the values *Green*, *Yellow*, *Orange*, *Purple*, and *White*.

You can use numeric constants and characters (string constants of length 1) to define subrange types:

```
type
  SomeNumbers = -128..127;
  Caps = 'A'..'Z';
```

When you use numeric or character constants to define a subrange, the base type is the smallest integer or character type that contains the specified range.

The *Low..High* construction itself functions as a type name, so you can use it directly in variable declarations. For example,

```
var SomeNum: 1..500;
```

declares an integer variable whose value can be anywhere in the range from 1 to 500.

The ordinality of each value in a subrange is preserved from the base type. (In the first example above, if *Color* is a variable that holds the value *Green*, `Ord(Color)` returns 2 regardless of whether *Color* is of type *TColors* or *TMyColors*.) Values do not wrap around the beginning or end of a subrange, even if the base is an integer or character type; incrementing or decrementing past the boundary of a subrange simply converts the value to the base type. Hence, while

```
type Percentile = 0..99;
var I: Percentile;
⋮
I := 100;
```

produces an error,

```
⋮
I := 99;
Inc(I);
```

assigns the value 100 to *I* (unless compiler range-checking is enabled).

The use of constant expressions in subrange definitions introduces a syntactic difficulty. In any type declaration, when the first meaningful character after **=** is a left parenthesis, the compiler assumes that an enumerated type is being defined. Hence the code

```
const
  X = 50;
  Y = 10;
type
  Scale = (X - Y) * 2..(X + Y) * 2;
```

produces an error. Work around this problem by rewriting the type declaration to avoid the leading parenthesis:

```
type
  Scale = 2 * (X - Y)..(X + Y) * 2;
```

Real types

A real type defines a set of numbers that can be represented with floating-point notation. The table below gives the ranges and storage formats for the fundamental real types.

Table 5.3 Fundamental real types

Type	Range	Significant digits	Size in bytes
Real48	2.9 x 10^{-39} .. 1.7 x 10^{38}	11–12	6
Single	1.5 x 10^{-45} .. 3.4 x 10^{38}	7–8	4
Double	5.0 x 10^{-324} .. 1.7 x 10^{308}	15–16	8
Extended	3.6 x 10^{-4951} .. 1.1 x 10^{4932}	19–20	10
Comp	$-2^{63}+1$ .. $2^{63}-1$	19–20	8
Currency	–922337203685477.5808.. 922337203685477.5807	19–20	8

The generic type *Real*, in its current implementation, is equivalent to *Double*.

Table 5.4 Generic real types

Type	Range	Significant digits	Size in bytes
Real	5.0×10^{-324} .. 1.7×10^{308}	15–16	8

Note The six-byte *Real48* type was called *Real* in earlier versions of Object Pascal. If you are recompiling code that uses the older, six-byte *Real* type, you may want to change it to *Real48*. You can also use the **{$REALCOMPATIBILITY ON}** compiler directive to turn *Real* back into the six-byte type.

The following remarks apply to fundamental real types.

- *Real48* is maintained for backward compatibility. Since its storage format is not native to the Intel CPU family, it results in slower performance than other floating-point types.
- *Extended* offers greater precision than other real types but is less portable. Be careful using *Extended* if you are creating data files to share across platforms.
- The *Comp* (computational) type is native to the Intel CPU and represents a 64-bit integer. It is classified as a real, however, because it does not behave like an ordinal type. (For example, you cannot increment or decrement a *Comp* value.) *Comp* is maintained for backward compatibility only. Use the *Int64* type for better performance.
- *Currency* is a fixed-point data type that minimizes rounding errors in monetary calculations. It is stored as a scaled 64-bit integer with the four least-significant digits implicitly representing decimal places. When mixed with other real types in assignments and expressions, *Currency* values are automatically divided or multiplied by 10000.

String types

A string represents a sequence of characters. Object Pascal supports the following predefined string types.

Table 5.5 String types

Type	Maximum length	Memory required	Used for
ShortString	255 characters	2 to 256 bytes	backward compatibility
AnsiString	~2^{31} characters	4 bytes to 2GB	8-bit (ANSI) characters
WideString	~2^{30} characters	4 bytes to 2GB	Unicode characters; multiuser servers and multi-language applications

AnsiString, sometimes called the *long string*, is the preferred type for most purposes.

String types can be mixed in assignments and expressions; the compiler automatically performs required conversions. But strings passed by reference to a function or procedure (as **var** and **out** parameters) must be of the appropriate type. Strings can be explicitly cast to a different string type (see “Typecasts” on page 4-14).

The reserved word **string** functions like a generic type identifier. For example,

```
var S: string;
```

creates a variable *S* that holds a string. In the default **{$H+}** state, the compiler interprets **string** (when it appears without a bracketed number after it) as *AnsiString*. Use the **{$H–}** directive to turn **string** into *ShortString*.

The standard function *Length* returns the number of characters in a string. The *SetLength* procedure adjusts the length of a string. See the online Help for details.

Comparison of strings is defined by the ordering of the characters in corresponding positions. Between strings of unequal length, each character in the longer string without a corresponding character in the shorter string takes on a greater-than value. For example, “AB” is greater than “A”; that is, `'AB' > 'A'` returns *True*. Zero-length strings hold the lowest values.

You can index a string variable just as you would an array. If *S* is a string variable and *i* an integer expression, `S[i]` represents the *i*th character—or, strictly speaking, the *i*th byte—in *S*. For a *ShortString* or *AnsiString*, `S[i]` is of type *AnsiChar*; for a *WideString*, `S[i]` is of type *WideChar*. The statement `MyString[2] := 'A';` assigns the value *A* to the second character of *MyString*. The following code uses the standard *UpCase* function to convert *MyString* to uppercase.

```
var I: Integer;
begin
  I := Length(MyString);
  while I > 0 do
  begin
    MyString[I] := UpCase(MyString[I]);
    I := I - 1;
  end;
end;
```

Be careful indexing strings in this way, since overwriting the end of a string can cause access violations. Also, avoid passing long-string indexes as **var** parameters, because this results in inefficient code.

You can assign the value of a string constant—or any other expression that returns a string—to a variable. The length of the string changes dynamically when the assignment is made. Examples:

```
MyString := 'Hello world!';
MyString := 'Hello ' + 'world';
MyString := MyString + '!';
MyString := ' ';             { space }
MyString := '';              { empty string }
```

For more information, see “Character strings” on page 4-4 and “String operators” on page 4-9.

Short strings

A *ShortString* is 0 to 255 characters long. While the length of a *ShortString* can change dynamically, its memory is a statically allocated 256 bytes; the first byte stores the length of the string, and the remaining 255 bytes are available for characters. If *S* is a *ShortString* variable, `Ord(S[0])`, like `Length(S)`, returns the length of *S*; assigning a value to `S[0]`, like calling *SetLength*, changes the length of *S*. *ShortString* uses 8-bit ANSI characters and is maintained for backward compatibility only.

Object Pascal supports short-string types—in effect, subtypes of *ShortString*—whose maximum length is anywhere from 0 to 255 characters. These are denoted by a bracketed numeral appended to the reserved word **string**. For example,

```
var MyString: string[100];
```

creates a variable called *MyString* whose maximum length is 100 characters. This is equivalent to the declarations

```
type CString = string[100];
var MyString: CString;
```

Variables declared in this way allocate only as much memory as the type requires—that is, the specified maximum length plus one byte. In our example, *MyString* uses 101 bytes, as compared to 256 bytes for a variable of the predefined *ShortString* type.

When you assign a value to a short-string variable, the string is truncated if it exceeds the maximum length for the type.

The standard functions *High* and *Low* operate on short-string type identifiers and variables. *High* returns the maximum length of the short-string type, while *Low* returns zero.

Long strings

AnsiString, also called a *long string*, represents a dynamically allocated string whose maximum length is limited only by available memory. It uses 8-bit ANSI characters.

A long-string variable is a pointer occupying four bytes of memory. When the variable is empty—that is, when it contains a zero-length string—the pointer is **nil** and the string uses no additional storage. When the variable is nonempty, it points to a dynamically allocated block of memory that contains the string value, a 32-bit length indicator, and a 32-bit reference count. This memory is allocated on the heap, but its management is entirely automatic and requires no user code.

Because long-string variables are pointers, two or more of them can reference the same value without consuming additional memory. The compiler exploits this to conserve resources and execute assignments faster. Whenever a long-string variable is destroyed or assigned a new value, the reference count of the old string (the variable's previous value) is decremented and the reference count of the new value (if there is one) is incremented; if the reference count of a string reaches zero, its memory is deallocated. This process is called *reference-counting*. When indexing is used to change the value of a single character in a string, a copy of the string is made if—but only if—its reference count is greater than one. This is called *copy-on-write* semantics.

WideString

The *WideString* type represents a dynamically allocated string of 16-bit Unicode characters. In most respects it is similar to *AnsiString*.

On Win32, *WideString* is compatible with the COM *BSTR* type. Borland development tools have support features that convert *AnsiString* values to *WideString*, but you may need to explicitly cast or convert your strings to *WideString*.

About extended character sets

Windows and Linux both support *single-byte* and *multibyte* character sets as well as *Unicode*. With a single-byte character set (SBCS), each byte in a string represents one character. The ANSI character set used by many Western operating systems is a single-byte character set.

In a multibyte character set (MBCS), some characters are represented by one byte and others by more than one byte. The first byte of a multibyte character is called the *lead byte*. In general, the lower 128 characters of a multibyte character set map to the 7-bit ASCII characters, and any byte whose ordinal value is greater than 127 is the lead byte of a multibyte character. Only single-byte characters can contain the null value (#0). Multibyte character sets—especially double-byte character sets (DBCS)—are widely used for Asian languages, while the UTF-8 character set used by Linux is a multibyte encoding of Unicode.

In the Unicode character set, each character is represented by two bytes. Thus a Unicode string is a sequence not of individual bytes but of two-byte words. Unicode characters and strings are also called *wide characters* and *wide character strings*. The first 256 Unicode characters map to the ANSI character set. The Windows operating system supports Unicode (UCS-2). The Linux operating system supports UCS-4, a superset of UCS-2. Delphi/Kylix supports UCS-2 on both platforms.

Object Pascal supports single-byte and multibyte characters and strings through the *Char*, *PChar*, *AnsiChar*, *PAnsiChar*, and *AnsiString* types. Indexing of multibyte strings is not reliable, since `S[i]` represents the *i*th byte (not necessarily the *i*th character) in *S*. However, the standard string-handling functions have multibyte-enabled counterparts that also implement locale-specific ordering for characters. (Names of multibyte functions usually start with *Ansi-*. For example, the multibyte version of *StrPos* is *AnsiStrPos*.) Multibyte character support is operating-system dependent and based on the current locale.

Object Pascal supports Unicode characters and strings through the *WideChar*, *PWideChar*, and *WideString* types.

Working with null-terminated strings

Many programming languages, including C and C++, lack a dedicated string data type. These languages, and environments that are built with them, rely on *null-terminated* strings. A null-terminated string is a zero-based array of characters that ends with NULL (#0); since the array has no length indicator, the first NULL character marks the end of the string. You can use Object Pascal constructions and special routines in the *SysUtils* unit (see Chapter 8, "Standard routines and I/O") to handle null-terminated strings when you need to share data with systems that use them.

For example, the following type declarations could be used to store null-terminated strings.

```
type
  TIdentifier = array[0..15] of Char;
  TFileName = array[0..259] of Char;
  TMemoText = array[0..1023] of WideChar;
```

With extended syntax enabled (**{$X+}**), you can assign a string constant to a statically allocated zero-based character array. (Dynamic arrays won't work for this purpose.) If you initialize an array constant with a string that is shorter than the declared length of the array, the remaining characters are set to #0. For more information about arrays, see "Arrays" on page 5-18.

Using pointers, arrays, and string constants

To manipulate null-terminated strings, it is often necessary to use pointers. (See "Pointers and pointer types" on page 5-25.) String constants are assignment-compatible with the *PChar* and *PWideChar* types, which represent pointers to null-terminated arrays of *Char* and *WideChar* values. For example,

```
var P: PChar;
 ⋮
P := 'Hello world!';
```

points *P* to an area of memory that contains a null-terminated copy of "Hello world!" This is equivalent to

```
const TempString: array[0..12] of Char = 'Hello world!'#0;
var P: PChar;
 ⋮
P := @TempString;
```

You can also pass string constants to any function that takes value or **const** parameters of type *PChar* or *PWideChar*—for example `StrUpper('Hello world!')`. As with assignments to a *PChar*, the compiler generates a null-terminated copy of the string and gives the function a pointer to that copy. Finally, you can initialize *PChar* or *PWideChar* constants with string literals, alone or in a structured type. Examples:

```
const
Message: PChar = 'Program terminated';
  Prompt: PChar = 'Enter values: ';
  Digits: array[0..9] of PChar = (
    'Zero', 'One', 'Two', 'Three', 'Four',
    'Five', 'Six', 'Seven', 'Eight', 'Nine');
```

Zero-based character arrays are compatible with *PChar* and *PWideChar*. When you use a character array in place of a pointer value, the compiler converts the array to a pointer constant whose value corresponds to the address of the first element of the array. For example,

```
var
  MyArray: array[0..32] of Char;
  MyPointer: PChar;
begin
  MyArray := 'Hello';
  MyPointer := MyArray;
  SomeProcedure(MyArray);
  SomeProcedure(MyPointer);
end;
```

This code calls *SomeProcedure* twice with the same value.

A character pointer can be indexed as if it were an array. In the example above, `MyPointer[0]` returns *H*. The index specifies an offset added to the pointer before it is dereferenced. (For *PWideChar* variables, the index is automatically multiplied by two.) Thus, if *P* is a character pointer, *P*`[0]` is equivalent to *P*^ and specifies the first character in the array, *P*`[1]` specifies the second character in the array, and so forth; *P*`[-1]` specifies the "character" immediately to the left of *P*`[0]`. *The compiler performs no range checking on these indexes.*

The *StrUpper* function illustrates the use of pointer indexing to iterate through a null-terminated string:

```
function StrUpper(Dest, Source: PChar; MaxLen: Integer): PChar;
var
  I: Integer;
begin
  I := 0;
  while (I < MaxLen) and (Source[I] <> #0) do
  begin
    Dest[I] := UpCase(Source[I]);
    Inc(I);
  end;
  Dest[I] := #0;
  Result := Dest;
end;
```

Mixing Pascal strings and null-terminated strings

You can mix long strings (*AnsiString* values) and null-terminated strings (*PChar* values) in expressions and assignments, and you can pass *PChar* values to functions or procedures that take long-string parameters. The assignment *S* `:=` *P*, where *S* is a string variable and *P* is a *PChar* expression, copies a null-terminated string into a long string.

In a binary operation, if one operand is a long string and the other a *PChar*, the *PChar* operand is converted to a long string.

You can cast a *PChar* value as a long string. This is useful when you want to perform a string operation on two *PChar* values. For example,

```
S := string(P1) + string(P2);
```

You can also cast a long string as a null-terminated string. The following rules apply.

- If *S* is a long-string expression, `PChar(S)` casts *S* as a null-terminated string; it returns a pointer to the first character in *S*.

  On Windows: For example, if *Str1* and *Str2* are long strings, you could call the Win32 API *MessageBox* function like this:

  ```
  MessageBox(0, PChar(Str1), PChar(Str2), MB_OK);
  ```

  (The declaration of *MessageBox* is in the *Windows* interface unit.)

  On Linux: For example, if *Str* is a long string, you could call the *opendir* system function like this:

  ```
  opendir(PChar(Str));
  ```

  (The declaration of *opendir* is in the *Libc* interface unit.)

- You can also use `Pointer(S)` to cast a long string to an untyped pointer. But if *S* is empty, the typecast returns **nil**.
- When you cast a long-string variable to a pointer, the pointer remains valid until the variable is assigned a new value or goes out of scope. If you cast any other long-string expression to a pointer, the pointer is valid only within the statement where the typecast is performed.
- When you cast a long-string expression to a pointer, the pointer should usually be considered read-only. You can safely use the pointer to modify the long string only when all of the following conditions are satisfied.
  - The expression cast is a long-string *variable*.
  - The string is not empty.
  - The string is unique—that is, has a reference count of one. To guarantee that the string is unique, call the *SetLength*, *SetString*, or *UniqueString* procedure.
  - The string has not been modified since the typecast was made.
  - The characters modified are all within the string. Be careful not to use an out-of-range index on the pointer.

The same rules apply when mixing *WideString* values with *PWideChar* values.

Structured types

Instances of a structured type hold more than one value. Structured types include *sets*, *arrays*, *records*, and *files* as well as *class*, *class-reference*, and *interface* types. (For information about class and class-reference types, see Chapter 7, “Classes and objects”. For information about interfaces, see Chapter 10, “Object interfaces”.) Except for sets, which hold ordinal values only, structured types can contain other structured types; a type can have unlimited levels of structuring.

By default, the values in a structured type are aligned on word or double-word boundaries for faster access. When you declare a structured type, you can include the reserved word **packed** to implement compressed data storage. For example,

```
type TNumbers = packed array[1..100] of Real;
```

Using **packed** slows data access and, in the case of a character array, affects type compatibility. For more information, see Chapter 11, “Memory management”.

Sets

A set is a collection of values of the same ordinal type. The values have no inherent order, nor is it meaningful for a value to be included twice in a set.

The range of a set type is the power set of a specific ordinal type, called the *base type*; that is, the possible values of the set type are all the subsets of the base type, including the empty set. The base type can have no more than 256 possible values, and their ordinalities must fall between 0 and 255. Any construction of the form

```
set of baseType
```

where *baseType* is an appropriate ordinal type, identifies a set type.

Because of the size limitations for base types, set types are usually defined with subranges. For example, the declarations

```
type
  TSomeInts = 1..250;
  TIntSet = set of TSomeInts;
```

create a set type called *TIntSet* whose values are collections of integers in the range from 1 to 250. You could accomplish the same thing with

```
type TIntSet = set of 1..250;
```

Given this declaration, you can create a sets like this:

```
var Set1, Set2: TIntSet;
  ⋮
Set1 := [1, 3, 5, 7, 9];
Set2 := [2, 4, 6, 8, 10]
```

You can also use the **set of ...** construction directly in variable declarations:

```
var MySet: set of 'a'..'z';
  ⋮
MySet := ['a','b','c'];
```

Other examples of set types include

```
set of Byte
set of (Club, Diamond, Heart, Spade)
set of Char;
```

The **in** operator tests set membership:

```
if 'a' in MySet then ... { do something } ;
```

Every set type can hold the empty set, denoted by `[]`. For more information about sets, see “Set constructors” on page 4-13 and “Set operators” on page 4-10.

Arrays

An array represents an indexed collection of elements of the same type (called the *base type*). Because each element has a unique index, arrays, unlike sets, can meaningfully contain the same value more than once. Arrays can be allocated *statically* or *dynamically*.

Static arrays

Static array types are denoted by constructions of the form

```
array[indexType1, ..., indexTypen] of baseType
```

where each *indexType* is an ordinal type whose range does not exceed 2GB. Since the *indexType*s index the array, the number of elements an array can hold is limited by the product of the sizes of the *indexType*s. In practice, *indexType*s are usually integer subranges.

In the simplest case of a one-dimensional array, there is only a single *indexType*. For example,

```
var MyArray: array[1..100] of Char;
```

declares a variable called *MyArray* that holds an array of 100 character values. Given this declaration, `MyArray[3]` denotes the third character in *MyArray*. If you create a static array but don't assign values to all its elements, the unused elements are still allocated and contain random data; they are like uninitialized variables.

A multidimensional array is an array of arrays. For example,

```
type TMatrix = array[1..10] of array[1..50] of Real;
```

is equivalent to

```
type TMatrix = array[1..10, 1..50] of Real;
```

Whichever way *TMatrix* is declared, it represents an array of 500 real values. A variable *MyMatrix* of type *TMatrix* can be indexed like this: `MyMatrix[2,45]`; or like this: `MyMatrix[2][45]`. Similarly,

```
packed array[Boolean,1..10,TShoeSize] of Integer;
```

is equivalent to

```
packed array[Boolean] of packed array[1..10] of packed array[TShoeSize] of Integer;
```

The standard functions *Low* and *High* operate on array type identifiers and variables. They return the low and high bounds of the array's first index type. The standard function *Length* returns the number of elements in the array's first dimension.

A one-dimensional, packed, static array of *Char* values is called a *packed string*. Packed-string types are compatible with string types and with other packed-string types that have the same number of elements. See "Type compatibility and identity" on page 5-34.

An array type of the form `array[0..x] of Char` is called a *zero-based character array*. Zero-based character arrays are used to store null-terminated strings and are compatible with *PChar* values. See "Working with null-terminated strings" on page 5-13.

Dynamic arrays

Dynamic arrays do not have a fixed size or length. Instead, memory for a dynamic array is reallocated when you assign a value to the array or pass it to the *SetLength* procedure. Dynamic-array types are denoted by constructions of the form

```
array of baseType
```

For example,

```
var MyFlexibleArray: array of Real;
```

declares a one-dimensional dynamic array of reals. The declaration does not allocate memory for *MyFlexibleArray*. To create the array in memory, call *SetLength*. For example, given the declaration above,

```
SetLength(MyFlexibleArray, 20);
```

allocates an array of 20 reals, indexed 0 to 19. Dynamic arrays are always integer-indexed, always starting from 0.

Dynamic-array variables are implicitly pointers and are managed by the same reference-counting technique used for long strings. To deallocate a dynamic array, assign **nil** to a variable that references the array or pass the variable to *Finalize*; either of these methods disposes of the array, provided there are no other references to it. Dynamic arrays of length 0 have the value **nil**. Do not apply the dereference operator (**^**) to a dynamic-array variable or pass it to the *New* or *Dispose* procedure.

If *X* and *Y* are variables of the same dynamic-array type, *X* `:=` *Y* points *X* to the same array as *Y*. (There is no need to allocate memory for *X* before performing this operation.) Unlike strings and static arrays, dynamic arrays are not automatically copied before they are written to. For example, after this code executes—

```
var
  A, B: array of Integer;
begin
  SetLength(A, 1);
  A[0] := 1;
  B := A;
  B[0] := 2;
end;
```

—the value of `A[0]` is 2. (If *A* and *B* were static arrays, `A[0]` would still be 1.)

Assigning to a dynamic-array index (for example, `MyFlexibleArray[2] := 7`) does not reallocate the array. Out-of-range indexes are not reported at compile time.

When dynamic-array variables are compared, their references are compared, not their array values. Thus, after execution of the code

```
var
  A, B: array of Integer;
begin
  SetLength(A, 1);
  SetLength(B, 1);
  A[0] := 2;
  B[0] := 2;
end;
```

`A = B` returns *False* but `A[0] = B[0]` returns *True*.

To truncate a dynamic array, pass it to *SetLength* or *Copy* and assign the result back to the array variable. (The *SetLength* procedure is usually faster.) For example, if *A* is a dynamic array, `A := SetLength(A, 0, 20)` truncates all but the first 20 elements of *A*.

Once a dynamic array has been allocated, you can pass it to the standard functions *Length*, *High*, and *Low*. *Length* returns the number of elements in the array, *High* returns the array's highest index (that is, *Length*–1), and *Low* returns 0. In the case of a zero-length array, *High* returns –1 (with the anomalous consequence that *High* < *Low*).

Note In some function and procedure declarations, array parameters are represented as `array of` *baseType*, without any index types specified. For example,

```
function CheckStrings(A: array of string): Boolean;
```

This indicates that the function operates on all arrays of the specified base type, regardless of their size, how they are indexed, or whether they are allocated statically or dynamically. See "Open array parameters" on page 6-15.

Multidimensional dynamic arrays

To declare multidimensional dynamic arrays, use iterated **array of ...** constructions. For example,

```
type TMessageGrid = array of array of string;
var Msgs: TMessageGrid;
```

declares a two-dimensional array of strings. To instantiate this array, call *SetLength* with two integer arguments. For example, if *I* and *J* are integer-valued variables,

```
SetLength(Msgs,I,J);
```

allocates an *I*-by-*J* array, and `Msgs[0,0]` denotes an element of that array.

You can create multidimensional dynamic arrays that are not rectangular. The first step is to call *SetLength*, passing it parameters for the first *n* dimensions of the array. For example,

```
var Ints: array of array of Integer;
SetLength(Ints,10);
```

allocates ten rows for *Ints* but no columns. Later, you can allocate the columns one at a time (giving them different lengths); for example

```
SetLength(Ints[2], 5);
```

makes the third column of *Ints* five integers long. At this point (even if the other columns haven't been allocated) you can assign values to the third column—for example, `Ints[2,4] := 6`.

The following example uses dynamic arrays (and the *IntToStr* function declared in the *SysUtils* unit) to create a triangular matrix of strings.

```
var
  A : array of array of string;
  I, J : Integer;
begin
  SetLength(A, 10);
  for I := Low(A) to High(A) do
```

```
    begin
      SetLength(A[I], I);
      for J := Low(A[I]) to High(A[I]) do
        A[I,J] := IntToStr(I) + ',' + IntToStr(J) + ' ';
    end;
  end;
```

Array types and assignments

Arrays are assignment-compatible only if they are of the same type. Because Pascal uses name-equivalence for types, the following code will not compile.

```
var
  Int1: array[1..10] of Integer;
  Int2: array[1..10] of Integer;
  ⋮
Int1 := Int2;
```

To make the assignment work, declare the variables as

```
var Int1, Int2: array[1..10] of Integer;
```

or

```
type IntArray = array[1..10] of Integer;
var
  Int1: IntArray;
  Int2: IntArray;
```

Records

A record (analogous to a *structure* in some languages) represents a heterogeneous set of elements. Each element is called a *field*; the declaration of a record type specifies a name and type for each field. The syntax of a record type declaration is

```
type recordTypeName = record
  fieldList1: type1;
  ⋮
  fieldListn: typen;
end
```

where *recordTypeName* is a valid identifier, each *type* denotes a type, and each *fieldList* is a valid identifier or a comma-delimited list of identifiers. The final semicolon is optional.

For example, the following declaration creates a record type called *TDateRec*.

```
type
  TDateRec = record
    Year: Integer;
    Month: (Jan, Feb, Mar, Apr, May, Jun,
            Jul, Aug, Sep, Oct, Nov, Dec);
    Day: 1..31;
  end;
```

Each *TDateRec* contains three fields: an integer value called *Year*, a value of an enumerated type called *Month*, and another integer between 1 and 31 called *Day*. The identifiers *Year*, *Month*, and *Day* are the *field designators* for *TDateRec*, and they behave like variables. The *TDateRec* type declaration, however, does not allocate any memory for the *Year*, *Month*, and *Day* fields; memory is allocated when you instantiate the record, like this:

```
var Record1, Record2: TDateRec;
```

This variable declaration creates two instances of *TDateRec*, called *Record1* and *Record2*.

You can access the fields of a record by qualifying the field designators with the record's name:

```
Record1.Year := 1904;
Record1.Month := Jun;
Record1.Day := 16;
```

Or use a **with** statement:

```
with Record1 do
begin
  Year := 1904;
  Month := Jun;
  Day := 16;
end;
```

You can now copy the values of *Record1*'s fields to *Record2*:

```
Record2 := Record1;
```

Because the scope of a field designator is limited to the record in which it occurs, you don't have to worry about naming conflicts between field designators and other variables.

Instead of defining record types, you can use the **record ...** construction directly in variable declarations:

```
var S: record
  Name: string;
  Age: Integer;
end;
```

However, a declaration like this largely defeats the purpose of records, which is to avoid repetitive coding of similar groups of variables. Moreover, separately declared records of this kind will not be assignment-compatible, even if their structures are identical.

Variant parts in records

A record type can have a *variant* part, which looks like a **case** statement. The variant part must follow the other fields in the record declaration.

To declare a record type with a variant part, use the following syntax.

```
type recordTypeName = record
  fieldList1: type1;
  ⋮
  fieldListn: typen;
case tag: ordinalType of
  constantList1: (variant1);
  ⋮
  constantListn: (variantn);
end;
```

The first part of the declaration—up to the reserved word **case**—is the same as that of a standard record type. The remainder of the declaration—from **case** to the optional final semicolon—is called the variant part. In the variant part,

- *tag* is optional and can be any valid identifier. If you omit *tag*, omit the colon (**:**) after it as well.
- *ordinalType* denotes an ordinal type.
- Each *constantList* is a constant denoting a value of type o*rdinalType*, or a comma-delimited list of such constants. No value can be represented more than once in the combined *constantList*s.
- Each *variant* is a comma-delimited list of declarations resembling the *fieldList*: *type* constructions in the main part of the record type. That is, a *variant* has the form

  ```
  fieldList1: type1;
    ⋮
  fieldListn: typen;
  ```

  where each *fieldList* is a valid identifier or comma-delimited list of identifiers, each *type* denotes a type, and the final semicolon is optional. The *types* must not be long strings, dynamic arrays, variants (that is, *Variant* types), or interfaces, nor can they be structured types that contain long strings, dynamic arrays, variants, or interfaces; but they can be pointers to these types.

Records with variant parts are complicated syntactically but deceptively simple semantically. The variant part of a record contains several *variant*s which share the same space in memory. You can read or write to any field of any *variant* at any time; but if you write to a field in one *variant* and then to a field in another *variant*, you may be overwriting your own data. The *tag*, if there is one, functions as an extra field (of type *ordinalType*) in the non-variant part of the record.

Variant parts have two purposes. First, suppose you want to create a record type that has fields for different kinds of data, but you know that you will never need to use all of the fields in a single record instance. For example,

```
type
  TEmployee = record
  FirstName, LastName: string[40];
  BirthDate: TDate;
  case Salaried: Boolean of
    True: (AnnualSalary: Currency);
    False: (HourlyWage: Currency);
end;
```

The idea here is that every employee has either a salary or an hourly wage, but not both. So when you create an instance of *TEmployee*, there is no reason to allocate enough memory for both fields. In this case, the only difference between the *variant*s is in the field names, but the fields could just as easily have been of different types. Consider some more complicated examples:

```
type
  TPerson = record
  FirstName, LastName: string[40];
  BirthDate: TDate;
  case Citizen: Boolean of
    True: (Birthplace: string[40]);
    False: (Country: string[20];
            EntryPort: string[20];
            EntryDate, ExitDate: TDate);
  end;

type
  TShapeList = (Rectangle, Triangle, Circle, Ellipse, Other);
  TFigure = record
    case TShapeList of
      Rectangle: (Height, Width: Real);
      Triangle: (Side1, Side2, Angle: Real);
      Circle: (Radius: Real);
      Ellipse, Other: ();
  end;
```

For each record instance, the compiler allocates enough memory to hold all the fields in the largest *variant*. The optional *tag* and the *constantList*s (like *Rectangle*, *Triangle*, and so forth in the last example above) play no role in the way the compiler manages the fields; they are there only for the convenience of the programmer.

The second reason for variant parts is that they let you treat the same data as belonging to different types, even in cases where the compiler would not allow a typecast. For example, if you have a 64-bit *Real* as the first field in one *variant* and a 32-bit *Integer* as the first field in another, you can assign a value to the *Real* field and then read back the first 32 bits of it as the value of the *Integer* field (passing it, say, to a function that requires integer parameters).

File types

A file is an ordered set of elements of the same type. Standard I/O routines use the predefined *TextFile* or *Text* type, which represents a file containing characters organized into lines. For more information about file input and output, see Chapter 8, "Standard routines and I/O".

To declare a file type, use the syntax

```
type fileTypeName = file of type
```

where *fileTypeName* is any valid identifier and *type* is a fixed-size type. Pointer types—whether implicit or explicit—are not allowed, so a file cannot contain dynamic arrays, long strings, classes, objects, pointers, variants, other files, or structured types that contain any of these.

For example,

```
type
  PhoneEntry = record
    FirstName, LastName: string[20];
    PhoneNumber: string[15];
    Listed: Boolean;
  end;
  PhoneList = file of PhoneEntry;
```

declares a file type for recording names and telephone numbers.

You can also use the **file of ...** construction directly in a variable declaration. For example,

```
var List1: file of PhoneEntry;
```

The word **file** by itself indicates an untyped file:

```
var DataFile: file;
```

For more information, see "Untyped files" on page 8-4.

Files are not allowed in arrays or records.

Pointers and pointer types

A pointer is a variable that denotes a memory address. When a pointer holds the address of another variable, we say that it *points* to the location of that variable in memory or to the data stored there. In the case of an array or other structured type, a pointer holds the address of the first element in the structure.

Pointers are *typed* to indicate the kind of data stored at the addresses they hold. The general-purpose *Pointer* type can represent a pointer to any data, while more specialized pointer types reference only specific types of data. Pointers occupy four bytes of memory.

Overview of pointers

To see how pointers work, look at the following example.

```
1    var
2      X, Y: Integer;   // X and Y are Integer variables
3      P: ^Integer;     // P points to an Integer
4    begin
5      X := 17;         // assign a value to X
6      P := @X;         // assign the address of X to P
7      Y := P^;         // dereference P; assign the result to Y
8    end;
```

Line 2 declares *X* and *Y* as variables of type *Integer*. Line 3 declares *P* as a pointer to an *Integer* value; this means that *P* can point to the location of *X* or *Y*. Line 5 assigns a value to *X*, and line 6 assigns the address of *X* (denoted by `@X`) to *P*. Finally, line 7 retrieves the value at the location pointed to by *P* (denoted by `^P`) and assigns it to *Y*. After this code executes, *X* and *Y* have the same value, namely 17.

The @ operator, which we have used here to take the address of a variable, also operates on functions and procedures. For more information, see "The @ operator" on page 4-12 and "Procedural types in statements and expressions" on page 5-29.

The symbol **^** has two purposes, both of which are illustrated in our example. When it appears before a type identifier—

^typeName

—it denotes a type that represents pointers to variables of type *typeName*. When it appears after a pointer variable—

*pointer^*

—it *dereferences* the pointer; that is, it returns the value stored at the memory address held by the pointer.

Our example may seem like a roundabout way of copying the value of one variable to another—something that we could have accomplished with a simple assignment statement. But pointers are useful for several reasons. First, understanding pointers will help you to understand Object Pascal, since pointers often operate behind the scenes in code where they don't appear explicitly. Any data type that requires large, dynamically allocated blocks of memory uses pointers. Long-string variables, for instance, are implicitly pointers, as are class variables. Moreover, some advanced programming techniques require the use of pointers.

Finally, pointers are sometimes the only way to circumvent Object Pascal's strict data typing. By referencing a variable with an all-purpose *Pointer*, casting the *Pointer* to a more specific type, and then dereferencing it, you can treat the data stored by any variable as if it belonged to any type. For example, the following code assigns data stored in a real variable to an integer variable.

```
type
  PInteger = ^Integer;
var
  R: Single;
  I: Integer;
  P: Pointer;
  PI: PInteger;
begin
  ⋮
  P := @R;
  PI := PInteger(P);
  I := PI^;
end;
```

Of course, reals and integers are stored in different formats. This assignment simply copies raw binary data from *R* to *I*, without converting it.

In addition to assigning the result of an @ operation, you can use several standard routines to give a value to a pointer. The *New* and *GetMem* procedures assign a memory address to an existing pointer, while the *Addr* and *Ptr* functions return a pointer to a specified address or variable.

Dereferenced pointers can be qualified and can function as qualifiers, as in the expression `P1^.Data^`.

The reserved word **nil** is a special constant that can be assigned to any pointer. When **nil** is assigned to a pointer, the pointer doesn't reference anything.

Pointer types

You can declare a pointer to any type, using the syntax

`type` *pointerTypeName* `= ^`*type*

When you define a record or other data type, it's a common practice also to define a pointer to that type. This makes it easy to manipulate instances of the type without copying large blocks of memory.

Standard pointer types exist for many purposes. The most versatile is *Pointer*, which can point to data of any kind. But a *Pointer* variable cannot be dereferenced; placing the **^** symbol after a *Pointer* variable causes a compilation error. To access the data referenced by a *Pointer* variable, first cast it to another pointer type and then dereference it.

Character pointers

The fundamental types *PAnsiChar* and *PWideChar* represent pointers to *AnsiChar* and *WideChar* values, respectively. The generic *PChar* represents a pointer to a *Char* (that is, in its current implementation, to an *AnsiChar*). These character pointers are used to manipulate null-terminated strings. (See "Working with null-terminated strings" on page 5-13.)

Other standard pointer types

The *System* and *SysUtils* units declare many standard pointer types that are commonly used.

Table 5.6 Selected pointer types declared in System and SysUtils

Pointer type	Points to variables of type
PAnsiString, *PString*	*AnsiString*
PByteArray	*TByteArray* (declared in *SysUtils*). Used to typecast dynamically allocated memory for array access.
PCurrency, *PDouble*, *PExtended*, *PSingle*	*Currency*, *Double*, *Extended*, *Single*
PInteger	*Integer*
POleVariant	*OleVariant*
PShortString	*ShortString*. Useful when porting legacy code that uses the old *PString* type.
PTextBuf	*TTextBuf* (declared in *SysUtils*). *TTextBuf* is the internal buffer type in a *TTextRec* file record.)
PVarRec	*TVarRec* (declared in *System*)
PVariant	*Variant*

Table 5.6 Selected pointer types declared in System and SysUtils (continued)

Pointer type	Points to variables of type
PWideString	*WideString*
PWordArray	*TWordArray* (declared in *SysUtils*). Used to typecast dynamically allocated memory for arrays of 2-byte values.

Procedural types

Procedural types allow you to treat procedures and functions as values that can be assigned to variables or passed to other procedures and functions. For example, suppose you define a function called *Calc* that takes two integer parameters and returns an integer:

```
function Calc(X,Y: Integer): Integer;
```

You can assign the *Calc* function to the variable *F*:

```
var F: function(X,Y: Integer): Integer;
F := Calc;
```

If you take any procedure or function heading and remove the identifier after the word **procedure** or **function**, what's left is the name of a procedural type. You can use such type names directly in variable declarations (as in the example above) or to declare new types:

```
type
  TIntegerFunction = function: Integer;
  TProcedure = procedure;
  TStrProc = procedure(const S: string);
  TMathFunc = function(X: Double): Double;
var
  F: TIntegerFunction;            { F is a parameterless function that returns an integer }
  Proc: TProcedure;               { Proc is a parameterless procedure }
  SP: TStrProc;                   { SP is a procedure that takes a string parameter }
  M: TMathFunc;                   { M is a function that takes a Double (real) parameter
                                      and returns a Double }
procedure FuncProc(P: TIntegerFunction);  { FuncProc is a procedure whose only parameter
                                              is a parameterless integer-valued function }
```

The variables above are all *procedure pointers*—that is, pointers to the address of a procedure or function. If you want to reference a method of an instance object (see Chapter 7, "Classes and objects"), you need to add the words **of object** to the procedural type name. For example

```
type
  TMethod = procedure of object;
  TNotifyEvent = procedure(Sender: TObject) of object;
```

These types represent *method pointers*. A method pointer is really a pair of pointers; the first stores the address of a method, and the second stores a reference to the object the method belongs to. Given the declarations

```
type
  TNotifyEvent = procedure(Sender: TObject) of object;
  TMainForm = class(TForm)
    procedure ButtonClick(Sender: TObject);
    ⋮
  end;
var
  MainForm: TMainForm;
  OnClick: TNotifyEvent
```

we could make the following assignment.

```
OnClick := MainForm.ButtonClick;
```

Two procedural types are compatible if they have

- the same calling convention,
- the same return value (or no return value), and
- the same number of parameters, with identically typed parameters in corresponding positions. (Parameter names do not matter.)

Procedure pointer types are always incompatible with method pointer types. The value **nil** can be assigned to any procedural type.

Nested procedures and functions (routines declared within other routines) cannot be used as procedural values, nor can predefined procedures and functions. If you want to use a predefined routine like *Length* as a procedural value, write a wrapper for it:

```
function FLength(S: string): Integer;
begin
  Result := Length(S);
end;
```

Procedural types in statements and expressions

When a procedural variable is on the left side of an assignment statement, the compiler expects a procedural value on the right. The assignment makes the variable on the left a pointer to the function or procedure indicated on the right. In other contexts, however, using a procedural variable results in a call to the referenced procedure or function. You can even use a procedural variable to pass parameters:

```
var
  F: function(X: Integer): Integer;
  I: Integer;
function SomeFunction(X: Integer): Integer;
 ⋮
F := SomeFunction;  // assign SomeFunction to F
I := F(4);          // call function; assign result to I
```

In assignment statements, the type of the variable on the left determines the interpretation of procedure or method pointers on the right. For example,

```
var
  F, G: function: Integer;
  I: Integer;
```

```
function SomeFunction: Integer;
 ⋮
F := SomeFunction;  // assign SomeFunction to F
G := F;             // copy F to G
I := G;             // call function; assign result to I
```

The first statement assigns a procedural value to *F*. The second statement copies that value to another variable. The third statement makes a call to the referenced function and assigns the result to *I*. Because *I* is an integer variable, not a procedural one, the last assignment actually calls the function (which returns an integer).

In some situations it is less clear how a procedural variable should be interpreted. Consider the statement

```
if F = MyFunction then ...;
```

In this case, the occurrence of *F* results in a function call; the compiler calls the function pointed to by *F*, then calls the function *MyFunction*, then compares the results. The rule is that whenever a procedural variable occurs within an expression, it represents a call to the referenced procedure or function. In a case where *F* references a procedure (which doesn't return a value), or where *F* references a function that requires parameters, the statement above causes a compilation error. To compare the procedural value of *F* with *MyFunction*, use

```
if @F = @MyFunction then ...;
```

`@F` converts *F* into an untyped pointer variable that contains an address, and `@MyFunction` returns the address of *MyFunction*.

To get the memory address of a procedural variable (rather than the address stored in it), use @@. For example, `@@F` returns the address of *F*.

The @ operator can also be used to assign an untyped pointer value to a procedural variable. For example,

```
var StrComp: function(Str1, Str2: PChar): Integer;
 ⋮
@StrComp := GetProcAddress(KernelHandle, 'lstrcmpi');
```

calls the *GetProcAddress* function and points *StrComp* to the result.

Any procedural variable can hold the value **nil**, which means that it points to nothing. But attempting to *call* a **nil**-valued procedural variable is an error. To test whether a procedural variable is assigned, use the standard function *Assigned*:

```
if Assigned(OnClick) then OnClick(X);
```

Variant types

Sometimes it is necessary to manipulate data whose type varies or cannot be determined at compile time. In these cases, one option is to use variables and parameters of type *Variant*, which represent values that can change type at runtime. Variants offer greater flexibility but consume more memory than regular variables, and operations on them are slower than on statically bound types. Moreover, illicit operations on variants often result in runtime errors, where similar mistakes with regular variables would have been caught at compile time. You can also create custom variant types.

By default, Variants can hold values of any type except records, sets, static arrays, files, classes, class references, and pointers. In other words, variants can hold anything but structured types and pointers. They can hold interfaces, whose methods and properties can be accessed through them. (See Chapter 10, "Object interfaces".) They can hold dynamic arrays, and they can hold a special kind of static array called a *variant array*. (See "Variant arrays" on page 5-33.) Variants can mix with other variants and with integer, real, string, and Boolean values in expressions and assignments; the compiler automatically performs type conversions.

Variants that contain strings cannot be indexed. That is, if *V* is a variant that holds a string value, the construction `V[1]` causes a runtime error.

You can define custom Variants that extend the Variant type to hold arbitrary values. For example, you can define a Variant string type that allows indexing or that holds a particular class reference, record type, or static array. Custom Variant types are defined by creating descendants to the *TCustomVariantType* class.

A variant occupies 16 bytes of memory and consists of a type code and a value, or pointer to a value, of the type specified by the code. All variants are initialized on creation to the special value *Unassigned*. The special value *Null* indicates unknown or missing data.

The standard function *VarType* returns a variant's type code. The *varTypeMask* constant is a bit mask used to extract the code from *VarType*'s return value, so that, for example,

```
VarType(V) and varTypeMask = varDouble
```

returns *True* if *V* contains a *Double* or an array of *Double*. (The mask simply hides the first bit, which indicates whether the variant holds an array.) The *TVarData* record type defined in the *System* unit can be used to typecast variants and gain access to their internal representation. See the online Help on *VarType* for a list if codes, and note that new type codes may be added in future implementations of Object Pascal.

Variant type conversions

All integer, real, string, character, and Boolean types are assignment-compatible with *Variant*. Expressions can be explicitly cast as variants, and the *VarAsType* and *VarCast* standard routines can be used to change the internal representation of a variant. The following code demonstrates the use of variants and some of the automatic conversions performed when variants are mixed with other types.

```
var
  V1, V2, V3, V4, V5: Variant;
  I: Integer;
  D: Double;
  S: string;
begin
  V1 := 1; { integer value }
  V2 := 1234.5678; { real value }
```

```
    V3 := 'Hello world!'; { string value }
    V4 := '1000'; { string value }
    V5 := V1 + V2 + V4; { real value 2235.5678}
    I := V1; { I = 1 (integer value) }
    D := V2; { D = 1234.5678 (real value) }
    S := V3; { S = 'Hello world!' (string value) }
    I := V4; { I = 1000 (integer value) }
    S := V5; { S = '2235.5678' (string value) }
  end;
```

The compiler performs type conversions according to the following rules.

Table 5.7 Variant type conversion rules

Target Source	integer	real	string	character	Boolean
integer	converts integer formats	converts to real	converts to string representation	same as string (left)	returns *False* if 0, *True* otherwise
real	rounds to nearest integer	converts real formats	converts to string representation using regional settings	same as string (left)	returns *False* if 0, *True* otherwise
string	converts to integer, truncating if necessary; raises exception if string is not numeric	converts to real using regional settings; raises exception if string is not numeric	converts string/ character formats	same as string (left)	returns *False* if string is “false” (non–case-sensitive) or a numeric string that evaluates to 0, *True* if string is “true” or a nonzero numeric string; raises exception otherwise
character	same as string (above)	same as string (above)	same as string (above)	same as string-to-string	same as string (above)
Boolean	*False* = 0, *True* = –1 (255 if *Byte*)	*False* = 0, *True* = –1	*False* = “0”, *True* = “–1”	same as string (left)	*False* = *False*, *True* = *True*
Unassigned	returns 0	returns 0	returns empty string	same as string (left)	returns *False*
Null	raises exception	raises exception	raises exception	same as string (left)	raises exception

Out-of-range assignments often result in the target variable getting the highest value in its range. Invalid assignments or casts raise the *EVariantError* exception.

Special conversion rules apply to the *TDateTime* real type declared in the *System* unit. When a *TDateTime* is converted to any other type, it treated as a normal *Double*. When an integer, real, or Boolean is converted to a *TDateTime*, it is first converted to a *Double*, then read as a date-time value. When a string is converted to a *TDateTime*, it is interpreted as a date-time value using the regional settings. When an *Unassigned* value is converted to *TDateTime*, it is treated like the real or integer value 0. Converting a *Null* value to *TDateTime* raises an exception.

On Windows, if a variant references a COM interface, any attempt to convert it reads the object's default property and converts that value to the requested type. If the object has no default property, an exception is raised.

Variants in expressions

All operators except **^**, **is**, and **in** take variant operands. Operations on variants return *Variant* values; they return *Null* if one or both operands is *Null*, and raise an exception if one or both operands is *Unassigned*. In a binary operation, if only one operand is a variant, the other is converted to a variant.

The return type of an operation is determined by its operands. In general, the same rules that apply to operands of statically bound types apply to variants. For example, if *V1* and *V2* are variants that hold an integer and a real value, then `V1 + V2` returns a real-valued variant. (See "Operators" on page 4-6.) With variants, however, you can perform binary operations on combinations of values that would not be allowed using statically typed expressions. When possible, the compiler converts mismatched variants using the rules summarized in Table 5.7. For example, if *V3* and *V4* are variants that hold a numeric string and an integer, the expression `V3 + V4` returns an integer-valued variant; the numeric string is converted to an integer before the operation is performed.

Variant arrays

You cannot assign an ordinary static array to a variant. Instead, create a *variant array* by calling either of the standard functions *VarArrayCreate* or *VarArrayOf*. For example,

```
V: Variant;
 ⋮
V := VarArrayCreate([0,9], varInteger);
```

creates a variant array of integers (of length 10) and assigns it to the variant *V*. The array can be indexed using `V[0]`, `V[1]`, and so forth, but it is not possible to pass a variant array element as a **var** parameter. Variant arrays are always indexed with integers.

The second parameter in the call to *VarArrayCreate* is the type code for the array's base type. For a list of these codes, see the online Help on *VarType*. Never pass the code *varString* to *VarArrayCreate*; to create a variant array of strings, use *varOleStr*.

Variants can hold variant arrays of different sizes, dimensions, and base types. The elements of a variant array can be of any type allowed in variants except *ShortString* and *AnsiString*, and if the base type of the array is *Variant*, its elements can even be heterogeneous. Use the *VarArrayRedim* function to resize a variant array. Other standard routines that operate on variant arrays include *VarArrayDimCount*, *VarArrayLowBound*, *VarArrayHighBound*, *VarArrayRef*, *VarArrayLock*, and *VarArrayUnlock*.

When a variant containing a variant array is assigned to another variant or passed as a value parameter, the entire array is copied. Don't perform such operations unnecessarily, since they are memory-inefficient.

OleVariant

The *OleVariant* type exists on both the Windows and Linux platforms. The main difference between *Variant* and *OleVariant* is that *Variant* can contain data types that only the current application knows what to do with. *OleVariant* can only contain the data types defined as compatible with Ole Automation which means that the data types that can be passed between programs or across the network without worrying about whether the other end will know how to handle the data.

When you assign a *Variant* that contains custom data (such as a Pascal string, or a one of the new custom variant types) to an *OleVariant*, the runtime library tries to convert the *Variant* into one of the *OleVariant* standard data types (such as a Pascal string converts to an Ole BSTR string). For example, if a variant containing an *AnsiString* is assigned to an *OleVariant*, the *AnsiString* becomes a *WideString*. The same is true when passing a *Variant* to an *OleVariant* function parameter.

Type compatibility and identity

To understand which operations can be performed on which expressions, we need to distinguish several kinds of compatibility among types and values. These include *type identity*, *type compatibility*, and *assignment-compatibility*.

Type identity

Type identity is almost straightforward. When one type identifier is declared using another type identifier, without qualification, they denote the same type. Thus, given the declarations

```
type
  T1 = Integer;
  T2 = T1;
  T3 = Integer;
  T4 = T2;
```

T1, *T2*, *T3*, *T4*, and *Integer* all denote the same type. To create distinct types, repeat the word **type** in the declaration. For example,

```
type TMyInteger = type Integer;
```

creates a new type called *TMyInteger* which is not identical to *Integer*.

Language constructions that function as type names denote a different type each time they occur. Thus the declarations

```
type
  TS1 = set of Char;
  TS2 = set of Char;
```

create two distinct types, *TS1* and *TS2*. Similarly, the variable declarations

```
var
  S1: string[10];
  S2: string[10];
```

create two variables of distinct types. To create variables of the same type, use

```
var S1, S2: string[10];
```

or

```
type MyString = string[10];
var
  S1: MyString;
  S2: MyString;
```

Type compatibility

Every type is compatible with itself. Two distinct types are compatible if they satisfy at least one of the following conditions.

- They are both real types.
- They are both integer types.
- One type is a subrange of the other.
- Both types are subranges of the same type.
- Both are set types with compatible base types.
- Both are packed-string types with the same number of components.
- One is a string type and the other is a string, packed-string, or *Char* type.
- One type is *Variant* and the other is an integer, real, string, character, or Boolean type.
- Both are class, class-reference, or interface types, and one type is derived from the other.
- One type is *PChar* or *PWideChar* and the other is a zero-based character array of the form `array[0..`*n*`] of Char`.
- One type is *Pointer* (an untyped pointer) and the other is any pointer type.
- Both types are (typed) pointers to the same type and the **{$T+}** compiler directive is in effect.
- Both are procedural types with the same result type, the same number of parameters, and type-identity between parameters in corresponding positions.

Assignment-compatibility

Assignment-compatibility is not a symmetric relation. An expression of type *T2* can be assigned to a variable of type *T1* if the value of the expression falls in the range of *T1* and at least one of the following conditions is satisfied.

- *T1* and *T2* are of the same type, and it is not a file type or structured type that contains a file type at any level.
- *T1* and *T2* are compatible ordinal types.
- *T1* and *T2* are both real types.
- *T1* is a real type and *T2* is an integer type.
- *T1* is *PChar* or any string type and the expression is a string constant.
- *T1* and *T2* are both string types.
- *T1* is a string type and *T2* is a *Char* or packed-string type.
- *T1* is a long string and *T2* is *PChar*.
- *T1* and *T2* are compatible packed-string types.
- *T1* and *T2* are compatible set types.
- *T1* and *T2* are compatible pointer types.
- *T1* and *T2* are both class, class-reference, or interface types and *T2* is a derived from *T1*.
- *T1* is an interface type and *T2* is a class type that implements *T1*.
- *T1* is *PChar* or *PWideChar* and *T2* is a zero-based character array of the form `array[0..`*n*`] of Char`.
- *T1* and *T2* are compatible procedural types. (A function or procedure identifier is treated, in certain assignment statements, as an expression of a procedural type. See "Procedural types in statements and expressions" on page 5-29.)
- *T1* is *Variant* and *T2* is an integer, real, string, character, Boolean, or interface type.
- *T1* is an integer, real, string, character, or Boolean type and *T2* is *Variant*.
- *T1* is the *IUnknown* or *IDispatch* interface type and *T2* is *Variant*. (The variant's type code must be *varEmpty*, *varUnknown*, or *varDispatch* if *T1* is *IUnknown*, and *varEmpty* or *varDispatch* if *T1* is *IDispatch*.)

Declaring types

A type declaration specifies an identifier that denotes a type. The syntax for a type declaration is

`type` *newTypeName* `=` *type*

where *newTypeName* is a valid identifier. For example, given the type declaration

```
type TMyString = string;
```

you can make the variable declaration

```
var S: TMyString;
```

A type identifier's scope doesn't include the type declaration itself (except for pointer types). So you cannot, for example, define a record type that uses itself recursively.

When you declare a type that is identical to an existing type, the compiler treats the new type identifier as an alias for the old one. Thus, given the declarations

```
type TValue = Real;
var
  X: Real;
  Y: TValue;
```

X and *Y* are of the same type; at runtime, there is no way to distinguish *TValue* from *Real*. This is usually of little consequence, but if your purpose in defining a new type is to utilize runtime type information—for example, to associate a property editor with properties of a particular type—the distinction between “different name” and “different type” becomes important. In this case, use the syntax

```
type newTypeName = type type
```

For example,

```
type TValue = type Real;
```

forces the compiler to create a new, distinct type called *TValue*.

Variables

A variable is an identifier whose value can change at runtime. Put differently, a variable is a name for a location in memory; you can use the name to read or write to the memory location. Variables are like containers for data, and, because they are typed, they tell the compiler how to interpret the data they hold.

Declaring variables

The basic syntax for a variable declaration is

```
var identifierList: type;
```

where *identifierList* is a comma-delimited list of valid identifiers and *type* is any valid type. For example,

```
var I: Integer;
```

declares a variable *I* of type *Integer*, while

```
var X, Y: Real;
```

declares two variables—*X* and *Y*—of type *Real*.

Consecutive variable declarations do not have to repeat the reserved word **var**:

```
var
  X, Y, Z: Double;
  I, J, K: Integer;
  Digit: 0..9;
  Okay: Boolean;
```

Variables declared within a procedure or function are sometimes called *local*, while other variables are called *global*. Global variables can be initialized at the same time they are declared, using the syntax

```
var identifier: type = constantExpression;
```

where *constantExpression* is any constant expression representing a value of type *type*. (For more information about constant expressions, see “Constant expressions” on page 5-41.) Thus the declaration

```
var I: Integer = 7;
```

is equivalent to the declaration and statement

```
var I: Integer;
 ⋮
I := 7;
```

Multiple variable declarations (such as `var X, Y, Z: Real;`) cannot include initializations, nor can declarations of variant and file-type variables.

If you don't explicitly initialize a global variable, the compiler initializes it to 0. Local variables, in contrast, cannot be initialized in their declarations and contain random data until a value is assigned to them.

When you declare a variable, you are allocating memory which is freed automatically when the variable is no longer used. In particular, local variables exist only until the program exits from the function or procedure in which they are declared. For more information about variables and memory management, see Chapter 11, "Memory management".

Absolute addresses

You can create a new variable that resides at the same address as another variable. To do so, put the directive **absolute** after the type name in the declaration of the new variable, followed by the name of an existing (previously declared) variable. For example,

```
var
  Str: string[32];
  StrLen: Byte absolute Str;
```

specifies that the variable *StrLen* should start at the same address as *Str*. Since the first byte of a short string contains the string's length, the value of *StrLen* is the length of *Str*.

You cannot initialize a variable in an **absolute** declaration or combine **absolute** with any other directives.

Dynamic variables

You can create dynamic variables by calling the *GetMem* or *New* procedure. Such variables are allocated on the heap and are not managed automatically. Once you create one, it is your responsibility ultimately to free the variable's memory; use *FreeMem* to destroy variables created by *GetMem* and *Dispose* to destroy variables created by *New*. Other standard routines that operate on dynamic variables include *ReallocMem*, *Initialize*, *StrAlloc*, and *StrDispose*.

Long strings, wide strings, dynamic arrays, variants, and interfaces are also heap-allocated dynamic variables, but their memory is managed automatically.

Thread-local variables

Thread-local (or *thread*) variables are used in multithreaded applications. A thread-local variable is like a global variable, except that each thread of execution gets its own private copy of the variable, which cannot be accessed from other threads. Thread-local variables are declared with **threadvar** instead of **var**. For example,

```
threadvar X: Integer;
```

Thread-variable declarations

- cannot occur within a procedure or function.
- cannot include initializations.
- cannot specify the **absolute** directive.

Do not create pointer- or procedural-type thread variables, and do not use thread variables in dynamically loadable libraries (other than packages).

Dynamic variables that are ordinarily managed by the compiler—long strings, wide strings, dynamic arrays, variants, and interfaces—can be declared with **threadvar**, but the compiler does not automatically free the heap-allocated memory created by each thread of execution. If you use these data types in thread variables, it is your responsibility to dispose of their memory. For example,

```
threadvar S: AnsiString;
S := 'ABCDEFGHIJKLMNOPQRSTUVWXYZ';
 ⋮
S := '';  // free the memory used by S
```

(You can free a variant by setting it to *Unassigned* and an interface or dynamic array by setting it to **nil**.)

Declared constants

Several different language constructions are referred to as "constants". There are numeric constants (also called *numerals*) like `17`, and string constants (also called *character strings* or *string literals*) like `'Hello world!'`; for information about numeric and string constants, see Chapter 4, "Syntactic elements". Every enumerated type defines constants that represent the values of that type. There are predefined constants like *True*, *False*, and **nil**. Finally, there are constants that, like variables, are created individually by declaration.

Declared constants are either *true constants* or *typed constants*. These two kinds of constant are superficially similar, but they are governed by different rules and used for different purposes.

True constants

A true constant is a declared identifier whose value cannot change. For example,

```
const MaxValue = 237;
```

declares a constant called *MaxValue* that returns the integer 237. The syntax for declaring a true constant is

const *identifier* = *constantExpression* where *identifier* is any valid identifier and *constantExpression* is an expression that the compiler can evaluate without executing your program. (See “Constant expressions” on page 5-41 for more information.)

If *constantExpression* returns an ordinal value, you can specify the type of the declared constant using a value typecast. For example

```
const MyNumber = Int64(17);
```

declares a constant called *MyNumber*, of type *Int64*, that returns the integer 17. Otherwise, the type of the declared constant is the type of the *constantExpression*.

- If *constantExpression* is a character string, the declared constant is compatible with any string type. If the character string is of length 1, it is also compatible with any character type.
- If *constantExpression* is a real, its type is *Extended*. If it is an integer, its type is given by the table below.

Table 5.8 Types for integer constants

Range of constant (hexadecimal)	Range of constant (decimal)	Type
–$8000000000000000..–$80000001	$–2^{63}$..–2147483649	*Int64*
–$80000000..–$8001	–2147483648..–32769	*Integer*
–$8000..–$81	–32768..–129	*Smallint*
–$80..–1	–128..–1	*Shortint*
0..$7F	0..127	0..127
$80..$FF	128..255	*Byte*
$0100..$7FFF	256..32767	0..32767
$8000..$FFFF	32768..65535	*Word*
$10000..$7FFFFFFF	65536..2147483647	0..2147483647
$80000000..$FFFFFFFF	2147483648..4294967295	*Cardinal*
$100000000..$7FFFFFFFFFFFFFFF	4294967296..2^{63}–1	*Int64*

Here are some examples of constant declarations:

```
const
  Min = 0;
  Max = 100;
  Center = (Max - Min) div 2;
  Beta = Chr(225);
  NumChars = Ord('Z') - Ord('A') + 1;
  Message = 'Out of memory';
  ErrStr = ' Error: ' + Message + '. ';
  ErrPos = 80 - Length(ErrStr) div 2;
  Ln10 = 2.302585092994045684;
  Ln10R = 1 / Ln10;
  Numeric = ['0'..'9'];
  Alpha = ['A'..'Z', 'a'..'z'];
  AlphaNum = Alpha + Numeric;
```

Constant expressions

A *constant expression* is an expression that the compiler can evaluate without executing the program in which it occurs. Constant expressions include numerals; character strings; true constants; values of enumerated types; the special constants *True*, *False*, and **nil**; and expressions built exclusively from these elements with operators, typecasts, and set constructors. Constant expressions cannot include variables, pointers, or function calls, except calls to the following predefined functions:

Abs
Chr
Hi
High
Length
Lo
Low
Odd
Ord
Pred
Round
SizeOf
Succ
Swap
Trunc

This definition of a *constant expression* is used in several places in Object Pascal's syntax specification. Constant expressions are required for initializing global variables, defining subrange types, assigning ordinalities to values in enumerated types, specifying default parameter values, writing **case** statements, and declaring both true and typed constants.

Examples of constant expressions:

```
100
'A'
256 - 1
(2.5 + 1) / (2.5 - 1)
'Borland' + ' ' + 'Developer'
Chr(32)
Ord('Z') - Ord('A') + 1
```

Resource strings

Resource strings are stored as resources and linked into the executable or library so that they can be modified without recompiling the program. For more information, see the online Help topics on localizing applications.

Resource strings are declared like other true constants, except that the word **const** is replaced by **resourcestring**. The expression to the right of the **=** symbol must be a constant expression and must return a string value. For example,

```
resourcestring
  CreateError = 'Cannot create file %s';        {  for explanations of format specifiers, }
  OpenError = 'Cannot open file %s';            { see 'Format strings' in the online Help }
  LineTooLong = 'Line too long';
  ProductName = 'Borland Rocks\000\000';
  SomeResourceString = SomeTrueConstant;
```

The compiler automatically resolves naming conflicts among resource strings in different libraries.

Typed constants

Typed constants, unlike true constants, can hold values of array, record, procedural, and pointer types. Typed constants cannot occur in constant expressions.

In the default **{$J-}** compiler state, typed constants can not have new values assigned to them; they are, in effect, read-only variables. However, if the **{$J+}** compiler directive is in effect, typed constants can have new values assigned to them; they behave essentially like initialized variables.

Declare a typed constant like this:

```
const identifier: type = value
```

where *identifier* is any valid identifier, *type* is any type except files and variants, and *value* is an expression of type *type*. For example,

```
const Max: Integer = 100;
```

In most cases, *value* must be a constant expression; but if *type* is an array, record, procedural, or pointer type, special rules apply.

Array constants

To declare an array constant, enclose the values of the array's elements, separated by commas, in parentheses at the end of the declaration. These values must be represented by constant expressions. For example,

```
const Digits: array[0..9] of Char = ('0', '1', '2', '3', '4', '5', '6', '7', '8', '9');
```

declares a typed constant called *Digits* that holds an array of characters.

Zero-based character arrays often represent null-terminated strings, and for this reason string constants can be used to initialize character arrays. So the declaration above can be more conveniently represented as

```
const Digits: array[0..9] of Char = '0123456789';
```

To define a multidimensional array constant, enclose the values of each dimension in a separate set of parentheses, separated by commas. For example,

```
type TCube = array[0..1, 0..1, 0..1] of Integer;
const Maze: TCube = (((0, 1), (2, 3)), ((4, 5), (6,7)));
```

creates an array called *Maze* where

Maze[0,0,0] = 0
Maze[0,0,1] = 1
Maze[0,1,0] = 2
Maze[0,1,1] = 3
Maze[1,0,0] = 4
Maze[1,0,1] = 5
Maze[1,1,0] = 6
Maze[1,1,1] = 7

Array constants cannot contain file-type values at any level.

Record constants

To declare a record constant, specify the value of each field—as *fieldName*: *value*, with the field assignments separated by semicolons—in parentheses at the end of the declaration. The values must be represented by constant expressions. The fields must be listed in the order in which they appear in the record type declaration, and the tag field, if there is one, must have a value specified; if the record has a variant part, only the variant selected by the tag field can be assigned values.

Examples:

```
type
  TPoint = record
    X, Y: Single;
  end;
  TVector = array[0..1] of TPoint;
  TMonth = (Jan, Feb, Mar, Apr, May, Jun, Jul, Aug, Sep, Oct, Nov, Dec);
  TDate = record
    D: 1..31;
    M: TMonth;
    Y: 1900..1999;
  end;
const
  Origin: TPoint = (X: 0.0; Y: 0.0);
  Line: TVector = ((X: -3.1; Y: 1.5), (X: 5.8; Y: 3.0));
  SomeDay: TDate = (D: 2; M: Dec; Y: 1960);
```

Record constants cannot contain file-type values at any level.

Procedural constants

To declare a procedural constant, specify the name of a function or procedure that is compatible with the declared type of the constant. For example,

```
function Calc(X, Y: Integer): Integer;
begin
 ⋮
end;

type TFunction = function(X, Y: Integer): Integer;
const MyFunction: TFunction = Calc;
```

Given these declarations, you can use the procedural constant *MyFunction* in a function call:

```
I := MyFunction(5, 7)
```

You can also assign the value **nil** to a procedural constant.

Pointer constants

When you declare a pointer constant, you must initialize it to a value that can be resolved—at least as a relative address—at compile time. There are three ways to do this: with the @ operator, with **nil**, and (if the constant is of type *PChar*) with a string literal. For example, if *I* is a global variable of type *Integer*, you can declare a constant like

```
const PI: ^Integer = @I;
```

The compiler can resolve this because global variables are part of the code segment. So are functions and global constants:

```
const PF: Pointer = @MyFunction;
```

Because string literals are allocated as global constants, you can initialize a *PChar* constant with a string literal:

```
const WarningStr: PChar = 'Warning!';
```

Addresses of local (stack-allocated) and dynamic (heap-allocated) variables cannot be assigned to pointer constants.

Chapter

6

Procedures and functions

Procedures and functions, referred to collectively as *routines*, are self-contained statement blocks that can be called from different locations in a program. A *function* is a routine that returns a value when it executes. A *procedure* is a routine that does not return a value.

Function calls, because they return a value, can be used as expressions in assignments and operations. For example,

```
I := SomeFunction(X);
```

calls *SomeFunction* and assigns the result to *I*. Function calls cannot appear on the left side of an assignment statement.

Procedure calls—and, when extended syntax is enabled (**{$X+}**), function calls—can be used as complete statements. For example,

```
DoSomething;
```

calls the *DoSomething* routine; if *DoSomething* is a function, its return value is discarded.

Procedures and functions can call themselves recursively.

Declaring procedures and functions

When you declare a procedure or function, you specify its name, the number and type of parameters it takes, and, in the case of a function, the type of its return value; this part of the declaration is sometimes called the *prototype*, *heading*, or *header*. Then you write a block of code that executes whenever the procedure or function is called; this part is sometimes called the routine's *body* or *block*.

The standard procedure *Exit* can occur within the body of any procedure or function. *Exit* halts execution of the routine where it occurs and immediately passes program control back to the point from which the routine was called.

Procedure declarations

A procedure declaration has the form

```
procedure procedureName(parameterList); directives;
localDeclarations;
begin
  statements
end;
```

where *procedureName* is any valid identifier, *statements* is a sequence of statements that execute when the procedure is called, and (*parameterList*), *directives*;, and *localDeclarations*; are optional.

- For information about the *parameterList*, see "Parameters" on page 6-11.
- For information about *directives*, see "Calling conventions" on page 6-4, "Forward and interface declarations" on page 6-5, "External declarations" on page 6-6, "Overloading procedures and functions" on page 6-8, and "Writing dynamically loadable libraries" on page 9-3. If you include more than one directive, separate them with semicolons.
- For information about *localDeclarations*, which declares local identifiers, see "Local declarations" on page 6-10.

Here is an example of a procedure declaration:

```
procedure NumString(N: Integer; var S: string);
var
  V: Integer;
begin
  V := Abs(N);
  S := '';
  repeat
    S := Chr(V mod 10 + Ord('0')) + S;
    V := V div 10;
  until V = 0;
  if N < 0 then S := '-' + S;
end;
```

Given this declaration, you can call the *NumString* procedure like this:

```
NumString(17, MyString);
```

This procedure call assigns the value "17" to *MyString* (which must be a **string** variable).

Within a procedure's statement block, you can use variables and other identifiers declared in the *localDeclarations* part of the procedure. You can also use the parameter names from the parameter list (like *N* and *S* in the example above); the parameter list defines a set of local variables, so don't try to redeclare the parameter names in the *localDeclarations* section. Finally, you can use any identifiers within whose scope the procedure declaration falls.

Function declarations

A function declaration is like a procedure declaration except that it specifies a return type and a return value. Function declarations have the form

```
function functionName(parameterList): returnType; directives;
localDeclarations;
begin
  statements
end;
```

where *functionName* is any valid identifier, *returnType* is any type, *statements* is a sequence of statements that execute when the function is called, and (*parameterList*), *directives*;, and *localDeclarations*; are optional.

- For information about the *parameterList*, see "Parameters" on page 6-11.
- For information about *directives*, see "Calling conventions" on page 6-4, "Forward and interface declarations" on page 6-5, "External declarations" on page 6-6, "Overloading procedures and functions" on page 6-8, and "Writing dynamically loadable libraries" on page 9-3. If you include more than one directive, separate them with semicolons.
- For information about *localDeclarations*, which declares local identifiers, see "Local declarations" on page 6-10.

The function's statement block is governed by the same rules that apply to procedures. Within the statement block, you can use variables and other identifiers declared in the *localDeclarations* part of the function, parameter names from the parameter list, and any identifiers within whose scope the function declaration falls. In addition, the function name itself acts as a special variable that holds the function's return value, as does the predefined variable *Result*.

For example,

```
function WF: Integer;
begin
  WF := 17;
end;
```

defines a constant function called *WF* that takes no parameters and always returns the integer value 17. This declaration is equivalent to

```
function WF: Integer;
begin
  Result := 17;
end;
```

Here is a more complicated function declaration:

```
function Max(A: array of Real; N: Integer): Real;
var
  X: Real;
  I: Integer;
begin
  X := A[0];
```

```
    for I := 1 to N - 1 do
      if X < A[I] then X := A[I];
    Max := X;
  end;
```

You can assign a value to *Result* or to the function name repeatedly within a statement block, as long as you assign only values that match the declared return type. When execution of the function terminates, whatever value was last assigned to *Result* or to the function name becomes the function's return value. For example,

```
function Power(X: Real; Y: Integer): Real;
var
  I: Integer;
begin
  Result := 1.0;
  I := Y;
  while I > 0 do
  begin
    if Odd(I) then Result := Result * X;
    I := I div 2;
    X := Sqr(X);
  end;
end;
```

Result and the function name always represent the same value. Hence

```
function MyFunction: Integer;
begin
  MyFunction := 5;
  Result := Result * 2;
  MyFunction := Result + 1;
end;
```

returns the value 11. But *Result* is not completely interchangeable with the function name. When the function name appears on the left side of an assignment statement, the compiler assumes that it is being used (like *Result*) to track the return value; when the function name appears anywhere else in the statement block, the compiler interprets it as a recursive call to the function itself. *Result*, on the other hand, can be used as a variable in operations, typecasts, set constructors, indexes, and calls to other routines.

As long as extended syntax is enabled (**{$X+}**), *Result* is implicitly declared in every function. Do not try to redeclare it.

If execution terminates without an assignment being made to *Result* or the function name, then the function's return value is undefined.

Calling conventions

When you declare a procedure or function, you can specify a *calling convention* using one of the directives **register**, **pascal**, **cdecl**, **stdcall**, and **safecall**. For example,

```
function MyFunction(X, Y: Real): Real; cdecl;
  ⋮
```

Calling conventions determine the order in which parameters are passed to the routine. They also affect the removal of parameters from the stack, the use of registers for passing parameters, and error and exception handling. The default calling convention is **register**.

- The **register** and **pascal** conventions pass parameters from left to right; that is, the leftmost parameter is evaluated and passed first and the rightmost parameter is evaluated and passed last. The **cdecl**, **stdcall**, and **safecall** conventions pass parameters from right to left.
- For all conventions except **cdecl**, the procedure or function removes parameters from the stack upon returning. With the **cdecl** convention, the caller removes parameters from the stack when the call returns.
- The **register** convention uses up to three CPU registers to pass parameters, while the other conventions pass all parameters on the stack.
- The **safecall** convention implements exception "firewalls." On Windows, this implements interprocess COM error notification.

The table below summarizes calling conventions.

Table 6.1 Calling conventions

Directive	Parameter order	Clean-up	Passes parameters in registers?
register	Left-to-right	Routine	Yes
pascal	Left-to-right	Routine	No
cdecl	Right-to-left	Caller	No
stdcall	Right-to-left	Routine	No
safecall	Right-to-left	Routine	No

The default **register** convention is the most efficient, since it usually avoids creation of a stack frame. (Access methods for published properties must use **register**.) The **cdecl** convention is useful when you call functions from shared libraries written in C or C++, while **stdcall** and **safecall** are recommended, in general, for calls to external code. On Windows, the operating system APIs are **stdcall** and **safecall**. Other operating systems generally use **cdecl**. (Note that **stdcall** is more efficient than **cdecl**.)

The **safecall** convention must be used for declaring dual-interface methods (see Chapter 10, "Object interfaces"). The **pascal** convention is maintained for backward compatibility. For more information on calling conventions, see Chapter 12, "Program control".

The directives **near**, **far**, and **export** refer to calling conventions in 16-bit Windows programming. They have no effect in 32-bit applications and are maintained for backward compatibility only.

Forward and interface declarations

The **forward** directive replaces the block, including local variable declarations and statements, in a procedure or function declaration. For example,

```
function Calculate(X, Y: Integer): Real; forward;
```

declares a function called *Calculate*. Somewhere after the **forward** declaration, the routine must be redeclared in a *defining declaration* that includes a block. The defining declaration for *Calculate* might look like this:

```
function Calculate;
 ⋮   { declarations }
begin
 ⋮   { statement block }
end;
```

Ordinarily, a defining declaration does not have to repeat the routine's parameter list or return type, but if it does repeat them, they must match those in the **forward** declaration exactly (except that default parameters can be omitted). If the **forward** declaration specifies an overloaded procedure or function (see "Overloading procedures and functions" on page 6-8), then the defining declaration must repeat the parameter list.

Between a **forward** declaration and its defining declaration, you can place nothing except other declarations. The defining declaration can be an **external** or **assembler** declaration, but it cannot be another **forward** declaration.

The purpose of a **forward** declaration is to extend the scope of a procedure or function identifier to an earlier point in the source code. This allows other procedures and functions to call the **forward**-declared routine before it is actually defined. Besides letting you organize your code more flexibly, **forward** declarations are sometimes necessary for mutual recursions.

The **forward** directive is not allowed in the **interface** section of a unit. Procedure and function headers in the **interface** section, however, behave like **forward** declarations and must have defining declarations in the **implementation** section. A routine declared in the **interface** section is available from anywhere else in the unit and from any other unit or program that uses the unit where it is declared.

External declarations

The **external** directive, which replaces the block in a procedure or function declaration, allows you to call routines that are compiled separately from your program. External routines can come from object files or dynamically loadable libraries.

When importing a C++ function that takes a variable number of parameters, use the **varargs** directive. For example,

```
function printf(Format: PChar): Integer; cdecl; varargs;
```

The **varargs** directive works only with external routines and only with the **cdecl** calling convention.

Linking to object files

To call routines from a separately compiled object file, first link the object file to your application using the **$L** (or **$LINK**) compiler directive. For example,

```
On Windows: {$L BLOCK.OBJ}

On Linux:   {$L block.o}
```

links BLOCK.OBJ (Windows) or block.o (Linux) into the program or unit in which it occurs. Next, declare the functions and procedures that you want to call:

```
procedure MoveWord(var Source, Dest; Count: Integer); external;
procedure FillWord(var Dest; Data: Integer; Count: Integer); external;
```

Now you can call the *MoveWord* and *FillWord* routines from BLOCK.OBJ (Windows) or block.o (Linux).

Declarations like the ones above are frequently used to access external routines written in assembly language. You can also place assembly-language routines directly in your Object Pascal source code; for more information, see Chapter 13, “Inline assembler code”.

Importing functions from libraries

To import routines from a dynamically loadable library (.so or .DLL), attach a directive of the form

```
external stringConstant;
```

to the end of a normal procedure or function header, where *stringConstant* is the name of the library file in single quotation marks. For example, on Windows

```
function SomeFunction(S: string): string; external 'strlib.dll';
```

imports a function called *SomeFunction* from strlib.dll.

On Linux,

```
function SomeFunction(S: string): string; external 'strlib.so';
```

imports a function called *SomeFunction* from strlib.so.

You can import a routine under a different name from the one it has in the library. If you do this, specify the original name in the **external** directive:

```
external stringConstant1 name stringConstant2;
```

where the first *stringConstant* gives the name of the library file and the second *stringConstant* is the routine’s original name.

On Windows: For example, the following declaration imports a function from user32.dll (part of the Windows API).

```
function MessageBox(HWnd: Integer; Text, Caption: PChar; Flags: Integer): Integer;
  stdcall; external 'user32.dll' name 'MessageBoxA';
```

The function’s original name is *MessageBoxA*, but it is imported as *MessageBox*.

Instead of a name, you can use a number to identify the routine you want to import:

```
external stringConstant index integerConstant;
```

where *integerConstant* is the routine’s index in the export table.

On Linux: For example, the following declaration imports a standard system function from libc.so.6.

```
function OpenFile(const PathName: PChar; Flags: Integer): Integer; cdecl;
  external 'libc.so.6' name 'open';
```

The function's original name is *open*, but it is imported as *OpenFile*.

In your importing declaration, be sure to match the exact spelling and case of the routine's name. Later, when you call the imported routine, the name is case-insensitive.

For more information about libraries, see Chapter 9, "Libraries and packages".

Overloading procedures and functions

You can declare more than one routine in the same scope with the same name. This is called *overloading*. Overloaded routines must be declared with the **overload** directive and must have distinguishing parameter lists. For example, consider the declarations

```
function Divide(X, Y: Real): Real; overload;
begin
  Result := X/Y;
end;

function Divide(X, Y: Integer): Integer; overload;
begin
  Result := X div Y;
end;
```

These declarations create two functions, both called *Divide*, that take parameters of different types. When you call *Divide*, the compiler determines which function to invoke by looking at the actual parameters passed in the call. For example, `Divide(6.0, 3.0)` calls the first *Divide* function, because its arguments are real-valued.

You can pass to an overloaded routine parameters that are not identical in type with those in any of the routine's declarations, but that are assignment-compatible with the parameters in more than one declaration. This happens most frequently when a routine is overloaded with different integer types or different real types—for example,

```
procedure Store(X: Longint); overload;
procedure Store(X: Shortint); overload;
```

In these cases, when it is possible to do so without ambiguity, the compiler invokes the routine whose parameters are of the type with the smallest range that accommodates the actual parameters in the call. (Remember that real-valued constant expressions are always of type *Extended*.)

Overloaded routines must be distinguished by the number of parameters they take or the types of their parameters. Hence the following pair of declarations causes a compilation error.

```
function Cap(S: string): string; overload;
  ⋮
procedure Cap(var Str: string); overload;
  ⋮
```

But the declarations

```
function Func(X: Real; Y: Integer): Real; overload;
 ⋮
function Func(X: Integer; Y: Real): Real; overload;
 ⋮
```

are legal.

When an overloaded routine is declared in a **forward** or interface declaration, the defining declaration must repeat the routine's parameter list.

The compiler can distinguish between overloaded functions that contain AnsiString/PChar and WideString/WideChar parameters in the same parameter position. String constants or literals passed into such an overload situation are translated into the native string or character type, which is AnsiString/PChar.

```
procedure test(const S: String);  overload;
procedure test(const W: WideString); overload;

var
    a: string;
    b: widestring;
begin
   a := 'a';
   b := 'b';
   test(a);    // calls String version
   test(b);    // calls WideString version
   test('abc');    // calls String version
   test(WideString('abc'));   // calls widestring version
end;
```

Variants can also be used as parameters in overloaded function declarations. Variant is considered more general than any simple type. Preference is always given to exact type matches over variant matches. If a variant is passed into such an overload situation, and an overload that takes a variant exists in that parameter position, it is considered to be an exact match for the Variant type.

This can cause some minor side effects with float types. Float types are matched by size. If there is no exact match for the float variable passed to the overload call but a variant parameter is available, the variant is taken over any smaller float type.

For example:

```
procedure foo(i: integer); overload;
procedure foo(d: double);  overload;
procedure foo(v: variant); overload;
var
  v: variant;
begin
  foo(1);       // integer version
  foo(v);       // variant version
  foo(1.2);     // variant version (float literals -> extended precision)
end;
```

This example calls the variant version of foo, not the double version, because the 1.2 constant is implicitly an extended type and extended is not an exact match for double. Extended is also not an exact match for variant, but variant is considered a more general type (whereas double is a smaller type than extended).

```
foo(Double(1.2));
```

This typecast does not work. You should use typed consts instead.

```
const  d: double = 1.2;
  begin
    foo(d);
  end;
```

The above code works correctly, and calls the double version.

```
  const  s: single = 1.2;
  begin
    foo(s);
  end;
```

The above code also calls the double version of foo. Single is a better fit to double than to variant.

When declaring a set of overloaded routines, the best way to avoid float promotion to variant is to declare a version of your overloaded function for each float type (Single, Double, Extended) along with the variant version.

If you use default parameters in overloaded routines, be careful of ambiguous parameter signatures. For more information, see “Default parameters and overloaded routines” on page 6-18.

You can limit the potential effects of overloading by qualifying a routine’s name when you call it. For example, `Unit1.MyProcedure(X, Y)` can call only routines declared in *Unit1*; if no routine in *Unit1* matches the name and parameter list in the call, an error results.

For information about distributing overloaded methods in a class hierarchy, see “Overloading methods” on page 7-12. For information about exporting overloaded routines from a shared library, see “The exports clause” on page 9-5.

Local declarations

The body of a function or procedure often begins with declarations of local variables used in the routine’s statement block. These declarations can also include constants, types, and other routines. The scope of a local identifier is limited to the routine where it is declared.

Nested routines

Functions and procedures sometimes contain other functions and procedures within the local-declarations section of their blocks. For example, the following declaration of a procedure called *DoSomething* contains a nested procedure.

```
procedure DoSomething(S: string);
var
  X, Y: Integer;
```

```
   procedure NestedProc(S: string);
   begin
     ⋮
   end;

begin
  ⋮
  NestedProc(S);
  ⋮
end;
```

The scope of a nested routine is limited to the procedure or function in which it is declared. In our example, *NestedProc* can be called only within *DoSomething*.

For real examples of nested routines, look at the *DateTimeToString* procedure, the *ScanDate* function, and other routines in the *SysUtils* unit.

Parameters

Most procedure and function headers include a *parameter list*. For example, in the header

```
function Power(X: Real; Y: Integer): Real;
```

the parameter list is `(X: Real; Y: Integer)`.

A parameter list is a sequence of parameter declarations separated by semicolons and enclosed in parentheses. Each declaration is a comma-delimited series of parameter names, followed in most cases by a colon and a type identifier, and in some cases by the = symbol and a default value. Parameter names must be valid identifiers. Any declaration can be preceded by one of the reserved words **var**, **const**, and **out**. Examples:

```
(X, Y: Real)
(var S: string; X: Integer)
(HWnd: Integer; Text, Caption: PChar; Flags: Integer)
(const P; I: Integer)
```

The parameter list specifies the number, order, and type of parameters that must be passed to the routine when it is called. If a routine does not take any parameters, omit the identifier list and the parentheses in its declaration:

```
procedure UpdateRecords;
begin
 ⋮
end;
```

Within the procedure or function body, the parameter names (*X* and *Y* in the first example above) can be used as local variables. Do not redeclare the parameter names in the local declarations section of the procedure or function body.

Parameter semantics

Parameters are categorized in several ways:

- Every parameter is classified as *value*, *variable*, *constant*, or *out*. Value parameters are the default; the reserved words **var**, **const**, and **out** indicate variable, constant, and out parameters, respectively.
- Value parameters are always *typed*, while constant, variable, and out parameters can be either typed or *untyped*.
- Special rules apply to array parameters. See "Array parameters" on page 6-15.

Files and instances of structured types that contain files can be passed only as variable (**var**) parameters.

Value and variable parameters

Most parameters are either value parameters (the default) or variable (**var**) parameters. Value parameters are passed *by value*, while variable parameters are passed *by reference*. To see what this means, consider the following functions.

```
function DoubleByValue(X: Integer): Integer;     // X is a value parameter
begin
  X := X * 2;
  Result := X;
end;

function DoubleByRef(var X: Integer): Integer;   // X is a variable parameter
begin
  X := X * 2;
  Result := X;
end;
```

These functions return the same result, but only the second one—*DoubleByRef*—can change the value of a variable passed to it. Suppose we call the functions like this:

```
var
  I, J, V, W: Integer;
begin
  I := 4;
  V := 4;
  J := DoubleByValue(I);   // J = 8, I = 4
  W := DoubleByRef(V);     // W = 8, V = 8
end;
```

After this code executes, the variable *I*, which was passed to *DoubleByValue*, has the same value we initially assigned to it. But the variable *V*, which was passed to *DoubleByRef*, has a different value.

A value parameter acts like a local variable that gets initialized to the value passed in the procedure or function call. If you pass a variable as a value parameter, the procedure or function creates a copy of it; changes made to the copy have no effect on the original variable and are lost when program execution returns to the caller.

A variable parameter, on the other hand, acts like a pointer rather than a copy. Changes made to the parameter within the body of a function or procedure persist after program execution returns to the caller and the parameter name itself has gone out of scope.

Even if the same variable is passed in two or more **var** parameters, no copies are made. This is illustrated in the following example.

```
procedure AddOne(var X, Y: Integer);
begin
  X := X + 1;
  Y := Y + 1;
end;

var I: Integer;
begin
  I := 1;
  AddOne(I, I);
end;
```

After this code executes, the value of *I* is 3.

If a routine's declaration specifies a **var** parameter, you must pass an assignable expression—that is, a variable, typed constant (in the **{$J+}** state), dereferenced pointer, field, or indexed variable—to the routine when you call it. To use our previous examples, `DoubleByRef(7)` produces an error, although `DoubleByValue(7)` is legal.

Indexes and pointer dereferences passed in **var** parameters—for example, `DoubleByRef(MyArray[I])`—are evaluated once, before execution of the routine.

Constant parameters

A constant (**const**) parameter is like a local constant or read-only variable. Constant parameters are similar to value parameters, except that you can't assign a value to a constant parameter within the body of a procedure or function, nor can you pass one as a **var** parameter to another routine. (But when you pass an object reference as a constant parameter, you can still modify the object's properties.)

Using **const** allows the compiler to optimize code for structured- and string-type parameters. It also provides a safeguard against unintentionally passing a parameter by reference to another routine.

Here, for example, is the header for the *CompareStr* function in the *SysUtils* unit:

```
function CompareStr(const S1, S2: string): Integer;
```

Because *S1* and *S2* are not modified in the body of *CompareStr*, they can be declared as constant parameters.

Out parameters

An **out** parameter, like a variable parameter, is passed by reference. With an **out** parameter, however, the initial value of the referenced variable is discarded by the routine it is passed to. The **out** parameter is for output only; that is, it tells the function or procedure where to store output, but doesn't provide any input.

For example, consider the procedure heading

```
procedure GetInfo(out Info: SomeRecordType);
```

When you call *GetInfo*, you must pass it a variable of type *SomeRecordType*:

```
var MyRecord: SomeRecordType;
```

```
  ⋮
GetInfo(MyRecord);
```

But you’re not using *MyRecord* to pass any data to the *GetInfo* procedure; *MyRecord* is just a container where you want *GetInfo* to store the information it generates. The call to *GetInfo* immediately frees the memory used by *MyRecord*, before program control passes to the procedure.

Out parameters are frequently used with distributed-object models like COM and CORBA. In addition, you should use **out** parameters when you pass an uninitialized variable to a function or procedure.

Untyped parameters

You can omit type specifications when declaring **var**, **const**, and **out** parameters. (Value parameters must be typed.) For example,

```
procedure TakeAnything(const C);
```

declares a procedure called *TakeAnything* that accepts a parameter of any type. When you call such a routine, you cannot pass it a numeral or untyped numeric constant.

Within a procedure or function body, untyped parameters are incompatible with every type. To operate on an untyped parameter, you must cast it. In general, the compiler cannot verify that operations on untyped parameters are valid.

The following example uses untyped parameters in a function called *Equal* that compares a specified number of bytes of any two variables.

```
function Equal(var Source, Dest; Size: Integer): Boolean;
type
  TBytes = array[0..MaxInt - 1] of Byte;
var
  N: Integer;
begin
  N := 0;
  while (N < Size) and (TBytes(Dest)[N] = TBytes(Source)[N]) do
    Inc(N);
  Equal := N = Size;
end;
```

Given the declarations

```
type
  TVector = array[1..10] of Integer;
  TPoint = record
    X, Y: Integer;
  end;
var
  Vec1, Vec2: TVector;
  N: Integer;
  P: TPoint;
```

you could make the following calls to *Equal*:

```
Equal(Vec1, Vec2, SizeOf(TVector))            // compare Vec1 to Vec2
Equal(Vec1, Vec2, SizeOf(Integer) * N)        // compare first N elements of Vec1 and Vec2
Equal(Vec1[1], Vec1[6], SizeOf(Integer) * 5)  // compare first 5 to last 5 elements of Vec1
Equal(Vec1[1], P, 4)                        // compare Vec1[1] to P.X and Vec1[2] to P.Y
```

String parameters

When you declare routines that take short-string parameters, you cannot include length specifiers in the parameter declarations. That is, the declaration

```
procedure Check(S: string[20]);   // syntax error
```

causes a compilation error. But

```
type TString20 = string[20];
procedure Check(S: TString20);
```

is valid. The special identifier *OpenString* can be used to declare routines that take short-string parameters of varying length:

```
procedure Check(S: OpenString);
```

When the **{$H–}** and **{$P+}** compiler directives are both in effect, the reserved word **string** is equivalent to *OpenString* in parameter declarations.

Short strings, *OpenString*, **$H**, and **$P** are supported for backward compatibility only. In new code, you can avoid these considerations by using long strings.

Array parameters

When you declare routines that take array parameters, you cannot include index type specifiers in the parameter declarations. That is, the declaration

```
procedure Sort(A: array[1..10] of Integer);   // syntax error
```

causes a compilation error. But

```
type TDigits = array[1..10] of Integer;
procedure Sort(A: TDigits);
```

is valid. For most purposes, however, *open array parameters* are a better solution.

Open array parameters

Open array parameters allow arrays of different sizes to be passed to the same procedure or function. To define a routine with an open array parameter, use the syntax `array of` *type* (rather than `array[`*X*`..`*Y*`] of` *type*) in the parameter declaration. For example,

```
function Find(A: array of Char): Integer;
```

declares a function called *Find* that takes a character array of any size and returns an integer.

Note The syntax of open array parameters resembles that of dynamic array types, but they do not mean the same thing. The example above creates a function that takes any array of *Char* elements, including (but not limited to) dynamic arrays. To declare parameters that must be dynamic arrays, you need to specify a type identifier:

```
type TDynamicCharArray = array of Char;
```

```
function Find(A: TDynamicCharArray): Integer;
```

For information about dynamic arrays, see "Dynamic arrays" on page 5-19.

Within the body of a routine, open array parameters are governed by the following rules.

- They are always zero-based. The first element is 0, the second element is 1, and so forth. The standard *Low* and *High* functions return 0 and *Length*−1, respectively. The *SizeOf* function returns the size of the actual array passed to the routine.
- They can be accessed by element only. Assignments to an entire open array parameter are not allowed.
- They can be passed to other procedures and functions only as open array parameters or untyped **var** parameters. They cannot be passed to *SetLength*.
- Instead of an array, you can pass a variable of the open array parameter's base type. It will be treated as an array of length 1.

When you pass an array as an open array value parameter, the compiler creates a local copy of the array within the routine's stack frame. Be careful not to overflow the stack by passing large arrays.

The following examples use open array parameters to define a *Clear* procedure that assigns zero to each element in an array of reals and a *Sum* function that computes the sum of the elements in an array of reals.

```
procedure Clear(var A: array of Real);
var
  I: Integer;
begin
  for I := 0 to High(A) do A[I] := 0;
end;

function Sum(const A: array of Real): Real;
var
  I: Integer;
  S: Real;
begin
  S := 0;
  for I := 0 to High(A) do S := S + A[I];
  Sum := S;
end;
```

When you call routines that use open array parameters, you can pass *open array constructors* to them. See "Open array constructors" on page 6-19.

Variant open array parameters

Variant open array parameters allow you to pass an array of differently-typed expressions to a single procedure or function. To define a routine with a variant open array parameter, specify **array of const** as the parameter's type. Thus

```
procedure DoSomething(A: array of const);
```

declares a procedure called *DoSomething* that can operate on heterogeneous arrays.

The **array of const** construction is equivalent to **array of** *TVarRec*. *TVarRec*, declared in the *System* unit, represents a record with a variant part that can hold values of integer, Boolean, character, real, string, pointer, class, class reference, interface, and variant types. *TVarRec*'s *VType* field indicates the type of each element in the array. Some types are passed as pointers rather than values; in particular, long strings are passed as *Pointer* and must be typecast to **string**. See the online Help on *TVarRec* for details.

The following example uses a variant open array parameter in a function that creates a string representation of each element passed to it and concatenates the results into a single string. The string-handling routines called in this function are defined in *SysUtils*.

```
function MakeStr(const Args: array of const): string;
const
  BoolChars: array[Boolean] of Char = ('F', 'T');
var
  I: Integer;
begin
  Result := '';
  for I := 0 to High(Args) do
    with Args[I] do
      case VType of
        vtInteger:    Result := Result + IntToStr(VInteger);
        vtBoolean:    Result := Result + BoolChars[VBoolean];
        vtChar:       Result := Result + VChar;
        vtExtended:   Result := Result + FloatToStr(VExtended^);
        vtString:     Result := Result + VString^;
        vtPChar:      Result := Result + VPChar;
        vtObject:     Result := Result + VObject.ClassName;
        vtClass:      Result := Result + VClass.ClassName;
        vtAnsiString: Result := Result + string(VAnsiString);
        vtCurrency:   Result := Result + CurrToStr(VCurrency^);
        vtVariant:    Result := Result + string(VVariant^);
        vtInt64:      Result := Result + IntToStr(VInt64^);
    end;
end;
```

We can call this function using an open array constructor (see "Open array constructors" on page 6-19). For example,

```
MakeStr(['test', 100, ' ', True, 3.14159, TForm])
```

returns the string "test100 T3.14159TForm".

Default parameters

You can specify default parameter values in a procedure or function heading. Default values are allowed only for typed **const** and value parameters. To provide a default value, end the parameter declaration with the **=** symbol followed by a constant expression that is assignment-compatible with the parameter's type.

For example, given the declaration

```
procedure FillArray(A: array of Integer; Value: Integer = 0);
```

the following procedure calls are equivalent.

```
FillArray(MyArray);
FillArray(MyArray, 0);
```

A multiple-parameter declaration cannot specify a default value. Thus, while

```
function MyFunction(X: Real = 3.5; Y: Real = 3.5): Real;
```

is legal,

```
function MyFunction(X, Y: Real = 3.5): Real;   // syntax error
```

is not.

Parameters with default values must occur at the end of the parameter list. That is, all parameters following the first declared default value must also have default values. So the following declaration is illegal.

```
procedure MyProcedure(I: Integer = 1; S: string);   // syntax error
```

Default values specified in a procedural type override those specified in an actual routine. Thus, given the declarations

```
type TResizer = function(X: Real; Y: Real = 1.0): Real;
function Resizer(X: Real; Y: Real = 2.0): Real;
var
  F: TResizer;
  N: Real;
```

the statements

```
F := Resizer;
F(N);
```

result in the values (*N*, 1.0) being passed to *Resizer*.

Default parameters are limited to values that can be specified by a constant expression. (See "Constant expressions" on page 5-41.) Hence parameters of a dynamic-array, procedural, class, class-reference, or interface type can have no value other than **nil** as their default. Parameters of a record, variant, file, static-array, or object type cannot have default values at all.

For information about calling routines with default parameter values, see "Calling procedures and functions" on page 6-19.

Default parameters and overloaded routines

If you use default parameter values in an overloaded routine, avoid ambiguous parameter signatures. Consider, for example, the following.

```
procedure Confused(I: Integer); overload;
  ⋮
procedure Confused(I: Integer; J: Integer = 0); overload;
  ⋮
Confused(X);    //  Which procedure is called?
```

In fact, neither procedure is called. This code generates a compilation error.

Default parameters in forward and interface declarations

If a routine has a **forward** declaration or appears in the interface section of a unit, default parameter values—if there are any—must be specified in the **forward** or interface declaration. In this case, the default values can be omitted from the defining (implementation) declaration; but if the defining declaration includes default values, they must match those in the **forward** or interface declaration exactly.

Calling procedures and functions

When you call a procedure or function, program control passes from the point where the call is made to the body of the routine. You can make the call using the routine's declared name (with or without qualifiers) or using a procedural variable that points to the routine. In either case, if the routine is declared with parameters, your call to it must pass parameters that correspond in order and type to the routine's parameter list. The parameters you pass to a routine are called *actual parameters*, while the parameters in the routine's declaration are called *formal parameters*.

When calling a routine, remember that

- expressions used to pass typed **const** and value parameters must be assignment-compatible with the corresponding formal parameters.
- expressions used to pass **var** and **out** parameters must be identically typed with the corresponding formal parameters, unless the formal parameters are untyped.
- only assignable expressions can be used to pass **var** and **out** parameters.
- if a routine's formal parameters are untyped, numerals and true constants with numeric values cannot be used as actual parameters.

When you call a routine that uses default parameter values, all actual parameters following the first accepted default must also use the default values; calls of the form `SomeFunction(,,X)` are not legal.

You can omit parentheses when passing all and only the default parameters to a routine. For example, given the procedure

```
procedure DoSomething(X: Real = 1.0; I: Integer = 0; S: string = '');
```

the following calls are equivalent.

```
DoSomething();
DoSomething;
```

Open array constructors

Open array constructors allow you to construct arrays directly within function and procedure calls. They can be passed only as open array parameters or variant open array parameters.

An open array constructor, like a set constructor, is a sequence of expressions separated by commas and enclosed in brackets.

For example, given the declarations

```
var I, J: Integer;
procedure Add(A: array of Integer);
```

you could call the *Add* procedure with the statement

```
Add([5, 7, I, I + J]);
```

This is equivalent to

```
var Temp: array[0..3] of Integer;
 ⋮
Temp[0] := 5;
Temp[1] := 7;
Temp[2] := I;
Temp[3] := I + J;
Add(Temp);
```

Open array constructors can be passed only as value or **const** parameters. The expressions in a constructor must be assignment-compatible with the base type of the array parameter. In the case of a variant open array parameter, the expressions can be of different types.

Chapter

7

Classes and objects

A *class*, or *class type*, defines a structure consisting of *fields*, *methods*, and *properties*. Instances of a class type are called *objects*. The fields, methods, and properties of a class are called its *components* or *members*.

- A field is essentially a variable that is part of an object. Like the fields of a record, a class's fields represent data items that exist in each instance of the class.
- A method is a procedure or function associated with a class. Most methods operate on objects—that is, instances of a class. Some methods (called *class methods*) operate on class types themselves.
- A property is an interface to data associated with an object (often stored in a field). Properties have *access specifiers*, which determine how their data are read and modified. From other parts of a program—outside of the object itself—a property appears in most respects like a field.

Objects are dynamically allocated blocks of memory whose structure is determined by their class type. Each object has a unique copy of every field defined in the class, but all instances of a class share the same methods. Objects are created and destroyed by special methods called *constructors* and *destructors*.

A variable of a class type is actually a pointer that references an object. Hence more than one variable can refer to the same object. Like other pointers, class-type variables can hold the value **nil**. But you don't have to explicitly dereference a class-type variable to access the object it points to. For example, `SomeObject.Size := 100` assigns the value 100 to the *Size* property of the object referenced by *SomeObject*; you would *not* write this as `SomeObject^.Size := 100`.

Class types

A class type must be declared and given a name before it can be instantiated. (You cannot define a class type within a variable declaration.) Declare classes only in the outermost scope of a program or unit, not in a procedure or function declaration.

A class type declaration has the form

```
type className = class (ancestorClass)
  memberList
 end;
```

where *className* is any valid identifier, (*ancestorClass*) is optional, and *memberList* declares members—that is, fields, methods, and properties—of the class. If you omit (*ancestorClass*), then the new class inherits directly from the predefined *TObject* class. If you include (*ancestorClass*) and *memberList* is empty, you can omit `end`. A class type declaration can also include a list of *interfaces* implemented by the class; see "Implementing interfaces" on page 10-4.

Methods appear in a class declaration as function or procedure headings, with no body. Defining declarations for each method occur elsewhere in the program.

For example, here is the declaration of the *TMemoryStream* class from the *Classes* unit.

```
type
TMemoryStream = class(TCustomMemoryStream)
  private
    FCapacity: Longint;
    procedure SetCapacity(NewCapacity: Longint);
  protected
    function Realloc(var NewCapacity: Longint): Pointer; virtual;
    property Capacity: Longint read FCapacity write SetCapacity;
  public
    destructor Destroy; override;
    procedure Clear;
    procedure LoadFromStream(Stream: TStream);
    procedure LoadFromFile(const FileName: string);
    procedure SetSize(NewSize: Longint); override;
    function Write(const Buffer; Count: Longint): Longint; override;
  end;
```

TMemoryStream descends from *TStream* (in the *Classes* unit), inheriting most of its members. But it defines—or redefines—several methods and properties, including its destructor method, *Destroy*. Its constructor, *Create*, is inherited without change from *TObject*, and so is not redeclared. Each member is declared as *private*, *protected*, or *public* (this class has no *published* members); for explanations of these terms, see "Visibility of class members" on page 7-4.

Given this declaration, you can create an instance of *TMemoryStream* as follows:

```
var stream: TMemoryStream;
stream := TMemoryStream.Create;
```

Inheritance and scope

When you declare a class, you can specify its immediate ancestor. For example,

```
type TSomeControl = class(TControl);
```

declares a class called *TSomeControl* that descends from *TControl*. A class type automatically inherits all of the members from its immediate ancestor. Each class can declare new members and can redefine inherited ones, but a class cannot remove members defined in an ancestor. Hence *TSomeControl* contains all of the members defined in *TControl* and in each of *TControl*'s ancestors.

The scope of a member's identifier starts at the point where the member is declared, continues to the end of the class declaration, and extends over all descendants of the class and the blocks of all methods defined in the class and its descendants.

TObject and TClass

The *TObject* class, declared in the *System* unit, is the ultimate ancestor of all other classes. *TObject* defines only a handful of methods, including a basic constructor and destructor. In addition to *TObject*, the *System* unit declares the class-reference type *TClass*:

```
TClass = class of TObject;
```

For more information about *TObject*, see the online help. For more information about class-reference types, see "Class references" on page 7-23.

If the declaration of a class type doesn't specify an ancestor, the class inherits directly from *TObject*. Thus

```
type TMyClass = class
  ⋮
end;
```

is equivalent to

```
type TMyClass = class(TObject)
  ⋮
end;
```

The latter form is recommended for readability.

Compatibility of class types

A class type is assignment-compatible with its ancestors. Hence a variable of a class type can reference an instance of any descendant type. For example, given the declarations

```
type
  TFigure = class(TObject);
  TRectangle = class(TFigure);
  TSquare = class(TRectangle);
var
  Fig: TFigure;
```

the variable *Fig* can be assigned values of type *TFigure*, *TRectangle*, and *TSquare*.

Object types

As an alternative to class types, you can declare *object types* using the syntax

```
type objectTypeName = object (ancestorObjectType)
  memberList
end;
```

where *objectTypeName* is any valid identifier, (*ancestorObjectType*) is optional, and *memberList* declares fields, methods, and properties. If (*ancestorObjectType*) is omitted, then the new type has no ancestor. Object types cannot have published members.

Since object types do not descend from *TObject*, they provide no built-in constructors, destructors, or other methods. You can create instances of an object type using the *New* procedure and destroy them with the *Dispose* procedure, or you can simply declare variables of an object type, just as you would with records.

Object types are supported for backward compatibility only. Their use is not recommended.

Visibility of class members

Every member of a class has an attribute called *visibility*, which is indicated by one of the reserved words **private**, **protected**, **public**, **published**, or **automated**. For example,

```
published property Color: TColor read GetColor write SetColor;
```

declares a published property called *Color*. Visibility determines where and how a member can be accessed, with private representing the least accessibility, protected representing an intermediate level of accessibility, and public, published, and automated representing the greatest accessibility.

If a member's declaration appears without its own visibility specifier, the member has the same visibility as the one that precedes it. Members at the beginning of a class declaration that don't have a specified visibility are by default published, provided the class is compiled in the **{$M+}** state or is derived from a class compiled in the **{$M+}** state; otherwise, such members are public.

For readability, it is best to organize a class declaration by visibility, placing all the private members together, followed by all the protected members, and so forth. This way each visibility reserved word appears at most once and marks the beginning of a new "section" of the declaration. So a typical class declaration should like this:

```
type
  TMyClass = class(TControl)
  private
   ⋮ { private declarations here}
  protected
   ⋮ { protected declarations here }
  public
   ⋮ { public declarations here }
  published
   ⋮ { published declarations here }
  end;
```

You can increase the visibility of a member in a descendant class by redeclaring it, but you cannot decrease its visibility. For example, a protected property can be made public in a descendant, but not private. Moreover, published members cannot become public in a descendant class. For more information, see “Property overrides and redeclarations” on page 7-22.

Private, protected, and public members

A *private* member is invisible outside of the unit or program where its class is declared. In other words, a private method cannot be called from another module, and a private field or property cannot be read or written to from another module. By placing related class declarations in the same module, you can give the classes access to one another’s private members without making those members more widely accessible.

A *protected* member is visible anywhere in the module where its class is declared and from any descendant class, regardless of the module where the descendant class appears. In other words, a protected method can be called, and a protected field or property read or written to, from the definition of any method belonging to a class that descends from the one where the protected member is declared. Members that are intended for use only in the implementation of derived classes are usually protected.

A *public* member is visible wherever its class can be referenced.

Published members

Published members have the same visibility as public members. The difference is that *runtime type information* (RTTI) is generated for published members. RTTI allows an application to query the fields and properties of an object dynamically and to locate its methods. RTTI is used to access the values of properties when saving and loading form files, to display properties in the Object Inspector, and to associate specific methods (called *event handlers*) with specific properties (called *events*).

Published properties are restricted to certain data types. Ordinal, string, class, interface, and method-pointer types can be published. So can set types, provided the upper and lower bounds of the base type have ordinal values between 0 and 31. (In other words, the set must fit in a byte, word, or double word.) Any real type except *Real48* can be published. Properties of an array type (as distinct from *array properties*, discussed below) cannot be published.

Some properties, although publishable, are not fully supported by the streaming system. These include properties of record types, array properties of all publishable types (see “Array properties” on page 7-19), and properties of enumerated types that include anonymous values (see “Enumerated types with explicitly assigned ordinality” on page 5-7). If you publish a property of this kind, the Object Inspector won’t display it correctly, nor will the property’s value be preserved when objects are streamed to disk.

All methods are publishable, but a class cannot publish two or more overloaded methods with the same name. Fields can be published only if they are of a class or interface type.

A class cannot have published members unless it is compiled in the **{$M+}** state or descends from a class compiled in the **{$M+}** state. Most classes with published members derive from *TPersistent*, which is compiled in the **{$M+}** state, so it is seldom necessary to use the **$M** directive.

Automated members

Automated members have the same visibility as public members. The difference is that *Automation type information* (required for Automation servers) is generated for automated members. Automated members typically appear only in Windows classes and is not recommended for Linux programming. The **automated** reserved word is maintained for backward compatibility. The *TAutoObject* class in the *ComObj* unit does not use **automated**.

The following restrictions apply to methods and properties declared as automated.

- The types of all properties, array property parameters, method parameters, and function results must be automatable. The automatable types are *Byte*, *Currency*, *Real*, *Double*, *Longint*, *Integer*, *Single*, *Smallint*, *AnsiString*, *WideString*, *TDateTime*, *Variant*, *OleVariant*, *WordBool*, and all interface types.
- Method declarations must use the default **register** calling convention. They can be virtual, but not dynamic.
- Property declarations can include access specifiers (**read** and **write**) but other specifiers (**index**, **stored**, **default**, and **nodefault**) are not allowed. Access specifiers must list a method identifier that uses the default **register** calling convention; field identifiers are not allowed.
- Property declarations must specify a type. Property overrides are not allowed.

The declaration of an automated method or property can include a **dispid** directive. Specifying an already used ID in a **dispid** directive causes an error.

On Windows, this directive must be followed by an integer constant that specifies an Automation dispatch ID for the member. Otherwise, the compiler automatically assigns the member a dispatch ID that is one larger than the largest dispatch ID used by any method or property in the class and its ancestors. For more information about Automation (on Windows only), see “Automation objects (Windows only)” on page 10-10.

Forward declarations and mutually dependent classes

If the declaration of a class type ends with the word **class** and a semicolon—that is, if it has the form

```
type className = class;
```

with no ancestor or class members listed after the word **class**—then it is a *forward declaration*. A forward declaration must be resolved by a *defining declaration* of the same class within the same type declaration section. In other words, between a forward declaration and its defining declaration, nothing can occur except other type declarations.

Forward declarations allow mutually dependent classes. For example,

```
type
  TFigure = class;  // forward declaration
  TDrawing = class
    Figure: TFigure;
     ⋮
  end;

  TFigure = class  // defining declaration
    Drawing: TDrawing;
     ⋮
  end;
```

Do not confuse forward declarations with complete declarations of types that derive from *TObject* without declaring any class members.

```
type
  TFirstClass = class;           // this is a forward declaration

  TSecondClass = class           // this is a complete class declaration
    end;                         //

  TThirdClass = class(TObject);  // this is a complete class declaration
```

Fields

A field is like a variable that belongs to an object. Fields can be of any type, including class types. (That is, fields can hold object references.) Fields are usually private.

To define a field member of a class, simply declare the field as you would a variable. All field declarations must occur before any property or method declarations. For example, the following declaration creates a class called *TNumber* whose only member, other than the methods is inherits from *TObject*, is an integer field called *Int*.

```
type TNumber = class
  Int: Integer;
end;
```

Fields are statically bound; that is, references to them are fixed at compile time. To see what this means, consider the following code.

```
type
  TAncestor = class
    Value: Integer;
  end;

  TDescendant = class(TAncestor)
    Value: string;  // hides the inherited Value field
  end;

var
  MyObject: TAncestor;

begin
  MyObject := TDescendant.Create;
  MyObject.Value := 'Hello!';  // error
  TDescendant(MyObject).Value := 'Hello!';  // works!
end;
```

Although *MyObject* holds an instance of *TDescendant*, it is declared as *TAncestor*. The compiler therefore interprets *MyObject.Value* as referring to the (integer) field declared in *TAncestor*. Both fields, however, exist in the *TDescendant* object; the inherited *Value* is hidden by the new one, and can be accessed through a typecast.

Methods

A method is a procedure or function associated with a class. A call to a method specifies the object (or, if it is a class method, the class) that the method should operate on. For example,

```
SomeObject.Free
```

calls the *Free* method in *SomeObject*.

Method declarations and implementations

Within a class declaration, methods appear as procedure and function headings, which work like **forward** declarations. Somewhere after the class declaration, but within the same module, each method must be implemented by a defining declaration. For example, suppose the declaration of *TMyClass* includes a method called *DoSomething*:

```
type
  TMyClass = class(TObject)
     ⋮
    procedure DoSomething;
     ⋮
  end;
```

A defining declaration for *DoSomething* must occur later in the module:

```
procedure TMyClass.DoSomething;
begin
 ⋮
end;
```

While a class can be declared in either the interface or the implementation section of a unit, defining declarations for a class's methods must be in the implementation section.

In the heading of a defining declaration, the method name is always qualified with the name of the class to which it belongs. The heading can repeat the parameter list from the class declaration; if it does so, the order, type, and names of the parameters must match exactly, and, if the method is a function, so must the return value.

Method declarations can include special directives that are not used with other functions or procedures. Directives should appear in the class declaration only, not in the defining declaration, and should always be listed in the following order:

reintroduce; **overload**; *binding*; *calling convention*; **abstract**; *warning* where *binding* is **virtual**, **dynamic**, or **override**; *calling convention* is **register**, **pascal**, **cdecl**, **stdcall**, or **safecall**; and *warning* is **platform**, **deprecated**, or **library**.

Inherited

The reserved word **inherited** plays a special role in implementing polymorphic behavior. It can occur in method definitions, with or without an identifier after it.

If **inherited** is followed by the name of a member, it represents a normal method call or reference to a property or field—except that the search for the referenced member begins with the immediate ancestor of the enclosing method's class. For example, when

```
inherited Create(...);
```

occurs in the definition of a method, it calls the inherited *Create*.

When **inherited** has no identifier after it, it refers to the inherited method with the same name as the enclosing method. In this case, **inherited** takes no explicit parameters, but passes to the inherited method the same parameters with which the enclosing method was called. For example,

```
inherited;
```

occurs frequently in the implementation of constructors. It calls the inherited constructor with the same parameters that were passed to the descendant.

Self

Within the implementation of a method, the identifier *Self* references the object in which the method is called. For example, here is the implementation of *TCollection*'s *Add* method in the *Classes* unit.

```
function TCollection.Add: TCollectionItem;
begin
  Result := FItemClass.Create(Self);
end;
```

The *Add* method calls the *Create* method in the class referenced by the *FItemClass* field, which is always a *TCollectionItem* descendant. *TCollectionItem.Create* takes a single parameter of type *TCollection*, so *Add* passes it the *TCollection* instance object where *Add* is called. This is illustrated in the following code.

```
var MyCollection: TCollection;
 ⋮
MyCollection.Add  // MyCollection is passed to the TCollectionItem.Create method
```

Self is useful for a variety of reasons. For example, a member identifier declared in a class type might be redeclared in the block of one of the class's methods. In this case, you can access the original member identifier as `Self`.*Identifier*.

For information about *Self* in class methods, see "Class methods" on page 7-25.

Method binding

Methods can be *static* (the default), *virtual*, or *dynamic*. Virtual and dynamic methods can be *overridden*, and they can be *abstract*. These designations come into play when a variable of one class type holds a value of a descendant class type. They determine which implementation is activated when a method is called.

Static methods

Methods are by default static. When a static method is called, the declared (compile-time) type of the class or object variable used in the method call determines which implementation to activate. In the following example, the *Draw* methods are static.

```
type
  TFigure = class
    procedure Draw;
  end;
  TRectangle = class(TFigure)
    procedure Draw;
  end;
```

Given these declarations, the following code illustrates the effect of calling a static method. In the second call to *Figure.Draw*, the *Figure* variable references an object of class *TRectangle*, but the call invokes the implementation of *Draw* in *TFigure*, because the declared type of the *Figure* variable is *TFigure*.

```
var
  Figure: TFigure;
  Rectangle: TRectangle;
begin
  Figure := TFigure.Create;
  Figure.Draw;  // calls TFigure.Draw
  Figure.Destroy;
  Figure := TRectangle.Create;
  Figure.Draw;  // calls TFigure.Draw
  TRectangle(Figure).Draw;  // calls TRectangle.Draw
  Figure.Destroy;
  Rectangle := TRectangle.Create;
  Rectangle.Draw;  // calls TRectangle.Draw
  Rectangle.Destroy;
end;
```

Virtual and dynamic methods

To make a method virtual or dynamic, include the **virtual** or **dynamic** directive in its declaration. Virtual and dynamic methods, unlike static methods, can be *overridden* in descendant classes. When an overridden method is called, the actual (runtime) type of the class or object used in the method call—not the declared type of the variable—determines which implementation to activate.

To override a method, redeclare it with the **override** directive. An **override** declaration must match the ancestor declaration in the order and type of its parameters and in its result type (if any).

In the following example, the *Draw* method declared in *TFigure* is overridden in two descendant classes.

```
type
  TFigure = class
    procedure Draw; virtual;
  end;
  TRectangle = class(TFigure)
    procedure Draw; override;
  end;
  TEllipse = class(TFigure)
    procedure Draw; override;
  end;
```

Given these declarations, the following code illustrates the effect of calling a virtual method through a variable whose actual type varies at runtime.

```
var
  Figure: TFigure;
begin
  Figure := TRectangle.Create;
  Figure.Draw;  // calls TRectangle.Draw
  Figure.Destroy;
  Figure := TEllipse.Create;
  Figure.Draw;  // calls TEllipse.Draw
  Figure.Destroy;
end;
```

Only virtual and dynamic methods can be overridden. All methods, however, can be *overloaded*; see “Overloading methods”.

Virtual versus dynamic

Virtual and dynamic methods are semantically equivalent. They differ only in the implementation of method-call dispatching at runtime. Virtual methods optimize for speed, while dynamic methods optimize for code size.

In general, virtual methods are the most efficient way to implement polymorphic behavior. Dynamic methods are useful when a base class declares many overridable methods which are inherited by many descendant classes in an application, but only occasionally overridden.

Overriding versus hiding

If a method declaration specifies the same method identifier and parameter signature as an inherited method, but doesn’t include **override**, the new declaration merely *hides* the inherited one without overriding it. Both methods exist in the descendant class, where the method name is statically bound. For example,

```
type
  T1 = class(TObject)
    procedure Act; virtual;
  end;
  T2 = class(T1)
    procedure Act;  // Act is redeclared, but not overridden
  end;
```

```
var
  SomeObject: T1;
begin
  SomeObject := T2.Create;
  SomeObject.Act;  // calls T1.Act
end;
```

Reintroduce

The **reintroduce** directive suppresses compiler warnings about hiding previously declared virtual methods. For example,

```
procedure DoSomething; reintroduce;  // the ancestor class also has a DoSomething method
```

Use **reintroduce** when you want to hide an inherited virtual method with a new one.

Abstract methods

An abstract method is a virtual or dynamic method that has no implementation in the class where it is declared. Its implementation is deferred to a descendant class. Abstract methods must be declared with the directive **abstract** after **virtual** or **dynamic**. For example,

```
procedure DoSomething; virtual; abstract;
```

You can call an abstract method only in a class or instance of a class in which the method has been overridden.

Overloading methods

A method can be redeclared using the **overload** directive. In this case, if the redeclared method has a different parameter signature from its ancestor, it overloads the inherited method without hiding it. Calling the method in a descendant class activates whichever implementation matches the parameters in the call.

If you overload a virtual method, use the **reintroduce** directive when you redeclare it in descendant classes. For example,

```
type
  T1 = class(TObject)
    procedure Test(I: Integer); overload; virtual;
  end;
  T2 = class(T1)
    procedure Test(S: string); reintroduce; overload;
  end;
   ⋮
  SomeObject := T2.Create;
  SomeObject.Test('Hello!');  // calls T2.Test
  SomeObject.Test(7);         // calls T1.Test
```

Within a class, you cannot publish multiple overloaded methods with the same name. Maintenance of runtime type information requires a unique name for each published member.

```
type
  TSomeClass = class
  published
    function Func(P: Integer): Integer;
    function Func(P: Boolean): Integer  // error
     ⋮
```

Methods that serve as property **read** or **write** specifiers cannot be overloaded.

The implementation of an overloaded method must repeat the parameter list from the class declaration. For more information about overloading, see “Overloading procedures and functions” on page 6-8.

Constructors

A constructor is a special method that creates and initializes instance objects. The declaration of a constructor looks like a procedure declaration, but it begins with the word **constructor**. Examples:

```
constructor Create;
constructor Create(AOwner: TComponent);
```

Constructors must use the default **register** calling convention. Although the declaration specifies no return value, a constructor returns a reference to the object it creates or is called in.

A class can have more than one constructor, but most have only one. It is conventional to call the constructor *Create*.

To create an object, call the constructor method in a class type. For example,

```
MyObject := TMyClass.Create;
```

This allocates storage for the new object on the heap, sets the values of all ordinal fields to zero, assigns **nil** to all pointer and class-type fields, and makes all string fields empty. Other actions specified in the constructor implementation are performed next; typically, objects are initialized based on values passed as parameters to the constructor. Finally, the constructor returns a reference to the newly allocated and initialized object. The type of the returned value is the same as the class type specified in the constructor call.

If an exception is raised during execution of a constructor that was invoked on a class reference, the *Destroy* destructor is automatically called to destroy the unfinished object.

When a constructor is called using an object reference (rather than a class reference), it does not create an object. Instead, the constructor operates on the specified object, executing only the statements in the constructor’s implementation, and then returns a reference to the object. A constructor is typically invoked on an object reference in conjunction with the reserved word **inherited** to execute an inherited constructor.

Here is an example of a class type and its constructor.

```
type
  TShape = class(TGraphicControl)
  private
    FPen: TPen;
    FBrush: TBrush;
    procedure PenChanged(Sender: TObject);
    procedure BrushChanged(Sender: TObject);
  public
    constructor Create(Owner: TComponent); override;
    destructor Destroy; override;
    ⋮
  end;

constructor TShape.Create(Owner: TComponent);
begin
  inherited Create(Owner);  // Initialize inherited parts
  Width := 65;  // Change inherited properties
  Height := 65;
  FPen := TPen.Create;  // Initialize new fields
  FPen.OnChange := PenChanged;
  FBrush := TBrush.Create;
  FBrush.OnChange := BrushChanged;
end;
```

The first action of a constructor is usually to call an inherited constructor to initialize the object's inherited fields. The constructor then initializes the fields introduced in the descendant class. Because a constructor always clears the storage it allocates for a new object, all fields start with a value of zero (ordinal types), **nil** (pointer and class types), empty (string types), or *Unassigned* (variants). Hence there is no need to initialize fields in a constructor's implementation except to nonzero or nonempty values.

When invoked through a class-type identifier, a constructor declared as **virtual** is equivalent to a static constructor. When combined with class-reference types, however, virtual constructors allow polymorphic construction of objects—that is, construction of objects whose types aren't known at compile time. (See "Class references" on page 7-23.)

Destructors

A destructor is a special method that destroys the object where it is called and deallocates its memory. The declaration of a destructor looks like a procedure declaration, but it begins with the word **destructor**. Examples:

```
destructor Destroy;
destructor Destroy; override;
```

Destructors must use the default **register** calling convention. Although a class can have more than one destructor, it is recommended that each class override the inherited *Destroy* method and declare no other destructors.

To call a destructor, you must reference an instance object. For example,

```
MyObject.Destroy;
```

When a destructor is called, actions specified in the destructor implementation are performed first. Typically, these consist of destroying any embedded objects and freeing resources that were allocated by the object. Then the storage that was allocated for the object is disposed of.

Here is an example of a destructor implementation.

```
destructor TShape.Destroy;
begin
  FBrush.Free;
  FPen.Free;
  inherited Destroy;
end;
```

The last action in a destructor's implementation is typically to call the inherited destructor to destroy the object's inherited fields.

When an exception is raised during creation of an object, *Destroy* is automatically called to dispose of the unfinished object. This means that *Destroy* must be prepared to dispose of partially constructed objects. Because a constructor sets the fields of a new object to zero or empty values before performing other actions, class-type and pointer-type fields in a partially constructed object are always **nil**. A destructor should therefore check for **nil** values before operating on class-type or pointer-type fields. Calling the *Free* method (defined in *TObject*), rather than *Destroy*, offers a convenient way of checking for **nil** values before destroying an object.

Message methods

Message methods implement responses to dynamically dispatched messages. The message method syntax is supported on all platforms. The VCL uses message methods to respond to Windows messages. CLX does not use message methods to respond to system events.

A message method is created by including the **message** directive in a method declaration, followed by an integer constant between 1 and 49151 which specifies the message ID. For message methods in VCL controls, the integer constant can be one of the Windows message IDs defined, along with corresponding record types, in the *Messages* unit. A message method must be a procedure that takes a single **var** parameter.

For example, on Windows:

```
type
  TTextBox = class(TCustomControl)
  private
    procedure WMChar(var Message: TWMChar); message WM_CHAR;
    ⋮
  end;
```

For example, on Linux or for cross-platform programming, you would handle messages as follows:

```
const
  ID_REFRESH = $0001;

type
  TTextBox = class(TCustomControl)
  private
    procedure Refresh(var Message: TMessageRecordType); message ID_REFRESH;
    ⋮
  end;
```

A message method does not have to include the **override** directive to override an inherited message method. In fact, it doesn't have to specify the same method name or parameter type as the method it overrides. The message ID alone determines which message the method responds to and whether it is an override.

Implementing message methods

The implementation of a message method can call the inherited message method, as in this example (for Windows):

```
procedure TTextBox.WMChar(var Message: TWMChar);
begin
  if Chr(Message.CharCode) = #13 then
    ProcessEnter
  else
    inherited;
end;
```

On Linux or for cross-platform programming, you would write the same example as follows:

```
procedure TTextBox.Refresh(var Message: TMessageRecordType);
begin
  if Chr(Message.Code) = #13 then
    ...
  else
    inherited;
end;
```

The **inherited** statement searches backward through the class hierarchy and invokes the first message method with the same ID as the current method, automatically passing the message record to it. If no ancestor class implements a message method for the given ID, **inherited** calls the *DefaultHandler* method originally defined in *TObject*.

The implementation of *DefaultHandler* in *TObject* simply returns without performing any actions. By overriding *DefaultHandler*, a class can implement its own default handling of messages. On Windows, the *DefaultHandler* method for VCL controls calls the Windows *DefWindowProc* function.

Message dispatching

Message handlers are seldom called directly. Instead, messages are dispatched to an object using the *Dispatch* method inherited from *TObject*:

```
procedure Dispatch(var Message);
```

The *Message* parameter passed to *Dispatch* must be a record whose first entry is a field of type *Cardinal* containing a message ID.

Dispatch searches backward through the class hierarchy (starting from the class of the object where it is called) and invokes the first message method for the ID passed to it. If no message method is found for the given ID, *Dispatch* calls *DefaultHandler*.

Properties

A property, like a field, defines an attribute of an object. But while a field is merely a storage location whose contents can be examined and changed, a property associates specific actions with reading or modifying its data. Properties provide control over access to an object's attributes, and they allow attributes to be computed.

The declaration of a property specifies a name and a type, and includes at least one access specifier. The syntax of a property declaration is

`property` *propertyName*`[`*indexes*`]:` *type* `index` *integerConstant specifiers*`;`

where

- *propertyName* is any valid identifier.
- `[`*indexes*`]` is optional and is a sequence of parameter declarations separated by semicolons. Each parameter declaration has the form *identifier*$_1$`,` ...`,` *identifier*$_n$`:` *type*. For more information, see "Array properties" on page 7-19.
- *type* must be a predefined or previously declared data type. That is, property declarations like **`property`** `Num: 0..9 ...` are invalid.
- the `index` *integerConstant* clause is optional. For more information, see "Index specifiers" on page 7-20.
- *specifiers* is a sequence of **read**, **write**, **stored**, **default** (or **nodefault**), and **implements** specifiers. Every property declaration must have at least one **read** or **write** specifier. (For information about **implements**, see "Implementing interfaces by delegation" on page 10-6.)

Properties are defined by their access specifiers. Unlike fields, properties cannot be passed as **var** parameters, nor can the @ operator be applied to a property. The reason is that a property doesn't necessarily exist in memory. It could, for instance, have a **read** method that retrieves a value from a database or generates a random value.

Property access

Every property has a **read** specifier, a **write** specifier, or both. These are called *access specifiers* and they have the form

`read` *fieldOrMethod*
`write` *fieldOrMethod*

where *fieldOrMethod* is the name of a field or method declared in the same class as the property or in an ancestor class.

- If *fieldOrMethod* is declared in the same class, it must occur before the property declaration. If it is declared in an ancestor class, it must be visible from the descendant; that is, it cannot be a private field or method of an ancestor class declared in a different unit.
- If *fieldOrMethod* is a field, it must be of the same type as the property.
- If *fieldOrMethod* is a method, it cannot be overloaded. Moreover, access methods for a published property must use the default **register** calling convention.
- In a **read** specifier, if *fieldOrMethod* is a method, it must be a parameterless function whose result type is the same as the property's type.
- In a **write** specifier, if *fieldOrMethod* is a method, it must be a procedure that takes a single value or **const** parameter of the same type as the property.

For example, given the declaration

```
property Color: TColor read GetColor write SetColor;
```

the *GetColor* method must be declared as

```
function GetColor: TColor;
```

and the *SetColor* method must be declared as one of these:

```
procedure SetColor(Value: TColor);
procedure SetColor(const Value: TColor);
```

(The name of *SetColor*'s parameter, of course, doesn't have to be *Value*.)

When a property is referenced in an expression, its value is read using the field or method listed in the **read** specifier. When a property is referenced in an assignment statement, its value is written using the field or method listed in the **write** specifier.

The example below declares a class called *TCompass* with a published property called *Heading*. The value of *Heading* is read through the *FHeading* field and written through the *SetHeading* procedure.

```
type
  THeading = 0..359;
  TCompass = class(TControl)
  private
    FHeading: THeading;
    procedure SetHeading(Value: THeading);
  published
    property Heading: THeading read FHeading write SetHeading;
    ⋮
  end;
```

Given this declaration, the statements

```
if Compass.Heading = 180 then GoingSouth;
Compass.Heading := 135;
```

correspond to

```
if Compass.FHeading = 180 then GoingSouth;
Compass.SetHeading(135);
```

In the *TCompass* class, no action is associated with reading the *Heading* property; the **read** operation consists of retrieving the value stored in the *FHeading* field. On the other hand, assigning a value to the *Heading* property translates into a call to the *SetHeading* method, which, presumably, stores the new value in the *FHeading* field as well as performing other actions. For example, *SetHeading* might be implemented like this:

```
procedure TCompass.SetHeading(Value: THeading);
begin
  if FHeading <> Value then
  begin
    FHeading := Value;
    Repaint;  // update user interface to reflect new value
  end;
end;
```

A property whose declaration includes only a **read** specifier is a *read-only* property, and one whose declaration includes only a **write** specifier is a *write-only* property. It is an error to assign a value to a read-only property or use a write-only property in an expression.

Array properties

Array properties are indexed properties. They can represent things like items in a list, child controls of a control, and pixels of a bitmap.

The declaration of an array property includes a parameter list that specifies the names and types of the indexes. For example,

```
property Objects[Index: Integer]: TObject read GetObject write SetObject;
property Pixels[X, Y: Integer]: TColor read GetPixel write SetPixel;
property Values[const Name: string]: string read GetValue write SetValue;
```

The format of an index parameter list is the same as that of a procedure's or function's parameter list, except that the parameter declarations are enclosed in brackets instead of parentheses. Unlike arrays, which can use only ordinal-type indexes, array properties allow indexes of any type.

For array properties, access specifiers must list methods rather than fields. The method in a **read** specifier must be a function that takes the number and type of parameters listed in the property's index parameter list, in the same order, and whose result type is identical to the property's type. The method in a **write** specifier must be a procedure that takes the number and type of parameters listed in the property's index parameter list, in the same order, plus an additional value or **const** parameter of the same type as the property.

For example, the access methods for the array properties above might be declared as

```
function GetObject(Index: Integer): TObject;
function GetPixel(X, Y: Integer): TColor;
function GetValue(const Name: string): string;
procedure SetObject(Index: Integer; Value: TObject);
procedure SetPixel(X, Y: Integer; Value: TColor);
procedure SetValue(const Name, Value: string);
```

An array property is accessed by indexing the property identifier. For example, the statements

```
if Collection.Objects[0] = nil then Exit;
Canvas.Pixels[10, 20] := clRed;
Params.Values['PATH'] := 'C:\DELPHI\BIN';
```

correspond to

```
if Collection.GetObject(0) = nil then Exit;
Canvas.SetPixel(10, 20, clRed);
Params.SetValue('PATH', 'C:\DELPHI\BIN');
```

On Linux, you would use a path such as '/usr/local/bin' in place of 'C:\DELPHI\BIN' in the above example.

The definition of an array property can be followed by the **default** directive, in which case the array property becomes the default property of the class. For example,

```
type
  TStringArray = class
  public
    property Strings[Index: Integer]: string ...; default;
    ⋮
  end;
```

If a class has a default property, you can access that property with the abbreviation *object*[*index*], which is equivalent to *object*.*property*[*index*]. For example, given the declaration above, `StringArray.Strings[7]` can be abbreviated to `StringArray[7]`. A class can have only one default property. Changing or hiding the default property in descendant classes may lead to unexpected behavior, since the compiler always determines an object's default property statically.

Index specifiers

Index specifiers allow several properties to share the same access method while representing different values. An index specifier consists of the directive **index** followed by an integer constant between –2147483647 and 2147483647. If a property has an index specifier, its **read** and **write** specifiers must list methods rather than fields. For example,

```
type
  TRectangle = class
  private
    FCoordinates: array[0..3] of Longint;
    function GetCoordinate(Index: Integer): Longint;
    procedure SetCoordinate(Index: Integer; Value: Longint);
  public
    property Left: Longint index 0 read GetCoordinate write SetCoordinate;
    property Top: Longint index 1 read GetCoordinate write SetCoordinate;
    property Right: Longint index 2 read GetCoordinate write SetCoordinate;
    property Bottom: Longint index 3 read GetCoordinate write SetCoordinate;
    property Coordinates[Index: Integer]: Longint read GetCoordinate write SetCoordinate;
    ⋮
  end;
```

An access method for a property with an index specifier must take an extra value parameter of type *Integer*. For a **read** function, it must be the last parameter; for a **write** procedure, it must be the second-to-last parameter (preceding the parameter that specifies the property value). When a program accesses the property, the property's integer constant is automatically passed to the access method.

Given the declaration above, if *Rectangle* is of type *TRectangle*, then

```
Rectangle.Right := Rectangle.Left + 100;
```

corresponds to

```
Rectangle.SetCoordinate(2, Rectangle.GetCoordinate(0) + 100);
```

Storage specifiers

The optional **stored**, **default**, and **nodefault** directives are called *storage specifiers*. They have no effect on program behavior, but control the way runtime type information (RTTI) is maintained. Specifically, storage specifiers determine whether or not to save the values of published properties in form files.

The **stored** directive must be followed by *True*, *False*, the name of a *Boolean* field, or the name of a parameterless method that returns a *Boolean* value. For example,

```
property Name: TComponentName read FName write SetName stored False;
```

If a property has no **stored** directive, it is treated as if `stored True` were specified.

The **default** directive must be followed by a constant of the same type as the property. For example,

```
property Tag: Longint read FTag write FTag default 0;
```

To override an inherited **default** value without specifying a new one, use the **nodefault** directive. The **default** and **nodefault** directives are supported only for ordinal types and for set types, provided the upper and lower bounds of the set's base type have ordinal values between 0 and 31; if such a property is declared without **default** or **nodefault**, it is treated as if **nodefault** were specified. For reals, pointers, and strings, there is an implicit **default** value of 0, **nil**, and `''` (the empty string), respectively.

When saving a component's state, the storage specifiers of the component's published properties are checked. If a property's current value is different from its **default** value (or if there is no **default** value) and the **stored** specifier is *True*, then the property's value is saved. Otherwise, the property's value is not saved.

Note Storage specifiers are not supported for array properties. The **default** directive has a different meaning when used in an array property declaration. See "Array properties" on page 7-19.

Property overrides and redeclarations

A property declaration that doesn't specify a type is called a *property override*. Property overrides allow you to change a property's inherited visibility or specifiers. The simplest override consists only of the reserved word **property** followed by an inherited property identifier; this form is used to change a property's visibility. For example, if an ancestor class declares a property as protected, a derived class can redeclare it in a public or published section of the class. Property overrides can include **read**, **write**, **stored**, **default**, and **nodefault** directives; any such directive overrides the corresponding inherited directive. An override can replace an inherited access specifier, add a missing specifier, or increase a property's visibility, but it cannot remove an access specifier or decrease a property's visibility. An override can include an **implements** directive, which adds to the list of implemented interfaces without removing inherited ones.

The following declarations illustrate the use of property overrides.

```
type
  TAncestor = class
   ⋮
  protected
    property Size: Integer read FSize;
    property Text: string read GetText write SetText;
    property Color: TColor read FColor write SetColor stored False;
    ⋮
  end;
type
  TDerived = class(TAncestor)
   ⋮
  protected
    property Size write SetSize;
  published
    property Text;
    property Color stored True default clBlue;
    ⋮
  end;
```

The override of *Size* adds a **write** specifier to allow the property to be modified. The overrides of *Text* and *Color* change the visibility of the properties from protected to published. The property override of *Color* also specifies that the property should be filed if its value isn't *clBlue*.

A redeclaration of a property that includes a type identifier hides the inherited property rather than overriding it. This means that a new property is created with the same name as the inherited one. Any property declaration that specifies a type must be a complete declaration, and must therefore include at least one access specifier.

Whether a property is hidden or overridden in a derived class, property look-up is always *static*. That is, the declared (compile-time) type of the variable used to identify an object determines the interpretation of its property identifiers. Hence, after the following code executes, reading or assigning a value to *MyObject.Value* invokes *Method1* or *Method2*, even though *MyObject* holds an instance of *TDescendant*. But you can cast *MyObject* to *TDescendant* to access the descendant class's properties and their access specifiers.

```
type
  TAncestor = class
     ⋮
    property Value: Integer read Method1 write Method2;
  end;

  TDescendant = class(TAncestor)
     ⋮
    property Value: Integer read Method3 write Method4;
  end;

var MyObject: TAncestor;
 ⋮
MyObject := TDescendant.Create;
```

Class references

Sometimes operations are performed on a class itself, rather than on instances of a class (that is, objects). This happens, for example, when you call a constructor method using a class reference. You can always refer to a specific class using its name, but at times it is necessary to declare variables or parameters that take classes as values, and in these situations you need *class-reference types*.

Class-reference types

A class-reference type, sometimes called a *metaclass*, is denoted by a construction of the form

`class of` *type*

where *type* is any class type. The identifier *type* itself denotes a value whose type is `class of` *type*. If *type*$_1$ is an ancestor of *type*$_2$, then `class of` *type*$_2$ is assignment-compatible with `class of` *type*$_1$. Thus

```
type TClass = class of TObject;
var AnyObj: TClass;
```

declares a variable called *AnyObj* that can hold a reference to any class. (The definition of a class-reference type cannot occur directly in a variable declaration or parameter list.) You can assign the value **nil** to a variable of any class-reference type.

To see how class-reference types are used, look at the declaration of the constructor for *TCollection* (in the *Classes* unit):

```
type TCollectionItemClass = class of TCollectionItem;
  ⋮
constructor Create(ItemClass: TCollectionItemClass);
```

This declaration says that to create a *TCollection* instance object, you must pass to the constructor the name of a class descending from *TCollectionItem*.

Class-reference types are useful when you want to invoke a class method or virtual constructor on a class or object whose actual type is unknown at compile time.

Constructors and class references

A constructor can be called using a variable of a class-reference type. This allows construction of objects whose type isn't known at compile time. For example,

```
type TControlClass = class of TControl;

function CreateControl(ControlClass: TControlClass;
  const ControlName: string; X, Y, W, H: Integer): TControl;
begin
  Result := ControlClass.Create(MainForm);
  with Result do
  begin
    Parent := MainForm;
    Name := ControlName;
    SetBounds(X, Y, W, H);
    Visible := True;
  end;
end;
```

The *CreateControl* function requires a class-reference parameter to tell it what kind of control to create. It uses this parameter to call the class's constructor. Because class-type identifiers denote class-reference values, a call to *CreateControl* can specify the identifier of the class to create an instance of. For example,

```
CreateControl(TEdit, 'Edit1', 10, 10, 100, 20);
```

Constructors called using class references are usually virtual. The constructor implementation activated by the call depends on the runtime type of the class reference.

Class operators

Every class inherits from *TObject* methods called *ClassType* and *ClassParent* that return, respectively, a reference to the class of an object and of an object's immediate ancestor. Both methods return a value of type *TClass* (where `TClass = class of TObject`), which can be cast to a more specific type. Every class also inherits a method called *InheritsFrom* that tests whether the object where it is called descends from a specified class. These methods are used by the **is** and **as** operators, and it is seldom necessary to call them directly.

The is operator

The **is** operator, which performs dynamic type checking, is used to verify the actual runtime class of an object. The expression

object `is` *class*

returns *True* if *object* is an instance of the class denoted by *class* or one of its descendants, and *False* otherwise. (If *object* is **nil**, the result is *False*.) If the declared type of *object* is unrelated to *class*—that is, if the types are distinct and one is not an ancestor of the other—a compilation error results. For example,

```
if ActiveControl is TEdit then TEdit(ActiveControl).SelectAll;
```

This statement casts a variable to *TEdit* after first verifying that the object it references is an instance of *TEdit* or one of its descendants.

The as operator

The **as** operator performs checked typecasts. The expression

```
   object as class
```

returns a reference to the same object as *object*, but with the type given by *class*. At runtime, *object* must be an instance of the class denoted by *class* or one of its descendants, or be **nil**; otherwise an exception is raised. If the declared type of *object* is unrelated to *class*—that is, if the types are distinct and one is not an ancestor of the other—a compilation error results. For example,

```
with Sender as TButton do
begin
  Caption := '&Ok';
  OnClick := OkClick;
end;
```

The rules of operator precedence often require **as** typecasts to be enclosed in parentheses. For example,

```
(Sender as TButton).Caption := '&Ok';
```

Class methods

A class method is a method (other than a constructor) that operates on classes instead of objects. The definition of a class method must begin with the reserved word **class**. For example,

```
type
  TFigure = class
  public
    class function Supports(Operation: string): Boolean; virtual;
    class procedure GetInfo(var Info: TFigureInfo); virtual;
    ⋮
  end;
```

The defining declaration of a class method must also begin with **class**. For example,

```
class procedure TFigure.GetInfo(var Info: TFigureInfo);
begin
  ⋮
end;
```

In the defining declaration of a class method, the identifier *Self* represents the class where the method is called (which could be a descendant of the class in which it is defined). If the method is called in the class *C*, then *Self* is of the type `class of` *C*. Thus you cannot use *Self* to access fields, properties, and normal (object) methods, but you can use it to call constructors and other class methods.

A class method can be called through a class reference or an object reference. When it is called through an object reference, the class of the object becomes the value of *Self*.

Exceptions

An *exception* is raised when an error or other event interrupts normal execution of a program. The exception transfers control to an *exception handler*, which allows you to separate normal program logic from error-handling. Because exceptions are objects, they can be grouped into hierarchies using inheritance, and new exceptions can be introduced without affecting existing code. An exception can carry information, such as an error message, from the point where it is raised to the point where it is handled.

When an application uses the *SysUtils* unit, all runtime errors are automatically converted into exceptions. Errors that would otherwise terminate an application—such as insufficient memory, division by zero, and general protection faults—can be caught and handled.

When to use exceptions

Exceptions provide an elegant way to trap runtime errors without halting the program and without awkward conditional statements. The complexity of Object Pascal's exception-handling mechanism, however, makes it inefficient, and it should therefore be used judiciously. While it is possible to raise exceptions for almost any reason, and to protect almost any block of code by wrapping it in a **try...except** or **try...finally** statement, in practice these tools are best reserved for special situations.

Exception handling is appropriate for errors whose chances of occurring are low or difficult to assess, but whose consequences are likely to be catastrophic (such as crashing the application); for error conditions that are complicated or difficult to test for in **if...then** statements; and when you need to respond to exceptions raised by the operating system or by routines whose source code you don't control. Exceptions are commonly used for hardware, memory, I/O, and operating-system errors.

Conditional statements are often the best way to test for errors. For example, suppose you want to make sure that a file exists before trying to open it. You could do it this way:

```
try
  AssignFile(F, FileName);
  Reset(F);  // raises an EInOutError exception if file is not found
except
  on Exception do ...
end;
```

But you could also avoid the overhead of exception handling by using

```
if FileExists(FileName) then  // returns False if file is not found; raises no exception
begin
```

```
    AssignFile(F, FileName);
    Reset(F);
  end;
```

Assertions provide another way of testing a Boolean condition anywhere in your source code. When an *Assert* statement fails, the program either halts or (if it uses the *SysUtils* unit) raises an *EAssertionFailed* exception. Assertions should be used only to test for conditions that you do not expect to occur. For more information, see the online Help for the standard procedure *Assert*.

Declaring exception types

Exception types are declared just like other classes. In fact, it is possible to use an instance of any class as an exception, but it is recommended that exceptions be derived from the *Exception* class defined in *SysUtils*.

You can group exceptions into families using inheritance. For example, the following declarations in *SysUtils* define a family of exception types for math errors.

```
type
  EMathError = class(Exception);
  EInvalidOp = class(EMathError);
  EZeroDivide = class(EMathError);
  EOverflow = class(EMathError);
  EUnderflow = class(EMathError);
```

Given these declarations, you can define a single *EMathError* exception handler that also handles *EInvalidOp*, *EZeroDivide*, *EOverflow*, and *EUnderflow*.

Exception classes sometimes define fields, methods, or properties that convey additional information about the error. For example,

```
type EInOutError = class(Exception)
    ErrorCode: Integer;
  end;
```

Raising and handling exceptions

To create an exception object, call the exception class's constructor within a **raise** statement. For example,

```
raise EMathError.Create;
```

In general, the form of a **raise** statement is

`raise` *object* `at` *address*

where *object* and `at` *address* are both optional. If *object* is omitted, the statement re-raises the current exception; see "Re-raising exceptions" on page 7-30. When an *address* is specified, it is usually a pointer to a procedure or function; use this option to raise the exception from an earlier point in the stack than the one where the error actually occurred.

When an exception is *raised*—that is, referenced in a **raise** statement—it is governed by special exception-handling logic. A **raise** statement never returns control in the normal way. Instead, it transfers control to the innermost exception handler that can handle exceptions of the given class. (The innermost handler is the one whose **try...except** block was most recently entered but has not yet exited.)

For example, the function below converts a string to an integer, raising an *ERangeError* exception if the resulting value is outside a specified range.

```
function StrToIntRange(const S: string; Min, Max: Longint): Longint;
begin
  Result := StrToInt(S);  // StrToInt is declared in SysUtils
  if (Result < Min) or (Result > Max) then
    raise ERangeError.CreateFmt(
      '%d is not within the valid range of %d..%d',
      [Result, Min, Max]);
end;
```

Notice the *CreateFmt* method called in the **raise** statement. *Exception* and its descendants have special constructors that provide alternative ways to create exception messages and context IDs. See the online Help for details.

A raised exception is destroyed automatically after it is handled. Never attempt to destroy a raised exception manually.

Note Raising an exception in the initialization section of a unit may not produce the intended result. Normal exception support comes from the *SysUtils* unit, which must be initialized before such support is available. If an exception occurs during initialization, all initialized units—including *SysUtils*—are finalized and the exception is re-raised. Then the exception is caught and handled, usually by interrupting the program.

Try...except statements

Exceptions are handled within **try...except** statements. For example,

```
try
  X := Y/Z;
except
  on EZeroDivide do HandleZeroDivide;
end;
```

This statement attempts to divide *Y* by *Z*, but calls a routine named *HandleZeroDivide* if an *EZeroDivide* exception is raised.

The syntax of a **try...except** statement is

`try` *statements* `except` *exceptionBlock* `end`

where *statements* is a sequence of statements (delimited by semicolons) and *exceptionBlock* is either

- another sequence of statements or
- a sequence of exception handlers, optionally followed by

  `else` *statements*

An exception handler has the form

on *identifier*: *type* do *statement*

where *identifier*: is optional (if included, *identifier* can be any valid identifier), *type* is a type used to represent exceptions, and *statement* is any statement.

A **try...except** statement executes the statements in the initial *statements* list. If no exceptions are raised, the exception block (*exceptionBlock*) is ignored and control passes to the next part of the program.

If an exception is raised during execution of the initial *statements* list, either by a **raise** statement in the *statements* list or by a procedure or function called from the *statements* list, an attempt is made to "handle" the exception:

- If any of the handlers in the exception block matches the exception, control passes to the first such handler. An exception handler "matches" an exception just in case the *type* in the handler is the class of the exception or an ancestor of that class.
- If no such handler is found, control passes to the *statement* in the **else** clause, if there is one.
- If the exception block is just a sequence of statements without any exception handlers, control passes to the first statement in the list.

If none of the conditions above is satisfied, the search continues in the exception block of the next-most-recently entered **try...except** statement that has not yet exited. If no appropriate handler, **else** clause, or statement list is found there, the search propagates to the next-most-recently entered **try...except** statement, and so forth. If the outermost **try...except** statement is reached and the exception is still not handled, the program terminates.

When an exception is handled, the stack is traced back to the procedure or function containing the **try...except** statement where the handling occurs, and control is transferred to the executed exception handler, **else** clause, or statement list. This process discards all procedure and function calls that occurred after entering the **try...except** statement where the exception is handled. The exception object is then automatically destroyed through a call to its *Destroy* destructor and control is passed to the statement following the **try...except** statement. (If a call to the *Exit*, *Break*, or *Continue* standard procedure causes control to leave the exception handler, the exception object is still automatically destroyed.)

In the example below, the first exception handler handles division-by-zero exceptions, the second one handles overflow exceptions, and the final one handles all other math exceptions. *EMathError* appears last in the exception block because it is the ancestor of the other two exception classes; if it appeared first, the other two handlers would never be invoked.

```
try
 ⋮
except
  on EZeroDivide do HandleZeroDivide;
  on EOverflow do HandleOverflow;
  on EMathError do HandleMathError;
end;
```

An exception handler can specify an identifier before the name of the exception class. This declares the identifier to represent the exception object during execution of the statement that follows **on...do**. The scope of the identifier is limited to that statement. For example,

```
try
 ⋮
except
  on E: Exception do ErrorDialog(E.Message, E.HelpContext);
end;
```

If the exception block specifies an **else** clause, the **else** clause handles any exceptions that aren't handled by the block's exception handlers. For example,

```
try
 ⋮
except
  on EZeroDivide do HandleZeroDivide;
  on EOverflow do HandleOverflow;
  on EMathError do HandleMathError;
else
  HandleAllOthers;
end;
```

Here, the **else** clause handles any exception that isn't an *EMathError*.

An exception block that contains no exception handlers, but instead consists only of a list of statements, handles all exceptions. For example,

```
try
 ⋮
except
  HandleException;
end;
```

Here, the *HandleException* routine handles any exception that occurs as a result of executing the statements between **try** and **except**.

Re-raising exceptions

When the reserved word **raise** occurs in an exception block without an object reference following it, it raises whatever exception is handled by the block. This allows an exception handler to respond to an error in a limited way and then *re-raise* the exception. Re-raising is useful when a procedure or function has to clean up after an exception occurs but cannot fully handle the exception.

For example, the *GetFileList* function allocates a *TStringList* object and fills it with file names matching a specified search path:

```
function GetFileList(const Path: string): TStringList;
var
  I: Integer;
  SearchRec: TSearchRec;
begin
  Result := TStringList.Create;
  try
    I := FindFirst(Path, 0, SearchRec);
```

```
      while I = 0 do
      begin
        Result.Add(SearchRec.Name);
        I := FindNext(SearchRec);
      end;
    except
      Result.Free;
      raise;
    end;
  end;
```

GetFileList creates a *TStringList* object, then uses the *FindFirst* and *FindNext* functions (defined in *SysUtils*) to initialize it. If the initialization fails—for example because the search path is invalid, or because there is not enough memory to fill in the string list—*GetFileList* needs to dispose of the new string list, since the caller does not yet know of its existence. For this reason, initialization of the string list is performed in a **try...except** statement. If an exception occurs, the statement's exception block disposes of the string list, then re-raises the exception.

Nested exceptions

Code executed in an exception handler can itself raise and handle exceptions. As long as these exceptions are also handled within the exception handler, they do not affect the original exception. However, once an exception raised in an exception handler propagates beyond that handler, the original exception is lost. This is illustrated by the *Tan* function below.

```
type
  ETrigError = class(EMathError);

function Tan(X: Extended): Extended;
begin
  try
    Result := Sin(X) / Cos(X);
  except
    on EMathError do
      raise ETrigError.Create('Invalid argument to Tan');
  end;
end;
```

If an *EMathError* exception occurs during execution of *Tan*, the exception handler raises an *ETrigError*. Since *Tan* does not provide a handler for *ETrigError*, the exception propagates beyond the original exception handler, causing the *EMathError* exception to be destroyed. To the caller, it appears as if the *Tan* function has raised an *ETrigError* exception.

Try...finally statements

Sometimes you want to ensure that specific parts of an operation are completed, whether or not the operation is interrupted by an exception. For example, when a routine acquires control of a resource, it is often important that the resource be released, regardless of whether the routine terminates normally. In these situations, you can use a **try...finally** statement.

The following example shows how code that opens and processes a file can ensure that the file is ultimately closed, even if an error occurs during execution.

```
Reset(F);
try
 ⋮ // process file F
finally
  CloseFile(F);
end;
```

The syntax of a **try...finally** statement is

try *statementList*$_1$ finally *statementList*$_2$ end

where each *statementList* is a sequence of statements delimited by semicolons. The **try...finally** statement executes the statements in *statementList*$_1$ (the **try** clause). If *statementList*$_1$ finishes without raising exceptions, *statementList*$_2$ (the **finally** clause) is executed. If an exception is raised during execution of *statementList*$_1$, control is transferred to *statementList*$_2$; once *statementList*$_2$ finishes executing, the exception is re-raised. If a call to the *Exit*, *Break*, or *Continue* procedure causes control to leave *statementList*$_1$, *statementList*$_2$ is automatically executed. Thus the **finally** clause is always executed, regardless of how the **try** clause terminates.

If an exception is raised but not handled in the **finally** clause, that exception is propagated out of the **try...finally** statement, and any exception already raised in the **try** clause is lost. The **finally** clause should therefore handle all locally raised exceptions, so as not to disturb propagation of other exceptions.

Standard exception classes and routines

The *SysUtils* unit declares several standard routines for handling exceptions, including *ExceptObject*, *ExceptAddr*, and *ShowException*. *SysUtils* and other units also include dozens of exception classes, all of which (aside from *OutlineError*) derive from *Exception*.

The *Exception* class has properties called *Message* and *HelpContext* that can be used to pass an error description and a context ID for context-sensitive online documentation. It also defines various constructor methods that allow you to specify the description and context ID in different ways. See the online Help for details.

Chapter

8

Standard routines and I/O

This chapter discusses text and file I/O and summarizes standard library routines. Many of the procedures and functions listed here are defined in the *System* unit, which is implicitly compiled with every application. Others are built into the compiler but are treated as if they were in the *System* unit.

Some standard routines are in units such as *SysUtils*, which must be listed in a **uses** clause to make them available in programs. You cannot, however, list *System* in a **uses** clause, nor should you modify the *System* unit or try to rebuild it explicitly.

For more information about the routines listed here, see the online Help.

File input and output

The table below lists input and output routines.

Table 8.1 Input and output procedures and functions

Procedure or function	Description
Append	Opens an existing text file for appending.
AssignFile	Assigns the name of an external file to a file variable.
BlockRead	Reads one or more records from an untyped file.
BlockWrite	Writes one or more records into an untyped file.
ChDir	Changes the current directory.
CloseFile	Closes an open file.
Eof	Returns the end-of-file status of a file.
Eoln	Returns the end-of-line status of a text file.
Erase	Erases an external file.
FilePos	Returns the current file position of a typed or untyped file.
FileSize	Returns the current size of a file; not used for text files.

Table 8.1 Input and output procedures and functions (continued)

Procedure or function	Description
Flush	Flushes the buffer of an output text file.
GetDir	Returns the current directory of a specified drive.
IOResult	Returns an integer value that is the status of the last I/O function performed.
MkDir	Creates a subdirectory.
Read	Reads one or more values from a file into one or more variables.
Readln	Does what *Read* does and then skips to beginning of next line in the text file.
Rename	Renames an external file.
Reset	Opens an existing file.
Rewrite	Creates and opens a new file.
RmDir	Removes an empty subdirectory.
Seek	Moves the current position of a typed or untyped file to a specified component. Not used with text files.
SeekEof	Returns the end-of-file status of a text file.
SeekEoln	Returns the end-of-line status of a text file.
SetTextBuf	Assigns an I/O buffer to a text file.
Truncate	Truncates a typed or untyped file at the current file position.
Write	Writes one or more values to a file.
Writeln	Does the same as *Write*, and then writes an end-of-line marker to the text file.

A file variable is any variable whose type is a file type. There are three classes of file: *typed*, *text*, and *untyped*. The syntax for declaring file types is given in “File types” on page 5-24.

Before a file variable can be used, it must be associated with an external file through a call to the *AssignFile* procedure. An external file is typically a named disk file, but it can also be a device, such as the keyboard or the display. The external file stores the information written to the file or supplies the information read from the file.

Once the association with an external file is established, the file variable must be “opened” to prepare it for input or output. An existing file can be opened via the *Reset* procedure, and a new file can be created and opened via the *Rewrite* procedure. Text files opened with *Reset* are read-only and text files opened with *Rewrite* and *Append* are write-only. Typed files and untyped files always allow both reading and writing regardless of whether they were opened with *Reset* or *Rewrite*.

Every file is a linear sequence of components, each of which has the component type (or record type) of the file. The components are numbered starting with zero.

Files are normally accessed sequentially. That is, when a component is read using the standard procedure *Read* or written using the standard procedure *Write*, the current file position moves to the next numerically ordered file component. Typed files and untyped files can also be accessed randomly through the standard procedure *Seek*, which moves the current file position to a specified component. The standard functions *FilePos* and *FileSize* can be used to determine the current file position and the current file size.

When a program completes processing a file, the file must be closed using the standard procedure *CloseFile*. After a file is closed, its associated external file is updated. The file variable can then be associated with another external file.

By default, all calls to standard I/O procedures and functions are automatically checked for errors, and if an error occurs an exception is raised (or the program is terminated if exception handling is not enabled). This automatic checking can be turned on and off using the **{$I+}** and **{$I–}** compiler directives. When I/O checking is off—that is, when a procedure or function call is compiled in the **{$I–}** state—an I/O error doesn't cause an exception to be raised; to check the result of an I/O operation, you must call the standard function *IOResult* instead.

You must call the *IOResult* function to clear an error, even if you aren't interested in the error. If you don't clear an error and **{$I+}** is the current state, the next I/O function call will fail with the lingering *IOResult* error.

Text files

This section summarizes I/O using file variables of the standard type *Text*.

When a text file is opened, the external file is interpreted in a special way: It is considered to represent a sequence of characters formatted into lines, where each line is terminated by an end-of-line marker (a carriage-return character, possibly followed by a linefeed character). The type *Text* is distinct from the type `file of Char`.

For text files, there are special forms of *Read* and *Write* that let you read and write values that are not of type *Char*. Such values are automatically translated to and from their character representation. For example, `Read(F, I)`, where *I* is a type *Integer* variable, reads a sequence of digits, interprets that sequence as a decimal integer, and stores it in *I*.

There are two standard text-file variables, *Input* and *Output*. The standard file variable *Input* is a read-only file associated with the operating system's standard input (typically, the keyboard). The standard file variable *Output* is a write-only file associated with the operating system's standard output (typically, the display). Before an application begins executing, *Input* and *Output* are automatically opened, as if the following statements were executed:

```
AssignFile(Input, '');
Reset(Input);
AssignFile(Output, '');
Rewrite(Output);
```

Note Text-oriented I/O is available only in console applications—that is, applications compiled with the “Generate console application” option checked on the Linker page of the Project Options dialog box or with the **-cc** command-line compiler option. In a GUI (non-console) application, any attempt to read or write using *Input* or *Output* will produce an I/O error.

Some of the standard I/O routines that work on text files don't need to have a file variable explicitly given as a parameter. If the file parameter is omitted, *Input* or *Output* is assumed by default, depending on whether the procedure or function is input- or output-oriented. For example, `Read(X)` corresponds to `Read(Input, X)` and `Write(X)` corresponds to `Write(Output, X)`.

If you do specify a file when calling one of the input or output routines that work on text files, the file must be associated with an external file using *AssignFile*, and opened using *Reset*, *Rewrite*, or *Append*. An exception is raised if you pass a file that was opened with *Reset* to an output-oriented procedure or function. An exception is also raised if you pass a file that was opened with *Rewrite* or *Append* to an input-oriented procedure or function.

Untyped files

Untyped files are low-level I/O channels used primarily for direct access to disk files regardless of type and structuring. An untyped file is declared with the word **file** and nothing more. For example,

```
var DataFile: file;
```

For untyped files, the *Reset* and *Rewrite* procedures allow an extra parameter to specify the record size used in data transfers. For historical reasons, the default record size is 128 bytes. A record size of 1 is the only value that correctly reflects the exact size of any file. (No partial records are possible when the record size is 1.)

Except for *Read* and *Write*, all typed-file standard procedures and functions are also allowed on untyped files. Instead of *Read* and *Write*, two procedures called *BlockRead* and *BlockWrite* are used for high-speed data transfers.

Text-file device drivers

You can define your own text-file device drivers for your programs. A text-file device driver is a set of four functions that completely implement an interface between Object Pascal's file system and some device.

The four functions that define each device driver are *Open*, *InOut*, *Flush*, and *Close*. The function header of each function is

```
function DeviceFunc(var F: TTextRec): Integer;
```

where *DeviceFunc* is the name of the function (that is, *Open*, *InOut*, *Flush*, or *Close*). For information about the *TTextRec* type, see the online Help. The return value of a device-interface function becomes the value returned by *IOResult*. If the return value is zero, the operation was successful.

To associate the device-interface functions with a specific file, you must write a customized *Assign* procedure. The *Assign* procedure must assign the addresses of the four device-interface functions to the four function pointers in the text-file variable. In addition, it should store the *fmClosed* "magic" constant in the *Mode* field, store the size of the text-file buffer in *BufSize*, store a pointer to the text-file buffer in *BufPtr*, and clear the *Name* string.

Assuming, for example, that the four device-interface functions are called *DevOpen*, *DevInOut*, *DevFlush*, and *DevClose*, the *Assign* procedure might look like this:

```
procedure AssignDev(var F: Text);
begin
  with TTextRec(F) do
  begin
    Mode := fmClosed;
    BufSize := SizeOf(Buffer);
    BufPtr := @Buffer;
    OpenFunc := @DevOpen;
    InOutFunc := @DevInOut;
    FlushFunc := @DevFlush;
    CloseFunc := @DevClose;
    Name[0] := #0;
  end;
end;
```

The device-interface functions can use the *UserData* field in the file record to store private information. This field isn't modified by the product file system at any time.

Device functions

The functions that make up a text-file device driver are described below.

The Open function

The *Open* function is called by the *Reset*, *Rewrite*, and *Append* standard procedures to open a text file associated with a device. On entry, the *Mode* field contains *fmInput*, *fmOutput*, or *fmInOut* to indicate whether the *Open* function was called from *Reset*, *Rewrite*, or *Append*.

The *Open* function prepares the file for input or output, according to the *Mode* value. If *Mode* specified *fmInOut* (indicating that *Open* was called from *Append*), it must be changed to *fmOutput* before *Open* returns.

Open is always called before any of the other device-interface functions. For that reason, *AssignDev* only initializes the *OpenFunc* field, leaving initialization of the remaining vectors up to *Open*. Based on *Mode*, *Open* can then install pointers to either input- or output-oriented functions. This saves the *InOut*, *Flush* functions and the *CloseFile* procedure from determining the current mode.

The InOut function

The *InOut* function is called by the *Read*, *Readln*, *Write*, *Writeln*, *Eof*, *Eoln*, *SeekEof*, *SeekEoln*, and *CloseFile* standard routines whenever input or output from the device is required.

When *Mode* is *fmInput*, the *InOut* function reads up to *BufSize* characters into `BufPtr^`, and returns the number of characters read in *BufEnd*. In addition, it stores zero in *BufPos*. If the *InOut* function returns zero in *BufEnd* as a result of an input request, *Eof* becomes *True* for the file.

When *Mode* is *fmOutput*, the *InOut* function writes *BufPos* characters from `BufPtr^`, and returns zero in *BufPos*.

The Flush function

The *Flush* function is called at the end of each *Read*, *Readln*, *Write*, and *Writeln*. It can optionally flush the text-file buffer.

If *Mode* is *fmInput*, the *Flush* function can store zero in *BufPos* and *BufEnd* to flush the remaining (unread) characters in the buffer. This feature is seldom used.

If *Mode* is *fmOutput*, the *Flush* function can write the contents of the buffer exactly like the *InOut* function, which ensures that text written to the device appears on the device immediately. If *Flush* does nothing, the text doesn't appear on the device until the buffer becomes full or the file is closed.

The Close function

The *Close* function is called by the *CloseFile* standard procedure to close a text file associated with a device. (The *Reset*, *Rewrite*, and *Append* procedures also call *Close* if the file they are opening is already open.) If *Mode* is *fmOutput*, then before calling *Close*, the file system calls the *InOut* function to ensure that all characters have been written to the device.

Handling null-terminated strings

Object Pascal's extended syntax allows the *Read*, *Readln*, *Str*, and *Val* standard procedures to be applied to zero-based character arrays, and allows the *Write*, *Writeln*, *Val*, *AssignFile*, and *Rename* standard procedures to be applied to both zero-based character arrays and character pointers. In addition, the following functions are provided for handling null-terminated strings. For more information about null-terminated strings, see "Working with null-terminated strings" on page 5-13.

Table 8.2 Null-terminated string functions

Function	Description
StrAlloc	Allocates a character buffer of a given size on the heap.
StrBufSize	Returns the size of a character buffer allocated using *StrAlloc* or *StrNew*.
StrCat	Concatenates two strings.
StrComp	Compares two strings.
StrCopy	Copies a string.
StrDispose	Disposes a character buffer allocated using *StrAlloc* or *StrNew*.
StrECopy	Copies a string and returns a pointer to the end of the string.
StrEnd	Returns a pointer to the end of a string.
StrFmt	Formats one or more values into a string.
StrIComp	Compares two strings without case sensitivity.
StrLCat	Concatenates two strings with a given maximum length of the resulting string.
StrLComp	Compares two strings for a given maximum length.
StrLCopy	Copies a string up to a given maximum length.
StrLen	Returns the length of a string.
StrLFmt	Formats one or more values into a string with a given maximum length.

Table 8.2 Null-terminated string functions (continued)

Function	Description
StrLIComp	Compares two strings for a given maximum length without case sensitivity.
StrLower	Converts a string to lowercase.
StrMove	Moves a block of characters from one string to another.
StrNew	Allocates a string on the heap.
StrPCopy	Copies a Pascal string to a null-terminated string.
StrPLCopy	Copies a Pascal string to a null-terminated string with a given maximum length.
StrPos	Returns a pointer to the first occurrence of a given substring within a string.
StrRScan	Returns a pointer to the last occurrence of a given character within a string.
StrScan	Returns a pointer to the first occurrence of a given character within a string.
StrUpper	Converts a string to uppercase.

Standard string-handling functions have multibyte-enabled counterparts that also implement locale-specific ordering for characters. Names of multibyte functions start with *Ansi-*. For example, the multibyte version of *StrPos* is *AnsiStrPos*. Multibyte character support is operating-system dependent and based on the current locale.

Wide-character strings

The *System* unit provides three functions, *WideCharToString*, *WideCharLenToString*, and *StringToWideChar*, that can be used to convert null-terminated wide character strings to single- or double-byte long strings.

For more information about wide-character strings, see “About extended character sets” on page 5-13.

Other standard routines

The table below lists frequently used procedures and functions found in Borland product libraries. This is not an exhaustive inventory of standard routines. For more information about these and other routines, see the online Help.

Table 8.3 Other standard routines

Procedure or function	Description
Abort	Ends the process without reporting an error.
Addr	Returns a pointer to a specified object.
AllocMem	Allocates a memory block and initializes each byte to zero.
ArcTan	Calculates the arctangent of the given number.
Assert	Tests whether a boolean expression is *True*.
Assigned	Tests for a **nil** (unassigned) pointer or procedural variable.
Beep	Generates a standard beep using the computer speaker.

Table 8.3 Other standard routines (continued)

Procedure or function	Description
Break	Causes control to exit a **for**, **while**, or **repeat** statement.
ByteToCharIndex	Returns the position of the character containing a specified byte in a string.
Chr	Returns the character for a specified value.
Close	Terminates the association between a file variable and an external file.
CompareMem	Performs a binary comparison of two memory images.
CompareStr	Compares strings case sensitively.
CompareText	Compares strings by ordinal value and is not case sensitive.
Continue	Returns control to the next iteration of **for**, **while**, or **repeat** statements.
Copy	Returns a substring of a string or a segment of a dynamic array.
Cos	Calculates the cosine of an angle.
CurrToStr	Converts a currency variable to a string.
Date	Returns the current date.
DateTimeToStr	Converts a variable of type *TDateTime* to a string.
DateToStr	Converts a variable of type *TDateTime* to a string.
Dec	Decrements an ordinal variable.
Dispose	Releases memory allocated for a dynamic variable.
ExceptAddr	Returns the address at which the current exception was raised.
Exit	Exits from the current procedure.
Exp	Calculates the exponential of X.
FillChar	Fills contiguous bytes with a specified value.
Finalize	Uninitializes a dynamically allocated variable.
FloatToStr	Converts a floating point value to a string.
FloatToStrF	Converts a floating point value to a string, using specified format.
FmtLoadStr	Returns formatted output using a resourced format string.
FmtStr	Assembles a formatted string from a series of arrays.
Format	Assembles a string from a format string and a series of arrays.
FormatDateTime	Formats a date-and-time value.
FormatFloat	Formats a floating point value.
FreeMem	Disposes of a dynamic variable.
GetMem	Creates a dynamic variable and a pointer to the address of the block.
GetParentForm	Returns the form or property page that contains a specified control.
Halt	Initiates abnormal termination of a program.
Hi	Returns the high-order byte of an expression as an unsigned value.
High	Returns the highest value in the range of a type, array, or string.
Inc	Increments an ordinal variable.
Initialize	Initializes a dynamically allocated variable.
Insert	Inserts a substring at a specified point in a string.
Int	Returns the integer part of a real number.
IntToStr	Converts an integer to a string.

Table 8.3 Other standard routines (continued)

Procedure or function	**Description**
Length	Returns the length of a string or array.
Lo	Returns the low-order byte of an expression as an unsigned value.
Low	Returns the lowest value in the range of a type, array, or string.
LowerCase	Converts an ASCII string to lowercase.
MaxIntValue	Returns the largest signed value in an integer array.
MaxValue	Returns the largest signed value in an array.
MinIntValue	Returns the smallest signed value in an integer array.
MinValue	Returns smallest signed value in an array.
New	Creates a new dynamic variable and references it with a specified pointer.
Now	Returns the current date and time.
Ord	Returns the ordinal value of an ordinal-type expression.
Pos	Returns the index of the first character of a specified substring in a string.
Pred	Returns the predecessor of an ordinal value.
Ptr	Converts a specified address to a pointer.
Random	Generates random numbers within a specified range.
ReallocMem	Reallocates a dynamic variable.
Round	Returns the value of a real rounded to the nearest whole number.
SetLength	Sets the dynamic length of a string variable or array.
SetString	Sets the contents and length of the given string.
ShowException	Displays an exception message with its address.
ShowMessage	Displays a message box with an unformatted string and an OK button.
ShowMessageFmt	Displays a message box with a formatted string and an OK button.
Sin	Returns the sine of an angle in radians.
SizeOf	Returns the number of bytes occupied by a variable or type.
Sqr	Returns the square of a number.
Sqrt	Returns the square root of a number.
Str	Formats a string and returns it to a variable.
StrToCurr	Converts a string to a currency value.
StrToDate	Converts a string to a date format (*TDateTime*).
StrToDateTime	Converts a string to a *TDateTime*.
StrToFloat	Converts a string to a floating-point value.
StrToInt	Converts a string to an integer.
StrToTime	Converts a string to a time format (*TDateTime*).
StrUpper	Returns a string in upper case.
Succ	Returns the successor of an ordinal value.
Sum	Returns the sum of the elements from an array.
Time	Returns the current time.
TimeToStr	Converts a variable of type *TDateTime* to a string.
Trunc	Truncates a real number to an integer.

Table 8.3 Other standard routines (continued)

Procedure or function	Description
UniqueString	Ensures that a string has only one reference. (The string may be copied to produce a single reference.)
UpCase	Converts a character to uppercase.
UpperCase	Returns a string in uppercase.
VarArrayCreate	Creates a variant array.
VarArrayDimCount	Returns number of dimensions of a variant array.
VarARrayHighBound	Returns high bound for a dimension in a variant array.
VarArrayLock	Locks a variant array and returns a pointer to the data.
VarArrayLowBound	Returns the low bound of a dimension in a variant array.
VarArrayOf	Creates and fills a one-dimensional variant array.
VarArrayRedim	Resizes a variant array.
VarArrayRef	Returns a reference to the passed variant array.
VarArrayUnlock	Unlocks a variant array.
VarAsType	Converts a variant to specified type.
VarCast	Converts a variant to a specified type, storing the result in a variable.
VarClear	Clears a variant.
VarCopy	Copies a variant.
VarToStr	Converts variant to string.
VarType	Returns type code of specified variant.

For information on format strings, see “Format strings” in the online Help.

Part

II

Special topics

The chapters in Part II cover specialized language features and advanced topics. These chapters include:

- Chapter 9, “Libraries and packages”
- Chapter 10, “Object interfaces”
- Chapter 11, “Memory management”
- Chapter 12, “Program control”
- Chapter 13, “Inline assembler code”

Chapter

9

Libraries and packages

A dynamically loadable library is a dynamic-link library (DLL) on Windows or a shared object library file on Linux. It is a collection of routines that can be called by applications and by other DLLs or shared objects. Like units, dynamically loadable libraries contain sharable code or resources. But this type of library is a separately compiled executable that is linked at runtime to the programs that use it.

To distinguish them from standalone executables, on Windows files containing compiled DLLs are named with the .DLL extension. On Linux, files containing shared object files are named with a .so extension. Object Pascal programs can call DLLs or shared objects written in other languages, and applications written in other languages can call DLLs or shared objects written in Object Pascal.

Calling dynamically loadable libraries

You can call operating system routines directly, but they are not linked to your application until runtime. This means that the library need not be present when you compile your program. It also means that there is no compile-time validation of attempts to import a routine.

Before you can call routines defined in a shared object, you must *import* them. This can be done in two ways: by declaring an **external** procedure or function, or by direct calls to the operating system. Whichever method you use, the routines are not linked to your application until runtime.

Object Pascal does not support importing of variables from shared libraries.

Static loading

The simplest way to import a procedure or function is to declare it using the **external** directive. For example,

```
On Windows: procedure DoSomething; external 'MYLIB.DLL';

On Linux:   procedure DoSomething; external 'mylib.so';
```

If you include this declaration in a program, MYLIB.DLL (Windows) or mylib.so (Linux) is loaded once, when the program starts. Throughout execution of the program, the identifier *DoSomething* always refers to the same entry point in the same shared library.

Declarations of imported routines can be placed directly in the program or unit where they are called. To simplify maintenance, however, you can collect **external** declarations into a separate "import unit" that also contains any constants and types required for interfacing with the library. Other modules that use the import unit can call any routines declared in it.

For more information about **external** declarations, see "External declarations" on page 6-6.

Dynamic loading

You can access routines in a library through direct calls to OS library functions, including *LoadLibrary*, *FreeLibrary*, and *GetProcAddress.* In Windows, these functions are declared in Windows.pas; on Linux, they are implemented for compatibility in SysUtils.pas; the actual Linux OS routines are *dlopen*, *dlclose*, and *dlsym* (all declared in Kylix's *Libc* unit; see the man pages for more information). In this case, use procedural-type variables to reference the imported routines.

For example, on Windows or Linux:

```
uses Windows, ...; {On Linux, replace Windows with SysUtils }

type
  TTimeRec = record
    Second: Integer;
    Minute: Integer;
    Hour: Integer;
  end;

  TGetTime = procedure(var Time: TTimeRec);
  THandle = Integer;

var
  Time: TTimeRec;
  Handle: THandle;
  GetTime: TGetTime;
  ⋮
begin
  Handle := LoadLibrary('libraryname');
  if Handle <> 0 then
  begin
    @GetTime := GetProcAddress(Handle, 'GetTime');
    if @GetTime <> nil then
    begin
      GetTime(Time);
      with Time do
        WriteLn('The time is ', Hour, ':', Minute, ':', Second);
    end;
    FreeLibrary(Handle);
  end;
end;
```

When you import routines this way, the library is not loaded until the code containing the call to *LoadLibrary* executes. The library is later unloaded by the call to *FreeLibrary*. This allows you to conserve memory and to run your program even when some of the libraries it uses are not present.

This same example can also be written on Linux as follows:

```
uses Libc, ...;

type
  TTimeRec = record
    Second: Integer;
    Minute: Integer;
    Hour: Integer;
  end;

  TGetTime = procedure(var Time: TTimeRec);
  THandle = Pointer;

var
  Time: TTimeRec;
  Handle: THandle;
  GetTime: TGetTime;
  ⋮
begin
  Handle := dlopen('datetime.so', RTLD_LAZY);
  if Handle <> 0 then
  begin
    @GetTime := dlsym(Handle, 'GetTime');
    if @GetTime <> nil then
    begin
      GetTime(Time);
      with Time do
        WriteLn('The time is ', Hour, ':', Minute, ':', Second);
    end;
    dlclose(Handle);
  end;
end;
```

In this case, when importing routines, the shared object is not loaded until the code containing the call to *dlopen* executes. The shared object is later unloaded by the call to *dlclose*. This also allows you to conserve memory and to run your program even when some of the shared objects it uses are not present.

Writing dynamically loadable libraries

The main source for a dynamically loadable library is identical to that of a program, except that it begins with the reserved word **library** (instead of **program**).

Only routines that a library explicitly exports are available for importing by other libraries or programs. The following example shows a library with two exported functions, *Min* and *Max*.

```
library MinMax;

function Min(X, Y: Integer): Integer; stdcall;
begin
  if X < Y then Min := X else Min := Y;
end;

function Max(X, Y: Integer): Integer; stdcall;
begin
  if X > Y then Max := X else Max := Y;
end;

exports
  Min,
  Max;

begin
end.
```

If you want your library to be available to applications written in other languages, it's safest to specify **stdcall** in the declarations of exported functions. Other languages may not support Object Pascal's default **register** calling convention.

Libraries can be built from multiple units. In this case, the library source file is frequently reduced to a **uses** clause, an **exports** clause, and the initialization code. For example,

```
library Editors;

uses EdInit, EdInOut, EdFormat, EdPrint;

exports
  InitEditors,
  DoneEditors name Done,
  InsertText name Insert,
  DeleteSelection name Delete,
  FormatSelection,
  PrintSelection name Print,
   ⋮
  SetErrorHandler;

begin
  InitLibrary;
end.
```

You can put **exports** clauses in the **interface** or **implementation** section of a unit. Any library that includes such a unit in its **uses** clause automatically exports the routines listed the unit's **exports** clauses—without the need for an **exports** clause of its own.

The directive **local**, which marks routines as unavailable for export, is platform-specific and has no effect in Windows programming.

On Linux, the **local** directive provides a slight performance optimization for routines that are compiled into a library but are not exported. This directive can be specified for standalone procedures and functions, but not for methods. A routine declared with **local**—for example,

```
function Contraband(I: Integer): Integer; local;
```

—does not refresh the EBX register and hence

- cannot be exported from a library.
- cannot be declared in the **interface** section of a unit.
- cannot have its address taken or be assigned to a procedural-type variable.
- if it is a pure assembler routine, cannot be called from another unit unless the *caller* sets up EBX.

The exports clause

A routine is exported when it is listed in an **exports** clause, which has the form

exports *entry*$_1$, ..., *entry*$_n$;

where each *entry* consists of the name of a procedure, function, or variable (which must be declared prior to the **exports** clause), followed by a parameter list (only if exporting a routine that is overloaded), and an optional **name** specifier. You can qualify the procedure or function name with the name of a unit.

(Entries can also include the directive **resident**, which is maintained for backward compatibility and is ignored by the compiler.)

On Windows only, an **index** specifier consists of the directive **index** followed by a numeric constant between 1 and 2,147,483,647. (For more efficient programs, use low index values.) If an entry has no **index** specifier, the routine is automatically assigned a number in the export table.

Note Use of **index** specifiers, which are supported for backward compatibility only, is discouraged and may cause problems for other development tools.

A **name** specifier consists of the directive **name** followed by a string constant. If an entry has no **name** specifier, the routine is exported under its original declared name, with the same spelling and case. Use a **name** clause when you want to export a routine under a different name. For example,

```
exports
  DoSomethingABC name 'DoSomething';
```

When you export an overloaded function or procedure from a dynamically loadable library, you must specify its parameter list in the **exports** clause. For example,

```
exports
  Divide(X, Y: Integer) name 'Divide_Ints',
  Divide(X, Y: Real) name 'Divide_Reals';
```

On Windows, do not include **index** specifiers in entries for overloaded routines.

An **exports** clause can appear anywhere and any number of times in the declaration part of a program or library, or in the **interface** or **implementation** section of a unit. Programs seldom contain an **exports** clause.

Library initialization code

The statements in a library's block constitute the library's *initialization code*. These statements are executed once every time the library is loaded. They typically perform tasks like registering window classes and initializing variables. Library initialization code can also install an exit procedure using the *ExitProc* variable, as described in "Exit procedures" on page 12-4; the exit procedure executes when the library is unloaded.

Library initialization code can signal an error by setting the *ExitCode* variable to a nonzero value. *ExitCode* is declared in the *System* unit and defaults to zero, indicating successful initialization. If a library's initialization code sets *ExitCode* to another value, the library is unloaded and the calling application is notified of the failure. Similarly, if an unhandled exception occurs during execution of the initialization code, the calling application is notified of a failure to load the library.

Here is an example of a library with initialization code and an exit procedure.

```
library Test;

var
  SaveExit: Pointer;

procedure LibExit;
begin
  ⋮  // library exit code
  ExitProc := SaveExit;  // restore exit procedure chain
end;

begin
  ⋮  // library initialization code
  SaveExit := ExitProc;  // save exit procedure chain
  ExitProc := @LibExit;  // install LibExit exit procedure
end.
```

When a library is unloaded, it's exit procedures are executed by repeated calls to the address stored in *ExitProc*, until *ExitProc* becomes **nil**. The initialization parts of all units used by a library are executed before the library's initialization code, and the finalization parts of those units are executed after the library's exit procedure.

Global variables in a library

Global variables declared in a shared library cannot be imported by an Object Pascal application.

A library can be used by several applications at once, but each application has a copy of the library in its own process space with its own set of global variables. For multiple libraries—or multiple instances of a library—to share memory, they must use memory-mapped files. Refer to the your system documentation for further information.

Libraries and system variables

Several variables declared in the *System* unit are of special interest to those programming libraries. Use *IsLibrary* to determine whether code is executing in an application or in a library; *IsLibrary* is always *False* in an application and *True* in a library. During a library's lifetime, *HInstance* contains its instance handle. *CmdLine* is always **nil** in a library.

The *DLLProc* variable allows a library to monitor calls that the operating system makes to the library entry point. This feature is normally used only by libraries that support multithreading. *DLLProc* is available on both Windows and Linux but its use differs on each. On Windows, *DLLProc* is used in multithreading applications; on Linux, it is used to determine when your library is being unloaded. You should use finalization sections, rather than exit procedures, for all exit behavior. (See “The finalization section” on page 3-5.)

To monitor operating-system calls, create a callback procedure that takes a single integer parameter—for example,

```
procedure DLLHandler(Reason: Integer);
```

—and assign the address of the procedure to the *DLLProc* variable. When the procedure is called, it passes to it one of the following values.

DLL_PROCESS_DETACH	Indicates that the library is detaching from the address space of the calling process as a result of a clean exit or a call to *FreeLibrary* or (*dlclose* on Linux).
DLL_THREAD_ATTACH	Indicates that the current process is creating a new thread (Windows only).
DLL_THREAD_DETACH	Indicates that a thread is exiting cleanly (Windows only).

On Linux, these are defined in the *Libc* unit.

In the body of the procedure, you can specify actions to take depending on which parameter is passed to the procedure.

Exceptions and runtime errors in libraries

When an exception is raised but not handled in a dynamically loadable library, it propagates out of the library to the caller. If the calling application or library is itself written in Object Pascal, the exception can be handled through a normal **try...except** statement.

Note Under Linux this is only possible if the library and application have both been built with the same set of (base) runtime packages (which contains the EH code) or if both link to ShareExcept.

If the calling application or library is written in another language, the exception can be handled as an operating-system exception with the exception code $0EEDFACE. The first entry in the *ExceptionInformation* array of the operating-system exception record contains the exception address, and the second entry contains a reference to the Object Pascal exception object.

Generally, you should not let exceptions escape from your library. On Windows, Delphi exceptions map to the OS exception model; Linux does not have an exception model.

If a library does not use the *SysUtils* unit, exception support is disabled. In this case, when a runtime error occurs in the library, the calling application terminates.

Because the library has no way of knowing whether it was called from an Object Pascal program, it cannot invoke the application's exit procedures; the application is simply aborted and removed from memory.

Shared-memory manager (Windows only)

On Windows, if a DLL exports routines that pass long strings or dynamic arrays as parameters or function results (whether directly or nested in records or objects), then the DLL and its client applications (or DLLs) must all use the *ShareMem* unit. The same is true if one application or DLL allocates memory with *New* or *GetMem* which is deallocated by a call to *Dispose* or *FreeMem* in another module. *ShareMem* should always be the first unit listed in any program or library **uses** clause where it occurs.

ShareMem is the interface unit for the BORLANDMM.DLL memory manager, which allows modules to share dynamically allocated memory. BORLANDMM.DLL must be deployed with applications and DLLs that use *ShareMem*. When an application or DLL uses *ShareMem*, its memory manager is replaced by the memory manager in BORLANDMM.DLL.

Linux uses glibc's *malloc* to manage shared memory.

Packages

A package is a specially compiled library used by applications, the IDE, or both. Packages allow you to rearrange when code resides without affecting the source code. This is sometimes referred to as *application partitioning*.

Runtime packages provide functionality when a user runs an application. *Design-time packages* are used to install components in the IDE and to create special property editors for custom components. A single package can function at both design time and runtime, and design-time packages frequently work by referencing runtime packages in their **requires** clauses.

To distinguish them from other libraries, packages are stored in files:

- On Windows, package files end with the .bpl (Borland package library) extension.
- On Linux, packages generally begin with the prefix bpl and have a .so extension.

Ordinarily, packages are loaded statically when an applications starts. But you can use the *LoadPackage* and *UnloadPackage* routines (in the *SysUtils* unit) to load packages dynamically.

Note When an application utilizes packages, the name of each packaged unit still must appear in the **uses** clause of any source file that references it. For more information about packages, see the online Help.

Package declarations and source files

Each package is declared in a separate source file, which should be saved with the .dpk extension to avoid confusion with other files containing Object Pascal code. A package source file does not contain type, data, procedure, or function declarations. Instead, it contains

- A *name* for the package.
- A list of other packages *required* by the new package. These are packages to which the new package is linked.
- A list of unit files *contained* by, or bound into, the package when it is compiled. The package is essentially a wrapper for these source-code units, which provide the functionality of the compiled package.

A package declaration has the form

```
package packageName;
  requiresClause;
  containsClause;
end.
```

where *packageName* is any valid identifier. The *requiresClause* and *containsClause* are both optional. For example, the following code declares the *DATAX* package.

```
package DATAX;
requires
  baseclx,
  visualclx;
  contains Db, DBLocal, DBXpress, ... ;
end.
```

The **requires** clause lists other, external packages used by the package being declared. It consists of the directive **requires**, followed by a comma-delimited list of package names, followed by a semicolon. If a package does not reference other packages, it does not need a **requires** clause.

The **contains** clause identifies the unit files to be compiled and bound into the package. It consists of the directive **contains**, followed by a comma-delimited list of unit names, followed by a semicolon. Any unit name may be followed by the reserved word **in** and the name of a source file, with or without a directory path, in single quotation marks; directory paths can be absolute or relative. For example,

```
contains MyUnit in 'C:\MyProject\MyUnit.pas'; // Windows

contains MyUnit in '\home\developer\MyProject\MyUnit.pas'; // Linux
```

Note Thread-local variables (declared with **threadvar**) in a packaged unit cannot be accessed from clients that use the package.

Naming packages

A compiled package involves several generated files. For example, the source file for the package called *DATAX* is DATAX.dpk, from which the compiler generates an executable and a binary image called

- On Windows: DATAX.bpl and DATAX.dcp
- On Linux: bplDATAX.so and DATAX.dcp.

DATAX is used to refer to the package in the **requires** clauses of other packages, or when using the package in an application. Package names must be unique within a project.

The requires clause

The **requires** clause lists other, external packages that are used by the current package. It functions like the **uses** clause in a unit file. An external package listed in the **requires** clause is automatically linked at compile time into any application that uses both the current package and one of the units contained in the external package.

If the unit files contained in a package make references to other packaged units, the other packages should be included in the first package's **requires** clause. If the other packages are omitted from the **requires** clause, the compiler loads the referenced units from their .dcu (Windows) or .dpu (Linux) files.

Avoiding circular package references

Packages cannot contain circular references in their **requires** clauses. This means that

- A package cannot reference itself in its own **requires** clause.
- A chain of references must terminate without rereferencing any package in the chain. If package *A* requires package *B*, then package *B* cannot require package *A*; if package *A* requires package *B* and package *B* requires package *C*, then package *C* cannot require package *A*.

Duplicate package references

The compiler ignores duplicate references in a package's **requires** clause. For programming clarity and readability, however, duplicate references should be removed.

The contains clause

The **contains** clause identifies the unit files to be bound into the package. Do not include file-name extensions in the **contains** clause.

Avoiding redundant source code uses

A package cannot be listed in the **contains** clause of another package or the **uses** clause of a unit.

All units included directly in a package's **contains** clause, or indirectly in the **uses** clauses of those units, are bound into the package at compile time. The units contained (directly or indirectly) in a package cannot be contained in any other packages referenced in **requires** clause of that package.

A unit cannot be contained (directly or indirectly) in more than one package used by the same application.

Compiling packages

Packages are ordinarily compiled from the IDE using .dpk files generated by the Package editor. You can also compile .dpk files directly from the command line. When you build a project that contains a package, the package is implicitly recompiled, if necessary.

Generated files

The following table lists the files produced by the successful compilation of a package.

Table 9.1 Compiled package files

File extension	Contents
dcp	A binary image containing a package header and the concatenation of all dcu (Windows) or dpu (Linux) files in the package. A single dcp file is created for each package. The base name for the dcp is the base name of the dpk source file.
dcu (Windows) dpu (Linux)	A binary image for a unit file contained in a package. One dcu or dpu file is created, when necessary, for each unit file.
.bpl on Windows bpl<package>.so on Linux	The runtime package. This file is a shared library with special Borland-specific features. The base name for the package is the base name of the dpk source file.

Several compiler directives and command-line switches are available to support package compilation.

Package-specific compiler directives

The following table lists package-specific compiler directives that can be inserted into source code. See the online Help for details.

Table 9.2 Package-specific compiler directives

Directive	Purpose
{$IMPLICITBUILD OFF}	Prevents a package from being implicitly recompiled later. Use in .dpk files when compiling packages that provide low-level functionality, that change infrequently between builds, or whose source code will not be distributed.
{$G–} or {$IMPORTEDDATA OFF}	Disables creation of imported data references. This directive increases memory-access efficiency, but prevents the unit where it occurs from referencing variables in other packages.
{$WEAKPACKAGEUNIT ON}	Packages unit “weakly”, as explained in the online Help.

Table 9.2 Package-specific compiler directives (continued)

Directive	Purpose
{$DENYPACKAGEUNIT ON}	Prevents unit from being placed in a package.
{$DESIGNONLY ON}	Compiles the package for installation in the IDE. (Put in .dpk file.)
{$RUNONLY ON}	Compiles the package as runtime only. (Put in .dpk file.)

Including **{$DENYPACKAGEUNIT ON}** in source code prevents the unit file from being packaged. Including **{$G–}** or **{$IMPORTEDDATA OFF}** may prevent a package from being used in the same application with other packages.

Other compiler directives may be included, if appropriate, in package source code.

Package-specific command-line compiler switches

The following package-specific switches are available for the command-line compiler. See the online Help for details.

Table 9.3 Package-specific command-line compiler switches

Switch	Purpose
–$G–	Disables creation of imported data references. Using this switch increases memory-access efficiency, but prevents packages compiled with it from referencing variables in other packages.
–LE *path*	Specifies the directory where the compiled package file will be placed.
–LN *path*	Specifies the directory where the package dcp file will be placed.
–LU*packageName [;packageName2;...]*	Specifies additional runtime packages to use in an application. Used when compiling a project.
–Z	Prevents a package from being implicitly recompiled later. Use when compiling packages that provide low-level functionality, that change infrequently between builds, or whose source code will not be distributed.

Using the **–$G–** switch may prevent a package from being used in the same application with other packages.

Other command-line options may be used, if appropriate, when compiling packages.

Chapter

10

Object interfaces

An *object interface*—or simply *interface*—defines methods that can be implemented by a class. Interfaces are declared like classes, but cannot be directly instantiated and do not have their own method definitions. Rather, it is the responsibility of any class that supports an interface to provide implementations for the interface's methods. A variable of an interface type can reference an object whose class implements that interface; however, only methods declared in the interface can be called using such a variable.

Interfaces offer some of the advantages of multiple inheritance without the semantic difficulties. They are also essential for using distributed object models. Custom objects built that support interfaces can interact with objects written in C++, Java, and other languages.

Interface types

Interfaces, like classes, can be declared only in the outermost scope of a program or unit, not in a procedure or function declaration. An interface type declaration has the form

```
type interfaceName = interface (ancestorInterface)
  ['{GUID}']
  memberList
end;
```

where (*ancestorInterface*) and ['{*GUID*}'] are optional. In most respects, interface declarations resemble class declarations, but the following restrictions apply.

- The *memberList* can include only methods and properties. Fields are not allowed in interfaces.
- Since an interface has no fields, property **read** and **write** specifiers must be methods.

- All members of an interface are public. Visibility specifiers and storage specifiers are not allowed. (But an array property can be declared as **default**.)
- Interfaces have no constructors or destructors. They cannot be instantiated, except through classes that implement their methods.
- Methods cannot be declared as **virtual**, **dynamic**, **abstract**, or **override**. Since interfaces do not implement their own methods, these designations have no meaning.

Here is an example of an interface declaration:

```
type
  IMalloc = interface(IInterface)
    ['{00000002-0000-0000-C000-000000000046}']
    function Alloc(Size: Integer): Pointer; stdcall;
    function Realloc(P: Pointer; Size: Integer): Pointer; stdcall;
    procedure Free(P: Pointer); stdcall;
    function GetSize(P: Pointer): Integer; stdcall;
    function DidAlloc(P: Pointer): Integer; stdcall;
    procedure HeapMinimize; stdcall;
  end;
```

In some interface declarations, the **interface** reserved word is replaced by **dispinterface**. This construction (along with the **dispid**, **readonly**, and **writeonly** directives) is platform-specific and is not used in Linux programming.

IInterface and inheritance

An interface, like a class, inherits all of its ancestors' methods. But interfaces, unlike classes, do not *implement* methods. What an interface inherits is the *obligation* to implement methods—an obligation that devolves onto any class supporting the interface.

The declaration of an interface can specify an ancestor interface. If no ancestor is specified, the interface is a direct descendant of *IInterface*, which is defined in the *System* unit and is the ultimate ancestor of all other interfaces. *IInterface* declares three methods: *QueryInterface*, *_AddRef*, and *_Release*.

Note *IInterface* is equivalent to *IUnknown*. You should generally use *IInterface* for platform independent applications and reserve the use of *IUnknown* for specific programs that include Windows dependencies.

QueryInterface provides the means to move freely among the different interfaces that an object supports. *_AddRef* and *_Release* provide lifetime memory management for interface references. The easiest way to implement these methods is to derive the implementing class from the *System* unit's *TInterfacedObject*. It is also possible to dispense with any of these methods by implementing it as an empty function; COM objects (Windows only), however, must be managed through *_AddRef* and *_Release*.

Interface identification

An interface declaration can specify a globally unique identifier (GUID), represented by a string literal enclosed in brackets immediately preceding the member list. The GUID part of the declaration must have the form

```
['{xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx}']
```

where each *x* is a hexadecimal digit (0 through 9 or A through F). On Windows, the Type Library editor automatically generates GUIDs for new interfaces; you can also generate GUIDs by pressing *Ctrl+Shift+G* in the Code editor (on Linux, you must use *Ctrl+Shift+G*).

A GUID is a 16-byte binary value that uniquely identifies an interface. If an interface has a GUID, you can use interface querying to get references to its implementations. (See "Interface querying" on page 10-10.)

The *TGUID* and *PGUID* types, declared in the *System* unit, are used to manipulate GUIDs.

```
type
  PGUID = ^TGUID;
  TGUID = packed record
    D1: Longword;
    D2: Word;
    D3: Word;
    D4: array[0..7] of Byte;
  end;
```

When you declare a typed constant of type *TGUID*, you can use a string literal to specify its value. For example,

```
const IID_IMalloc: TGUID = '{00000002-0000-0000-C000-000000000046}';
```

In procedure and function calls, either a GUID or an interface identifier can serve as a value or constant parameter of type *TGUID*. For example, given the declaration

```
function Supports(Unknown: IInterface; const IID: TGUID): Boolean;
```

Supports can be called in either of two ways:

```
if Supports(Allocator, IMalloc) then ...
if Supports(Allocator, IID_IMalloc) then ...
```

Calling conventions for interfaces

The default calling convention is **register**, but interfaces shared among modules (especially if they are written in different languages) should declare all methods with **stdcall**. Use **safecall** to implement CORBA interfaces. On Windows, you can use **safecall** to implement methods of dual interfaces (as described in "Dual interfaces (Windows only)" on page 10-13).

For more information about calling conventions, see "Calling conventions" on page 6-4.

Interface properties

Properties declared in an interface are accessible only through expressions of the interface type; they cannot be accessed through class-type variables. Moreover, interface properties are visible only within programs where the interface is compiled. For example, on Windows, COM objects do not have properties.

In an interface, property **read** and **write** specifiers must be methods, since fields are not available.

Forward declarations

An interface declaration that ends with the reserved word **interface** and a semicolon, without specifying an ancestor, GUID, or member list, is a *forward declaration*. A forward declaration must be resolved by a *defining declaration* of the same interface within the same type declaration section. In other words, between a forward declaration and its defining declaration, nothing can occur except other type declarations.

Forward declarations allow mutually dependent interfaces. For example,

```
type
  IControl = interface;
  IWindow = interface
    ['{00000115-0000-0000-C000-000000000044}']
    function GetControl(Index: Integer): IControl;
    ⋮
  end;
  IControl = interface
    ['{00000115-0000-0000-C000-000000000049}']
    function GetWindow: IWindow;
    ⋮
  end;
```

Mutually derived interfaces are not allowed. For example, it is not legal to derive *IWindow* from *IControl* and also derive *IControl* from *IWindow*.

Implementing interfaces

Once an interface has been declared, it must be implemented in a class before it can be used. The interfaces implemented by a class are specified in the class's declaration, after the name of the class's ancestor. Such declarations have the form

```
type className = class (ancestorClass, interface1, ..., interfacen)
  memberList
 end;
```

For example,

```
type
  TMemoryManager = class(TInterfacedObject, IMalloc, IErrorInfo)
    ⋮
  end;
```

declares a class called *TMemoryManager* that implements the *IMalloc* and *IErrorInfo* interfaces. When a class implements an interface, it must implement (or inherit an implementation of) each method declared in the interface.

Here is the declaration of *TInterfacedObject* in the *System* unit.

```
type
TInterfacedObject = class(TObject, IInterface)
protected
    FRefCount: Integer;
    function QueryInterface(const IID: TGUID; out Obj): HResult; stdcall;
    function _AddRef: Integer; stdcall;
    function _Release: Integer; stdcall;
  public
    procedure AfterConstruction; override;
    procedure BeforeDestruction; override;
    class function NewInstance: TObject; override;
    property RefCount: Integer read FRefCount;
  end;
```

TInterfacedObject implements the *IInterface* interface. Hence *TInterfacedObject* declares and implements each of *IInterface*'s three methods.

Classes that implement interfaces can also be used as base classes. (The first example above declares *TMemoryManager* as a direct descendent of *TInterfacedObject*.) Since every interface inherits from *IInterface*, a class that implements interfaces must implement the *QueryInterface*, *_AddRef*, and *_Release* methods. The *System* unit's *TInterfacedObject* implements these methods and is thus a convenient base from which to derive other classes that implement interfaces.

When an interface is implemented, each of its methods is mapped onto a method in the implementing class that has the same result type, the same calling convention, the same number of parameters, and identically typed parameters in each position. By default, each interface method is mapped to a method of the same name in the implementing class.

Method resolution clauses

You can override the default name-based mappings by including *method resolution clauses* in a class declaration. When a class implements two or more interfaces that have identically named methods, use method resolution clauses to resolve the naming conflicts.

A method resolution clause has the form

```
procedure interface.interfaceMethod = implementingMethod;
```

or

```
function interface.interfaceMethod = implementingMethod;
```

where *implementingMethod* is a method declared in the class or one of its ancestors. The *implementingMethod* can be a method declared later in the class declaration, but cannot be a private method of an ancestor class declared in another module.

For example, the class declaration

```
type
  TMemoryManager = class(TInterfacedObject, IMalloc, IErrorInfo)
    function IMalloc.Alloc = Allocate;
    procedure IMalloc.Free = Deallocate;
    ⋮
  end;
```

maps *IMalloc*'s *Alloc* and *Free* methods onto *TMemoryManager*'s *Allocate* and *Deallocate* methods.

A method resolution clause cannot alter a mapping introduced by an ancestor class.

Changing inherited implementations

Descendant classes can change the way a specific interface method is implemented by overriding the implementing method. This requires that the implementing method be virtual or dynamic.

A class can also reimplement an entire interface that it inherits from an ancestor class. This involves relisting the interface in the descendant class's declaration. For example,

```
type
  IWindow = interface
    ['{00000115-0000-0000-C000-000000000146}']
    procedure Draw;
    ⋮
  end;

  TWindow = class(TInterfacedObject, IWindow)  // TWindow implements IWindow
    procedure Draw;
    ⋮
  end;

  TFrameWindow = class(TWindow, IWindow)  // TFrameWindow reimplements IWindow
    procedure Draw;
    ⋮
  end;
```

Reimplementing an interface hides the inherited implementation of the same interface. Hence method resolution clauses in an ancestor class have no effect on the reimplemented interface.

Implementing interfaces by delegation

The **implements** directive allows you to delegate implementation of an interface to a property in the implementing class. For example,

```
property MyInterface: IMyInterface read FMyInterface implements IMyInterface;
```

declares a property called *MyInterface* that implements the interface *IMyInterface*.

The **implements** directive must be the last specifier in the property declaration and can list more than one interface, separated by commas. The delegate property

- must be of a class or interface type.
- cannot be an array property or have an index specifier.
- must have a **read** specifier. If the property uses a **read** method, that method must use the default **register** calling convention and cannot be dynamic (though it can be virtual) or specify the **message** directive.

Note The class you use to implement the delegated interface should derive from *TAggregatedObject*.

Delegating to an interface-type property

If the delegate property is of an interface type, that interface, or an interface from which it derives, must occur in the ancestor list of the class where the property is declared. The delegate property must return an object whose class completely implements the interface specified by the **implements** directive, and which does so without method resolution clauses. For example,

```
type
  IMyInterface = interface
    procedure P1;
    procedure P2;
  end;

  TMyClass = class(TObject, IMyInterface)
    FMyInterface: IMyInterface;
    property MyInterface: IMyInterface read FMyInterface implements IMyInterface;
  end;

var
  MyClass: TMyClass;
  MyInterface: IMyInterface;
begin
  MyClass := TMyClass.Create;
  MyClass.FMyInterface := ...  // some object whose class implements IMyInterface
  MyInterface := MyClass;
  MyInterface.P1;
end;
```

Delegating to a class-type property

If the delegate property is of a class type, that class and its ancestors are searched for methods implementing the specified interface before the enclosing class and its ancestors are searched. Thus it is possible to implement some methods in the class specified by the property, and others in the class where the property is declared. Method resolution clauses can be used in the usual way to resolve ambiguities or specify a particular method. An interface cannot be implemented by more than one class-type property. For example,

```
type
  IMyInterface = interface
    procedure P1;
    procedure P2;
    end;
    TMyImplClass = class
      procedure P1;
      procedure P2;
    end;
    TMyClass = class(TInterfacedObject, IMyInterface)
      FMyImplClass: TMyImplClass;
      property MyImplClass: TMyImplClass read FMyImplClass implements IMyInterface;
      procedure IMyInterface.P1 = MyP1;
      procedure MyP1;
    end;
  procedure TMyImplClass.P1;
    ⋮
  procedure TMyImplClass.P2;
    ⋮
  procedure TMyClass.MyP1;
    ⋮
  var
    MyClass: TMyClass;
    MyInterface: IMyInterface;
  begin
    MyClass := TMyClass.Create;
    MyClass.FMyImplClass := TMyImplClass.Create;
    MyInterface := MyClass;
    MyInterface.P1;       // calls TMyClass.MyP1;
    MyInterface.P2;       // calls TImplClass.P2;
  end;
```

Interface references

If you declare a variable of an interface type, the variable can reference instances of any class that implements the interface. Such variables allow you to call interface methods without knowing at compile time where the interface is implemented. But they are subject to the following limitations.

- An interface-type expression gives you access only to methods and properties declared in the interface, not to other members of the implementing class.
- An interface-type expression cannot reference an object whose class implements a descendant interface, unless the class (or one that it inherits from) explicitly implements the ancestor interface as well.

For example,

```
  type
    IAncestor = interface
    end;

    IDescendant = interface(IAncestor)
      procedure P1;
    end;

    TSomething = class(TInterfacedObject, IDescendant)
      procedure P1;
    procedure P2;
  end;
  ⋮
var
  D: IDescendant;
  A: IAncestor;
begin
  D := TSomething.Create;  // works!
  A := TSomething.Create;  // error
  D.P1;  // works!
  D.P2;  // error
end;
```

In this example,

- *A* is declared as a variable of type *IAncestor*. Because *TSomething* does not list *IAncestor* among the interfaces it implements, a *TSomething* instance cannot be assigned to *A*. But if we changed *TSomething*'s declaration to

  ```
  TSomething = class(TInterfacedObject, IAncestor, IDescendant)
   ⋮
  ```

  the first error would become a valid assignment.
- *D* is declared as a variable of type *IDescendant*. While *D* references an instance of *TSomething*, we cannot use it to access *TSomething*'s *P2* method, since *P2* is not a method of *IDescendant*. But if we changed *D*'s declaration to

  ```
  D: TSomething;
  ```

  the second error would become a valid method call.

Interface references are managed through reference-counting, which depends on the *_AddRef* and *_Release* methods inherited from *IInterface*. When an object is referenced only through interfaces, there is no need to destroy it manually; the object is automatically destroyed when the last reference to it goes out of scope.

Global interface-type variables can be initialized only to **nil**.

To determine whether an interface-type expression references an object, pass it to the standard function *Assigned*.

Interface assignment-compatibility

A class type is assignment-compatible with any interface type implemented by the class. An interface type is assignment-compatible with any ancestor interface type. The value **nil** can be assigned to any interface-type variable.

An interface-type expression can be assigned to a variant. If the interface is of type *IDispatch* or a descendant, the variant receives the type code *varDispatch*. Otherwise, the variant receives the type code *varUnknown*.

A variant whose type code is *varEmpty*, *varUnknown*, or *varDispatch* can be assigned to an *IInterface* variable. A variant whose type code is *varEmpty* or *varDispatch* can be assigned to an *IDispatch* variable.

Interface typecasts

Interface types follow the same rules as class types in variable and value typecasts. Class-type expressions can be cast to interface types—for example, `IMyInterface(SomeObject)`—provided the class implements the interface.

An interface-type expression can be cast to *Variant*. If the interface is of type *IDispatch* or a descendant, the resulting variant has the type code *varDispatch*. Otherwise, the resulting variant has the type code *varUnknown*.

A variant whose type code is *varEmpty*, *varUnknown*, or *varDispatch* can be cast to *IInterface*. A variant whose type code is *varEmpty* or *varDispatch* can be cast to *IDispatch*.

Interface querying

You can use the **as** operator to perform checked interface typecasts. This is known as *interface querying*, and it yields an interface-type expression from an object reference or from another interface reference, based on the actual (runtime) type of the object. An interface query has the form

object `as` *interface*

where *object* is an expression of an interface or variant type or denotes an instance of a class that implements an interface, and *interface* is any interface declared with a GUID.

An interface query returns **nil** if *object* is **nil**. Otherwise, it passes the GUID of *interface* to the *QueryInterface* method in *object*, raising an exception unless *QueryInterface* returns zero. If *QueryInterface* returns zero (indicating that *object*'s class implements *interface*), the interface query returns an interface reference to *object*.

Automation objects (Windows only)

An object whose class implements the *IDispatch* interface (declared in the *System* unit) is an Automation object. Automation is available on Windows only.

Dispatch interface types (Windows only)

Dispatch interface types define the methods and properties that an Automation object implements through *IDispatch*. Calls to methods of a dispatch interface are routed through *IDispatch*'s *Invoke* method at runtime; a class cannot implement a dispatch interface.

A dispatch interface type declaration has the form

```
type interfaceName = dispinterface
  ['{GUID}']
  memberList
end;
```

where `['{`*GUID*`}']` is optional and *memberList* consists of property and method declarations. Dispatch interface declarations are similar to regular interface declarations, but they cannot specify an ancestor. For example,

```
type
  IStringsDisp = dispinterface
    ['{EE05DFE2-5549-11D0-9EA9-0020AF3D82DA}']
    property ControlDefault[Index: Integer]: OleVariant dispid 0; default;
    function Count: Integer; dispid 1;
    property Item[Index: Integer]: OleVariant dispid 2;
    procedure Remove(Index: Integer); dispid 3;
    procedure Clear; dispid 4;
    function Add(Item: OleVariant): Integer; dispid 5;
    function _NewEnum: IUnknown; dispid -4;
  end;
```

Dispatch interface methods (Windows only)

Methods of a dispatch interface are prototypes for calls to the *Invoke* method of the underlying *IDispatch* implementation. To specify an Automation dispatch ID for a method, include the **dispid** directive in its declaration, followed by an integer constant; specifying an already used ID causes an error.

A method declared in a dispatch interface cannot contain directives other than **dispid**. Parameter and result types must be automatable—that is, they must be *Byte*, *Currency*, *Real*, *Double*, *Longint*, *Integer*, *Single*, *Smallint*, *AnsiString*, *WideString*, *TDateTime*, *Variant*, *OleVariant*, *WordBool*, or any interface type.

Dispatch interface properties

Properties of a dispatch interface do not include access specifiers. They can be declared as **readonly** or **writeonly**. To specify a dispatch ID for a property, include the **dispid** directive in its declaration, followed by an integer constant; specifying an already used ID causes an error. Array properties can be declared as **default**. No other directives are allowed in dispatch-interface property declarations.

Accessing Automation objects (Windows only)

Use variants to access Automation objects. When a variant references an Automation object, you can call the object's methods and read or write to its properties through the variant. To do this, you must include *ComObj* in the **uses** clause of one of your units or your program or library.

Automation object method calls are bound at runtime and require no previous method declarations. The validity of these calls is not checked at compile time.

The following example illustrates Automation method calls. The *CreateOleObject* function (defined in *ComObj*) returns an *IDispatch* reference to an Automation object and is assignment-compatible with the variant *Word*.

```
var
  Word: Variant;
begin
  Word := CreateOleObject('Word.Basic');
  Word.FileNew('Normal');
  Word.Insert('This is the first line'#13);
  Word.Insert('This is the second line'#13);
  Word.FileSaveAs('c:\temp\test.txt', 3);
end;
```

You can pass interface-type parameters to Automation methods.

Variant arrays with an element type of *varByte* are the preferred method of passing binary data between Automation controllers and servers. Such arrays are subject to no translation of their data, and can be efficiently accessed using the *VarArrayLock* and *VarArrayUnlock* routines.

Automation object method-call syntax

The syntax of an Automation object method call or property access is similar to that of a normal method call or property access. Automation method calls, however, can use both *positional* and *named* parameters. (But some Automation servers do not support named parameters.)

A positional parameter is simply an expression. A named parameter consists of a parameter identifier, followed by the **:=** symbol, followed by an expression. Positional parameters must precede any named parameters in a method call. Named parameters can be specified in any order.

Some Automation servers allow you to omit parameters from a method call, accepting their default values. For example,

```
Word.FileSaveAs('test.doc');
Word.FileSaveAs('test.doc', 6);
Word.FileSaveAs('test.doc',,,'secret');
Word.FileSaveAs('test.doc', Password := 'secret');
Word.FileSaveAs(Password := 'secret', Name := 'test.doc');
```

Automation method call parameters can be of integer, real, string, Boolean, and variant types. A parameter is passed by reference if the parameter expression consists only of a variable reference, and if the variable reference is of type *Byte*, *Smallint*, *Integer*, *Single*, *Double*, *Currency*, *TDateTime*, *AnsiString*, *WordBool*, or *Variant*. If the expression is not of one of these types, or if it is not just a variable, the parameter is passed by value. Passing a parameter by reference to a method that expects a value parameter causes COM to fetch the value from the reference parameter. Passing a parameter by value to a method that expects a reference parameter causes an error.

Dual interfaces (Windows only)

A dual interface is an interface that supports both compile-time binding and runtime binding through Automation. Dual interfaces must descend from *IDispatch*.

All methods of a dual interface (except from those inherited from *IInterface* and *IDispatch*) must use the **safecall** convention, and all method parameter and result types must be automatable. (The automatable types are *Byte*, *Currency*, *Real*, *Double*, *Real48*, *Integer*, *Single*, *Smallint*, *AnsiString*, *ShortString*, *TDateTime*, *Variant*, *OleVariant*, and *WordBool*.)

Chapter

11

Memory management

This chapter explains how programs use memory and describes the internal formats of Object Pascal data types.

The memory manager (Windows only)

Note Linux uses glibc functions such as *malloc* for memory management. For information, refer to the *malloc* man page on your Linux system.

On Windows systems, the memory manager manages all dynamic memory allocations and deallocations in an application. The *New*, *Dispose*, *GetMem*, *ReallocMem*, and *FreeMem* standard procedures use the memory manager, and all objects and long strings are allocated through the memory manager.

On Windows, the memory manager is optimized for applications that allocate large numbers of small- to medium-sized blocks, as is typical for object-oriented applications and applications that process string data. Other memory managers, such as the implementations of *GlobalAlloc*, *LocalAlloc*, and private heap support in Windows, typically do not perform well in such situations, and would slow down an application if they were used directly.

To ensure the best performance, the memory manager interfaces directly with the Win32 virtual memory API (the *VirtualAlloc* and *VirtualFree* functions). The memory manager reserves memory from the operating system in 1-MB sections of address space, and commits memory as required in 16-KB increments. It decommits and releases unused memory in 16-KB and 1-MB sections. For smaller blocks, committed memory is further suballocated.

Memory manager blocks are always rounded upward to a 4-byte boundary, and always include a 4-byte header in which the size of the block and other status bits are stored. This means that memory manager blocks are always double-word-aligned, which guarantees optimal CPU performance when addressing the block.

The memory manager maintains two status variables, *AllocMemCount* and *AllocMemSize*, which contain the number of currently allocated memory blocks and the combined size of all currently allocated memory blocks. Applications can use these variables to display status information for debugging.

The *System* unit provides two procedures, *GetMemoryManager* and *SetMemoryManager*, that allow applications to intercept low-level memory manager calls. The *System* unit also provides a function called *GetHeapStatus* that returns a record containing detailed memory-manager status information. For further information about these routines, see the online Help.

Variables

Global variables are allocated on the application data segment and persist for the duration of the program. Local variables (declared within procedures and functions) reside in an application's stack. Each time a procedure or function is called, it allocates a set of local variables; on exit, the local variables are disposed of. Compiler optimization may eliminate variables earlier.

Note On Linux, stack size is set by the environment only.

On Windows, an application's stack is defined by two values: the *minimum stack size* and the *maximum stack size*. The values are controlled through the **$MINSTACKSIZE** and **$MAXSTACKSIZE** compiler directives, and default to 16,384 (16K) and 1,048,576 (1M) respectively. An application is guaranteed to have the minimum stack size available, and an application's stack is never allowed to grow larger than the maximum stack size. If there is not enough memory available to satisfy an application's minimum stack requirement, Windows will report an error upon attempting to start the application.

If a Windows application requires more stack space than specified by the minimum stack size, additional memory is automatically allocated in 4K increments. If allocation of additional stack space fails, either because more memory is not available or because the total size of the stack would exceed the maximum stack size, an *EStackOverflow* exception is raised. (Stack overflow checking is completely automatic. The **$S** compiler directive, which originally controlled overflow checking, is maintained for backward compatibility.)

On Windows or Linux, dynamic variables created with the *GetMem* or *New* procedure are heap-allocated and persist until they are deallocated with *FreeMem* or *Dispose*.

Long strings, wide strings, dynamic arrays, variants, and interfaces are heap-allocated, but their memory is managed automatically.

Internal data formats

The following sections describe the internal formats of Object Pascal data types.

Integer types

The format of an integer-type variable depends on its minimum and maximum bounds.

- If both bounds are within the range –128..127 (*Shortint*), the variable is stored as a signed byte.
- If both bounds are within the range 0..255 (*Byte*), the variable is stored as an unsigned byte.
- If both bounds are within the range –32768..32767 (*Smallint*), the variable is stored as a signed word.
- If both bounds are within the range 0..65535 (*Word*), the variable is stored as an unsigned word.
- If both bounds are within the range –2147483648..2147483647 (*Longint*), the variable is stored as a signed double word.
- If both bounds are within the range 0..4294967295 (*Longword*), the variable is stored as an unsigned double word.
- Otherwise, the variable is stored as a signed quadruple word (*Int64*).

Character types

A *Char*, an *AnsiChar*, or a subrange of a *Char* type is stored as an unsigned byte. A *WideChar* is stored as an unsigned word.

Boolean types

A *Boolean* type is stored as a *Byte*, a *ByteBool* is stored as a *Byte*, a *WordBool* type is stored as a *Word*, and a *LongBool* is stored as a *Longint*.

A *Boolean* can assume the values 0 (*False*) and 1 (*True*). *ByteBool*, *WordBool*, and *LongBool* types can assume the values 0 (*False*) or nonzero (*True*).

Enumerated types

An enumerated type is stored as an unsigned byte if the enumeration has no more than 256 values and the type was declared in the **{$Z1}** state (the default). If an enumerated type has more than 256 values, or if the type was declared in the **{$Z2}** state, it is stored as an unsigned word. If an enumerated type is declared in the **{$Z4}** state, it is stored as an unsigned double-word.

Real types

The real types store the binary representation of a sign (+ or –), an *exponent*, and a *significand*. A real value has the form

$$+/- \textit{significand} * 2^{\textit{exponent}}$$

where the *significand* has a single bit to the left of the binary decimal point. (That is, 0 <= *significand* < 2.)

In the figures that follow, the most significant bit is always on the left and the least significant bit on the right. The numbers at the top indicate the width (in bits) of each field, with the leftmost items stored at the highest addresses. For example, for a *Real48* value, *e* is stored in the first byte, *f* in the following five bytes, and *s* in the most significant bit of the last byte.

The Real48 type

A 6-byte (48-bit) *Real48* number is divided into three fields:

1	39	8
s	*f*	*e*

If 0 < *e* <= 255, the value *v* of the number is given by

$$v = (-1)^{s} * 2^{(e-129)} * (1.f)$$

If *e* = 0, then *v* = 0.

The *Real48* type can't store denormals, NaNs, and infinities. Denormals become zero when stored in a *Real48*, while NaNs and infinities produce an overflow error if an attempt is made to store them in a *Real48*.

The Single type

A 4-byte (32-bit) *Single* number is divided into three fields:

1	8	23
s	*e*	*f*

The value *v* of the number is given by

if $0 < e < 255$, then $v = (-1)^{s} * 2^{(e-127)} * (1.f)$

if $e = 0$ and $f <> 0$, then $v = (-1)^{s} * 2^{(-126)} * (0.f)$
if $e = 0$ and $f = 0$, then $v = (-1)^{s} * 0$
if $e = 255$ and $f = 0$, then $v = (-1)^{s} * \text{Inf}$
if $e = 255$ and $f <> 0$, then v is a NaN

The Double type

An 8-byte (64-bit) *Double* number is divided into three fields:

1	11	52
s	*e*	*f*

The value *v* of the number is given by

if $0 < e < 2047$, then $v = (-1)^s * 2^{(e-1023)} * (1.f)$

if $e = 0$ and $f <> 0$, then $v = (-1)^s * 2^{(-1022)} * (0.f)$
if $e = 0$ and $f = 0$, then $v = (-1)^s * 0$
if $e = 2047$ and $f = 0$, then $v = (-1)^s *$ Inf
if $e = 2047$ and $f <> 0$, then v is a NaN

The Extended type

A 10-byte (80-bit) *Extended* number is divided into four fields:

1	15	1	63
s	*e*	i	*f*

The value *v* of the number is given by

if $0 <= e < 32767$, then $v = (-1)^s * 2^{(e-16383)} * (i.f)$

if $e = 32767$ and $f = 0$, then $v = (-1)^s *$ Inf
if $e = 32767$ and $f <> 0$, then v is a NaN

The Comp type

An 8-byte (64-bit) *Comp* number is stored as a signed 64-bit integer.

The Currency type

An 8-byte (64-bit) *Currency* number is stored as a scaled and signed 64-bit integer with the four least-significant digits implicitly representing four decimal places.

Pointer types

A *Pointer* type is stored in 4 bytes as a 32-bit address. The pointer value **nil** is stored as zero.

Short string types

A string occupies as many bytes as its maximum length plus one. The first byte contains the current dynamic length of the string, and the following bytes contain the characters of the string.

The length byte and the characters are considered unsigned values. Maximum string length is 255 characters plus a length byte (**string**[255]).

Long string types

A long string variable occupies four bytes of memory which contain a pointer to a dynamically allocated string. When a long string variable is empty (contains a zero-length string), the string pointer is **nil** and no dynamic memory is associated with the string variable. For a nonempty string value, the string pointer points to a dynamically allocated block of memory that contains the string value in addition to a 32-bit length indicator and a 32-bit reference count. The table below shows the layout of a long-string memory block.

Table 11.1 Long string dynamic memory layout

Offset	Contents
–8	32-bit reference-count
–4	length in bytes
0..*Length* – 1	character string
Length	NULL character

The NULL character at the end of a long string memory block is automatically maintained by the compiler and the built-in string handling routines. This makes it possible to typecast a long string directly to a null-terminated string.

For string constants and literals, the compiler generates a memory block with the same layout as a dynamically allocated string, but with a reference count of –1. When a long string variable is assigned a string constant, the string pointer is assigned the address of the memory block generated for the string constant. The built-in string handling routines know not to attempt to modify blocks that have a reference count of –1.

Wide string types

Note On Linux, wide strings are implemented exactly as long strings.

On Windows, a wide string variable occupies four bytes of memory which contain a pointer to a dynamically allocated string. When a wide string variable is empty (contains a zero-length string), the string pointer is **nil** and no dynamic memory is associated with the string variable. For a nonempty string value, the string pointer points to a dynamically allocated block of memory that contains the string value in addition to a 32-bit length indicator. The table below shows the layout of a wide-string memory block on Windows.

Table 11.2 Wide string dynamic memory layout (Windows only)

Offset	Contents
–4	32-bit length indicator (in bytes)
0..*Length* – 1	character string
Length	NULL character

The string length is the number of bytes, so it is twice the number of wide characters contained in the string.

The NULL character at the end of a wide string memory block is automatically maintained by the compiler and the built-in string handling routines. This makes it possible to typecast a wide string directly to a null-terminated string.

Set types

A set is a bit array where each bit indicates whether an element is in the set or not. The maximum number of elements in a set is 256, so a set never occupies more than 32 bytes. The number of bytes occupied by a particular set is equal to

(*Max* div 8) – (*Min* div 8) + 1

where *Max* and *Min* are the upper and lower bounds of the base type of the set. The byte number of a specific element *E* is

(*E* div 8) – (*Min* div 8)

and the bit number within that byte is

E mod 8

where *E* denotes the ordinal value of the element. When possible, the compiler stores sets in CPU registers, but a set always resides in memory if it is larger than the generic *Integer* type or if the program contains code that takes the address of the set.

Static array types

A static array is stored as a contiguous sequence of variables of the component type of the array. The components with the lowest indexes are stored at the lowest memory addresses. A multidimensional array is stored with the rightmost dimension increasing first.

Dynamic array types

A dynamic-array variable occupies four bytes of memory which contain a pointer to the dynamically allocated array. When the variable is empty (uninitialized) or holds a zero-length array, the pointer is **nil** and no dynamic memory is associated with the variable. For a nonempty array, the variable points to a dynamically allocated block of memory that contains the array in addition to a 32-bit length indicator and a 32-bit reference count. The table below shows the layout of a dynamic-array memory block.

Table 11.3 Dynamic array memory layout

Offset	Contents
–8	32-bit reference-count
–4	32-bit length indicator (number of elements)
0..*Length* * (size of element) – 1	array elements

Record types

When a record type is declared in the **{$A+}** state (the default), and when the declaration does not include a **packed** modifier, the type is an *unpacked record type*, and the fields of the record are aligned for efficient access by the CPU. The alignment is controlled by the type of each field. Every data type has an inherent alignment, which is automatically computed by the compiler. The alignment can be 1, 2, 4, or 8, and represents the byte boundary that a value of the type must be stored on to provide the most efficient access. The table below lists the alignments for all data types.

Table 11.4 Type alignment masks

Type	Alignment
Ordinal types	size of the type (1, 2, 4, or 8)
Real types	2 for *Real48*, 4 for *Single*, 8 for *Double* and *Extended*
Short string types	1
Array types	same as the element type of the array.
Record types	the largest alignment of the fields in the record
Set types	size of the type if 1, 2, or 4, otherwise 1
All other types	4

To ensure proper alignment of the fields in an unpacked record type, the compiler inserts an unused byte before fields with an alignment of 2, and up to three unused bytes before fields with an alignment of 4, if required. Finally, the compiler rounds the total size of the record upward to the byte boundary specified by the largest alignment of any of the fields.

When a record type is declared in the **{$A–}** state, or when the declaration includes the **packed** modifier, the fields of the record are not aligned, but are instead assigned consecutive offsets. The total size of such a packed record is simply the size of all the fields. Because data alignment can change, it's a good idea to pack any record structure that you intend to write to disk or pass in memory to another module compiled using a different version of the compiler.

File types

File types are represented as records. Typed files and untyped files occupy 332 bytes, which are laid out as follows:

```
type
  TFileRec = packed record
    Handle: Integer;
    Mode: word;
    Flags: word;
    case Byte of
      0: (RecSize: Cardinal);
      1: (BufSize: Cardinal;
          BufPos: Cardinal;
```

```
            BufEnd: Cardinal;
            BufPtr: PChar;
            OpenFunc: Pointer;
            InOutFunc: Pointer;
            FlushFunc: Pointer;
            CloseFunc: Pointer;
            UserData: array[1..32] of Byte;
            Name: array[0..259] of Char; );
    end;
```

Text files occupy 460 bytes, which are laid out as follows:

```
type
  TTextBuf = array[0..127] of Char;
  TTextRec = packed record
    Handle: Integer;
    Mode: word;
    Flags: word;
    BufSize: Cardinal;
    BufPos: Cardinal;
    BufEnd: Cardinal;
    BufPtr: PChar;
    OpenFunc: Pointer;
    InOutFunc: Pointer;
    FlushFunc: Pointer;
    CloseFunc: Pointer;
    UserData: array[1..32] of Byte;
    Name: array[0..259] of Char;
    Buffer: TTextBuf;
  end;
```

Handle contains the file's handle (when the file is open).

The *Mode* field can assume one of the values

```
const
  fmClosed = $D7B0;
  fmInput  = $D7B1;
  fmOutput = $D7B2;
  fmInOut  = $D7B3;
```

where *fmClosed* indicates that the file is closed, *fmInput* and *fmOutput* indicate a text file that has been reset (*fmInput*) or rewritten (*fmOutput*), *fmInOut* indicates a typed or untyped file that has been reset or rewritten. Any other value indicates that the file variable is not assigned (and hence not initialized).

The *UserData* field is available for user-written routines to store data in.

Name contains the file name, which is a sequence of characters terminated by a null character (#0).

For typed files and untyped files, *RecSize* contains the record length in bytes, and the *Private* field is unused but reserved.

For text files, *BufPtr* is a pointer to a buffer of *BufSize* bytes, *BufPos* is the index of the next character in the buffer to read or write, and *BufEnd* is a count of valid characters in the buffer. *OpenFunc*, *InOutFunc*, *FlushFunc*, and *CloseFunc* are pointers to the I/O routines that control the file; see “Device functions” on page 8-5. Flags determines the line break style as follows:

bit 0 clear	LF line breaks
bit 0 set	CRLF line breaks

All other Flags bits are reserved for future use. See also *DefaultTextLineBreakStyle* and *SetLineBreakStyle*.

Procedural types

A procedure pointer is stored as a 32-bit pointer to the entry point of a procedure or function. A method pointer is stored as a 32-bit pointer to the entry point of a method, followed by a 32-bit pointer to an object.

Class types

A class-type value is stored as a 32-bit pointer to an instance of the class, which is called an *object*. The internal data format of an object resembles that of a record. The object’s fields are stored in order of declaration as a sequence of contiguous variables. Fields are always aligned, corresponding to an unpacked record type. Any fields inherited from an ancestor class are stored before the new fields defined in the descendant class.

The first 4-byte field of every object is a pointer to the *virtual method table* (VMT) of the class. There is exactly one VMT per class (not one per object); distinct class types, no matter how similar, never share a VMT. VMTs are built automatically by the compiler, and are never directly manipulated by a program. Pointers to VMTs, which are automatically stored by constructor methods in the objects they create, are also never directly manipulated by a program.

The layout of a VMT is shown in the following table. At positive offsets, a VMT consists of a list of 32-bit method pointers—one per user-defined virtual method in the class type—in order of declaration. Each slot contains the address of the corresponding virtual method’s entry point. This layout is compatible with a C++ v-table and with COM. At negative offsets, a VMT contains a number of fields that are internal to Object Pascal’s implementation. Applications should use the methods defined in *TObject* to query this information, since the layout is likely to change in future implementations of Object Pascal.

Table 11.5 Virtual method table layout

Offset	Type	Description
–76	*Pointer*	pointer to virtual method table (or **nil**)
–72	*Pointer*	pointer to interface table (or **nil**)
–68	*Pointer*	pointer to Automation information table (or **nil**)
–64	*Pointer*	pointer to instance initialization table (or **nil**)
–60	*Pointer*	pointer to type information table (or **nil**)

Table 11.5 Virtual method table layout (continued)

Offset	Type	Description
–56	*Pointer*	pointer to field definition table (or **nil**)
–52	*Pointer*	pointer to method definition table (or **nil**)
–48	*Pointer*	pointer to dynamic method table (or **nil**)
–44	*Pointer*	pointer to short string containing class name
–40	*Cardinal*	instance size in bytes
–36	*Pointer*	pointer to a pointer to ancestor class (or **nil**)
–32	*Pointer*	pointer to entry point of *SafecallException* method (or **nil**)
–28	*Pointer*	entry point of *AfterConstruction* method
–24	*Pointer*	entry point of *BeforeDestruction* method
–20	*Pointer*	entry point of *Dispatch* method
–16	*Pointer*	entry point of *DefaultHandler* method
–12	*Pointer*	entry point of *NewInstance* method
–8	*Pointer*	entry point of *FreeInstance* method
–4	*Pointer*	entry point of *Destroy* destructor
0	*Pointer*	entry point of first user-defined virtual method
4	*Pointer*	entry point of second user-defined virtual method
⋮	⋮	⋮

Class reference types

A class-reference value is stored as a 32-bit pointer to the virtual method table (VMT) of a class.

Variant types

A variant is stored as a 16-byte record that contains a type code and a value (or a reference to a value) of the type given by the code. The *System* and *Variants* units define constants and types for variants.

The *TVarData* type represents the internal structure of a *Variant* variable (on Windows, this is identical to the *Variant* type used by COM and the Win32 API). The *TVarData* type can be used in typecasts of *Variant* variables to access the internal structure of a variable.

The *VType* field of a *TVarData* record contains the type code of the variant in the lower twelve bits (the bits defined by the *varTypeMask* constant). In addition, the *varArray* bit may be set to indicate that the variant is an array, and the *varByRef* bit may be set to indicate that the variant contains a reference as opposed to a value.

The *Reserved1*, *Reserved2*, and *Reserved3* fields of a *TVarData* record are unused.

The contents of the remaining eight bytes of a *TVarData* record depend on the *VType* field. If neither the *varArray* nor the *varByRef* bits are set, the variant contains a value of the given type.

If the *varArray* bit is set, the variant contains a pointer to a *TVarArray* structure that defines an array. The type of each array element is given by the *varTypeMask* bits in the *VType* field.

If the *varByRef* bit is set, the variant contains a reference to a value of the type given by the *varTypeMask* and *varArray* bits in the *VType* field.

The *varString* type code is private. Variants containing a *varString* value should never be passed to a non-Delphi function. On Windows, Delphi's Automation support automatically converts *varString* variants to *varOleStr* variants before passing them as parameters to external functions.

On Linux, *VT_decimal* is not supported.

12

Program control

This chapter explains how parameters and function results are stored and transferred. The final section discusses exit procedures.

Parameters and function results

Treatment of parameters and function results is determined by several factors, including calling conventions, parameter semantics, and the type and size of the value being passed.

Parameter passing

Parameters are transferred to procedures and functions via CPU registers or the stack, depending on the routine's calling convention. For information about calling conventions, see "Calling conventions" on page 6-4.

Variable (**var**) parameters are always passed by reference, as 32-bit pointers that point to the actual storage location.

Value and constant (**const**) parameters are passed by value or by reference, depending on the type and size of the parameter:

- An ordinal parameter is passed as an 8-bit, 16-bit, 32-bit, or 64-bit value, using the same format as a variable of the corresponding type.
- A real parameter is always passed on the stack. A *Single* parameter occupies 4 bytes, and a *Double*, *Comp*, or *Currency* parameter occupies 8 bytes. A *Real48* occupies 8 bytes, with the *Real48* value stored in the lower 6 bytes. An *Extended* occupies 12 bytes, with the *Extended* value stored in the lower 10 bytes.
- A short-string parameter is passed as a 32-bit pointer to a short string.

- A long-string or dynamic-array parameter is passed as a 32-bit pointer to the dynamic memory block allocated for the long string. The value **nil** is passed for an empty long string.
- A pointer, class, class-reference, or procedure-pointer parameter is passed as a 32-bit pointer.
- A method pointer is passed on the stack as two 32-bit pointers. The instance pointer is pushed before the method pointer so that the method pointer occupies the lowest address.
- Under the **register** and **pascal** conventions, a variant parameter is passed as a 32-bit pointer to a *Variant* value.
- Sets, records, and static arrays of 1, 2, or 4 bytes are passed as 8-bit, 16-bit, and 32-bit values. Larger sets, records, and static arrays are passed as 32-bit pointers to the value. An exception to this rule is that records are always passed directly on the stack under the **cdecl**, **stdcall**, and **safecall** conventions; the size of a record passed this way is rounded upward to the nearest double-word boundary.
- An open-array parameter is passed as two 32-bit values. The first value is a pointer to the array data, and the second value is one less than the number of elements in the array.

When two parameters are passed on the stack, each parameter occupies a multiple of 4 bytes (a whole number of double words). For an 8-bit or 16-bit parameter, even though the parameter occupies only a byte or a word, it is passed as a double word. The contents of the unused parts of the double word are undefined.

Under the **pascal**, **cdecl**, **stdcall** and **safecall** conventions, all parameters are passed on the stack. Under the **pascal** convention, parameters are pushed in the order of their declaration (left-to-right), so that the first parameter ends up at the highest address and the last parameter ends up at the lowest address. Under the **cdecl**, **stdcall**, and **safecall** conventions, parameters are pushed in reverse order of declaration (right-to-left), so that the first parameter ends up at the lowest address and the last parameter ends up at the highest address.

Under the **register** convention, up to three parameters are passed in CPU registers, and the rest (if any) are passed on the stack. The parameters are passed in order of declaration (as with the **pascal** convention), and the first three parameters that qualify are passed in the EAX, EDX, and ECX registers, in that order. Real, method-pointer, variant, *Int64*, and structured types do not qualify as register parameters, but all other parameters do. If more than three parameters qualify as register parameters, the first three are passed in EAX, EDX, and ECX, and the remaining parameters are pushed onto the stack in order of declaration. For example, given the declaration

```
procedure Test(A: Integer; var B: Char; C: Double; const D: string; E: Pointer);
```

a call to *Test* passes *A* in EAX as a 32-bit integer, *B* in EDX as a pointer to a *Char*, and *D* in ECX as a pointer to a long-string memory block; *C* and *E* are pushed onto the stack as two double-words and a 32-bit pointer, in that order.

Register saving conventions

Procedures and functions must preserve the EBX, ESI, EDI, and EBP registers, but can modify the EAX, EDX, and ECX registers. When implementing a constructor or destructor in assembler, be sure to preserve the DL register. Procedures and functions are invoked with the assumption that the CPU's direction flag is cleared (corresponding to a CLD instruction) and must return with the direction flag cleared.

Function results

The following conventions are used for returning function result values.

- Ordinal results are returned, when possible, in a CPU register. Bytes are returned in AL, words are returned in AX, and double-words are returned in EAX.
- Real results are returned in the floating-point coprocessor's top-of-stack register (ST(0)). For function results of type *Currency*, the value in ST(0) is scaled by 10000. For example, the *Currency* value 1.234 is returned in ST(0) as 12340.
- For a string, dynamic array, method pointer, variant, or *Int64* result, the effects are the same as if the function result were declared as an additional **var** parameter following the declared parameters. In other words, the caller passes an additional 32-bit pointer that points to a variable in which to return the function result.
- Pointer, class, class-reference, and procedure-pointer results are returned in EAX.
- For static-array, record, and set results, if the value occupies one byte it is returned in AL; if the value occupies two bytes it is returned in AX; and if the value occupies four bytes it is returned in EAX. Otherwise, the result is returned in an additional **var** parameter that is passed to the function after the declared parameters.

Method calls

Methods use the same calling conventions as ordinary procedures and functions, except that every method has an additional implicit parameter *Self*, which is a reference to the instance or class in which the method is called. The *Self* parameter is passed as a 32-bit pointer.

- Under the **register** convention, *Self* behaves as if it were declared *before* all other parameters. It is therefore always passed in the EAX register.
- Under the **pascal** convention, *Self* behaves as if it were declared *after* all other parameters (including the additional **var** parameter sometimes passed for a function result). It is therefore pushed last, ending up at a lower address than all other parameters.
- Under the **cdecl**, **stdcall**, and **safecall** conventions, *Self* behaves as if it were declared *before* all other parameters, but *after* the additional **var** parameter (if any) passed for a function result. It is therefore the last to be pushed, except for the additional **var** parameter.

Constructors and destructors

Constructors and destructors use the same calling conventions as other methods, except that an additional *Boolean* flag parameter is passed to indicate the context of the constructor or destructor call.

A value of *False* in the flag parameter of a constructor call indicates that the constructor was invoked through an instance object or using the **inherited** keyword. In this case, the constructor behaves like an ordinary method. A value of *True* in the flag parameter of a constructor call indicates that the constructor was invoked through a class reference. In this case, the constructor creates an instance of the class given by *Self*, and returns a reference to the newly created object in EAX.

A value of *False* in the flag parameter of a destructor call indicates that the destructor was invoked using the **inherited** keyword. In this case, the destructor behaves like an ordinary method. A value of *True* in the flag parameter of a destructor call indicates that the destructor was invoked through an instance object. In this case, the destructor deallocates the instance given by *Self* just before returning.

The flag parameter behaves as if it were declared before all other parameters. Under the **register** convention, it is passed in the DL register. Under the **pascal** convention, it is pushed before all other parameters. Under the **cdecl**, **stdcall**, and **safecall** conventions, it is pushed just before the *Self* parameter.

Since the DL register indicates whether the constructor or destructor is the outermost in the call stack, you must restore the value of DL before exiting so that *BeforeDestruction* or *AfterConstruction* can be called properly.

Exit procedures

Exit procedures ensure that specific actions—such as updating and closing files—are carried out before a program terminates. The *ExitProc* pointer variable allows you to "install" an exit procedure, so that it is always called as part of the program's termination—whether the termination is normal, forced by a call to *Halt*, or the result of a runtime error. An exit procedure takes no parameters.

Note It is recommended that finalization sections, rather than exit procedures, be used for all exit behavior. (See "The finalization section" on page 3-5.) Exit procedures are available only for executables, shared objects (Linux) or .DLL (Windows) targets; for packages, exit behavior must be implemented in a finalization section. All exit procedures are called before execution of finalization sections.

Units as well as programs can install exit procedures. A unit can install an exit procedure as part of its initialization code, relying on the procedure to close files or perform other clean-up tasks.

When implemented properly, an exit procedure is part of a chain of exit procedures. The procedures are executed in reverse order of installation, ensuring that the exit code of one unit isn't executed before the exit code of any units that depend on it. To keep the chain intact, you must save the current contents of *ExitProc* before pointing it to the address of your own exit procedure. Also, the first statement in your exit procedure must reinstall the saved value of *ExitProc*.

The following code shows a skeleton implementation of an exit procedure.

```
var
  ExitSave: Pointer;

procedure MyExit;
begin
  ExitProc := ExitSave;  // always restore old vector first
  ⋮
end;

begin
  ExitSave := ExitProc;
  ExitProc := @MyExit;
  ⋮
end.
```

On entry, the code saves the contents of *ExitProc* in *ExitSave*, then installs the *MyExit* procedure. When called as part of the termination process, the first thing *MyExit* does is reinstall the previous exit procedure.

The termination routine in the runtime library keeps calling exit procedures until *ExitProc* becomes **nil**. To avoid infinite loops, *ExitProc* is set to **nil** before every call, so the next exit procedure is called only if the current exit procedure assigns an address to *ExitProc*. If an error occurs in an exit procedure, it is not called again.

An exit procedure can learn the cause of termination by examining the *ExitCode* integer variable and the *ErrorAddr* pointer variable. In case of normal termination, *ExitCode* is zero and *ErrorAddr* is **nil**. In case of termination through a call to *Halt*, *ExitCode* contains the value passed to *Halt* and *ErrorAddr* is **nil**. In case of termination due to a runtime error, *ExitCode* contains the error code and *ErrorAddr* contains the address of the invalid statement.

The last exit procedure (the one installed by the runtime library) closes the *Input* and *Output* files. If *ErrorAddr* is not **nil**, it outputs a runtime error message. To output your own runtime error message, install an exit procedure that examines *ErrorAddr* and outputs a message if it’s not **nil**; before returning, set *ErrorAddr* to **nil** so that the error is not reported again by other exit procedures.

Once the runtime library has called all exit procedures, it returns to the operating system, passing the value stored in *ExitCode* as a return code.

Chapter

13

Inline assembler code

The built-in assembler allows you to write assembler code within Object Pascal programs. It has the following features:

- Allows for inline assembly
- Supports all instructions found in the Intel Pentium III, SIMD, and the AMD Athlon (including 3D Now!)
- Provides no macro support, but allows for pure assembler function procedures
- Permits the use of Object Pascal identifiers, such as constants, types, and variables in assembler statements

As an alternative to the built-in assembler, you can link to object files that contain external procedures and functions. See "Linking to object files" on page 6-6 for more information.

Note If you have external assembler code that you want to use in your applications, you should consider rewriting it in Object Pascal or minimally reimplement it using the inline assembler.

The asm statement

The built-in assembler is accessed through **asm** statements, which have the form

`asm` *statementList* `end`

where *statementList* is a sequence of assembler statements separated by semicolons, end-of-line characters, or Object Pascal comments.

Comments in an **asm** statement must be in Object Pascal style. A semicolon does not indicate that the rest of the line is a comment.

The reserved word **inline** and the directive **assembler** are maintained for backward compatibility only. They have no effect on the compiler.

Register use

In general, the rules of register use in an **asm** statement are the same as those of an **external** procedure or function. An **asm** statement must preserve the EDI, ESI, ESP, EBP, and EBX registers, but can freely modify the EAX, ECX, and EDX registers. On entry to an **asm** statement, BP points to the current stack frame, SP points to the top of the stack, SS contains the segment address of the stack segment, and DS contains the segment address of the data segment. Except for ESP and EBP, an **asm** statement can assume nothing about register contents on entry to the statement.

Assembler statement syntax

This syntax of an assembler statement is

Label: *Prefix Opcode Operand*$_1$, *Operand*$_2$

where *Label* is a label, *Prefix* is an assembler prefix opcode (operation code), *Opcode* is an assembler instruction opcode or directive, and *Operand* is an assembler expression. *Label* and *Prefix* are optional. Some opcodes take only one operand, and some take none.

Comments are allowed between assembler statements, but not within them. For example,

```
MOV AX,1 {Initial value}     { OK }
MOV CX,100 {Count}           { OK }

MOV {Initial value} AX,1;    { Error! }
MOV CX, {Count} 100          { Error! }
```

Labels

Labels are used in built-in assembler statements as they are in Object Pascal—by writing the label and a colon before a statement. There is no limit to a label's length. As in Object Pascal, labels must be declared in a **label** declaration part in the block containing the **asm** statement. There is one exception to this rule: *local labels*.

Local labels are labels that start with an at-sign (@). They consist of an at-sign followed by one or more letters, digits, underscores, or at-signs. Use of local labels is restricted to **asm** statements, and the scope of a local label extends from the **asm** reserved word to the end of the **asm** statement that contains it. A local label doesn't have to be declared.

Instruction opcodes

The built-in assembler supports all of the Intel-documented opcodes for general application use. Note that operating system privileged instructions may not be supported. Specifically, the following families of instructions are supported:

- Pentium family

- Pentium Pro and Pentium II
- Pentium III
- Pentium IV

In addition, the built-in assembler supports the following instruction sets

- AMD 3DNow! (from the AMD K6 onwards)
- AMD Enhanced 3DNow (from the AMD Athlon onwards)

For a complete description of each instruction, refer to your microprocessor documentation.

RET instruction sizing

The RET instruction opcode always generates a near return.

Automatic jump sizing

Unless otherwise directed, the built-in assembler optimizes jump instructions by automatically selecting the shortest, and therefore most efficient, form of a jump instruction. This automatic jump sizing applies to the unconditional jump instruction (JMP), and to all conditional jump instructions when the target is a label (not a procedure or function).

For an unconditional jump instruction (JMP), the built-in assembler generates a short jump (one-byte opcode followed by a one-byte displacement) if the distance to the target label is –128 to 127 bytes. Otherwise it generates a near jump (one-byte opcode followed by a two-byte displacement).

For a conditional jump instruction, a short jump (one-byte opcode followed by a one-byte displacement) is generated if the distance to the target label is –128 to 127 bytes. Otherwise, the built-in assembler generates a short jump with the inverse condition, which jumps over a near jump to the target label (five bytes in total). For example, the assembler statement

```
JC       Stop
```

where *Stop* isn't within reach of a short jump, is converted to a machine code sequence that corresponds to this:

```
JNC      Skip
JMP      Stop
Skip:
```

Jumps to the entry points of procedures and functions are always near.

Assembler directives

The built-in assembler supports three assembler define directives: DB (define byte), DW (define word), and DD (define double word). Each generates data corresponding to the comma-separated operands that follow the directive.

The DB directive generates a sequence of bytes. Each operand can be a constant expression with a value between –128 and 255, or a character string of any length.

Constant expressions generate one byte of code, and strings generate a sequence of bytes with values corresponding to the ASCII code of each character.

The DW directive generates a sequence of words. Each operand can be a constant expression with a value between –32,768 and 65,535, or an address expression. For an address expression, the built-in assembler generates a near pointer—that is, a word that contains the offset part of the address.

The DD directive generates a sequence of double words. Each operand can be a constant expression with a value between –2,147,483,648 and 4,294,967,295, or an address expression. For an address expression, the built-in assembler generates a far pointer—that is, a word that contains the offset part of the address, followed by a word that contains the segment part of the address.

The DQ directive defines a quadword for Int64 values.

The data generated by the DB, DW, and DD directives is always stored in the code segment, just like the code generated by other built-in assembler statements. To generate uninitialized or initialized data in the data segment, you should use Object Pascal **var** or **const** declarations.

Some examples of DB, DW, and DD directives follow.

```
asm
  DB      0FFH                      { One byte }
  DB      0,99                      { Two bytes }
  DB      'A'                       { Ord('A') }
  DB      'Hello world...',0DH,0AH  { String followed by CR/LF }
  DB      12,"string"               { Object Pascal style string }
  DW      0FFFFH                    { One word }
  DW      0,9999                    { Two words }
  DW      'A'                       { Same as DB 'A',0 }
  DW      'BA'                      { Same as DB 'A','B' }
  DW      MyVar                     { Offset of MyVar }
  DW      MyProc                    { Offset of MyProc }
  DD      0FFFFFFFFH                { One double-word }
  DD      0,999999999               { Two double-words }
  DD      'A'                       { Same as DB 'A',0,0,0 }
  DD      'DCBA'                    { Same as DB 'A','B','C','D' }
  DD      MyVar                     { Pointer to MyVar }
  DD      MyProc                    { Pointer to MyProc }
end;
```

In Turbo Assembler, when an identifier precedes a DB, DW, or DD directive, it causes the declaration of a byte-, word-, or double-word-sized variable at the location of the directive. For example, Turbo Assembler allows the following:

```
ByteVar     DB     ?
WordVar     DW     ?
IntVar      DD     ?
  ⋮
            MOV    AL,ByteVar
            MOV    BX,WordVar
            MOV    ECX,IntVar
```

The built-in assembler doesn’t support such variable declarations. The only kind of symbol that can be defined in an inline assembler statement is a label. All variables must be declared using Object Pascal syntax; the preceding construction can be replaced by

```
var
  ByteVar: Byte;
  WordVar: Word;
  IntVar: Integer;
  ⋮
asm
  MOV     AL,ByteVar
  MOV     BX,WordVar
  MOV     ECX,IntVar
end;
```

SMALL and LARGE can be used determine the width of a displacement:

```
MOV eax, [large $1234]
```

This instruction generates a "normal" move with a 32-bit displacement ($00001234).

```
MOV eax, [small $1234]
```

The second instruction will generate a move with an address size override prefix and a 16-bit displacement ($1234).

SMALL can be used to save space. The following example generates an address size override and a 2-byte address (in total three bytes)

```
MOV eax, [SMALL 123]
```

as opposed to

```
mov eax, [123]
```

which will generate no address size override and a 4-byte address (in total four bytes).

Two additional directives allow assembly code to access dynamic and virtual method: VMTOFFSET and DMTINDEX.

VMTOFFSET retrives the offset in bytes of the virtual method pointer table entry of the virtual method argument from the beginning of the virtual method table (VMT). This directive needs a fully specified class name with a method name as a parameter, for example,TExample.VirtualMethod.

DMTINDEX retrieves the dynamic method table index of the passed dynamic method. This directive also needs a fully specified class name with a method name as a parameter, for example,TExample.DynamicMethod. To invoke the dynamic method, call System.@CallDynaInst with the (E)SI register containing the value obtained from DMTINDEX.

Note Methods with the "message" directive, are implemented as dynamic methods and can also be called using the DMTINDEX technique. For example:

```
TMyClass = class
  procedure x; message MYMESSAGE;
end;
```

The following example uses both DMTINDEX and VMTOFFSET to access dynamic and virtual methods:

```
program Project2;

type
  TExample = class
    procedure DynamicMethod; dynamic;
    procedure VirtualMethod; virtual;
  end;

procedure TExample.DynamicMethod;
begin

end;

procedure TExample.VirtualMethod;
begin

end;

procedure CallDynamicMethod(e: TExample);
asm
  // Save ESI register
  PUSH    ESI

  // Instance pointer needs to be in EAX
  MOV     EAX, e
  // DMT entry index needs to be in (E)SI
  MOV     ESI, DMTINDEX TExample.DynamicMethod
  // Now call the method
  CALL    System.@CallDynaInst

  // Restore ESI register
  POP ESI
end;

procedure CallVirtualMethod(e: TExample);
asm
  // Instance pointer needs to be in EAX
  MOV     EAX, e
```

```
    // Retrieve VMT table entry
    MOV     EDX, [EAX]

    // Now call the method at offset VMTOFFSET
    CALL    DWORD PTR [EDX + VMTOFFSET TExample.VirtualMethod]
  end;

  var
    e: TExample;

  begin
    e := TExample.Create;
    try
      CallDynamicMethod(e);
      CallVirtualMethod(e);
    finally
      e.Free;
    end;
  end.
```

Operands

Built-in assembler operands are expressions that consist of constants, registers, symbols, and operators.

Within operands, the following reserved words have predefined meanings

Table 13.1 Built-in assembler reserved words

AH	BYTE	DMTINDEX	EDI	HIGH	QWORD	TBYTE
AL	CH	DS	EDX	LARGE	SHL	TYPE
AND	CL	DWORD	EIP	LOW	SHR	VMTOFFSET
AX	CS	DX	ES	MOD	SI	WORD
BH	CX	EAX	ESI	NOT	SMALL	XOR
BL	DH	EBP	ESP	OFFSET	SP	
BP	DI	EBX	FS	OR	SS	
BX	DL	ECX	GS	PTR	ST	

Reserved words always take precedence over user-defined identifiers. For example,

```
var
  Ch: Char;
  ⋮
asm
  MOV     CH, 1
end;
```

loads 1 into the CH register, not into the *Ch* variable. To access a user-defined symbol with the same name as a reserved word, you must use the ampersand (&) override operator:

```
MOV     &Ch, 1
```

It is best to avoid user-defined identifiers with the same names as built-in assembler reserved words.

Expressions

The built-in assembler evaluates all expressions as 32-bit integer values. It doesn't support floating-point and string values, except string constants.

Expressions are built from *expression elements* and *operators*, and each expression has an associated *expression class* and *expression type*.

Differences between Object Pascal and assembler expressions

The most important difference between Object Pascal expressions and built-in assembler expressions is that assembler expressions must resolve to a constant value—a value that can be computed at compile time. For example, given the declarations

```
const
  X = 10;
  Y = 20;
var
  Z: Integer;
```

the following is a valid statement.

```
asm
  MOV     Z,X+Y
end;
```

Because both *X* and *Y* are constants, the expression `X + Y` is a convenient way of writing the constant 30, and the resulting instruction simply moves of the value 30 into the variable *Z*. But if *X* and *Y* are variables—

```
var
  X, Y: Integer;
```

—the built-in assembler cannot compute the value of `X + Y` at compile time. In this case, to move the sum of *X* and *Y* into *Z* you would use

```
asm
  MOV     EAX,X
  ADD     EAX,Y
  MOV     Z,EAX
end;
```

In an Object Pascal expression, a variable reference denotes the *contents* of the variable. But in an assembler expression, a variable reference denotes the *address* of the variable. In Object Pascal the expression `X + 4` (where *X* is a variable) means the contents of X plus 4, while to the built-in assembler it means the contents of the word at the address four bytes higher than the address of *X*. So, even though you're allowed to write

```
asm
```

```
  MOV     EAX,X+4
end;
```

this code doesn’t load the value of *X* plus 4 into AX; instead, it loads the value of a word stored four bytes beyond *X*. The correct way to add 4 to the contents of *X* is

```
asm
  MOV     EAX,X
  ADD     EAX,4
end;
```

Expression elements

The elements of an expression are *constants*, *register*s, and *symbols*.

Constants

The built-in assembler supports two types of constant: *numeric constants* and *string constants*.

Numeric constants

Numeric constants must be integers, and their values must be between –2,147,483,648 and 4,294,967,295.

By default, numeric constants use decimal notation, but the built-in assembler also supports binary, octal, and hexadecimal. Binary notation is selected by writing a *B* after the number, octal notation by writing an *O* after the number, and hexadecimal notation by writing an *H* after the number or a **$** before the number.

Numeric constants must start with one of the digits 0 through 9 or the **$** character. When you write a hexadecimal constant using the *H* suffix, an extra zero is required in front of the number if the first significant digit is one of the digits A through F. For example, `0BAD4H` and `$BAD4` are hexadecimal constants, but `BAD4H` is an identifier because it starts with a letter.

String constants

String constants must be enclosed in single or double quotation marks. Two consecutive quotation marks of the same type as the enclosing quotation marks count as only one character. Here are some examples of string constants:

```
'Z'
'Delphi'
‘Linux’
"That's all folks"
'"That''s all folks," he said.'
'100'
'"'
"'"
```

String constants of any length are allowed in DB directives, and cause allocation of a sequence of bytes containing the ASCII values of the characters in the string. In all other cases, a string constant can be no longer than four characters and denotes a numeric value which can participate in an expression. The numeric value of a string constant is calculated as

```
Ord(Ch1) + Ord(Ch2) shl 8 + Ord(Ch3) shl 16 + Ord(Ch4) shl 24
```

where *Ch1* is the rightmost (last) character and *Ch4* is the leftmost (first) character. If the string is shorter than four characters, the leftmost characters are assumed to be zero. The following table shows string constants and their numeric values.

Table 13.2 String examples and their values

String	Value
`'a'`	00000061H
`'ba'`	00006261H
`'cba'`	00636261H
`'dcba'`	64636261H
`'a '`	00006120H
`'   a'`	20202061H
`'a' * 2`	000000E2H
`'a'-'A'`	00000020H
not `'a'`	FFFFFF9EH

Registers

The following reserved symbols denote CPU registers:.

Table 13.3 CPU registers

32-bit general purpose	EAX EBX ECX EDX	32-bit pointer or index	ESP EBP ESI EDI
16-bit general purpose	AX BX CX DX	16-bit pointer or index	SP BP SI DI
8-bit low registers	AL BL CL DL	16-bit segment registers	CS DS SS ES
		32-bit segment registers	FS GS
8-bit high registers	AH BH CH DH	Coprocessor register stack	ST

When an operand consists solely of a register name, it is called a *register operand*. All registers can be used as register operands, and some registers can be used in other contexts.

The base registers (BX and BP) and the index registers (SI and DI) can be written within square brackets to indicate indexing. Valid base/index register combinations are [BX], [BP], [SI], [DI], [BX+SI], [BX+DI], [BP+SI], and [BP+DI]. You can also index with all the 32-bit registers—for example, [EAX+ECX], [ESP], and [ESP+EAX+5].

The segment registers (ES, CS, SS, DS, FS, and GS) are supported, but segments are normally not useful in 32-bit applications.

The symbol ST denotes the topmost register on the 8087 floating-point register stack. Each of the eight floating-point registers can be referred to using ST(*X*), where *X* is a constant between 0 and 7 indicating the distance from the top of the register stack.

Symbols

The built-in assembler allows you to access almost all Object Pascal identifiers in assembler expressions, including constants, types, variables, procedures, and functions. In addition, the built-in assembler implements the special symbol *@Result*, which corresponds to the *Result* variable within the body of a function. For example, the function

```
function Sum(X, Y: Integer): Integer;
begin
  Result := X + Y;
end;
```

could be written in assembler as

```
function Sum(X, Y: Integer): Integer; stdcall;
begin
  asm
    MOV     EAX,X
    ADD     EAX,Y
    MOV     @Result,EAX
  end;
end;
```

The following symbols cannot be used in **asm** statements:

- Standard procedures and functions (for example, *WriteLn* and *Chr*).
- String, floating-point, and set constants (except when loading registers).
- Labels that aren't declared in the current block.
- The *@Result* symbol outside of functions.

The following table summarizes the kinds of symbol that can be used in **asm** statements.

Table 13.4 Symbols recognized by the built-in assembler

Symbol	Value	Class	Type
Label	Address of label	Memory reference	Size of type
Constant	Value of constant	Immediate value	0
Type	0	Memory reference	Size of type
Field	Offset of field	Memory	Size of type
Variable	Address of variable	Memory reference	Size of type
Procedure	Address of procedure	Memory reference	Size of type
Function	Address of function	Memory reference	Size of type
Unit	0	Immediate value	0
@Result	Result variable offset	Memory reference	Size of type

With optimizations disabled, local variables (variables declared in procedures and functions) are always allocated on the stack and accessed relative to EBP, and the value of a local variable symbol is its signed offset from EBP. The assembler automatically adds [EBP] in references to local variables. For example, given the declaration

```
var Count: Integer;
```

within a function or procedure, the instruction

```
MOV     EAX,Count
```

assembles into MOV EAX,[EBP–4].

The built-in assembler treats **var** parameters as a 32-bit pointers, and the size of a **var** parameter is always 4. The syntax for accessing a **var** parameter is different from that for accessing a value parameter. To access the contents of a **var** parameter, you must first load the 32-bit pointer and then access the location it points to. For example,

```
function Sum(var X, Y: Integer): Integer; stdcall;
begin
  asm
    MOV     EAX,X
    MOV     EAX,[EAX]
    MOV     EDX,Y
    ADD     EAX,[EDX]
    MOV     @Result,EAX
  end;
end;
```

Identifiers can be qualified within **asm** statements. For example, given the declarations

```
type
  TPoint = record
    X, Y: Integer;
  end;
  TRect = record
    A, B: TPoint;
  end;
var
  P: TPoint;
  R: TRect;
```

the following constructions can be used in an **asm** statement to access fields.

```
MOV     EAX,P.X
MOV     EDX,P.Y
MOV     ECX,R.A.X
MOV     EBX,R.B.Y
```

A type identifier can be used to construct variables on the fly. Each of the following instructions generates the same machine code, which loads the contents of [EDX] into EAX.

```
MOV     EAX,(TRect PTR [EDX]).B.X
MOV     EAX,TRect([EDX]).B.X
MOV     EAX,TRect[EDX].B.X
MOV     EAX,[EDX].TRect.B.X
```

Expression classes

The built-in assembler divides expressions into three classes: *registers*, *memory references*, and *immediate values*.

An expression that consists solely of a register name is a *register* expression. Examples of register expressions are AX, CL, DI, and ES. Used as operands, register expressions direct the assembler to generate instructions that operate on the CPU registers.

Expressions that denote memory locations are memory references. Object Pascal's labels, variables, typed constants, procedures, and functions belong to this category.

Expressions that aren't registers and aren't associated with memory locations are immediate values. This group includes Object Pascal's untyped constants and type identifiers.

Immediate values and memory references cause different code to be generated when used as operands. For example,

```
const
  Start = 10;
var
  Count: Integer;
  ⋮
asm
  MOV     EAX,Start            { MOV EAX,xxxx }
  MOV     EBX,Count            { MOV EBX,[xxxx] }
  MOV     ECX,[Start]          { MOV ECX,[xxxx] }
  MOV     EDX,OFFSET Count     { MOV EDX,xxxx }
end;
```

Because *Start* is an immediate value, the first MOV is assembled into a move immediate instruction. The second MOV, however, is translated into a move memory instruction, as *Count* is a memory reference. In the third MOV, the brackets convert *Start* into a memory reference (in this case, the word at offset 10 in the data segment). In the fourth MOV, the OFFSET operator converts *Count* into an immediate value (the offset of *Count* in the data segment).

The brackets and OFFSET operator complement each other. The following **asm** statement produces identical machine code to the first two lines of the previous **asm** statement.

```
asm
  MOV     EAX,OFFSET [Start]
  MOV     EBX,[OFFSET Count]
end;
```

Memory references and immediate values are further classified as either *relocatable* or *absolute*. Relocation is the process by which the linker assigns absolute addresses to symbols. A relocatable expression denotes a value that requires relocation at link time, while an absolute expression denotes a value that requires no such relocation. Typically, expressions that refer to labels, variables, procedures, or functions are relocatable, since the final address of these symbols is unknown at compile time. Expressions that operate solely on constants are absolute.

The built-in assembler allows you to carry out any operation on an absolute value, but it restricts operations on relocatable values to addition and subtraction of constants.

Expression types

Every built-in assembler expression has a type—or, more correctly, a size, because the assembler regards the type of an expression simply as the size of its memory location. For example, the type of an *Integer* variable is four, because it occupies 4 bytes. The built-in assembler performs type checking whenever possible, so in the instructions

```
var
  QuitFlag: Boolean;
  OutBufPtr: Word;
  ⋮
asm
  MOV     AL,QuitFlag
  MOV     BX,OutBufPtr
end;
```

the assembler checks that the size of *QuitFlag* is one (a byte), and that the size of *OutBufPtr* is two (a word). The instruction

```
MOV     DL,OutBufPtr
```

produces an error because DL is a byte-sized register and *OutBufPtr* is a word. The type of a memory reference can be changed through a typecast; these are correct ways of writing the previous instruction:

```
MOV     DL,BYTE PTR OutBufPtr
MOV     DL,Byte(OutBufPtr)
MOV     DL,OutBufPtr.Byte
```

These MOV instructions all refer to the first (least significant) byte of the *OutBufPtr* variable.

In some cases, a memory reference is untyped. One example is an immediate value enclosed in square brackets:

```
MOV al, [Buffer]
MOV cx, [Buffer]
MOV edx, [Buffer]
```

The built-in assembler permits both of these instructions, because the expression [100H] has no type—it just means "the contents of address 100H in the data segment," and the type can be determined from the first operand (byte for AL, word for BX). In cases where the type can't be determined from another operand, the built-in assembler requires an explicit typecast:

```
INC     BYTE PTR [ECX]
IMUL    WORD PTR [EDX]
```

The following table summarizes the predefined type symbols that the built-in assembler provides in addition to any currently declared Object Pascal types.

Table 13.5 Predefined type symbols

Symbol	Type
BYTE	1
WORD	2

Table 13.5 Predefined type symbols (continued)

Symbol	Type
DWORD	4
QWORD	8
TBYTE	10

Expression operators

The built-in assembler provides a variety of operators. Precedence rules are different from Object Pascal; for example, in an **asm** statement, AND has lower precedence than the addition and subtraction operators. The following table lists the built-in assembler's expression operators in decreasing order of precedence.

Table 13.6 Precedence of built-in assembler expression operators

Operators	Remarks	Precedence
&		highest
(), **[]**, **.**, **HIGH**, **LOW**		
+, **–**	unary **+** and **–**	
:		
OFFSET, **TYPE**, **PTR**, *****, **/**, **MOD**, **SHL**, **SHR**, **+**, **–**	binary **+** and **–**	
NOT, **AND**, **OR**, **XOR**		lowest

The following table defines the built-in assembler's expression operators.

Table 13.7 Definitions of built-in assembler expression operators

Operator	Description
&	**Identifier override**. The identifier immediately following the ampersand is treated as a user-defined symbol, even if the spelling is the same as a built-in assembler reserved symbol.
(...)	**Subexpression**. Expressions within parentheses are evaluated completely prior to being treated as a single expression element. Another expression can precede the expression within the parentheses; the result in this case is the sum of the values of the two expressions, with the type of the first expression.
[...]	**Memory reference**. The expression within brackets is evaluated completely prior to being treated as a single expression element. Another expression can precede the expression within the brackets; the result in this case is the sum of the values of the two expressions, with the type of the first expression. The result is always a memory reference.
.	**Structure member selector**. The result is the sum of the expression before the period and the expression after the period, with the type of the expression after the period. Symbols belonging to the scope identified by the expression before the period can be accessed in the expression after the period.
HIGH	Returns the high-order 8 bits of the word-sized expression following the operator. The expression must be an absolute immediate value.

Table 13.7 Definitions of built-in assembler expression operators (continued)

Operator	Description
LOW	Returns the low-order 8 bits of the word-sized expression following the operator. The expression must be an absolute immediate value.
+	**Unary plus**. Returns the expression following the plus with no changes. The expression must be an absolute immediate value.
–	**Unary minus**. Returns the negated value of the expression following the minus. The expression must be an absolute immediate value.
+	**Addition**. The expressions can be immediate values or memory references, but only one of the expressions can be a relocatable value. If one of the expressions is a relocatable value, the result is also a relocatable value. If either of the expressions is a memory reference, the result is also a memory reference.
–	**Subtraction**. The first expression can have any class, but the second expression must be an absolute immediate value. The result has the same class as the first expression.
:	**Segment override**. Instructs the assembler that the expression after the colon belongs to the segment given by the segment register name (CS, DS, SS, FS, GS, or ES) before the colon. The result is a memory reference with the value of the expression after the colon. When a segment override is used in an instruction operand, the instruction is prefixed with an appropriate segment-override prefix instruction to ensure that the indicated segment is selected.
OFFSET	Returns the offset part (double word) of the expression following the operator. The result is an immediate value.
TYPE	Returns the type (size in bytes) of the expression following the operator. The type of an immediate value is 0.
PTR	**Typecast operator**. The result is a memory reference with the value of the expression following the operator and the type of the expression in front of the operator.
*	**Multiplication**. Both expressions must be absolute immediate values, and the result is an absolute immediate value.
/	**Integer division**. Both expressions must be absolute immediate values, and the result is an absolute immediate value.
MOD	**Remainder after integer division**. Both expressions must be absolute immediate values, and the result is an absolute immediate value.
SHL	**Logical shift left**. Both expressions must be absolute immediate values, and the result is an absolute immediate value.
SHR	**Logical shift right**. Both expressions must be absolute immediate values, and the result is an absolute immediate value.
NOT	**Bitwise negation.** The expression must be an absolute immediate value, and the result is an absolute immediate value.
AND	**Bitwise AND**. Both expressions must be absolute immediate values, and the result is an absolute immediate value.
OR	**Bitwise OR**. Both expressions must be absolute immediate values, and the result is an absolute immediate value.
XOR	**Bitwise exclusive OR**. Both expressions must be absolute immediate values, and the result is an absolute immediate value.

Assembler procedures and functions

You can write complete procedures and functions using inline assembler code, without including a **begin...end** statement. For example,

```
function LongMul(X, Y: Integer): Longint;
asm
  MOV     EAX,X
  IMUL    Y
end;
```

The compiler performs several optimizations on these routines:

- No code is generated to copy value parameters into local variables. This affects all string-type value parameters and other value parameters whose size isn't 1, 2, or 4 bytes. Within the routine, such parameters must be treated as if they were **var** parameters.
- Unless a function returns a string, variant, or interface reference, the compiler doesn't allocate a function result variable; a reference to the *@Result* symbol is an error. For strings, variants, and interfaces, the caller always allocates an *@Result* pointer.
- The compiler only generates stack frames for nested routines, for routines that have local parameters, or for routines that have parameters on the stack.
- The automatically generated entry and exit code for the routine looks like this:

```
PUSH    EBP             ;Present if Locals <> 0 or Params <> 0
MOV     EBP,ESP         ;Present if Locals <> 0 or Params <> 0
SUB     ESP,Locals      ;Present if Locals <> 0
 ⋮
MOV     ESP,EBP         ;Present if Locals <> 0
POP     EBP             ;Present if Locals <> 0 or Params <> 0
RET     Params          ;Always present
```

  If locals include variants, long strings, or interfaces, they are initialized to zero but not finalized.

- *Locals* is the size of the local variables and *Params* is the size of the parameters. If both *Locals* and *Params* are zero, there is no entry code, and the exit code consists simply of a RET instruction.

Assembler functions return their results as follows.

- Ordinal values are returned in AL (8-bit values), AX (16-bit values), or EAX (32-bit values).
- Real values are returned in ST(0) on the coprocessor's register stack. (*Currency* values are scaled by 10000.)
- Pointers, including long strings, are returned in EAX.
- Short strings and variants are returned in the temporary location pointed to by *@Result*.

Technical Information

Single User License Agreement

This is a legal Agreement between you, as the end user, and Nevrona Designs. By opening the enclosed sealed disk package, or by using the disk, you are agreeing to be bound by the terms of this Agreement. If you do not agree with the terms of this Agreement, promptly return the unopened disk package and accompanying items, (including written materials), to the place you obtained them for a full refund.

1. **Grant of License** - Nevrona Designs grants to you the right to use one copy of the enclosed Nevrona Designs program, (the Software), on a single terminal connected to a single computer (i.e. CPU). You may make one copy of the Software for back-up purposes for use on your own computer. You must reproduce and include the copyright notice on the back-up copy. You may not network the Software or use it on more than a single computer or computer terminal at any time, unless a copy is purchased for each computer or terminal on the network that will use the Software. You may transfer this Software from one computer to another, provided that the Software is used on only one computer at a time. You may not rent or lease the Software, but you may transfer the Software and accompanying written material and this license to another person on a permanent basis provided you retain no copies and the other person agrees to accept the terms and conditions of this Agreement. THIS SOFTWARE MAY NOT BE DISTRIBUTED, IN MODIFIED OR UNMODIFIED FORM, AS PART OF ANY APPLICATION PROGRAM OR OTHER SOFTWARE THAT IS A LIBRARY-TYPE PRODUCT, DEVELOPMENT TOOL OR OPERATING SYSTEM, OR THAT MAY BE COMPETITIVE WITH, OR USED IN LIEU OF, THE PROGRAM PRODUCT, WITHOUT THE EXPRESS WRITTEN PERMISSION OF NEVRONA DESIGNS. This license does include the right to distribute applications using the enclosed software provided the above requirements are met.

2. **Term** - This Agreement is effective until you terminate it by destroying the Software, together with all copies. It will also terminate if you fail to follow this agreement. You agree upon termination to destroy the Software, together with all copies thereof.

3. **Copyright** - The software is owned by Nevrona Designs and is protected by United States laws and international treaty provisions. Therefore, you must treat the Software like any other copyrighted material (e.g. a book or musical recording) **EXCEPT** that you may either (a) make one copy of the Software solely for back-up or archival purposes, or (b) transfer the Software to a single hard disk provided you keep the original solely for back-up or archival purposes. You may not copy the written materials accompanying the Software.

Limited Warranty

1. **Limited Warranty -** Nevrona Designs warrants that the disks on which the Software is furnished to be free from defects in material and workmanship, under normal use, for a period of 90 days after the date of the original purchase. If, during this 90-day period, a defect in the disk should occur, the disk may be returned with proof of purchase to Nevrona Designs, which will replace the disk without charge. Nevrona Designs warrants that the Software will perform substantially in accordance with the accompanying written materials. Nevrona Designs does not warrant that the functions contained in the Software will meet your requirements, or any operation of the Software will be uninterrupted or error-free. However, Nevrona Designs will, after being notified of significant errors during the 90-day period, correct demonstrable and significant Software or documentation errors within a reasonable period of time, or refund all or a fair portion of the price you have paid for the Software at Nevrona Designs' option.

2. **Disclaimer of Warranties - Nevrona Designs disclaims all other warranties, either**

expressed or implied, including but not limited to implied warranties of merchantability of fitness from particular purpose, with respect to the Software and accompanying written materials. This limited warranty gives you specific legal rights, you may have others, varying from state to state. Nevrona Designs will have no consequential damages. In no event, shall Nevrona Designs or its suppliers be liable for damages whatsoever, (including without limitation, damages for loss of business profits, business interruption, loss of business information, or any pecuniary loss), arising out of the use or the inability to this Nevrona Designs product, even if Nevrona Designs has been advised of the possibility of such damages. Some states do not allow the exclusion of limitation of liability for consequential or incidental damages, and this limitation may not apply to you.

3. **Sole Remedy -** Nevrona Designs' entire liability in your inclusive remedy shall be, at Nevrona Designs' option, either: (1) The return of the purchase price paid; or (2) Repair or replacement of the Software that does not meet Nevrona Designs' limited warranty, which is returned to Nevrona Designs with a copy of your receipt.

4. **Governing Law** - This Agreement will be construed and governed in accordance with laws of the State of Arizona.

5. **U.S. Government Restricted Rights -** This Software and documentation are provided with restrictive rights. Use, duplication or disclosure by the Government is subject to restrictions set forth in Section c(1)(ii) of the Rights and Technical Data in Computer Software clause at 52.227-7013.

Technical Support

Technical support, product updates, addons and other information relating to Rave Reports can be found at the Nevrona Designs web site. Please visit one of the following web pages for more information:

Updates - http:/www.nevrona.com/rave/download.html

Chapter 1
Introduction

In this Section:
• Rave is introduced and related to reporting needs. • Navigation of toolbars is introduced. • Introduction of the main component, the Page. • Brief overviews of the Toolbars, Project Tree Panel, and Property Panel are given.

What's All the RAVE About?

Reporting can be one of the most complex, yet most important tasks for anyone dealing with a database. Reports are the primary visual means to express information retrieved from a body of data. To solve the problems associated with presenting a visual report of data in a meaningful and informative manner, traditional visual reporting tools have offered banded layout tools geared towards table-style listings of data. Today, however, much more complex reporting requirements exist and are not easily handled by banded layout tools.

Welcome to the next level in visual reporting! The Rave visual designer offers many unique features that help to make the reporting process simpler, quicker and more efficient. Rave is an intuitive page based visual design environment that can easily handle a wide variety of report formats, much more than a purely banded style tool. Rave also includes mirroring and other technologies to encourage you to reuse the contents of your reports for quicker changes and easier maintenance. In general though, Rave has been designed to offer the most flexibility and functionality in an easy to learn format.

Where do you begin? Since Rave is page-based designer, many of its features should make sense and be easy to use with only a little practice. There are a lot of options and some might not be obvious when just starting. However, remember that many of these options can be ignored in the beginning, but as your needs and knowledge increases these options are readily available. In fact, Wizards generate "standard" reports without having to know behind-the-scene details. However, we do recommend that you take some time and do a quick read of this manual.

Included with the Rave installs is a project called "RaveDemo" that contains several report samples. To see several common designs, start the RaveDemo.exe and open the RaveDemo project to access the different report types. Exploring the RaveDemo project and other samples are excellent ways to learn Rave.

Report Authoring Visual Environment

A report might be described as data presented in a visual manner, whether it is printed on paper or displayed electronically. Typically, there are sets of database tables that provide data to create a report. For example, suppose there are: a Customer table, a Products table, and an Items Sold table. These tables could be combined to produce form letters, invoices or customer lists.

Let's begin with a quick overview of Rave. The first step to using Rave is to start the program. The first thing seen will be a sheet representing a page on the screen as well as two windows on the side of the page and toolbars across the top of the page. On a first impression, there appears to be many items in the Rave designer, so where do you start?

Let's start with what is shown when Rave is running. First, understand that there are two groups of toolbars displayed in the Rave designer; they are the components and tools.

Components are those items that are "dropped" or visible on the page editor. These might be bands, bar codes, lines, shapes, etc. Don't worry about what these things are yet. If the object can be seen on the page layout, it is a component.

Toolbars have the ability to change or modify components, thus distinguishing them as tools. There are several toolbars: alignment, color palette, font editor, etc. If there is a box on the page and it needs to be filled with a background color, first select that item (the box) by clicking on it. Then, use the color tool to change the fill color to any desired color. Toolbars can be hidden and seen by selecting them from the Tools menu. If there is a preference for a more simplified designer look, the toolbars can be hidden until they are needed.

Now that was the very fast overview. There are lots of settings or properties that control the behavior of almost every part of the visual designer. This manual has two main parts, a description of the Rave system including the components and tools, then a reference section that lists the details about each property. Go through the description section first, and then browse the reference section to get a better understanding on just how much control can be had over various design features.

First Glance

When Rave first starts, it will open a screen that looks like the image below. Since Rave remembers what file was last opened, your screen may look a little different. But, the areas shown are the fundamental pieces. We are going to first explore each part of this screen to give a general tour of the Rave Designer.

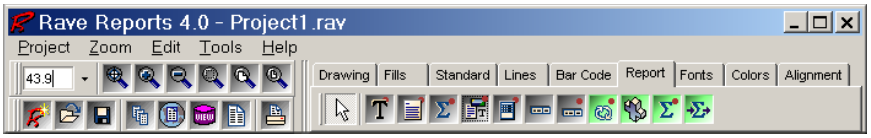
Navigation Area



The top of the visual designer is the Rave Navigation area. This is where toolbars can be docked individually, and can also be tab docked. Individually docking the toolbars will allow the user to see all the buttons on the toolbar and to see more than one toolbar at a time. Tab docking will allow easy access to each toolbar, but only one toolbar can be seen at a time.

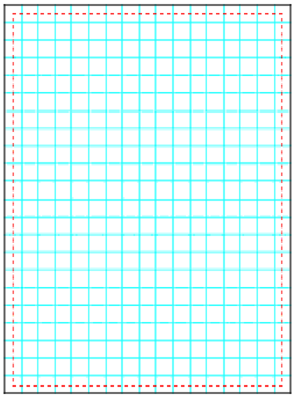
The toolbars contain both tools and components. A tool is a feature that will be used to modify an object already on the page, like the Font Editor or the Color Palette. A component is an object that will be placed on the page like a band, line, text, region, or section.

To find out the name of the button control on a toolbar, simply move the mouse pointer over a button, and a popup window will appear with the name of the tool or component. Also, notice the raising of the button when it is about to be selected. It will become 'depressed' when the button is clicked on.

Each toolbar can also be hidden. To hide or view a toolbar, go to the tool menu and select the desired toolbar from Toolbars menu.

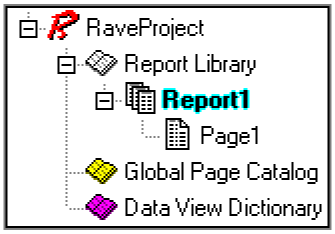
The Page (Foundation of Rave)

The starting point with the Rave Visual Designer is the Page. The page is the foundation and is where all the designing action is done. The Page is represented with the grid pattern, which will look something like the image shown to the right. The look and feel of the Page can be changed with the preference settings, which will be covered in Preferences chapter.



One important thing to know and remember is that the Page has properties, such as height and width. To see or change the Page properties, go to the "Project Tree" Panel and expand the Report node by clicking on the "+" sign, then click on the report name (default is "Report1") and this will show a line that will be defaulted to "Page1". Click once on the Page reference and the Page name will be highlighted in the "Project Tree". The highlight means that the Page has been selected and now the Page properties can be seen in the Property Panel.

Project Tree Panel



The Project Tree panel is a very informative part of the Rave designer and it also provides an easy way to navigate the reporting project structure.

For now just the parts of the Project Tree will be examined. More details are covered in the Project Tree Chapter.

There are three main nodes in the Project Tree: Report Library, Global Page Catalog, and Data View Dictionary. Each of these nodes (and any sub nodes) can be expanded or collapsed by clicking on the plus/minus symbol. Sub-nodes can be created and added, by selecting a desired option (New Report, New Global Page, and New Data Object) from the Project Menu.

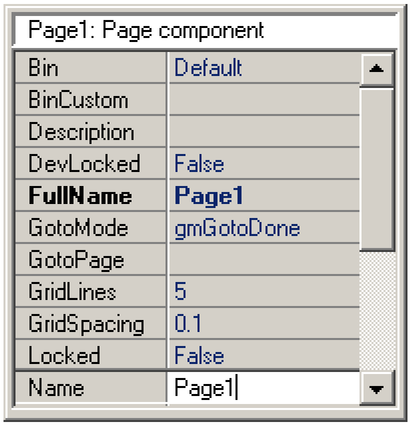
The Report Library node is where all of the reports within the project are contained. Each report will have one or more pages. Each of those pages will normally have one or more components within them.

The Global Page Catalog node is where reporting templates are managed. The reporting templates can contain one or more components. These reporting templates can then be reused via Rave's unique mirroring technology. This could include items such as letter headings and footers, pre-printed forms, watermark designs or complete page definitions that could be the foundation for other reports.

The Data View Dictionary node is where all the data connections for reports are defined. A data view retrieves data from the application through data connections installed within that application.

Property Panel

The Property Panel helps to customize the way components appear or behave. When a component is selected on the page, the Property Panel will reflect the selection by displaying the different properties associated with the selected component.

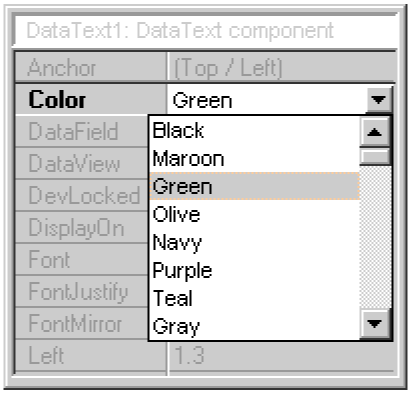


Page1: Page component

Bin	Default
BinCustom	
Description	
DevLocked	False
FullName	**Page1**
GotoMode	gmGotoDone
GotoPage	
GridLines	5
GridSpacing	0.1
Locked	False
Name	Page1

Changing the properties values is easily done by using various associated drop-down menus and edit boxes. If no component is selected, then the property panel will appear blank with no options to choose from.

Another way to change a property is select a value from a list of possible choices. For example, the Color property has a down arrow button. Clicking on the down arrow button will display a list of colors that can be selected. Any property that has a list of choices can also be double-clicked (instead of clicking on the down arrow button and selecting the option) to advance to the next item in the list.



DataText1: DataText component

Chapter 2
Toolbars and Tool Windows

In this Section:

- General information about the toolbars
- Toolbar placement in the Visual Designer environment
- How to manipulate Toolbars within the environment
- Introduction to Tool Windows and their movement

Toolbars

A toolbar is a collection of icons that relate in their function. Rave has several toolbars that can be docked to any side of the designer window, tab docked, or hidden to stay out of the way until they are needed.

To access the toolbars, go to the Tools menu, and then from Toolbars select the toolbar that is desired. Selecting a toolbar will place a check mark next to the toolbar.

The toolbars are designed to remember their last placement position. When a toolbar is closed and then opened again, the toolbar will be in the same position on the screen that it was in before it was closed.

Toolbar Placement

When a toolbar is visible it can be in one of two states: tab-docked or single docked. A tab-docked toolbar is docked with tabs displayed. A single docked toolbar has a ribbed section on the left of the toolbar. To change the toolbar state, right-click on one of its icons. This will reveal a small button with either a "dock" or "undock" label. Click on that button to change that toolbar's state.

When a toolbar is undocked, the "toolbar handle" is the ribbed section in docked style. To move a toolbar, place the mouse cursor somewhere on the "toolbar handle", press and hold the left mouse button while dragging the toolbar to a new location in the top portion of the designer window. The best way to get familiar with this is to try docking and undocking toolbars.

Below is an example of docked and tab docked. As previously mentioned, the single docked toolbars can only be placed at the top of the designer window. The user can practice docking and undocking the toolbars to get familiar with this process.

Toolbar Palette

The toolbar palette has a number of special features, which are worth mentioning in more detail. The region on the upper right hand corner of the visual designer and allows one or more toolbars to be docked. When the toolbars are docked, tabs are formed with the name of the toolbar as the name of the tab. As toolbars are placed in the tab docking area, a new tab will be created to reflect the current toolbar.

There is a tab grabber that allows the tabs to be moved to the left or to the right. When the tabs are moved to the far right, double arrows appear to allow movement through the tabs. The entire tabs area can be emptied by moving all the toolbars away from the tab area, or by closing the toolbars from the tool menu. The tab area can also be moved off to the every edge of the screen (moved to the far right) to allow room in the upper area of the visual designer. Use the Tab Grabber to move the Tab area (it can be filled or emptied) off to the far right.

Hiding Toolbars

There are a couple ways to hide toolbars. Hiding Toolbars allow the user to 'clean' up the Rave Designer. This is also helpful to get unused toolbars, or less frequently used toolbars, out of the way or out of the designer environment.

The method to do this is to use the Tools menu to uncheck, and thus hide, the toolbar.

Component vs. Utility Toolbars

There are two types of toolbars: Component toolbars and Utility toolbars.

The component toolbars are used for placing components that work and have function within a report; see the Components Overview Chapter for more details about components. Most of the components appear visually when placed on the page, however there are a few components that are non-visual. Non-visual means that the components only appear in the Project Tree, there will be no visual record of the component on the Page.

Utility toolbars are used to set properties that affect the look of components in a report. For example, the Utility Toolbar Color can change the color of text in a DataText component.

Below is a list of the toolbars classified by type:

Component Toolbars	**Utility Toolbars**
Standard	Alignment
Report	Colors
Bar Code	Fills
Drawing	Fonts
	Lines
	Zoom
	Project
	Designer

Tool Windows

Rave has two very helpful windows, which are generally called the Tool Windows. They are called this because the user will use them as tools to complete and navigate a report. The two Tool Windows are the Project Tree and the Property Panel.

These windows will most likely be displayed when Rave is started. But, if it is not displayed, then go to the Tools menu and select these windows to be opened by placing a check mark in front of them.

Property Panel

The Property Panel gives information about the characteristics of a project and the components within the project. It will be most helpful when designing reports because it gives easy access to component properties, and thus easy visual access to modifying the properties. More detailed information is given in the Property Panel Chapter.

The Property Panel displays and allows modification of values of any component that is placed on the Page, which includes non-visual components. To get property information about a certain component, remember to select that component before looking at the Property Panel (see Selecting a Component in the Page Designer Chapter for more information on how to select an object).

Project Tree

The Project Tree is a very informative part of the Rave designer. It provides an easy way to navigate the reporting project structure.

The Project Tree is composed of three main branches: Report Library, Global Page Catalog and Data View Dictionary. For more information about the functionality of each of these components, please see the Project Tree Panel chapter and the Project Components chapter.

Items within the Project Tree can be selected by clicking on the item. Also, remember that the components seen in the tree are also the components that are on the Page.

Note: the non-visual components are in the Project Tree and are usually a green color.

The details of navigating through the Project Tree are saved for a chapter in itself. For now just a general overview of the Project Tree is given.

Chapter 3
Components Overview

In this Section:

- Introduction to Components in general
- Lists Component Toolbars
- Overview of each Component toolbar is given

What is a Component

A component is defined as something placed on the page, such as a barcode, line, region, shape, etc. The components available in Rave can be found on any of the component toolbars (e.g. Standard, Drawing, Report and Barcode).

The toolbars are made available by clicking on the Tools menu followed by the Toolbars menu. The available toolbars will then be shown in another submenu and will have checkmarks showing the toolbars that are currently visible. Once a component toolbar is active and selected, a component can be selected and placed on the page. The Page is a special base component, and more details are given in the Page Designer chapter.

Special properties are associated with each component. These component properties can be seen using the Property Panel. Set the properties of each component to the desired setting by either typing the setting in a text dialog, using a drop down menu, or by using the special ellipse (…) button to get to the property dialog box.

There are many properties associated with each component, but don't be intimidated by the number of properties. The properties are there to allow adjustment for a component's behavior and in many cases the default settings are adequate. Also, please note that the number of properties listed with each component may vary depending on the user level that has been set under preferences. To adjust the user's level, please visit the environment tab in the preferences dialog. See the Preferences chapter for more details.

Since there are many properties associated with each component, this chapter will focus mainly on the component toolbars rather than their associated properties. The current chapter provides a good overview of what each component toolbar does without too much detail about the property specifics. Do note that many components share common properties, so once the common properties are learned for one component, they can be applied to other properties.

Components are also defined by their relationship relative to other components. This relationship is defined by a parent-child relationship. When a text component is placed on the page, the parent is the page component and the child is the text component. Another way to look at it is that the page contains the text component, thus the parent component contains the child component.

The parent-child relationship also extends into the positioning of the components. All positions are relative to the upper left corner of the parent, thus the Left property and Top property are used to define the relative position of a component. If the parent is like a Section component, which can contain any number of other components; then as the parent component is moved around, it's children components will move accordingly. If the parent component is deleted, all of its children will also be deleted.

A parent-child relationship is defined when the child component is initially created. If the child component is dropped within the parent component, then it will become the child of that parent. If the component is dropped on the page, then dragged on top of another component (such as a

Band or Section), it will still be considered a child of the page.

The Project Tree, which will be explained in more detail in a later chapter, visually shows the parent-child relationships of the components. In general, the Project component is the master parent of all reports, global pages and data objects. Reports are parents to the report pages. Pages are parents to the components that are placed on them. There are still other components that can be parents to components, such as Regions, Bands and Sections.

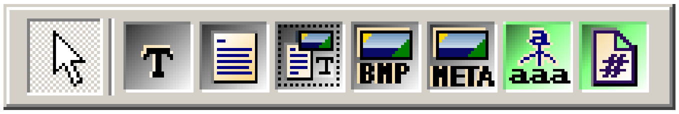
The Component Toolbars

There are four standard component toolbars. Other component toolbars may be present if add-on packages have been included. The normal set of component toolbars is: "Standard", "Drawing", "Report", and "Bar Code". There is one particular property that applies to all components, so it will be mentioned here.

The "Name" property is used to assign a new name to that control or to designate the name of the control to give it a unique meaning. By default, Rave assigns sequential names based on the type of the component, such as 'Section1', 'Section2', and so on. Change these to more meaningful names to make the Project Tree more readable and the reporting project easier to maintain. The "Name" property must not contain any spaces or special characters. This is the name that will be used in the Project Tree Panel.

The next several sections will give an overview of the four component toolbars. This will serve as an introduction, and more detail will be covered in later chapters.

Standard Components



The Standard Components toolbar controls the visibility of most frequently used components. Once the Standard components toolbar is active (either docked or undocked in the Rave environment), select and place components such as a bitmap, section, text control, etc. on the page.

The Text component creates a single line of text, which can be changed using the Property Panel.

The Memo component allows several lines of text to be displayed, including multi-line text.

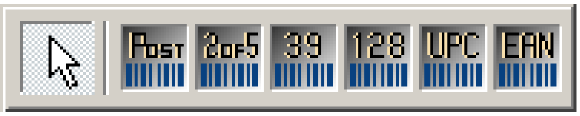
The Section component is a very special component that allows several components to be grouped together.

Bitmap and Metafile components allow images to be placed onto the report. The FontMaster component allows the user to define standard fonts for different parts of the report, like the headers, body, and footers.

The final component is called PageNumInit, this component allows the restart of page numbering within the report.

Use these components to create the base of a report, by inserting text and images.

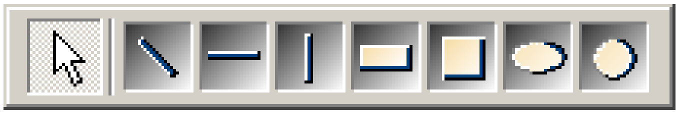
Bar Code Components



The BarCode Components toolbar contains six bar code components: PostNetBarCode, 2of5BarCode, Code39BarCode, 128BarCode, UPCBarCode, and EANBarCode.

These are used for making all sorts of bar codes for report usage.

Drawing Components

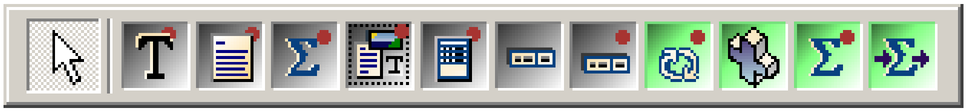


The Drawing toolbar controls all graphical drawing components. This includes drawing lines, boxes, rectangles, circles and elliptical circles.

The components from left to right are: Line, HLine, VLine, Rectangle, Square, Ellipse, and Circle.

These are used for creating graphical images and general report formatting. Use these to separate areas of a report, or to create an informative image.

Report Components



There are several report components: (left to right) DataText, DataMemo, CalcText, DataMirrorSection, Region, Band, DataBand, DataCycle, CalcOp, CalcTotal, CalcController. Use these components to interact with a database and make a functional report.

The components with a red dot in right corner are Data Aware and are capable of displaying information from a database. Each component has a DataView property, which allows the component to interact with a database.

The components with a green color are "non-visual". These can be seen in the Project Tree, but not on the Page layout.

Bands and DataBands must be placed within a Region. Therefore before placing a band on the Page, first place a Region in the area in which a Band or a DataBand will be established. There is no limit on the number of Bands within a region, nor is there a limit to a single region. There can be as many regions as needed. Each Band has its own set of properties to control its behavior. See the Report Components Chapter for more detailed information.

Chapter 4

Page Designer

In this Section:

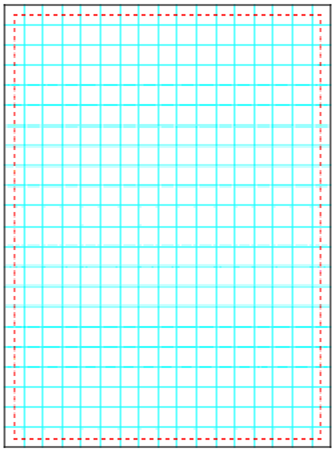
- Introduce the Page as a basic component
- Discuss how the Project Tree and Property Panel relates to the Page
- Show how to select component(s)
- Learn how to re-size and move components
- Overview of cutting and pasting in Rave

Overview

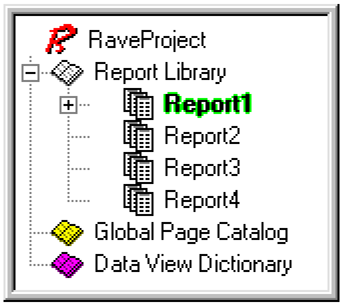
Just knowing the components and tools is not enough to work effectively in Rave. One must also learn about the most fundamental component of Rave, which is the Page. In this chapter the Page and its relation to the Project Tree and Property Panel are explained in detail. Although the Project Tree and the Property Panel have their own chapter, as each are important individually, this chapter explains how each is related to the Page. Also in this chapter, some basics on moving objects on the Page are given.

The Basic Component: The Page & it's Panels

The base component of the Rave Visual Designer is the Page. The Page is not a normal component in that it is not on a Component Toolbar, but it does have properties and it will help to think of it as the base component that provides the container for the report design. All Rave components must be placed on the Page. The Page is represented by the grid pattern on the page panel. The look and feel of the Page is controlled by preference settings that are covered in the Preferences Chapter. Changing the visual look of the Page is discussed in the Utility Toolbars Chapter in the Designer Toolbar section.



Like all components, the Page also has properties such as height, width, description and name. To see or change the Page properties, go to the "Project Tree" panel and expand the Report node by clicking on the "+" sign, then click on the report name ("Report1" is the default report). Clicking on the report name will show "Page1", which is the default name for a Page. Click once on this and notice that *"Page1"* will be highlighted. This means that the Page has been selected and now the Page properties for that Page will be seen in the Property Panel.



Page properties allow a report to be more informative. For example, rather than have a report with Page1, Page2, Page3, it might be desirable to have the pages named Invoice, PO, PackingSlip. To do this, use the "Name" property in the Property Panel. The name can be anything the user desires, but note that the name cannot have any spaces or special characters. Remember the Name is for the Rave designer only and is visible only in the Project Tree and on the tab(s) of the Page panel.

In the image of the Project Tree and Property Panel, the page names have been changed to show how useful it is to rename the Page. Now the project tree looks more informative. It is useful and helpful to adjust any properties associated with the Page to make the report more informative and useful for future use and revisions.

Selecting Components

Selecting components is as easy as clicking on them. Moving the mouse pointer to the region where the component is and clicking the left mouse button once will select any component that is placed on the Page. A selected component will appear surrounded with a line that has colored dots, called pips.

The "pips" can be of four different colors: green, gray, red, and yellow. Green pips indicate that the current component is the only one selected. Gray pips show that there is more than one component selected, and red pips indicate that the current component is locked. The yellow pips indicate objects that are that have been mirrored and cannot be modified.

Selecting more than one component at a time is done in a similar way to selecting one component. The difference is that when selecting multiple components; hold down the Shift key while clicking on the objects.

Another way to select either one or more components is to draw a "virtual" box around them. To do this, select an area that is adjacent to the component and drag the mouse to surround the component(s) keeping the left mouse button clicked.

To unselect a component, simply click on the Page Designer tab or move the cursor selection to a different component by clicking on it.

When multiple components are selected, only the common properties will be displayed in the Property Panel. When a property changes, the change will affect all the selected components at that time.

There is a special property for all components called Locked. If the Locked property is True, the component can be selected, but it's properties cannot be changed (except for the Locked property, of course). If selected components are locked, then the pips and the property name for those items will be red (as mentioned previously). If the component is a child component to a parent component, the parent will control the locked access. The Locked property state drop-down menu will show either a True/False indicating the lock status or it will show the parent component name that is controlling its lock state. The remaining discussion is about components that are NOT locked.

Sizing and Moving Components

To move a component, simply click on it with the left mouse button and drag it to the desired area. When more than one component has been selected, they can all be moved by just moving one of the components. Note that this will NOT affect components that have the Locked property set to True.

The main purpose of the "pips" that appear when selecting a component are for resizing. Resizing only works on ONE component at a time, i.e., a group of selected components cannot be resized at one time. A component can either be resized vertically, horizontally or diagonally. If the resizing is done diagonally, the component will resize both vertically and horizontally. Simply click on one of the pips with the left mouse button and drag the pip until the desired position. Locked components cannot be resized.

Cutting and Pasting

Cutting and pasting is achieved in the same way as in any other standard Windows applications. After selecting a component (or group of components), choose Cut or Copy from the Edit menu; or use the Ctrl-X or Ctrl-C key combinations; or right click on the component and selecting Cut or Copy from the popup menu.

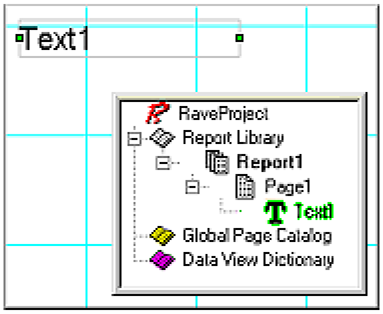
To paste the components, choose from any of the three previous methods (Edit menu, Ctrl-V or popup menu).

Again it is important to point out that Locked components cannot be cut since this would involve removing the object from its position.

Exercise: Selecting, Sizing, and Moving Components

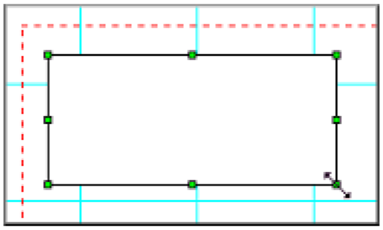
To select a component:

1. Click on the component. The pips and border will appear around it
2. Or, click on the component in the Project Tree, and notice that the selected component will be highlighted.



To resize a component:

1. Select the component
2. On a pip, place cursor over it until it changes to a double arrow
3. Click and hold the pip, then drag to the desired size



To move a component:

1. Select component
2. Move cursor over component (not near a pip, as that would be resizing the component). Click on component and hold
3. Move component by dragging cursor, and thus the component
4. Place in desired location.
5. Release cursor

Exercise: Cutting and Pasting

Using Edit menu:

1. Select the component.
2. Select Cut from the Edit menu. This will place the component into the clipboard, and the component will disappear visually from the page.
3. Paste by selecting Paste from the Edit menu.

Using the short-cut keys:

1. Select the component.
2. Press Ctrl-key and X-key. This will place the component into the clipboard, and the component will disappear visually from the page.
3. Paste by pressing Ctrl-key and V-key.

Using the pop-up menu:

1. Select the component.
2. Right-click on the component, in the pop-menu select Cut. This will place the component into the clipboard, and the component will disappear visually from the page.
3. Paste using one of the two previously mentioned ways.

Chapter 5

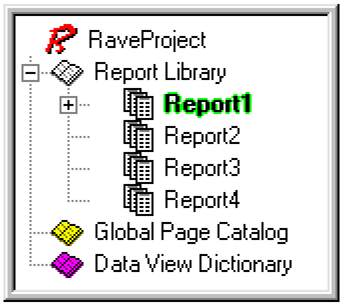
Project Tree Panel

In this Section:

- Project Tree structure introduced
- General discussion of Parent-Child relationships
- Introduce the main project categories
- Show How to Load/Unload Global Pages
- Discuss and explain the Drag and Drop features

Overview

The Project Tree Panel provides an easy way to navigate through the report design structure. This tree style view gives an outline overview of the report pages and the report structure. Thus, this makes the Project Tree a very informative part of the Rave designer. Once you have designed some simple or complex reports, remember to visit this panel and see just how informative it can be.



A project can contain multiple definitions within each main category: Report Library, Global Page Catalog and Data View Dictionary. Each node (and any sub nodes) can be expanded or collapsed by clicking on the plus/minus symbol. Any of these main nodes can be added from the "Project" menu option. There you will see an option for each of the nodes "New Report", "New Global Page" and "New Data View". In order to add a "New Page" to a Report in the Report Library, activate the Report that and use "New Page" from the Project menu.

Expanding and Right-Clicking

An easy way to complete tasks on items in the project tree is to right-click on the item. There are many different pop-up menus available. Clicking on a Main Node like the Report Library brings up a popup menu with two choices: Expand All and Collapse All. These two choices refer to expanding and collapsing all the nodes, which would provide easy fast access to all items in that tree.

A right-click on a sub-node, like on a Page, would reveal the option of deleting a page. Some of the available functions may be few or many, as in the next image.

Right-clicking on a component can display a pop up menu with many options. These options are the same options available as if a right-click was completed on the component on the designer page. Also, these items reflect the options available to the component through the Utility toolbars.

There are many options that may be available with a right-click of the mouse. To speed up the report making process or to make navigating a report fast and easy try to become familiar with the options that are available through these popup menus.

Parent-Child Relationship

Now, that you have seen how to click through the Project Tree, we'll review some lingo that is associated with a "tree".

The Project Tree is listed in a way that looks like an upside down tree. The base or the root of the tree is at the top of the list. Each subsequent branch is a child of the root. This makes the root also the parent of the child or branch. Each branch can also be its own parent and have its own child or children.

The techniques used in the previous section demonstrated how to move through the tree by expanding and collapsing the nodes associated with each parent. When a branch has children, a node will appear to the left of the branch name.

The Report Library is the root of the Tree, and has one child called Report1, shown with the text highlighted.

Report1 has several children: Page1, Page2, Page3, Page4, Page5, and Page6.

Page1 has the following children: Text1, Text2, and Memo1.

Also there are two sibling groups. Just like in a real family with parents and children, the children can have siblings. The first group of siblings: Page1, Page2, Page3, Page4, Page5, and Page6. The second group of siblings: Text1, Text2, and Memo1. There are other family associations, but the main two that we are concerned with is the Parent-Child relationship.

Report Library

The Report Library node is where the design structure, including all the components used, in each of the report(s) will be displayed. Normally, a component is selected via the Page in the Visual Designer layout panel by simply clicking on the component. However, the Report Library tree can also be used to select components by simply clicking on the component name. When a component name is clicked, that name will be highlighted. To select multiple components, hold the Shift- key down while selecting as many components as you like in the Project Tree.

A project can be simple with one or two report definitions, or it can be complex with many report definitions. Each report that is created would have it's own design structure. To select and switch to a different report, simply double-click on that report name in the Report Library tree structure.

TIP: To make navigation and understanding of a report easier, make use of the Name property. See the Name Exercise at the end of this chapter for help in using this property effectively.

Global Page Catalog

The Global Page Catalog node is where Page definitions, which contain templates to be mirrored, are kept. This includes things like Letterheads, Forms, Watermark designs, and other Page definitions that could be the foundation for several reports. This can even be a complete report design. An example would be mirroring a section component on a Global Page where the same contents (like an "Invoice") could be printed, but also with a different caption at the bottom of the pages like "Original", "File Copy", and "Shipping".

Loading and Unloading Global Pages

Global Pages are very useful and helpful to the designer, especially when they can be accessed quickly. These pages can hold all sorts of objects and components that can be repeated and mirrored throughout many pages in many different reports. Many of the reports in a Report Library could make use of any of the Global Pages in the Global Page Catalog.

When creating reports, a useful feature of the Rave Designer is the Page Designer Tabs. These are located at the top of the Page Designer window. They are the tabs of pages in use.

Global Pages can be added to this tab for quick referencing, meaning that the designer does not need to scroll through the whole Project Tree to find the right Global Pages frequently needed. Instead the designer just needs to load the page to the Page Designer Tab area and click on the tab when it is needed. Global Pages can be loaded and unloaded to/from the Page Designer Tab area by performing a right-click on the Global Page and using the speed menu to make their choice. A fast way to unload a Global Page is to select it from the tab area, then click on the Page and use the Ctrl-F4 keystroke.

Data View Dictionary

The Data View Dictionary node in the Rave Designer is where all the data connections for the reports would be listed. To add a Data View to this list, select a "New Data View" (from the "Project" menu). This will bring up a "Data Connections" dialog window. This window will show all the Rave data connections that are "active". Then select any of these and this will create a new Data View attached to that data connection.

Ctrl- (Control) Drag and Drop

Ctrl-Drag and Drop is used to create or mirror an item from the Project Tree structure either to another age node in that report structure or to the current page on the designer layout. When dragging from the Project Tree Panel to the page designer, the drop location will be the location where the mouse button is released. However, when dragging from one page node to another (in the Project Tree Panel), the location of the drop will default to the same place as the source.

NOTE:
When Ctrl-dragging a non-visual component, it must be one that can be mirrored. Copying a component that cannot be mirrored will NOT work. Regions and Bands are components that do not enable mirroring. To mirror a region, make the region part of a section, and then mirror that section. The section could include other components as well.

CAUTION:
Drag and drop will work from Report Page to Report Page, Global Page to Global Page, Global to Report Page, however, it will NOT work from the Report Page to Global Page, since components on Reports are not visible to other Reports and therefore cannot be used as mirrors on a Global Page.

Alt-Drag

The Alt-Drag is used to change the parent of a component to a new "container" component like a Section. All moves of that component need to be within that same Page design. When a new Section is created, the user may choose to have items from another Section placed in the new Section. In this case the parent must be changed from the old Section to the new Section and then the new Section can be mirrored.

NOTE:
The target component must be a container type. The Page, Region and Section are all holders or containers. So, if there are two or more sections on a Page, items can be dragged from one Section to the other Section. Also components can be dragged from the Page to one of the Sections.

Exercise: Navigating the Project Tree

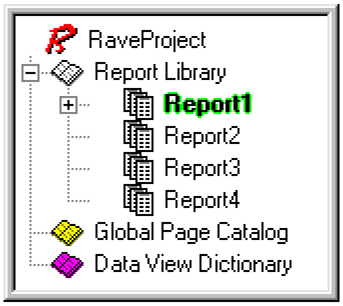
Because many report projects are complex, the Project Tree's hierarchy helps to navigate through the reports.

To navigate through the hierarchy (expand, collapse, and selection):

1. Expand an item by clicking the square icon with a "Plus" symbol. This will change the

item to a "Minus" symbol and expand the items into the sub-items such as Report1, Page1, etc., depending on which level of expansion is being expanded.

2. Collapse an item by clicking on the "Minus" Symbol. This will change the icon to a "Plus" symbol and collapse the items, so that they will no longer be visible.
3. Select an item in the Project Tree by clicking on the item. Selection will be indicated by that item being highlighted.



Exercise: Naming Components

Since projects can become very complex, it is highly suggested that the "Name" property be used to make items in the Project Tree easier to understand.

By default, the "Name" property will automatically default to something like "Report1", "Report2", and so on. However, it would be easier to maintain a project if the reports had useful names. This can be done through the "Name" property.

When developing a naming convention, be creative, but remember **no spaces or special characters** are allowed in the "Name" property.

In the example Project Tree Panel, the default report names have been changed. Instead of dealing with reports listed as "Report1" through "Report7", the reports were labeled accordingly: "CustomerList", "CustomerLabels", "CustomerDue", "Invoice", "PO", "ProductsOnHand", and "ProductsOnOrder". It is important to understand that the Project Tree Panel is there to make overseeing a project easier. But, without an informative naming system, the Project Tree Panel will not live up to it's full potential.

To rename a report (or any other component):

1. Select the report (component)
2. Ensure that the report to be renamed has been selected. A selected item is highlighted.
3. Go to the Property Panel and look at the Name Property.
4. In the "Name" Property edit box, type in the desired name.
5. Hit Enter or click somewhere out of the edit box, after a new name has been entered.
6. Look at the Project Tree and notice that the name of the report (component) has been changed from the default name.

Exercise: Loading and Unloading Global Pages

Loading and Unloading Global Pages to the Page Designer Tab area makes referencing these pages fast and helpful. This is especially true when dealing with mirroring sections and objects from Global Pages to the pages in different Reports.

To load a Global Page:

1. Start with a new report
2. Insert about 4 blank reports, by selecting **New Report** from the **Project** menu or by clicking on **New Report** from the Project toolbar
3. Next, select "Page1" in the first report. Do this by using the Project Tree. Click on "Page1" in the tree or click on the "Page 1" tab in the Page Designer Tab area. Once that Page has been selected, it's name will be highlighted.
4. Add about three Global Pages to the report. Do this by selecting **New Global Page** from the **Project** menu or by clicking on **New Global Page** from the Project toolbar
5. Notice that since the first page in the first report was selected when the Global Pages were added, the new Global Pages were added to the Page Designer Tab area. The pages are also added to the Project Tree under the Global Page Catalog
6. Click on a different Report page. Notice that once a different page is selected, the Page Designer Tab area only has that page in the Page Designer Tab area
7. To add Global Pages to the Page Designer Tab area right-click on a Global Page in the Project Tree and in the menu that pops **up select** Load Page. Try loading all three Global Pages
8. As the Global Pages are loaded they will be seen in the Page Designer Tab area
9. Try loading Global Pages to other pages in the last two reports

To unload a Global Page:

1. Complete the steps from the previous exercise
2. Select a page from Report 3 that contains all the loaded Global Pages
3. There are two ways to unload a page. One way is to use the speed menu; the other is to use quick keys
4. The first way, using the speed menu, requires that you first select the page that needs Global Pages unloaded
5. Next, right-click on the Global Page and **select Unload** Page from **the** speed menu. Do this for **all three** Global Pages in Report 3
6. We will use the second way to unload Global Pages next
7. Select the next page in "Report 4". Make sure it contains all the Global Pages in the Page Designer Tab area
8. Once the page in "Report 4" is selected and you can see the three Global Pages in the Page Designer Tab area, select one of the Global Pages from the Page Designer Tab area
9. Now use the **Ctrl-F4** keystroke to unload the Global Page
10. Try this with the rest of the Global Pages in the Global Page Catalog.

Exercise: Dragging a Component (Ctrl-Drag)

One of the more common items to drag would be to copy a Data Field over to the Page in the Visual Designer. The target could be an existing DataBand or just an open area on the Page. The Data Field will be converted to a DataText or DataMemo on the target area depending on the source's field type. Accomplish this by doing the following steps.

To drag a component:

1. Go to the "Data View Dictionary" node, expand it if it is collapsed
2. Select one of the Data Views and expand it if it is collapsed
3. Select (highlight) a field component to copy
4. Press and hold the Ctrl-key, now drag that field over to the Page

5. Release the mouse and Ctrl-key when it is at the desired location
6. Select the newly copied data field and set its properties as required

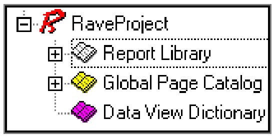
This exercise may have been a little advanced for this point in the manual, but it is put here to give the user the steps necessary to complete a dragging component. So, since a full report has not yet been created, don't worry about getting the report working yet.

Exercise: Changing the Parent of a Component (Alt-Drag)

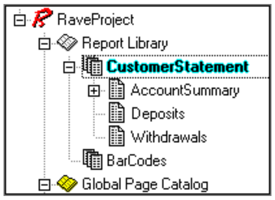
Changing the parent of a component can be very helpful, like when trying to group or ungroup components. For example, say there was a Page that contained components that would be better grouped together into a Section. The current status is that the Page is the parent component of the components that need to be grouped. To group the items together, the parent component would have to be changed to the section component. After this is done, the items will be in a section, which can then be moved around as such. In the reverse sense, maybe a component needs to be taken out of a section and needs to just lay on the Page and not the section, just use the Alt-Drag to complete this task.

Changing the parent of a component:

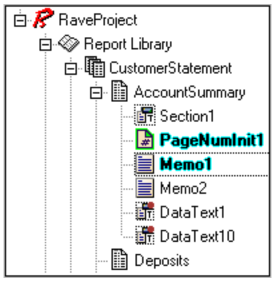
1. Go to the "Report Library" node; expand it if it is collapsed



2. Expand the Report node that contains the Page definition needed

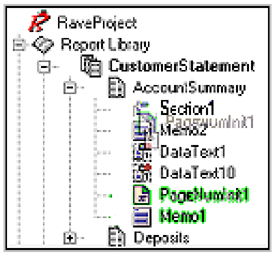


3. Expand the Report node so that both the source and target component can be seen. In Customer Statement, there is a Section component already on the Page. We will change the parent of PageNumInit and Memo1 from the Page to the Section



4. Select the components that will have their parent's changed. To select multiple components, hold the **Shift** key while clicking on each component. When done selecting release the **Shift** key. The desired components should be highlighted
5. Press and hold the Alt key, now drag the source components to the new parent component. In this example, the Alt key is held while selecting and dragging either of the two components. While dragging the components to the new parent, notice that cursor changes as it is placed over the target. When the cursor

indicates it is over the target, release the mouse button, then release the **Alt** key



RaveProject

7. When done, the newly moved components can be set as .
required

Chapter 6

Property Panel

In this Section:

- Defines and describes the Property Panel
- Explains the different types of properties
- Describes the property editor
- Covers the purpose and items in the speed menu

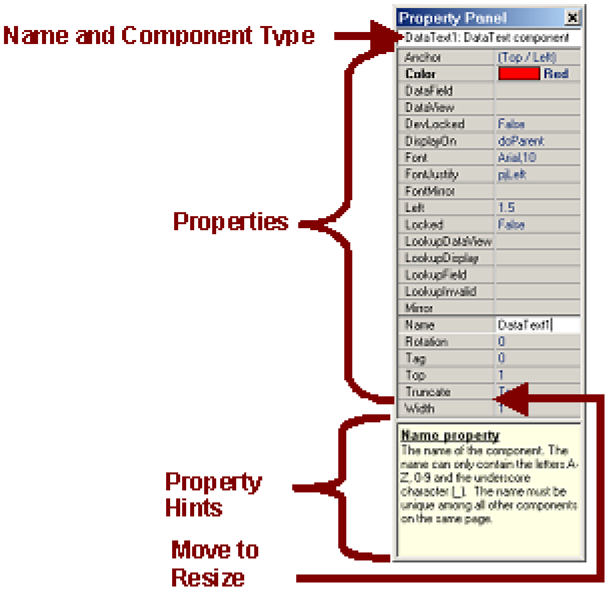
What is the Property Panel

The Property Panel gives information about the project components. It will be most helpful when designing reports because it gives an easy access to all properties associated with each component in a report.

The Property Panel displays and allows modification of values of any component that is placed on the Page. To get property information about a certain component, remember to select that component before looking at the Property Panel (see Selecting a Component in the Page Designer Chapter for more information on how to select an object).

The Property Panel displays the current properties of a component. For example, by clicking on a DataText component, the component will be selected and the Property Panel will display all the properties that are available for the component.

There are three areas to the Property Panel. The first is the very top, which gives the name and type of the component. The second area is the middle, where all the component properties are listed into two columns. The left column displays the property names and the right column displays the current value of those properties. At the bottom of the Property Panel is the third area. A Property Hints box, which gives a brief explanation of the currently selected property, is located in this third area.



Property Panel

DataText1: DataText component

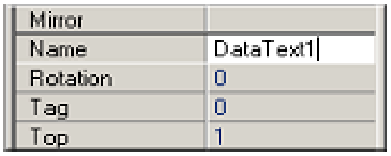
Name	DataText1
Rotation	0
Tag	0
Top	1
Truncate	T
Width	1

Name property
The name of the component. The name can only contain the letters A-Z, 0-9 and the underscore character (_). The name must be unique among all other components on the same page.

In the property listing section (middle), the line that separates the two columns can be moved to resize the columns to allow for better viewing of the names/values. To do this, move the cursor over the line until it changes into the double arrows. Press the left mouse and hold, then drag either left or right to resize the columns.

Remember a component must be selected before the Property Panel will reflect that component's properties. It is also possible to select multiple components at the same time. Once a component is selected, any of the properties in the Panel can be selected by clicking on the desired property name or it's adjacent box selection. With the property selected, it is then possible to change the property value. When any of the fields in the Property Panel are selected, the up/down arrow keys can be used to move up and down between properties.



Mirror	
Name	DataText1
Rotation	0
Tag	0
Top	1

Some of the property names appear in bold. This indicates that the current value differs from the default value. For example, when a DataText component is dropped onto the Page, the default color is Black. By changing the color to something other than Black, like Red, the property name "Color" changes to bold. When the setting is set back to the default value, the bolding will be removed.

Of what use is the bolding? Let's say for a moment that a report that has been designed by a colleague has a problem and it doesn't work. By quickly glancing at the changed properties, this will show what properties have been changed, which might in turn reveal the report functionality problem.

While most components can be selected by clicking directly on them, the Page is a special case. Clicking on the Page itself in the Visual Designer window will clear the Property Panel of all properties, thus not selecting the Page.

To select the properties of the Page, click on the tab at the top (in the area called the Page Designer Tab area) where it shows the page number. Another alternative is to select the Page by clicking on it from the Project Tree.

Types of Properties

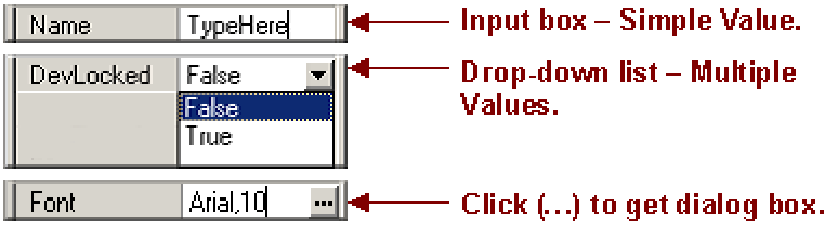
Every property has an associated type. These types can be numerous, different, and can be edited in the Property Panel. The property types can be string, or integer values.

When editing a string property, it is valid to enter any character that can be displayed on the screen. When editing integer values, it is valid to type any numeric value. Decimal numbers are another common property that may be edited.

Often times there are properties that have predefined values that may be selected. These values are displayed in the form of lists containing the valid items that can be selected. There are also properties that have themselves a number of different properties associated with them.

Property Editors

Depending on the type of property selected, there are three types of input boxes available. The first one is a simple input box where a value is typed. The value in the input box can be either numeric, alpha, alphanumeric or one of a set of possible values. A drop down list is the second type of input box a user can encounter. If the values of a property are from a set of previously defined values, a dropdown list will appear by clicking the small down arrow that appears on the right-hand side of the box. Select the desired value by clicking on it. The third option is a dialog box. Some properties require more than one value to set the property (such as fonts). With these properties, a button with three small dots (called an ellipse) appears on the right-hand corner of the property edit box. By clicking on the dots, a dialog box (or wizard) will appear and from this dialog box the multiple properties can be set.



Name TypeHere

DevLocked False
False
True

Font Arial,10

Input box – Simple Value.

Drop-down list – Multiple Values.

Click (...) to get dialog box.

Right-Click Menu

A popup menu will appear when the Property Panel is right-clicked on. This speed menu can be used to set various options of the Property Panel.

Property Hints, the first menu item, hides or shows the Property Hints box which is located at the very bottom of the Property Panel. Highlight Changes, the second menu item, enables or disables the showing of the properties in bold for items that have been changed. Exclude Name, Size and Pos Changes, the third menu item, determines whether Name, Size and position changes (like width and height) are included in the properties that will be bolded when the default value has been changed. The third menu item becomes helpful when many properties have been changed, and there is a need to see changed properties that are not commonly changed.

Exercise: Navigating the Property Panel

Opening the Property Panel

1. If the Property Panel is not visible, then go to the Tools Menu. From the **Tools** sub-menu, choose **Property Panel.** Make sure that there is a check mark next to the selection.

Identifying Property Panel Areas

2. For this example, the base component, the Page, will be used. So, to select the Page component, click on the page tab in the Page Designer Tab area. Notice that after selecting the Page, its properties are displayed in the Property Panel.
3. Next make sure that the Property Hints box is visible at the bottom of the Property Panel, if it isn't already. Right-click anywhere in the Property Panel. A pop-up menu will appear. In this menu, check all the options available.
4. Expand the Property Panel out so that you can see all the properties as well as the Property Hints box. On steps 5 to 8, read the Property Hints box to find more information about each property.

Note: The image to the right has been modified for the next few examples.

5. Click on the Name property. Notice that it corresponds to the name at the top of the Property Panel "Page1: Page component". The other half of this line is the kind of component that the line is referring to. The component is a Page component and thus it is recognized as that here. Type in any name in the Name property and see the change reflected in the top line. The Name property is an example of an edit box of type String.
6. Click on the Bin property down arrow. Notice that this displays a drop-down menu. Drop-down menus give many predetermined options from which to choose.
7. Click on the Grid Spacing input box. This is an example of a Numeric type property. To see what this does, change the Grid Spacing property value and look at the Page when done.
8. Click on the ellipse (…) on the Parameters property to see a dialog box appear. The dialog box is a way that a property with multiple values and options displays its choices.
9. In step 3, the option Highlight Changes was checked in the speed menu (right-click on the Property Panel). Go to the PaperSize property and choose a different paper size. Notice that not only does the paper size change, but that the property is bolded. This bolding becomes helpful in determining when properties have been changed from their default or initial values. Try changing other values such as the page width and height.
10. Also, checked in step 3, is the Exclude Name, Size, and Pos Changes option. This is a very helpful option. In most cases the name, size, and component position on a Page changes often. So, to avoid highlighting these commonly changed properties, this option excludes them from being bolded. Try unselecting this option and changing these properties.

Chapter 7
Generating Output

In this Section:
• Learn how to execute and preview Reports • Explains the options in the Printing Preferences • Learn about the toolbars and options in the Report Preview • Explains the differences in the Report Designer and the Print Preview Output Options dialog • Learn how to export reports to various formats: NDR, PRN, HTML, and PDF

Overview

After a report is created, displaying and making the report electronically mobile will become the next necessary step. There are several ways to get reports onto paper or into electronic formats. This chapter will cover the different ways to display report output and will also go through simple printing.

Executing Reports

One of the most common features used in Rave is the actual report execution. Executing a report allows the user to see the output of the report design. Execution is very similar to what many developers know as compiling and actually does involve a certain amount of internal "compiling".

There are various ways that a report can be executed. It is done either via the Project menu, using the F9 function key, or clicking on the Execute Report icon on the Project toolbar.

Using the F9 function key becomes very handy since execution becomes a very repetitive and common task performed during all phases of design.

When using any of the ways to execute a report, the user is presented with various options. The Output Options dialog shows the different options available at the time of execution.

In later sections of this chapter, each option will be explained in further detail.

Preferences Dialog

Before going through each execution option, there are some preferences that need to be covered and kept in mind before executing a report. Going to the Edit menu and selecting Preferences will display the Preferences dialog box.

The Printing tab in the Preferences dialog box allows various settings to be changed that effect report execution. Some of the options that can be set here are also reflected in the Output Options dialog box that appears when executing. In this section, each of the parameters in the Printing preferences will be explained.

In Output Options area of Printing Preferences, the Show Setup Dialog indicates whether the Output Options dialog (as shown here) is displayed when executing a report. It is sometimes convenient to disable the Output Options dialog, especially if it is during design and testing time. The drawback to this is that some of the parameters that are contained in the dialog box would have to be set before hiding this dialog. Also, any changes desired would have to be done either by re-activating the dialog box or specifying the changes in the Preferences dialog.

The default report print destination is determined by the settings under Print Destination in the Printing Preferences, and is reflected in the Output Options dialog box. Changing the value in the Print Destination area of the Printing Preferences will directly effect the default selection in the Output Options dialog box. There are two options that can be chosen: Preview and Printer. Selecting either one, by choosing the appropriate radio button, will make that option the default value and when the Output Options dialog appears the default value will be selected.

The Preview Grid Options act in much the same way as the Grid (which are the lines seen on the Page in the Visual Designer) does during design time. These Options allow a Grid to be displayed on the Print Preview screen underlying the Report. The Grid settings allow changes for the Print Preview Page, including Grid changes for color, style, and spacing adjustment. If the spacing is both 0 horizontally and vertically, no grid will be displayed in the preview. But, placing numbers in the horizontal and vertical spacing settings, will space the grid appropriately on the Print Preview Page. The Line Color will change the color of the Grid. The Line Style drop-down menu will give different options of line styles.

The Preview Options, as the name indicates, only affect previewing. There are six parameters that can be set. When using the Preview, the window displayed by default is in normal state. Like any other Window, the Preview can be Minimized or Maximized. To set the window display, use the drop down menu in the Initial Window State setting.

The Zoom Factor indicates the default zoom percentage when the preview is first displayed. The Zoom Increment specifies the Zoom percentage that will occur by each click on the Zoom In/Zoom Out icons. As with the Page Designer, the preview screen can have a horizontal ruler, vertical ruler, or both by specifying this in the Ruler Type (use the drop-down menu to make the selection). The measurements can be indicated in either centimeters or inches.

The ShadowDepth is the level of shadow that is displayed on the preview screen and it is only for on screen appearance and aesthetics.

The Monochrome Preview Display check box is there for backward-compatibility with some video cards that would give problems when displaying reports in color. This is not recommended for use, but is there if needed.

Report Preview

Although the Preview is primarily used for previewing a report, the Preview option has many more capabilities than what is intuitively understood from its name.

Begin by executing a report. When the Output Options dialog appears, the Preview radio button can be selected. Clicking OK will continue with the Preview process.

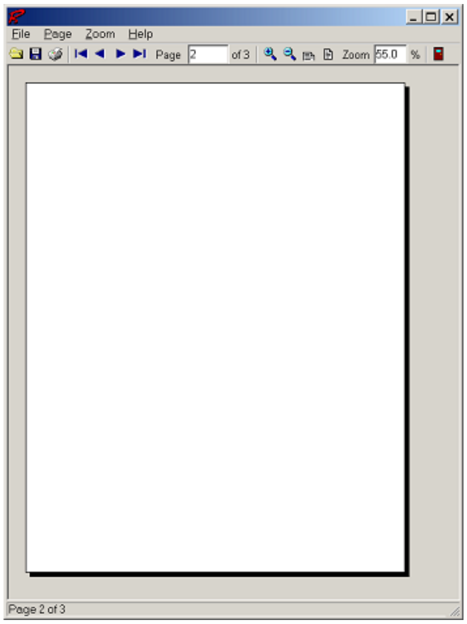
1

□ Collate

□ Duplex

The Preview screen is used to see the output of the designed report. The actual appearance on the screen resembles that of the printed report. The screen is based on a page-by-page output. There is a toolbar at the top of the Preview screen that allows navigation as well as other functions, which are explained in the following paragraphs.



Most of the functions permitted in the Preview screen can either be performed using the toolbar or through the Preview menu options. We will go through and explain the menu options in the rest of this section.

The first group of icons (separated by a vertical line on the toolbar), can be found in the File menu. They are used for opening, saving, printing, and exiting the Preview of a report.

Although the Preview screen displays the current report in the designer, it can also be used to load a previously saved report (with an NDR extension). This can be done by clicking on Open in the File menu. A dialog box appears prompting for the desired report file. When the NDR file is opened, the report that was previously in the Preview is discarded. This does not mean that the report can not be regenerated. To get the previous report, simply re-execute the report and choose Preview. Only the report that was Previewed upon execution can be regenerated. Other reports can only be revisited if they were previously saved or if their projects are re-opened and re-executed.

The Save As is used to save the report in the Preview. Click on Save As and the Save File dialog appears. Use this dialog to save the current report to various formats, including PDF and HTML (these two formats are covered later on this chapter). Another format that a report can be saved to is the NDR report type, again this is a Rave snapshot of the report.

Although reports can be printed directly by choosing Execute and then Printer, the Preview screen also provides this option, since many times it is necessary to check the preview of the report before actually printing it.

The remaining functions directly affect the viewing of the report on the Preview screen. The second section on the toolbar and the items in the Page menu are used for navigation between pages. The buttons used to designate the options will look familiar to database users, since they follow the same convention. The first button is used to move to the first page of the report. The second button moves to the previous page. The third button is used to move to the next page, and the last button can be used to move to the end of the report. On the toolbar, there is a page indicator, which at all times reflects the current page and the number of total pages. This page indicator can also be used to go to a page directly by typing the page in the edit box. Or use the Go to Page in the Page menu. For example, entering 10 in the edit box will display the 10th page of the report (providing there are 10 or more pages available).

Zooming is also available in Preview. The magnifying glass containing a plus sign will zoom in on the page, while the magnifying glass with a minus sign will zoom out. Similar to the page edit box, there is a zoom box that is used both for displaying the actual zoom and allowing the user to enter a specific percentage value. Just type in a number and the Preview will be zoomed in or out to that zoom percentage.

There are also two preset zoom values for fast navigation. The first one is the Fit to Page Width option. By clicking on this, the report can be adjusted so that the width of the page takes up the entire region of the preview screen. The second preset is Fit to Page. It can be used to view the entire page on the screen. The side effect of this is that although the report can be viewed as a whole, the actual contents might be difficult to read. Normally this can be used to get a general overview of the report layout.

The preview window can be exited by either clicking on the Door icon located on the far right of the toolbar or by clicking on the "X" button on the window (like any other window).

Executing to the Printer

Printing can be done, as mentioned before, via the Preview screen or directly when executing the Report and choosing Printer as the Report Destination. One thing to notice is that the Output Options dialogs are a little different when selected from the Rave Designer and from the Print Preview.

The Output Options dialog that appears from the Rave Designer has more options than just printing, as shown in the image.

In the Output Options Dialog there is a Setup option for Printing. The Setup button is underneath the Cancel button and can be used to adjust the printer settings prior to the actual printing. This includes options such as whether the report should be printed in landscape or portrait, the resolution of the printer, the color depth, paper size, etc.

The dialog box also includes several Options such as the number of copies to be printed, whether the copies should be collated, or duplex printed.

In the Output Options Dialog from the Report Preview (see image), there are some different options available. The Print Range has three different options. The All option means to print all pages in the report. The Selection option means to print a selection of pages not adjacent to each other, i.e. "1,3,5,7" or "1,9-5,20". The Pages option prints a range of consecutive pages, i.e. "1-10" or "15-19".

NDR & PRN Files

Printing to a file can be done several ways. We will discuss two that can be done directly from the Output Options dialog. The Output Options dialog is obtained by executing the report (use the F9 key or execute through the Project menu).

The NDR, or the Rave Format, is a Rave snapshot of the report. An NDR file can be seen and opened from the Preview window, but it cannot be changed or edited in the Rave Designer.

The PRN file is the Native Printer Output type file. When this option is selected, the information that is usually sent to the printer to print a report is instead sent to a file. This file is saved based on the file name the user gives.

To create either type of file, simply select desired format and then fill the empty File edit box with a name for the file.

The NDR can also be made using the Save As option in the File menu in the Report Preview window. Using the Save as type drop-down menu and entering a File name will create the NDR file.

There are other ways to print to a file. These are only two formats. We will cover PDF and HTML file in the next sections.

HTML

Rave has the capability to save reports as HTML files. This makes it easy to have reports readily available over the Internet or through a company intranet. HTML files can be created in the Visual Designer and in the Report Preview window.

To save a report as HTML from the Visual Designer, first get to the Output Options Dialog. Do this by using the Execute Report from the Project menu, or by using the F9 key.

In the Output Options dialog box, choose the File option from the Report Destination area. Using the Format drop down box to get to the HTML option will set the format to HTML. Clicking on the disk, will allow the user to set the path of where to save the file to and to name the HTML file.

Once a report is saved and properly formatted it may be helpful to first Preview the report. Preview the report by executing the report and choosing Preview from the Output Options dialog. After looking the report over in the Report Preview, choose the Save As option in the File menu. This will bring up the Save File dialog, where a report can be saved into HTML.

To save the HTML format, in the Save as type drop-down menu, select HTML files. Then type in the name of the new HTML file in the File name edit box. When done, click Save.

Each page of the report will be saved as an individual HTML file. For example, a three-page report would produce three pages of HTML. On each page, navigations links to the previous and next pages are provided. Once saved, the HTML files can be viewed with any Internet browser.

PDF

A truly useful report is one that is portable over many different platforms. The PDF feature of Rave makes this possible with the help of a free viewer. A report can be saved into PDF format, and through the use of the Free Adobe Acrobat Reader, any person can open, view, and print the report.

This option is available through the Execute Report (also F9) option in the Visual Designer File menu or through Save As in the Report Preview File menu. Using the Report Preview allows the user to see the layout of the report before saving it into PDF format.

After selecting Execute the Output Options dialog will appear from which the format can be chosen. Also, the file name of the PDF can be set.

In the Print Preview, using Save As will bring up the Save File dialog and from there you can save the report as a PDF type, as well as choose the file name.

To save a PDF, in the Save as type drop-down menu, select Adobe PDF. Then, type in the name of the new PDF in the File name edit box. When done, click Save.

RTF

Rave also has the capability to save reports as a RTF (Rich Text Format) file. This file format can be loaded into many word processors for a wide variety of reasons. For example, your report(s) could be included in a company document as an attachment. Or a report could be loaded into a word processor and then selected lines could be edited (highlighted, bold) to emphasis a point to a particular audience.

This option is available through the Execute Report (also F9) option in the Visual Designer File menu or through Save As in the Report Preview File menu. Using the Report Preview allows the user to see the layout of the report before saving it into RTF format.

After selecting Execute the Output Options dialog will appear from which the output format can be chosen. Also, the file name of the output file can be set.

In the Print Preview, using "Save As" will bring up the "Save File" dialog and from there you can save the report as a RTF type, as well as choose the file name.

To save a RTF, in the "Save As" type drop-down menu, select RTF. Then, type in the name of the new RTF in the File name edit box. When done, click Save.

Exercise: Changing Printing Preferences

Change Print Destination

1. Before beginning this exercise, create a new Project and place a few visual and text components on the Page.
2. First, go to the Printing Preferences tab by either using the Edit Preferences icon on the Designer Toolbar, or by selecting Preferences in the Edit menu.
3. Click on **Printing** in the Preferences option area (left of the screen).
4. Look at the Print Destination area and select **Preview**.
5. Now close the Preferences window by selecting the **OK** button.
6. Execute the report by pressing the **F9** key, or by selecting **Execute** from the **File** menu.
7. When the Output Options dialog appears, notice that the Preview option is the default value selected. Click **Cancel** when done.
8. Now, open the Printing Preferences again, and select **Printer** as the Print Destination. Click **OK** when done.
9. Execute the report again, and in the Output Options dialog, notice that the Printer is now the default value selected.

1. Before beginning this exercise, create a new Project and place a few visual and text components on the Page.
2. First, go to the Printing Preferences by either using the Edit Preferences icon on the Designer Toolbar, or by selecting **Preferences** in the Edit menu.
3. Next, make sure that Preview is selected in Print Destination.
4. Uncheck the **Show Output Options Dialog** in the Output Options area.
5. Select **OK** to close the Preferences dialog.
6. Execute the report by pressing the **F9** key, or by selecting **Execute** from the **File** menu. Notice that the Output Options Dialog did not appear; instead the execution went directly to the Preview. If Printer had been selected in the Print Destination, the report would have been sent to the printer.
7. To get the Output Options dialog back, go to the Printing Preferences and re-check the **Show Output Options Dialog** in the Output Options area.

Grid Lines and Options in Preview

1. Before beginning this exercise, create a new Project and place a few visual and text components on the Page.
2. First, go to Printing Preferences by either using the Edit Preferences icon on the Designer Toolbar, or by selecting **Preferences** in the **Edit** menu.
3. Next, make sure that **Preview** is selected in Print Destination and uncheck the **Show Output Options Dialog** in the Output Options area. We will be exploring the Preview for this exercise, so using the Print Destination and **Show Output Options Dialog** to

execute quickly to Preview will be very helpful.

4. When in the Printing Preferences dialog, make sure the initial values of the Preview Grid Options and the Preview Options are exactly as seen in the image.
5. Click **OK,** when done.
6. Execute the report and just view the Preview of the window.
7. Now close the Preview window, and Open up the Printing Preferences.
8. In the Preview Grid Options, change the **Horizontal Spacing** and **Vertical Spacing** to 1. Then change the line color by clicking on the color wheel.
9. Click **OK** when done.
10. Execute the report and notice the lines on the report in the Preview. These lines will not appear on a print out, but are there if needed to help check layout and formatting.
11. Now, close the Preview and go to the Printing Preferences again. Change the **Line Style** in the Preview Grid Options area to **Dash**. Also, change the **Initial Window State** to **Minimized**.
12. Then, in the Preview Options, change the **Ruler Type** to **BothIn**. This will display both the horizontal and vertical ruler in inches in the Preview. Also, change the **Shadow Depth** to **10**.
13. Click **OK** when done.
14. Execute the report.
15. First of all noticed that the Preview is minimized. This was set by the Initial Window State. To expand the window to see the Preview, click on the first or second button.
16. Once the window is restored or maximized. There are several things to notice. First see the dashed gridlines on the Page. These can be useful to check object alignment on the Page. Also, notice the vertical and horizontal ruler. At the very far right edge of the Page, notice the deep shadow behind the Page.
17. When done, go back into the Printing Preferences dialog. Put all settings back to their original values. The image shown displays our values. These values will be used for the remaining exercises in this chapter.

Exercise: Preview and Creating Portable Files

1. Before beginning, create a New Project. And on four pages, place text and objects.
2. Link the four pages together. Selecting the Page and the Property Panel was covered in the previous chapter. Select the first page and in the Property Panel use the drop-down menu in **GotoPage** to select **Page2**. Do this for every page. Select page 2, and make **GotoPage** equal to **Page3**. Select page 3, and make **GotoPage** equal to **Page4**.
3. Next, go to the Preview window by executing the report. Select Preview from the Output Options dialog.
4. At the top of the Preview window on the toolbar, there should be an edit box that has the number 1. That area should read Page 1 of 4.

Navigating through Preview

5. Since there is more than one page, use the navigation buttons on the toolbar or in the **Page** menu. Use the **Go to Page #** to jump to any page in the report.
6. Next, use the zoom tools to get a closer and an overall look of the report pages. This also will allow you to become more familiar with moving around in the Preview.

Creating an NDR File through the Preview

7. To create an NDR (a Rave Snapshot File) from the Preview Window, go to the **Save As** option in the **File** menu.

8. When the Save File dialog appears, use the **Save as type** drop-down menu to select NDR files. And put in the name of the NDR file in the **File name** edit box, in this example we used Text.ndr. Click **Save** when done.
9. Even though the file is already in the Preview, let's try opening the Test.ndr file.
10. Choose **Open** in the **File** menu.
11. The Open File dialog will appear. Look for the Test.ndr file in the directory you placed it. Click **Open** when done.
12. The Preview will most likely look the same, as we did not change the report. But, look at the top of the Preview window to where the name of the file is listed. So, as you peruse through different NDR files, the name will always be listed at the top of the Preview. Nothing in an NDR file can be changed; it is simply a way to view the report.

Creating a PDF file through the Preview

13. Since we are no longer using the executed file, close the Preview window. Execute the file and select **Preview** again.
14. Now, select **Open** from the **File** menu.
15. In the Save File dialog, select Adobe PDF from the **Save as type** drop-down menu. Then, type in a name in the **File name** edit box, this example uses test.pdf.
16. Click **Save** when done.
17. At this point you can go out to where your file was saved and open the PDF file. If you do not have the PDF reader, go to www.adobe.com and download the free reader.

Creating HTML Files

18. In the Preview window, select **Open** from the **File** menu.
19. In the Save File dialog, choose **HTML File** in the drop-down menu for **Save as type**. Then type in a name in the **File name** edit box.
20. Click **Save** when done.
21. When done you can go to the HTML file that was saved. We saved our html files in My Documents. You will notice that there are four pages of the test.html, with consecutive numbers after the test title. Each page in the report will have an associated HTML page.
22. Below is the first page of our test.html. This is test1.html, as it is the first page. Note that at the bottom there are navigation links to the get to the next pages.

Previous Page -------- Next Page

Document: Done

Exercise: Printing a Report through the Preview

1. In the Preview window, select **Print** from the **File** menu.
2. This will bring up the Output Options dialog. Use any of the print ranges to get any of the pages of the report that you want.
3. When done, close the preview window.
4. Then execute the report, and select Printer. This too will send your report to the printer.

Exercise: Printing to a File (NDR & PRN)

1. Execute a report and select **File**.
2. In the **Format** drop-down box, there will be two options. **Rave Format** (.NDR) and **Native Printer Output** (.PRN).
3. Make the desired choice.
4. In the edit box next to **File**, type in the name of the file.
5. Click **OK** when done

Chapter 8

Utility Toolbars

In this Section:

- Alignment Toolbar introduced with Order, Spacing, and Alignment of components
- Designer Toolbar introduced and its relation with Preferences explained
- How to read the Color Palette Toolbar and its designations
- Font Editor briefly introduced and explained
- Use of the Line Editor Toolbar is explained
- Functions of the Project Toolbar are introduced
- Zoom Toolbar functions covered

Tools are Tools

Even though the toolbars are called toolbars, there are two distinct types, relating to the function performed. There are Utility Toolbars and Component Toolbars.

A tool is typically used to modify an item already on the Page, usually a component. A component is an object placed on the Page, like a Region, Shape, Line, or Barcode (for more information regarding components, see the Components Overview chapter).

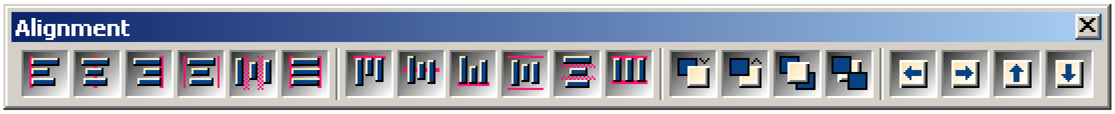
This chapter will cover the Utility Toolbars, which contains tools (Color, Alignment, etc.) used to modify components. Utility Toolbars include the Alignment Toolbar, the Color Palette Toolbar, the Fill Toolbar, the Font Editor Toolbar, the Line Editor Toolbar, the Project Toolbar, and the Zoom Toolbar.

Using Tools

The Utility Toolbars act on components and the Page Designer. Either a component or the Page has to be selected prior to using the toolbar. For example, to change the fill color of a Square, select the Square and then click on the required color.

By right clicking on a component, a popup menu will appear giving access to other options that can change the component. These options are also available from the toolbars; the popup menu just gives faster, easier access.

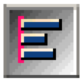
Alignment Toolbar



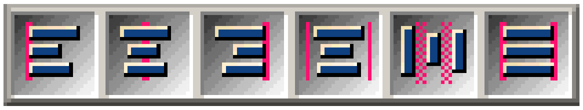
The Alignment Toolbar is used to align, order, and move a group of components on the Page. It is important to note that some of the Alignment options only make sense when more than one component is selected.

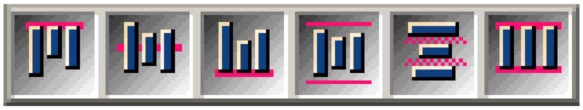
The first step is to select the components that need to be aligned. To select multiple items, hold the shift key down and click the mouse on each object that needs to be aligned.

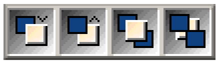
For most alignment options, the ***first*** component selected is what determines the alignment position. For example, when choosing Align Left, all selected components will be left aligned to the position of the first selected component. A red line on the icon designates the actual alignment.



The Alignment Toolbar is divided into four sections by separators. The first two sections control horizontal and vertical alignment options. Both allow components to align on the edges, centers, or to be spaced equally.

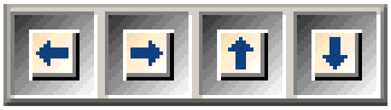




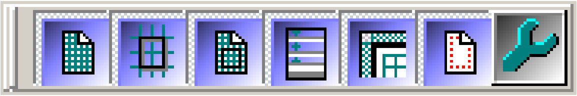


The Order Alignment determines the Z order (depth along the Z axis) between components. Order Alignment does not require more than one component to be selected. To establish the Z order of a component, select the component and right-click the mouse button to display the popup menu. From the Order submenu choose one of the four options: Move Forward, Move Behind, Bring to Front or Send to Back. The figure to the right shows a Rectangle with an Ellipse imposed in front of it. To move the Ellipse to the back of the Rectangle, right-click the Ellipse (by right-clicking on a component previously unselected, it will select it and bring up the popup menu) and choose Send to Back from the Order submenu.

There are an additional four buttons on the Alignment Toolbar, Tap Tools, which allows small incremented movements of a component (or group of components). To move selected component(s), click on the corresponding arrow to move the component(s) towards the desired direction.



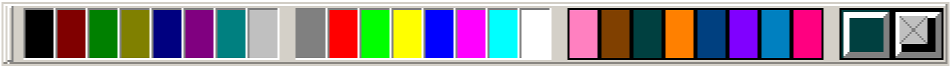
Designer Toolbar



The Designer Toolbar is used to control the Preferences for the Page. All of the Designer Toolbar items toggle. By clicking on a button, the property of the component associated with the button will change status. To change it back to the previous state, click on the button once more. The top toolbar shows what the buttons look like when they are not pressed (toggle status off) and the bottom toolbar is the resulting toolbar when the buttons have been depressed (toggle status on).

"Activate Grid"	controls whether the grid lines are visible or not on the Page Layout
"Snap To Grid"	controls whether the objects on the Page 'snap'. Snap means that the component will only move and resize according to where the Grid Lines are present
"Grid On Top"	determines whether the Grid Lines are always on top of the components or not (i.e. are not hidden when components are placed on the Page Designer)
"Always Show Band Headers"	controls the displaying of band headers
"Show Rulers"	toggles the appearance of guide rulers in the environment
"Show Waste Area"	displays the space between the Page boundary and the end of the Page Setup Boundary
"Edit Preferences"	will bring up the Preferences dialog

Color Palette



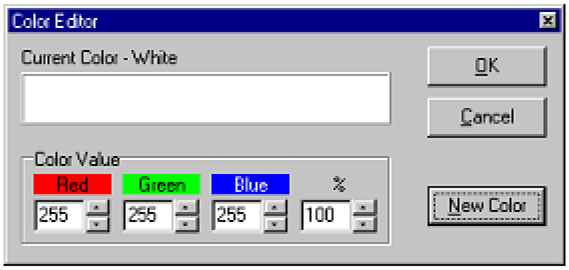
The Color Palette is the tool used to change a color of a selected object such as a Line, Text component, or the fill area in one of the shapes (Circle, Ellipse, Rectangle, or Square). Color palettes are composed of several sections that show custom, standard and current colors. The left button on the right side displays the currently selected Primary, while the right button shows current Secondary color. All other color squares serve as the Color Palette from which you can select.

To change the color of an object, select the object and either left or right-click on the Color Palette. A left-click selects the Foreground Color (Primary) while the right-click selects the Background Color (Secondary).

When a Primary Color is selected, a "1" will be placed on the corresponding color indicator on the palette. Similarly, a "2" will be placed indicating the Secondary Color.

To change the color of an object (like a Rectangle), first select it and then click on the desired color with the left mouse button. To change the Fill Color, click on the desired color with the right mouse button.

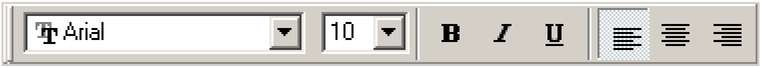
Double-clicking on the user defined Custom Colors (right side) or on the Foreground and Background Color boxes will open a more detailed color control window called the Color Editor. From the Color Editor, custom colors can be created by adjusting the red, green and blue values, as well as the saturation of the color by increasing or decreasing the color percentage.



To create and save a new color, use one of the Custom Colors to enter into the Color Editor, then click on the New Color button and choose the desired color from the Color dialog box. By entering the Color Editor from one of the Custom Color boxes, the new color will be saved. If the Color Editor is entered from either the Primary or Secondary Color boxes, the color will only be saved in those boxes until a new color is chosen (either by clicking on the right or left mouse button or by the creation of another color).

It is important to note that the actual exhibited colors are dependent on the display settings of the computer. If there are issues with colored objects when transferring reports from one system to another, check the display color settings. A 256-color setting only uses 256 colors for display, where as a True Color setting uses millions of colors. Thus, for example, if a Report is created on a system set at True Color, and then viewed on another system set at 256 Colors, some objects may appear grainy or to have the wrong color shadings.

Font Editor



The Font Editor can be used to change the type, size, attributes and alignment of any text component in the report. Its aspect and functioning is very similar to Font Toolbars found in the most commonly used Word Processors.

To change the Font settings of a Text component, first select the component. The font type can be adjusted by choosing a font from the drop-down list. Similarly the size can be changed by clicking on one of the available sizes for the font in question. The **Bold**, *Italic* and Underline buttons are toggled depending on the state of the text. To set the font to **Bold**, just click on the Text component and then press the **Bold** button. The button will then remain depressed until it is clicked on again or until focus is moved to a different text object that does not have the **Bold** set. The *Italics* and Underline button work in much the same way. There are three alignment buttons that indicate the alignment of the text within the area it is contained, and the options are left, centered, and right-justified. All text-based components have a property called Font that appears in the Property Panel when the component is selected. Any changes made to the Font, are reflected both in the font toolbar and in the Font property.

NOTE: It is important to note that if a font is chosen on the development machine and this font is not available on the deployment or any other machine, Rave will assign the next most similar font to the one chosen.

Line Editor

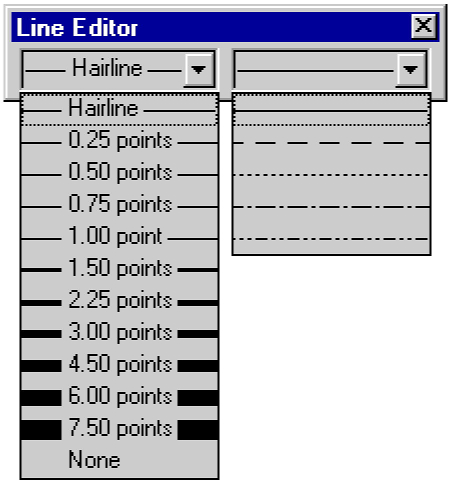
Use the Line Editor to modify the style and thickness of a line or the border of a shape. The Line

Editor Toolbar has several selections to choose from including line styles (solid or combinations of dots and dashes).

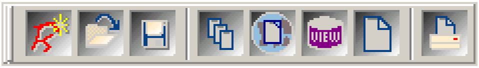
To change the style of a line, first select the line or shape, and then choose the point size of the line as Hairline. Finally, choose the style of the line.

To change the thickness of a solid line, first select the line or shape. Then choose the point size desired.

Line style only (dashes, dots, etc) applies if the line thickness is hairline. If a line is set to a certain style (like dashes) and then given a thickness other than hairline, the line style will be changed to a solid line.



Project Toolbar



The Project Toolbar provides the basic functionalities for a Project. It gives a quick easy way to complete the common tasks associated with managing a Project. All options available on the Project Toolbar are accessible through the main Project menu in Rave.

The first three icons deal with managing projects:

	"New Project"	creates a new Project
	"Open Project"	opens a previ ously saved Project
	"Save Project"	saves the current Project

The next three icons deal with creating specific aspects of the current project:

"New Report" will create a new Report that will be contained in the same Project file (.rav file). Rave can have more than one Report per Project file

"New Global Page" creates a new Global Page

"New Data View" allows the creation of DataViews that are associated to the current Project. Please see Connecting to Data chapter more information about DataViews.

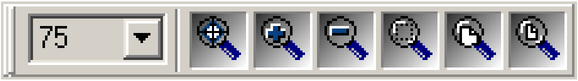
The last two icons deal with the currently selected Report.

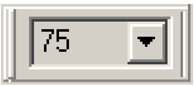
"New Page" creates a new Page in current Report

"Execute Report" execute (or print) the current Report

Zoom Toolbar

The Zoom Toolbar allows the user to Zoom In to view the details of a document better or Zoom Out to view the overall Page uniformity. Within the Zoom Toolbar, there are several ways to zoom into and out from the details of the document.





To Zoom by Percentage, the Zoom Factor drop menu has many preset percentage factors to Zoom in and Zoom out. Simply choose the desired Zoom Percentage. If one of the presets is not adequate the you can specify a percentage by typing the desired percentage into the edit box next to the zoom factor drop menu.

Another method to get a customized size is to click on the Zoom Tool (magnifying glass). Drag the tool over the specified area that needs to be magnified.

For a simple manual Zoom In and Zoom Out, click on the magnifying glasses with the "+" and "-" sign. Nothing will need to be selected to use this tool. Each click is set to a specified incremental amount that is set in the Preference settings. To get to the settings area, go to Preferences in the Edit Menu. In the Edit Menu, select the Designer Tab. In the area called "Zoom Increment", increase or decrease the percentage by using the up/down arrows to increase the percentage or simply type in the percentage.

To zoom in on selected items, use the magnifying glass with the dashed box. First select the desired item(s), and then click on this tool. The viewable area will frame all item(s) selected.

.

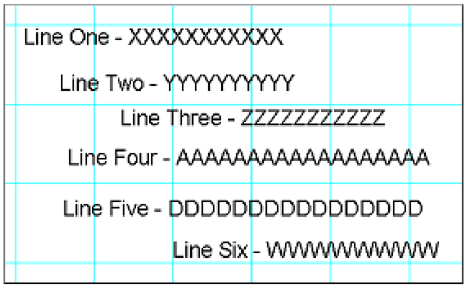
Use the "Page Width" button to zoom to the full width of the currently selected Page.

Use the "Whole Page" button to Zoom to the full page size of the current page.

Exercise: Aligning Components

This exercise will demonstrate how to align components. The example images have six numbered lines of text.

1. To begin, drop several Text components onto a Page. In this example, the components have been number labeled



Line One - XXXXXXXXXXX

Line Two - YYYYYYYYYY

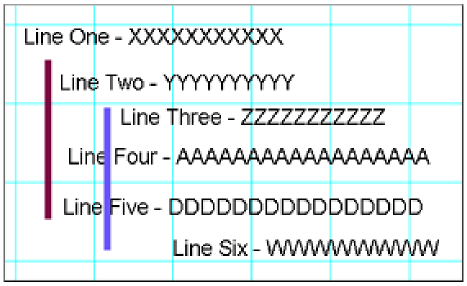
Line Three - ZZZZZZZZZZZ

Line Four - AAAAAAAAAAAAAAAAAA

Line Five - DDDDDDDDDDDDDDDD

Line Six - WWWWWWWWWWW

2. Lines two, four, and five will be aligned. Lines three and six will also be aligned



Line One - XXXXXXXXXXX

Line Two - YYYYYYYYYY

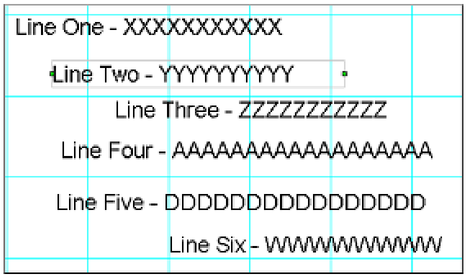
Line Three - ZZZZZZZZZZZ

Line Four - AAAAAAAAAAAAAAAAAA

Line Five - DDDDDDDDDDDDDDDD

Line Six - WWWWWWWWWWW

3. Select Line Two. This will be the primary component that the rest of the components alignments will be based on



Line One - XXXXXXXXXXX

Line Two - YYYYYYYYYY

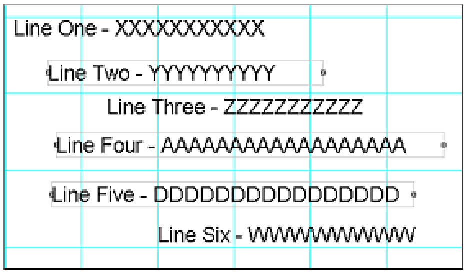
Line Three - ZZZZZZZZZZZ

Line Four - AAAAAAAAAAAAAAAAAA

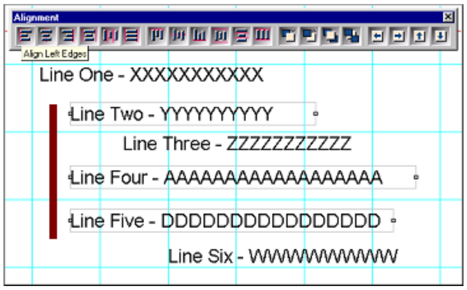
Line Five - DDDDDDDDDDDDDDDD

Line Six - WWWWWWWWWWW

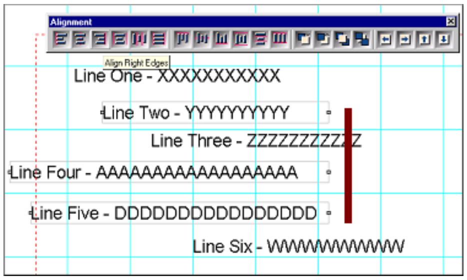
4. While holding the shift key, select lines Four and Five to be aligned with Line Two. Notice the light gray border that appears with pips



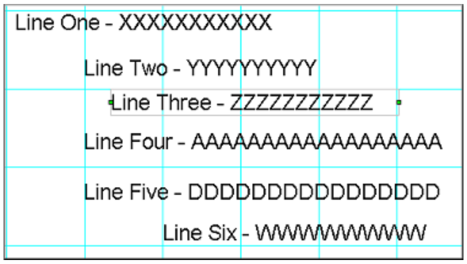
5. Once all components have been selected, choose Align Left Edges on the Alignment Toolbar. Notice that all three components left edges have been aligned



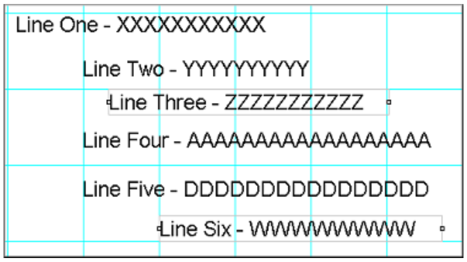
6. To further show how the alignment works, click on the Align Right Edges button on the Alignment Toolbar



7. Go through the rest of the Alignment tools to see how they function
8. Let's align the second set of text. First, select the primary component to base the alignment on, in this case Line Three



9. Then select the other component(s) that will be aligned, by holding the shift key and clicking on Line Six



Line One - XXXXXXXXXXX

Line Two - YYYYYYYYYY

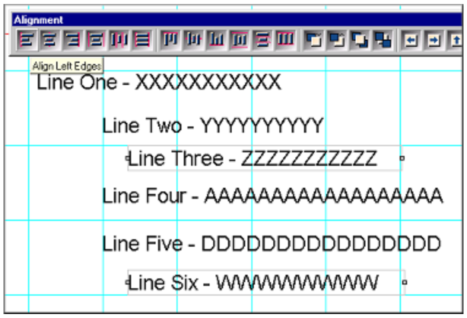
Line Three - ZZZZZZZZZZZ

Line Four - AAAAAAAAAAAAAAAAAA

Line Five - DDDDDDDDDDDDDDDD

Line Six - WWWWWWWWWWW

10. Then click on the Align Left Edges to align the components.



Line One - XXXXXXXXXXX

Line Two - YYYYYYYYYY

Line Three - ZZZZZZZZZZZ

Line Four - AAAAAAAAAAAAAAAAAA

Line Five - DDDDDDDDDDDDDDDD

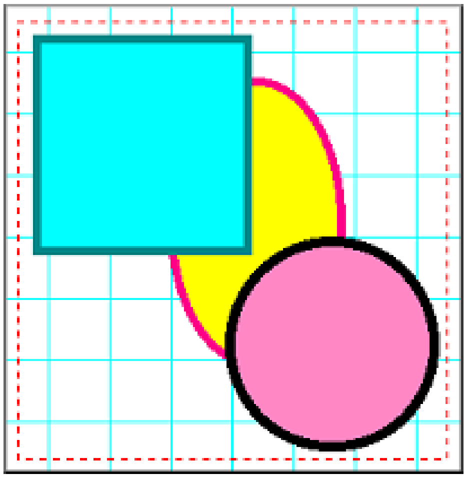
Line Six - WWWWWWWWWWW

Exercise: Ordering Components

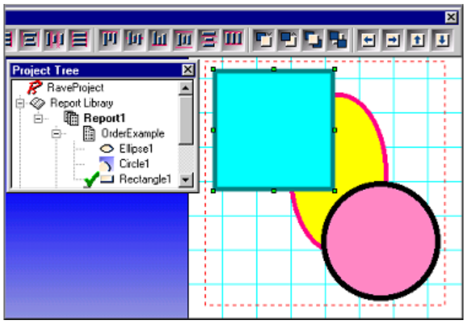
Ordering refers to the ordering of components along the Z-axis. This is the axis that comes out of the Page.

To order components along the Z-Axis, the order buttons on the Alignment Toolbar must be used.

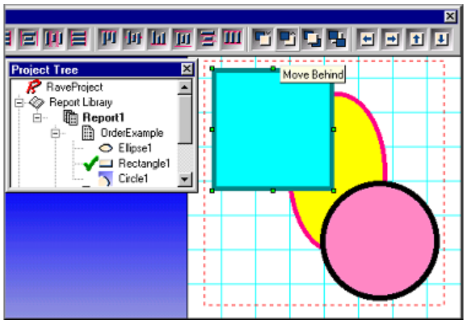
1. To begin, there must first be components on page. These can be any components. For this example we will use a Rectangle, Oval, and Circle



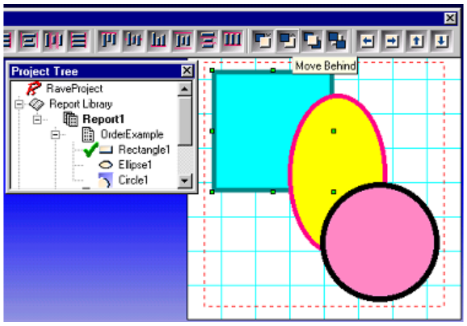
2. First select a component to move. In this example, the rectangle will be moved behind the Oval. Notice in the Project Tree the placement of the Rectangle component



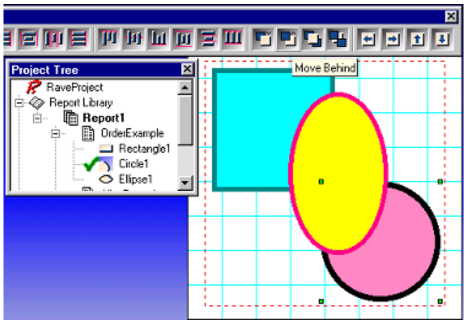
3. Once the rectangle is selected click on the Move Behind button on the Alignment Toolbar. Notice that after clicking the button once the rectangle has not moved behind anything yet, but on the Project Tree the rectangle has moved up the tree



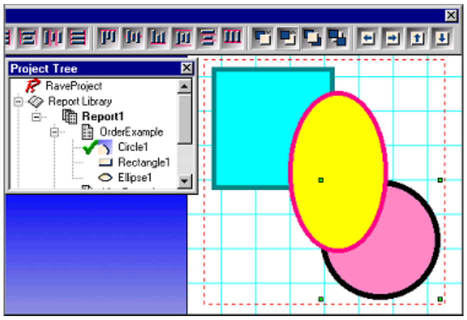
4. Try clicking on the Move Behind button one more time. The rectangle will move up the Project Tree and the Rectangle on the page will move behind the Ellipse



5. For the second component, select the circle and click the Move Behind button. The Circle component will move up the tree and move behind the Ellipse



6. Click on the Move Behind button once more and the Circle will move up the tree one more time and remain behind the Ellipse



Exercise: Snapping to the grid

Snapping to Grid refers to the moving and resizing of components according to where the grid lines on the page are present.

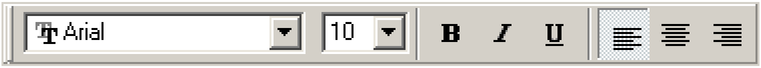
1. To begin, bring up the Preferences Dialog box by selecting Preferences from the Edit menu
2. Select the Defaults tab and look for the area labeled Grid Spacing
3. In Grid Spacing, change to .02 units. Then look for the area called Draw Grid Every
4. In Draw Grid Every, enter 1 line (type or use the up and down arrow). Draw Grid Every 1 (that's what we chose) line, will show every Grid line made. If this were changed to Draw Grid Every 3 lines, then for every third line the Grid would be marked in the Visual Designer
5. Next go to the Project menu and choose New. This will create a new Project, as well as a new Report Page, that is based on the preferences that were just changed in the previous steps. Remember the Grid lines serve only as page guides for designing reports; they do not show up in any report executions
6. Go to the Designer Toolbar and click on the Snap To Grid
7. Now that the Report Page is created, drop a rectangle on the page
8. Now move the rectangle around and notice that the rectangle only moves according to where the lines are located. Try using the tap buttons. Notice that the component doesn't seem to move until the tap button moves are on one of the grid lines
9. Now to go the Designer Toolbar and click on the Snap To Grid button to turn the feature off
10. Move the rectangle and notice that the rectangle will move to positions between the grid lines

Exercise: Changing Line Size and Color of a Rectangle

1. Create a new Report Page
2. Drop a rectangle component on the Page
3. Look at the Color Toolbar. Notice the color blocks marked 1 and 2, you can review Primary and Secondary Designations in this chapter
4. To make the color change more notable in this example we will increase the boundary lines of the Rectangle. Bring up the Lines Toolbar. Select the Rectangle. Then in the first Lines Toolbar drop-down box, choose a larger border size. In this example, the borderline has been increased from hairline to 2.25 points.
5. Left-click on any color in the Color Toolbar. In this example the color Olive was selected. Notice that the border has changed to Olive. Also notice that the Primary Color has changed. The Primary Color is the color of the border.
6. **Right-click** on any color. In this example the color Blue was selected. Notice that the fill inside the Rectangle has changed to Blue. Also notice that the Secondary Color has changed. The Secondary Color is the color of the inside of the Rectangle

Exercise: Changing Fonts

1. Create a new Report Page.
2. Drop four Text components on the Page.
3. Select a component, and then view the Font Toolbar.



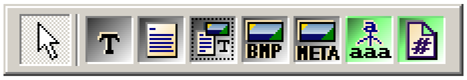
4. On drop-down menu displaying the Font Name, click on the down arrow and choose a desired font.
5. Go to the next component and repeat Steps 3 and 4. Do this for all remaining Text components.
6. Also, try using the font-sizing drop-down menu. As well as the **Bold**, *Italic*, and Underline options
7. The last three buttons to the far right deal with placing the font as left-justified, centered, and right-justified. Practice using these options to get the desired formatting effect.

Chapter 9
Standard Components

In this Section:

- Explains the difference between a Text component and a Memo component
- How to use a Section and its relationship to the Project Tree
- How to insert BMP and META files

Overview



The Standard Toolbar contains seven components: Text, Memo, Section, Bitmap, Metafile, FontMaster, and PageNumInit. Several of the Standard Components are used most frequently when designing reports. This chapter will provide a detailed explanation of the first five. The remaining two (FontMaster and PageNumInit) are covered in the Advanced Components chapter.

Access to the Standard Toolbar is achieved in the same way as with other toolbars. If it is not present on the screen, it can be displayed by selecting it from the Toolbar submenu in the Tools menu.

Text

The Text component is useful for displaying a single line of text on the report. It acts basically like a label that can contain simple text (not data). When placed on the report, the Text box is surrounded with a box that indicates its boundaries. This can only be seen while the text component is selected (represented by the pips).

The component can be used for labels, such as for figure or graphical titles, floating text, form titles, and in general just about anything that is denoted by a single line of text.

When the component is selected, the length of the text can be adjusted by resizing it using the pips. Note however that the height of the text is self-adjusting and does not require further intervention by the user.

Like any other text-based component, there is a Font property that can be used to change the font type, size and style. The color can be set using the Color property. The actual text of the component, which is seen on the screen, is denoted by the Text property.

There is an additional property called Rotation, which can be used to rotate the text by a specified number of degrees. The effect can only be seen at runtime.

Memo

Memo components are similar to Text components. However the most noticeable difference is that Memos can contain multiple lines of text. Memos can be used on forms for areas of explanation, and for titles or comments that are longer than one line.

Similar to the Text component, the border around the Memo can only be seen when the component is selected. When setting the Font of the Memo, all the lines of text in the Memo will have the same font. *It is not possible to set different fonts for certain parts of the text*.

To change the text in the Memo, go to the Property Panel and use the Text property. The Text property will show "(Memo)" and an ellipse button, which are three dots. Click on the ellipse button. This will open up the Memo Editor. Text can be entered into the Memo Editor.

One of the main problems with using multi-line text components is that the text might overlap in height on to other components on the Report. To prevent this, set the ExpandParent property to **True**. This will expand the Parent of the Memo component to properly accommodate the Memo component.

Once the text is entered, the Memo box can be resized. The text within the Memo box will be repositioned accordingly. If there appears to be text missing from the Memo box, after it has been entered into the Memo Editor, resize the box to allow all text to be visible.

Section

The Section component is used to group components. This provides advantages, such as allowing all the components that form part of the Section to be moved together with one mouse-click, as opposed to moving each component individually or trying to select all components before moving.

To use the Section Component, first press the Section Component button and then use the cursor/arrow to make a selection on the Page. When the selection is completed, there will be a box marked by dashes with green pips. Within this area, place any components that need to be grouped together.

The Project Tree becomes very helpful when dealing with the Section component. From an expanded Tee, it is easy to see what components are in each Section. Each Section and component can also be easily selected simply by clicking on the appropriate object in the Tree.

If an object is ever placed beyond the viewable section area, the Project Tree can be used to select the object. Once the object is selected, the object's border pips can be seen and thus its location. The object can then be deleted or moved (hint: to move use the tap buttons in the Alignment toolbar).

As seen from the relationship with the Project Tree and the Section component, there is a need to understand Parent-Child relationships between components. To read more on these types of relation ships see the Project Tree Panel chapter, it contains a section on Parent-Child Relationships. The Section component also becomes very important when mirroring. Mirroring will be covered in the Managing Report Projects chapter. For now, just know that once the Section component is mastered, using this with mirroring will become extremely helpful.

Bitmap and Meta File

The Bitmap and Metafile components enable images to be placed in a report. Bitmap supports image files with the extension ".bmp", and MetaFile supports image files with the extensions ".wmf" and ".emf".

To insert an image, first click on either the BMP or the META buttons on the Standard components toolbar, then click any location on the Page. A placeholder box with an X will appear on the Page, and the box may be bigger than what the image will be. This can be fixed after the image is loaded.

Once the BMP or META placeholder is on the Page, go to the Property Panel and to the FileLink property. Click on the ellipse, the button with three dots.

This will bring up the Open Dialog. Find the image file, select the file, and click Open.

Once the image is loaded, resize the placeholder pips on the image border.

Exercise: Text vs Memo

The decision to use either a Text or a Memo component is quite easy. If there is only a single line of text to be placed on a Page, use the Text component. Use the Memo component when there is more than one line of text to be used.

To place and change a text component:

1. Click on the Text component located on the Standard Toolbar. The component button will change colors to designate activation.
2. Click once on the Page. The Text component will appear on the Page. Also notice that a new component will be added to the Project Tree under the Page that it was placed.
3. Go to the Property Panel and in the Name property change the name of the Text component.
4. In the Text property, change the default text to the desired text to be displayed on the Page.
5. View the Property Panel and the Page. Notice that the Project Tree has the Text component changed to the name entered in the Name property. Also, on the Page the component has the desired text typed into the Text property.

To place and change a memo component:

1. Click on the Memo Component located on the Standard Toolbar. The component button will change colors to designate activation.
2. Click once on the Page. The Memo component will appear on the Page. Also notice a new Memo component will be added to the Project Tree under the Page that it was placed.
3. Go to the Property Panel and in the Name property change the name of the Memo component. This will change the name of the Memo component in the Project Tree under the Page that the component was placed on.
4. In the Property Panel, go to the Text property. Click on the ellipse, the button with three dots (…).
5. The Memo Editor will appear. In the Memo Editor, type in the text that needs to be placed on the Page. The Memo will recognize returns made with the Enter key. Remember though, that the Memo will be subject to the size of the Memo box on the Page.
6. When the text has been entered, click OK.
7. When done, the Memo component can be moved or resized by using the green pips.

Exercise: Section

To create and use a Section Component:

1. Click on the Section component. The component button will change colors to designate activation.
2. Click on the Page, and a dotted box will appear with pips at its boundaries. This is the Section component.
3. In the Project Tree, notice that the Section component was added under the Page it was

placed.

4. While the Section component is selected, place any other component into the Section. When done, notice that the placed components will now be under the section in the Project Tree.
5. Once components are placed into a Section, all the components can be moved together. To try this out, place the cursor on the border of the Section, click and hold, then drag the Section around the Page.
6. The Section can also be resized. Click and hold any of the pips and then move the cursor in the desired direction, the Section box will resize.
7. When done, click anywhere on the Page to deselect the Section component. The Section is an invisible border displayed by a dashed rectangle, but it will not be printed.

Exercise: Placing and Resizing Bitmaps

1. To complete this exercise, find a Bitmap (BMP) image on your computer. The image will have a ".bmp" extension at the end of the file name. Remember the location of this image.

2. Create a New Report Page. Do this by selecting New Report Page from the Project menu.

3. BMP On the Standard Toolbar, click on the BMP button.

4. Then click once on the Page to drop the Bitmap component. The green pips will appear around the edges to indicate that it is selected.
5. While the Bitmap component is still selected, go to the Property Panel. Look for a property called FileLink Property. There will be three dots, called an ellipse button, to the right of it. Click on the ellipse button.
6. Using the Look in drop-down menu and selecting the image in the box below. Once The Open Bitmap dialog will appear. Find your Bitmap image on your computer by the file is selected, click Open.
7. The image will appear on the Page with green pips around the image.
8. Now look at the Property Panel and look at the property MatchSide. This property deals with the proportions of the image when it is resized using the pips.
9. Click on each of the MatchSide choices and move the image around a bit to see the effects of the choices.
10. This is msBoth. The pips on all sides allow the resizing of all pictures in all directions.
11. This is msHeight. This helps in resizing the pips according to height, while still keeping the image proportional. Using the top and bottom pips will resize the image.
12. This is msInside. This allows proportional resizing, but all resizing is done with in the limits of the pip. The image doesn't leave the borders of the pips.
13. This is msWidth. This does proportional resizing according to the left and right pips of the image.

Chapter 10

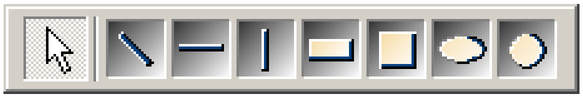
Drawing Components

In this Section:

- Explains how to place a Drawing Component.
- Describes all the Drawing Components.
- Discusses Pixels vs. Points.

Drawing Component Basics

All the Rave graphical components are created using the Drawing Components.



To use any of the Drawing Components, click on the desired component in the Drawing Toolbar then click once on the Page or other container component. This will create the object on the Page or other container component. Once the component object is created it can be resized to the desired dimensions by dragging the pips around the selected object border. Also, to color and stylize the components, use the Fills (where applicable), Lines, and Colors Toolbars. For more information on these toolbars, see the Utility Toolbars chapter.

The Property Panels of each drawing components are almost identical. The Name property may be the only thing that distinguishes one Property Panel from another.

The Line component can be used to draw a line in any direction. Angled lines may be used to draw lines between rotated lines of text. They may also be used as diagonal lines inside a square giving the effect of a box with an "X" in it.

Line styles may be set for the line; however, you should be aware that when setting line styles it is best to stick with a line width of one. Line styles are often ignored when the line width is any greater than this.

The HLine component may be used to draw horizontal lines. One of the common uses for the horizontal line is to drop one into a DataBand and set it so that it is positioned at the very bottom of the Band. It is also set to stretch the whole length of the Band. When the Band is printed, the line creates the effect of having the Band information printed on lined paper.

The VLine component may be used to draw vertical lines. One of the more common uses for the vertical line is to drop one into a DataBand and set it so that it is positioned in between various data fields that are being printed. The height of the line is set to the same height of the Band. When the Band is printed, the vertical line gives the effect of having the information printed in nice neat columns.

The Rectangle component may be used to draw rectangles. One of the more common uses for the Rectangle is to drop one into a DataBand and set it so that it is sized to completely fill the band. It is then moved to the back so that other components dropped on the Band will print over the top of the rectangle. When the Report is printed, this gives the effect of having a nice block around the rows of printed data.

The Square component may be used to draw squares. A common usage of this component is showing checked or unchecked boxes. The checked boxes are created with the use of the Square component and the Line component, or perhaps by simply by placing an "X" in the Square. This is useful when trying to illustrate items that have been selected.

The Ellipse component can be used to draw an ellipse or oval shape, more simply defined as a flattened circle. If you want to change the shape of the Ellipse, you can do this by clicking on the Ellipse with the left mouse button. Then move the mouse over one of the pips that will appear. Press the left mouse button again, and while continuing to hold the mouse button down, move the mouse until the Ellipse is the desired size and shape. You can also resize the Ellipse by setting the properties directly using the Property Panel. Simply enter new values for the Width or Height properties.

The Circle component can be used to draw a circle with a constant radius. If you want to change the size of the Circle, you can do this by clicking on the Circle with the left mouse button. Then move the mouse over one of the pips that will appear. Press the left mouse button again, and while continuing to hold the mouse button down, move the mouse until the Circle is the desired size. You can also resize the Circle by setting the properties directly using the property panel. Simply enter new values for the Width or Height properties.

Pixels vs Points

For every Drawing Component, the Property Panel has two properties that deal with Line Width. The LineWidth property is a numeric value for the width of the line, which depends on the LineWidthType. The LineWidthType property actually lets the user determine which type of value the line will be set. The Types available are Points and Pixels.

When creating drawing objects, it is important to determine in what format the audience will be seeing the Report. This is important when determining if Points or Pixels will be used for the line width type.

Points are a unit of print, not a unit of screen space. Points are the unit of measurement used most commonly with paper design. It has meaning in the paper medium. Unfortunately, points are meaningless on the screen and the web. Due to platform and resolution differences, something like 14pt can mean many things. What it does not mean is a specific unit of screen size. Pixels, on the other hand, are defined unit. A pixel is always equal to a pixel.

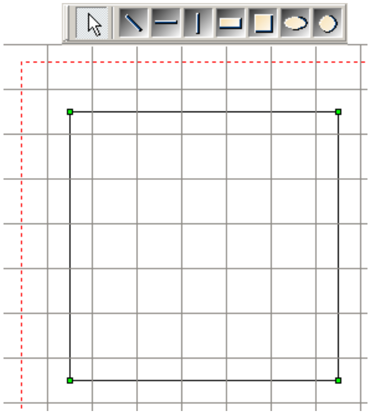
Points and Pixels Preferences are dependent upon what the designer wishes the user to experience. To let the user adjust the text size at will or let the user's internet browser preference determine the size, specify points. If the design depends on a rigid text size or if the text size must be consistent across platforms, specify Pixels.

To print the thinnest possible line, use a Line Width of 1 pixel. For thicker lines, values in points should be used for consistency across printers with different resolutions.

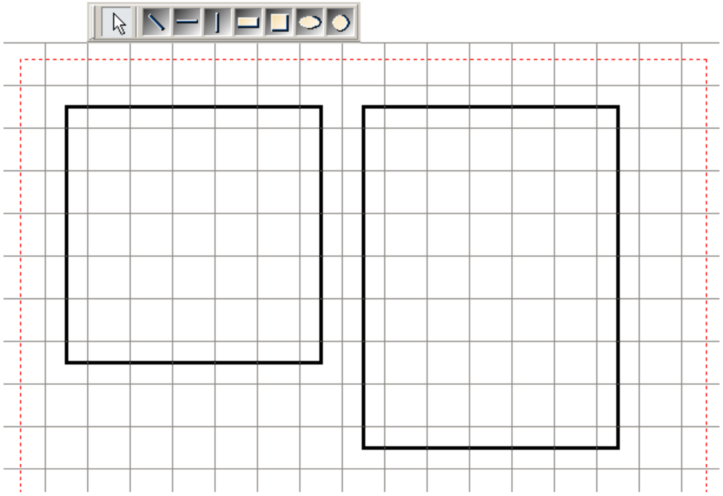
Exercise: Creating Drawing Components

1. First create a new Page. Use New Report Page from the File menu, or use the icon on the Project Toolbar.
2. Now, go to the Drawing Toolbar. Pull it down from the Tab area, so that we can concentrate on it here.
3. Click on the Square, notice that it's button changes to a depressed button and changes color. Click your cursor on the Page and hold down the left mouse

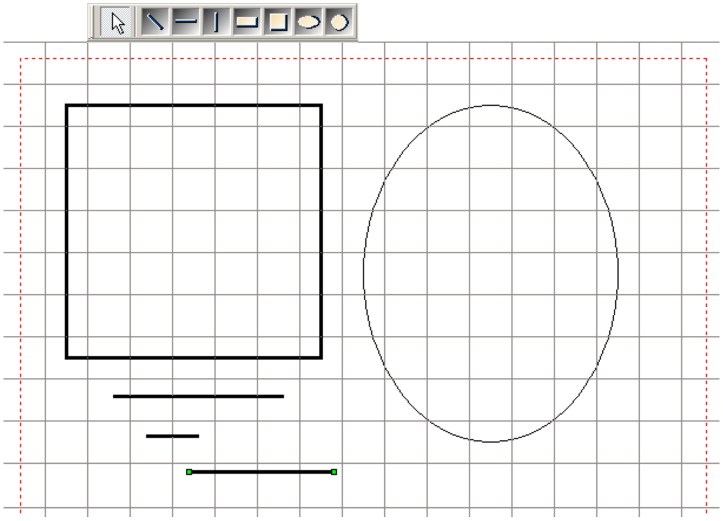
button while dragging out the shape of the square.



4. Next, click on the Ellipse. Click on the Page and hold down the left mouse button while dragging out the shape of the Ellipse. The Ellipse outline will look like a Rectangle, but once the mouse button is let go the ellipse shape will appear.

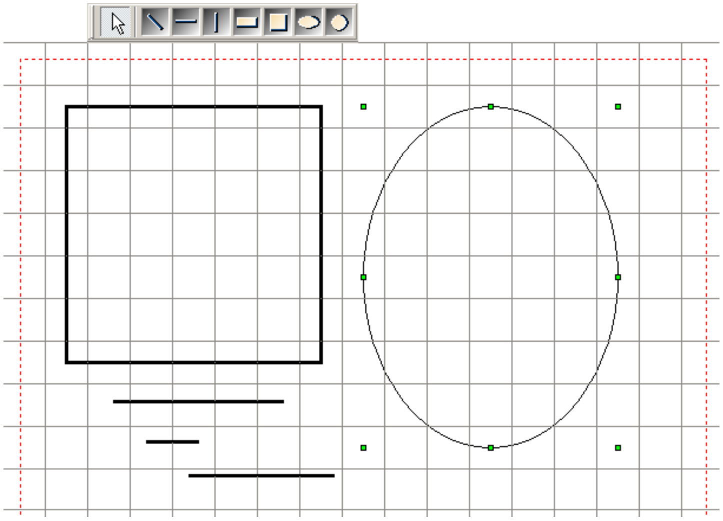


5. Then, click on the Horizontal Line and draw them on the Page. Do this for several lines. Make them different lengths.



6. One thing to notice for every shape, when the mouse button is released

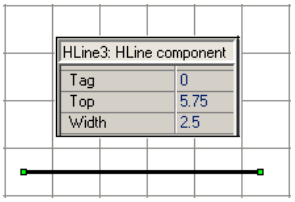
pips outline the shapes. When all shapes are selected the pips appear.



Exercise: Alignment

1. First create a new Page. Use New Report Page from the File menu, or use the icon on the Project Toolbar.
2. From the Drawing Toolbar, click on the horizontal line button then click on the Page. The line will appear as the default line size on the Page. The clicking on the button and clicking on the Page is what we call dropping an object on the Page.

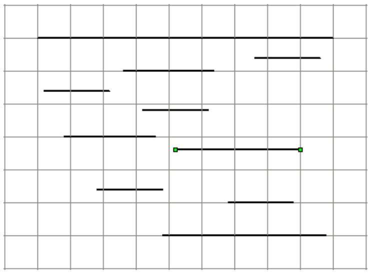
3. Select the horizontal line by clicking on it.



HLine3: HLine component

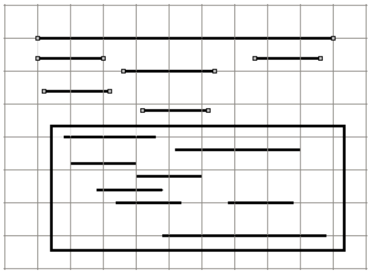
Tag	0
Top	5.75
Width	2.5

4. Go to the Property Panel and change the default value of the line by typing 2.5 into the Width property edit box.
5. Drop down at least 10 additional horizontal lines about an inch below the first one.

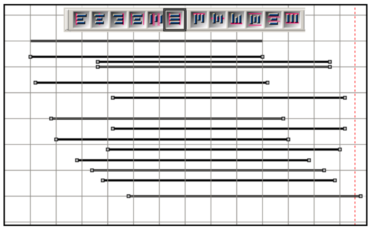


6. Drop down one more horizontal line about 3 inches below the first group of lines.
7. Select the top horizontal line by clicking on it. The green pips will appear at the ends of the line when selected.
8. While the first line is still selected, hold down the Shift

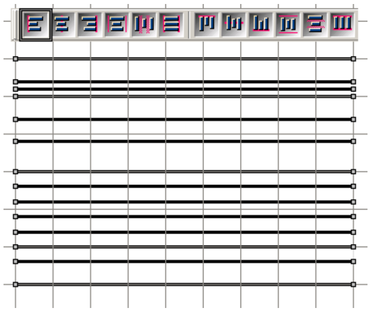
key and start clicking on the other lines. This will add all the other horizontal lines to the selection. To select the remaining lines faster, while the first line is selected and any other additional lines are also selected, keep holding the Shift key and click on the Page and drag the resulting box over the rest of the lines.



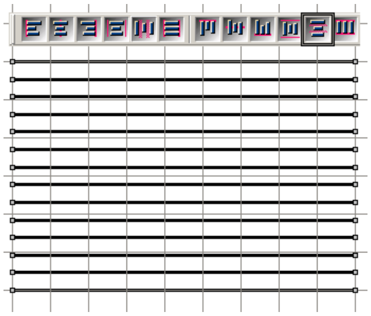
9. In the Alignment toolbar, click on Equate Widths alignment button. This will make all the lines the same width as the first selected line.



10. On the Alignment Toolbar, click on Align Left Edges button. This will align all the lines to the left edge of the first selected line.



11. Next, on the Alignment toolbar, click on Space Equally Vertically. This will space the lines equally away from each other on the vertical axis. For more exercises on Alignment, see the Utility Toolbars. Chapter.



Chapter 11

Database 101

In this Section:

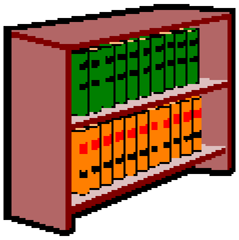
- Gives an overview of databases.
- Explains the needs to make up a database.
- Describes the data table structure and how it relates to reporting.
- Explains database relationships.

Overview

Information to the left, information to the right, information above and below, we are swimming in a sea of information. The advent of the computer age has not helped. In fact, we now have the ability to store absolutely huge amounts of data. This can easily result in information overload for both individuals and managers. Something is needed to manage this overload potential. The first thing is that the information must be organized and stored in an efficient manner that aids in the quest to extract answer(s) from that wealth of data. One of the methods to retrieve answers is to use a reporting tool (like RAVE) to organize and display the answers in a manner that is easily understood by the reader of the report. But before a reporting tool can extract the information, it must be aware of the structure of the source of information. That container of the information in simple terms is a data table.

This section is intended to assist those that are not familiar with database design goals or might need a quick refresher. This section is not designed to cover this subject in depth, as this is best left to the many thick books already published on this subject and to more formal educational courses.

What is a database?



Let's begin with some real world examples to describe the concepts of a data table. For example, a library contains lots of information stored in rows and rows of shelves containing books, pamphlets, etc., which is usually arranged according to the Dewey decimal system. To find a book, a card catalog is used to look up the subject or author, noting the Dewey decimal code. Then, the desired book is found and retrieved by going through the stack that contains the book code (if it isn't checked out).

Look up options are far more flexible if the library has a computerized card catalog. Now picture a library with no Dewey decimal system, no order but still the same amount of books. Try and find something in that library. It would be very tough and take a long period of time.

Now, change the words. Change book to information and library to database and we are on the way to explaining what and why of database management system. A library is a collection of knowledge (books) arranged by the Dewey decimal system.

A data table is a collection of information arranged according to some predefined table structure. We will now examine what is needed to design or use a data table.

Terms

To better understand what it takes to create a database, it is necessary to understand the database lingo.

Database Management System

A Database Management System (DBMS) is the complete system for managing data (information). There are many commercial examples of companies that are known for their DBMS programs. Some of the more well known include Informix, Interbase, Microsoft Access, Microsoft SQL, Oracle, Sybase, and many others. A DBMS can be confused with the physical data file(s). It must be noted that the data table is only one part of a DBMS. However, the real world does require that when extracting information from a DBMS that the structural concepts of a data table be understood. Fortunately, most of the terms are common between the various DBMS. This does not mean a person needs to be an expert in the database field, just knowledgeable.

Table

A data "Table" is a collection of things like phone numbers, names and addresses. The "report" of this example table would be a telephone book. Of course, a telephone book has some restrictions, like do not include unlisted phone numbers in any print outputs. In some cases, the phone company will have a billing address that is different from the address location for the phone itself.

Now look at a phone book and notice that it is arranged in rows and columns. A row (sometimes called a record) shows the items related to a single member (person) of that table. Each column (sometimes called a field) is giving a specific piece of information about that member, like their name or phone number. While we are here, the order of the phone book (table) is done with an index (sometimes called a key). So, a phone book could be arranged by last name or by phone number.

Structure

Each specific piece of information about a member of a table has attributes that define it for its DBMS.

Typical attributes for each table (file) include:

- date the table was created
- date the table was last modified
- number of columns defined for table

Typical attributes for each row (record) include:

- Length
- Record number
- Status (locked - deleted)

Typical attributes for each column (field) include:

- Name - a column name that usually "describes" its contents

- Type - character, numeric, date, time, blob etc.
- Length - maximum size of this item (might include number of decimals for numeric types)

A data table is comprised of information arranged according to a pre-defined structure. The structure of each table is important, because the row and column definitions are used by a reporting tool to extract, arrange and show information.

In the phone table example, there are the following fields: name, address, and phone number information. How are those columns (fields) defined? They are defined by the name of the column; meaning name might be called "name", address called "address", and phone number called "phone". But defining the main fields may not end at these simple definitions. For example the "name" field might be broken into three or more sub-fields, like "first", "middle" and "last". These three pieces as well as the first three main fields could then be manipulated as needed by any reporting tools. The three name sub-fields could be combined for a "full name" output or the first letter of the "first" name could be combined with "last" to make a short version of the name. Also, "phone" could be called "number" or "telephone" and the phone number could probably contain only the numbers with no formatting characters. Rave makes the task of understanding the table structure relatively easy as it does most of the work. Once the data connection is made, Rave will extract the table structure and from there the columns (fields) can be chosen as desired.

Query

Rarely is there a need to print all the information in a database. Frequently, there is a need to reduce data by selecting a range of rows (records) in a data table. Data reduction is an important part of information management. One method of accomplishing a reduction is to do a query of the table to only show those rows that meet the range limits that need to be retrieved.

One of the more common query methods is called SQL, which stands for Structured Query Language. Some data tables are SQL compliant. A SQL query allows inquires of a DBMS for information, and the DBMS searches its tables according to the given SQL statement and return a "set" of rows (records) that meet that query.

Client-Server

A method of setting up computer programs used by many people, where the database resides on a central computer accessible to all (the back end), and the user interface resides on the user's computer (the front end). All selection of specific data rows and processing is done back on the host computer minimizing the transmission of data through the network cabling. Significant improvements are achieved to the overall system performance by only transmitting relevant data through the cables. Thus, a well-configured Client-Server system can yield excellent performance gains in applications used by several people.

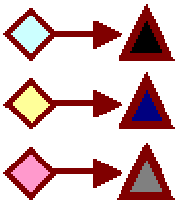
Relational Table

Now the phone book example is good for simple data tables (flat files). However, it is not an efficient design for many real-world needs. We can stay with the phone company, just not the phone book for a more typical need. Every month the phone company needs to send a bill out to each customer. This bill is a good example of a "master-detail" type report. One part of the bill comprises the master (static) information about the customer like: their name, billing address and phone number. Another part of the bill contains the detail (variable) information, like an output line for each phone call made including its length and cost. The variable information could be only one page or for some customers many pages.

There is one important detail in any master-detail work, understanding the concept of a primary key (link key). When a customer gets a phone bill, that customer expects only to receive a listing of their calls; they don't expect calls made by other people to be listed. In order for this customer bill to be created, this means that there needs to be only one master row, called a primary key, for all the detail rows. In the customer bill, the primary (link) key would be the phone number. The primary key must be unique, which in general usually makes it more difficult to change a primary key once it has been assigned. But, there are some DBMS that allow the primary key to be a combination of columns (fields).

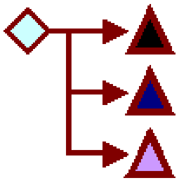
That is the quick review of Database operations. To ensure efficient design, with table structure control, there are a few more subjects to be aware of like: "Client-Server", "Normalization", "Relational DBMS", "One to One" "One to Many" and "Many to Many" relations.

One-to-One



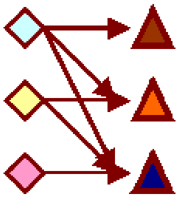
One-to-one is two separate tables with the same primary key. Therefore, knowing the primary key allows look up of data for a first row in one table, and for a second row in another table. One to one relationships are rare because it's usually easier to put both tables' columns into a single table. One-to-one relationships probably don't meet the first level of "Normalization" rules.

One-to-Many



This is accomplished by placing the primary key value of the ONE side of the relationship into an ordinary column of the MANY side of the relationship. For instance, if each employee can belong to only one department, then you could have a "department" column in the employee table, which, for each employee, would be filled with the primary key value for the row of his department in the department table.

Many-to-Many



This is difficult to explain, as the real-world examples are complex. If there were several employees that were part of several departments, then this would be a many to many situation

View

Some DBMS have an ability for a user to define a form to show contents of information taken from one or more other tables. A view is a definition of a form and has no data of its own. It often includes a query that is executed whenever the view is the subject of a command. Use views to control access to individual columns in a table, or to make two or more tables appear as one.

Reporting

How does all this relate to designing reports? With the definitions defined, understanding the report design structure and options will be easier. Now you are ready to read the sections on DataView Connection, DataField which will tell how to use Rave to connect to your data table(s) and how to identify the specific column (field) contents to the Rave designer.

Chapter 12
Connecting to Data

In this Section:

- Explains what a database connection is.
- Show the different methods of retrieving data from a database.
- Explains the SQL Editor and how it is used.

Database Connections

A reporting tool would be quite pointless if it did not allow methods of displaying information contained in databases. One could only go so far with designing non-data reports. Connecting to data in Rave is one of the more powerful features, not only because of the wide variety of databases and methods supported, but also due to the simplicity of the steps required to make a report data-enabled.

A database connection in Rave is the primary pillar for connecting to a database with SQL DataViews.

Creating a Database Connection

To create a new Database Connection, click on the DataView icon on the Report toolbar, bringing up the Data Connection Wizard. The first step is to select Database Connection from the list of options available. When done, click Next.

After clicking on the Next button, the second step of the wizard displays the different type of connection options available. The selection depends on the different Rave DIBL Links that are installed on the system. DIBL stands for Database Independent Layer. It is a proprietary system that allows interactions with databases independently of what these database system are (whether it be SQL Server, Interbase, Oracle, etc).

In a folder under the Rave root directory, there should be a folder called DIBLLinks. Inside the folder there are a certain amount of files with extension rvd. The files are loaded when the application first starts. Depending on the number of files, the number of available connection options varies.

It is possible to have many types of connections displayed in the Database Connection Type Dialog screen. It is left up to the user to decide which connection type is the most appropriate. Fewer connection types may be displayed depending on which drivers were installed.

Once one has been selected, the corresponding dialog box will appear in the next step asking for the connection details. This varies from one to another, but generally consists of a path to the database, a server name if the database is not local and optionally a username and password to access the server.

After creating a database connection, it will appear in the Project Tree from where it can be accessed. The properties for a Database Connection can be shown just like any other component by clicking on the connection component in the Project Tree panel.

There are several properties that are specific to the Database component. The most important ones are the AuthDesign and AuthRun properties. Many times, the platform (and server) that one develops the report on does not coincide with that of deployment. Specifically, one characteristic that is most likely to change is the access codes to the server (username and password). Rave has been designed keeping this in mind, and once again making the deployment task easier. For this, the AuthDesign and AuthRun properties can be used to provide design-time and runtime (deployment) information regarding the database and server.

AuthDesign contains the parameters that were specified when the Database component was made using the wizard and it can be changed by clicking on the ellipse button in the property field. AuthRun is the information for deployment.

LinkType represents the type that was selected when creating the Database connection. Again, similar to other components, there are common properties such as Name, FullName and Description, etc, which are not be explained again to prevent redundancy.

Direct DataViews (BE only)

DirectDataViews provide a link to data connection components located within an application. When a DirectDataView is created, a list of all available data connection components is displayed. The *Name* property value of the data connection components provides the link between it and the DirectDataView (through the *ConnectionName* property in Rave). If connecting to data connections that have event code attached to them, you must have the application actually running and the form containing the data connection components created.

Driver DataViews

DriverDataViews perform the same function as a DirectDataViews except they are self contained and typically obtain their data set from a SQL statement. DriverDataViews also require the use of a valid database connection.

Once the database connection has been established, click on New Data Object to create a new DriverDataView.

The Wizard will take the user through the necessary steps to complete the configuration. After selecting DriverDataView from the dialog box, choose the database connection that it is going to be connected to. If the connection to the database is successful, the wizard will then display the Query Editor dialog box. Before continuing with an explanation of the DriverDataView, let's examine the Query Editor.

Query Property Editor

The Query Property Editor is used for generating a SQL statement that returns a result set from the database.

There are two ways to use the editor. The first is to take advantage of the graphical interface for constructing the SQL sentence. On the left side of the dialog box, a list of tables available in the current database is displayed. By simply dragging and dropping from the list to the gray area, the corresponding SQL statement will be generated.

Once the table object appears, by clicking on the tick boxes, the list of fields that should appear in the result set can be defined. By default "*" is marked, which means that all fields will be returned. To select individual fields use the tick fields to make the appropriate selections.

Tables can also be linked (joined). To do this, simply drag another table over and trace a line from one field in the first table to another field in the second time (the figure above shows a join between PRODUCTID of table BUGS and PRODUCTID of table PRODUCTCODES. To view the results from here, click on the Results tab and the data will be displayed in a grid.

Alternatively, the editor can be used to write an SQL sentence directly. To do this, click on the Editor button that appears at the bottom. To enter a user-defined SQL statement, click on the "User Defined SQL" checkbox and type in the desired SQL.

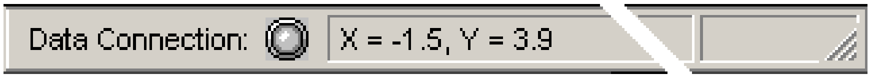
Once the query has been constructed, clicking on the Ok button will return control to the Rave designer.

The SQL Data View component should now appear in the Project Tree. By expanding the + sign next to it, a list of all the fields that have been selected in the SQL statement will drop down. Properties for each field can then be accessed from the Property Panel prior to selecting the field in the Project Tree.

Although fields can be placed in a report by using the corresponding component from the Report tab, it is much easier to work directly with the Project Tree to accomplish the same text. Pressing down the CTRL button, fields can be dragged and dropped directly from the Project Tree on to the form designer.

Once the DirectDataView has been setup using the Query Editor, none of the other properties are required for accessing the data.

Status Bar



Data Connection:

X = -1.5, Y = 3.9

At the bottom of the RAVE screen is the status bar. The status bar will provide some information about the item currently selected. So, watch the bar when designing a report.

The data connection LED will provi de status of the Rave data system by the color of the LED.

LED	Color	LED Status
Gray	●	Connection(s) are inactive
Yellow	●	Connection active but waiting for response
Green	●	Connection active and busy
Red	●	Connection active but has exceeded time-out delay

The X and Y figures are the coordinates of the mouse pointer. Move the mouse around and watch the X, Y amounts change. When a shape is dropped on the page, the size of a shape will appear while it is being created as seen by the dX and dY position. The "d" stands for delta.

Chapter 13

Wizards

In this Section:
• List guides to help in simple report structure. • Guides will provide detailed steps to complete a reporting task.

Wizards

Wizards are a new feature to Rave that allow certain types of reports to be created by answering a series of questions. They can be found under the "Tool" menu option. The Wizards can be added and tailored to each user's needs. It is a perfect way to minimize the end-users interface with reporting tasks.

There are two Wizards, a "Simple Table" and a "Master-Detail". Wizards can be designed to ask for the data connection and allow the user to choose the fields that are needed on a report. It is important to note that an active DataView should be available prior to running the wizards, whether it is a Direct Data View or an SQL Data View. Simple Reports are generally used for listings. Common uses include Client reports, Telephone lists, etc. The Master-Detail Wizard is used when more complex reporting is required, such as invoices, product order lists, etc.

Independent of the one that is executed, there are several steps that are common to both. These include the DataView selection, field selection, etc and are covered in greater detail in the exercises included at the end of this chapter.

It is very important that the user understands that these are general purpose reporting wizards and as such, some aspects are not treated with great detail (amount of text that would fit on a page, layout, etc). They can be used as the building blocks for a more complex report or can be adjusted to suite a particular layout required. If the intention is to build very complex reports, the wizards are not recommended for this purpose.

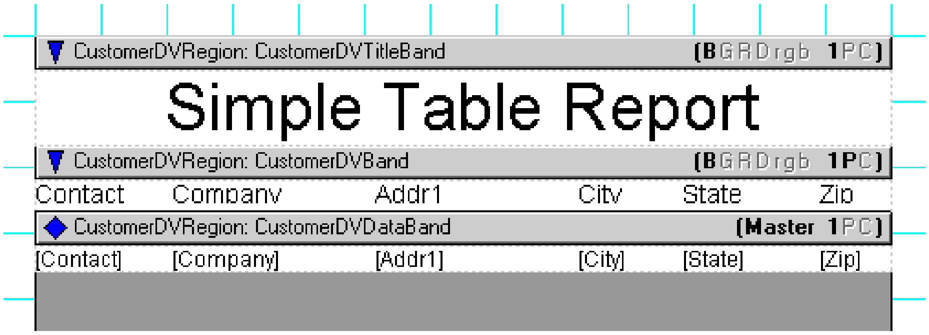
Exercises

Below are example exercises of both Simple and Master-Detail wizards. Since most of the steps are similar for both wizards, they will only be explained in detail in the first exercise. It is highly recommended to start with the Simple Wizard first to get a good grasp on the concepts presented.

Exercise: Simple Wizard

1. The first step is to select the desired DataView that will provide the data to the report.
2. Once the DataView has been selected, a list of fields that should appear on the report can be chosen. Fields are selected by clicking on the box on the left. All fields can be selected by clicking on the All button at the top. Note however that because this is a simple wizard, choosing more fields that would fit on the page will make them overlap. Manual intervention is required after the Wizard is complete to correct this problem.
3. If more than one field was selected in the previous step, the Wizard will ask for the ordering of the fields. Moving a field up will place it on the left side of the page. Move it to the lowest position will move the field to the right margin.
4. After the fields are placed in your desired order, the Report layout can be set. Values include the title and the page margins.
5. The last step of the Simple Report Wizard is to choose the fonts that are going to be used in the report. It gives the possibility of changing three fonts: title (of the report),

caption (headers of the field names) and the body (actual field values).



Exercise: Master Detail Wizard

The Master-Detail Report Wizard has a few additional steps more than the Simple Wizard Report. This is due to the fact that more than one table is going to be taking part in the report. In particular, there will be a master (for example customer information) and a detail (items ordered).

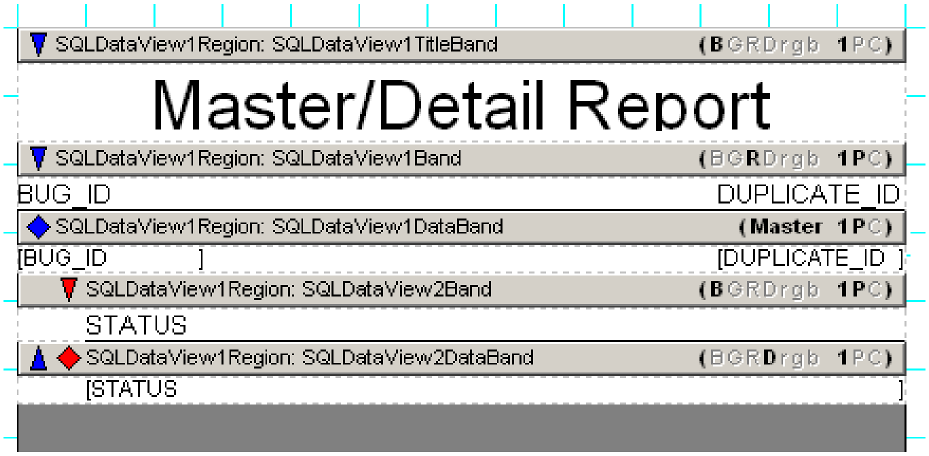
1. Similar to the Simple Report Wizard, the first step is to choose the DataView. However, in this case the DataView chosen corresponds to the Master table.
2. In step two, the Detail table can be selected. Note how the DataView selected in step 1 is no longer available to avoid errors.

Similar to the Simple Wizard, the next steps are for selecting the fields and ordering of both the master and the detail table.

A new step is determining the key fields. These are field that relate one table to the other.

After this, the remaining steps are identical to that of the Simple Report Wizard.

Once everything is complete, clicking on Generate will produce a simple master-detail report that, again, can later be adjusted and "touched up" to ones particular needs. The figure below shows a sample output of the Wizard.



SQLDataView1Region: SQLDataView1TitleBand
(BGRDrgb 1PC)
Master/Detail Report
SQLDataView1Region: SQLDataView1Band
(BGRDrgb 1PC)

Chapter 14

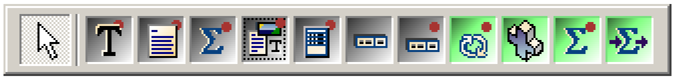
Report Components

In this Section:

- Gives more detail on using report components.
- Examples are given to aid in comprehension.

Overview

The Report Toolbar is one of the most used when working with data-aware reports. It is very vital to understand the function of each component, especially since the basics of all database reports are based on the Report Toolbar.



The following components are from the Report Toolbar that are frequently used in designing your reports:

Band, CalcText, DataBand, DataMemo, DataText, Region

The following components from the Report Toolbar will be covered in the Advanced Components section of the manual.

CalcController, CalcOp, CalcTotal, DataCycle, DataMirrorSection

The following Report components are non-visual components

CalcController, CalcOp, CalcTotal, DataCycle

There are some general characteristics of the components that need to be discussed before describing each component individually. First, let's talk about the visual color of the components. For the most part the components look similar in color to all other components, they are gray. But, at the end of the toolbar there are four green colored components. The green indicates that these are non-visual components. When placed on the Page, they cannot be seen on the screen, in preview, or in print. Instead, to 'see' the components the user must use the Project Tree to select, move, and delete the component from the Page.

Most of the Report Components can simply be placed on the Page. The only two exceptions are the Band and the DataBand. These must be placed in a Region component. The behavior of the component is also controlled by the settings made with the "Band Style Editor", which is found through the BandStyle property for both components.

A Report can be designed into a typical report, like one that uses strictly Bands. But, the unique feature of Rave is that the report can also be designed to other specifications. The Bands of the report can be moved and resized to any desired shape.

When designing a Report, the designer window can be changed to the preferences of the Report Designer.

There are several ways to control the "look" of the Bands while in the design mode. The first is whether ALL Band Headers need to be seen or not. This setting can be changed with the Designer Toolbar. Another method is to toggle the visibility of the Band contents. If some of the Band designs are stable and they need to be temporarily hidden, then try setting the

DesignerHide property to True. Only the Band(s) with DesignerHide set to False will show. This might be needed if there are a large number of Bands or a Band that occupies a large space. The setting of the DesignerHide property has NO effect on what will be printed, only what is shown on the designer Page.

Region

Before one can use a Region component properly, it is important to understand what it is. A Region is a container for Bands. In its simplest form the Region could be the whole Page. This would probably be True for reports that are a list type.

Many master-detail reports could be made to fit a single Region design. However, do not be limited by thinking of Regions as the whole Page. The properties for a Region basically deal with its size and location on the Page. Creative use of Regions will give more flexibility when trying to design complex reports. Multiple Regions can be placed on a single Page. They could be side-by-side, one above the other or stagger about the Page. Do NOT confuse a Region with a section. Region components contain Bands and only Bands. A Section component can contain any group of components, including other Region components.

When working with Bands, there is a simple rule that must be followed: Bands must be in a Region. Notice that the number of Regions on a Page is not limited nor is the number of Bands within a Region. As long as the report can be "visualized" mentally, a combination of Regions and Bands can be used to solve any difficulties faced when actually putting the visual thoughts into design. There are two band types: Band and DataBand. The latter is used when iteration is required, for example, in a master-detail report. The first is used for non-iterating needs.

DataBand

The DataBand component is a data-aware Band is used to display iterating information from a data view. In general, a DataBand will contain several DataText components.

A typical use for the DataBand would be on an invoice. An invoice normally consists of a header including information such as the date, invoice number, clients name and address, and one or more lines containing the items that are being invoiced. In this scenario, the customer table would be the master table and the items would be the detail table. Information about the items would be placed in the DataBand and the controller would be the master table.

Band

The Band component is for items that are "fixed" and do not change on the Page. In general, the Band component will contain Text and CalcText components. The primary examples of this would be headers and footers. The Band component can contain data-aware components, so a table field can be in the Band. A group footer might have a '{CustomerDV.CustomerName} Totals' on this Band.

An important property for the Band component is the "ControllerBand". This property determines which DataBand this Band belongs to (or is controlled by). When the controlling Band has been set notice that the graphic symbol on the Band will point in the direction of that controlling Band and that the color of the symbols will match.

There is a preference setting called "Always Show Band Headers". This setting will change the appearance of the Bands while in the design mode. Having this setting "off" will give an appearance closer to the actual output, but will not show the Band Headers with their symbols and codes. When first starting to use Rave it might be beneficial to try it with this setting "on" and take advantage of the visual clues provided by the Band Headers. Once comfortable with the use of Bands, change this setting to fit any necessary needs or preferences. The letter codes shown on the right of the Band are explained later in this chapter under the section called "Editor - Band Style". Basically, they give information about Band behavior. The bold letters are ON or active while the subdued letters are off or inactive.

Editor - Band Style

Go to a Band Style property on a Band or DataBand component and click on the ellipse button to open the editor for Band Styles.

This provides a simple method to select the features wanted for that Band by using the check boxes to activate or deactivate them. Note that a Band can have several different features active at a time. This means that it is even possible for a Band to be both a Body Header and Body Footer at the same time.

The display area in the Band Style Editor has been designed to represent the flow of a Report in pseudo layout style. DataBand(s) are duplicated 3 times on purpose to show that this is a repeating data area. The current Band that is being edited will be displayed with both **Bold** and Underline formatting.

Both symbols and letters are used on the Band Style Editor display area and one the Bands in the Page Layout Area and are designed be informative about each Band's behavior. The major difference between these two representations is that the Band style editor display will arrange the Bands in a pseudo flow according to the definitions of each Band. The Region display of the Bands will be arranged in the order that they are placed during design. The order of operation is controlled in some cases by this order. Headers (capital letters, BGR) will print first, then the DataBand, then the Footers (lower case letters, bgr) for each level. However, if there is more than one header defined for a particular level, then each header Band will be processed in the order that they are arranged in the Region. So, it is technically possible to put all the Headers at the top, all the DataBands in middle and all the Footers at the bottom of a Region for all levels of a master-detail. Or each level could be "grouped", with the appropriate Headers, Footers and DataBands all together for each level. Rave allows the Region layout maybe be used in a way that makes the most sense to the design flow. Just remember the order of precedence of like Bands at the same level is controlled by their order within the Region.

There are several symbols that are designed to show the Parent - Child/Master - Detail relations of the various Bands. The triangle symbol (up/down arrows) indicates that the Band is controlled by a Master Band with the same color (level) and can be found in the direction of the arrow. The Diamond symbol represents a Master or Controlling Band. These symbols are both color coded and indented to represent the level of Master - Detail flow. Remember that we could have Master - Detail - Detail where both details are both controlled by the same Master or one of the Details could be controlled by the other Detail.

The title bar of each Band contains information about that Band. On the left side of the Band is a name that indicates the Region it is in - "RegionName:BandName". The right side of Band uses several letters to remind you of the Band style settings for that Band. The order of these letters on a master Band is "MASTER 1PC". The order of these letters on a controlled Band is "BGRDrgb1PC". If the letter is subdued (gray) then that setting is inactive (off). If the letter is bold then the setting is active (ON). The following table shows the various letters and what they mean.

DataText

The DataText component is data-aware. This means it can be used to display a field from a dataset anywhere on the Page layout. For example, this could be used to print the customer information inside of a DataBand. The DataText component however is not limited to printing only database data. Through the Data Text Editor (accessible through the DataField property), Project Parameters can be printed, as can Report Variables as well as the DataFields. See the topic Editor-DataText, for more information. The LookupDataView, LookupDisplay and LookupField properties define a lookup definition to be displayed instead of the DataView:DataField properties.

Editor - DataText

There are two options available for entering data in a DataField property. The first is to select a single field using the drop option. This is fine for normal database reporting needs where only a single data field for each DataText item may be needed. However, there are many reporting requirements where various fields will need to be combined together. Two common examples are City State and Zip Code or Firstname Lastname combinations. In code this would be accomplished using a statement like the following:

City + '_' + State + '__' + Zip or FirstName + "_" + LastName

NOTE: The underscore character above represents a space for example purposes only.

The DataFhield property has a DataText Editor which assists in building complex composite fields. To do this click on the ellipsis and open the DataText Editor. This editor will give the power to concatenate fields, parameters, or variables together to build a very complex data aware text field simply by dropping the different list boxes and selecting the item desired.

There are a lot of combinations in this editor, they will be covered quickly here, but try the different combinations in practice and it should help the learning curve.

Note that the dialog box is divided into 4 groups: Data Fields, Report Variables, Project Parameters, Post Initialize Variables and Data Text. Data Text is the result window. Watch this window when inserting different items. The two buttons on the right side of this window are +, "plus", or &, "ampersand". The "plus" sign will add the two items together with no spaces while the "ampersand" will concatenate them with a single space. So, the first step is to decide on doing a + or &, then selecting the text from one of the three groups above the Data Text window.

So as an example, to add the field "OrderNo" to the "CustNo", click once on the "+" sign, go up to the DataField group, drop the DataField list box, and select "OrderNo". Then, click once on the "Insert Field" button and that will be added for the DataText window. The result in the DataText window would be "CustNo + OrderNumber". Even more DataFields can still be added. Notice the "Selected" item in the DataView group. If there is more than one data view active, then select another Data View, and then pick a field from that Data View.

However, do not be restricted to thinking of combining only DataFields. "Report Variables" and "Project Parameters" can be combined as well. Go to the "Report Variables" group and drop the list box for variables and take note of the ones that are available.

Another item available is Project Parameters. This could be a "UserName", "ReportTitle" or "UserOption" parameter initialized by the application. To create the list of "Project Parameters", select the Project node in the Project Tree (very top item). Then in the "Properties" panel there will be a "Parameters" property. Click on the ellipsis button to get a typical strings editor where you can enter the different parameters that will pass to Rave from the application, like "UserName" etc.

Caution:
Remember to use a "+" or "&" between each item that you are combining in the Data Text window. You can type in the Data Text window, so you can correct errors by highlighting, deleting or replacing erroneous entries made in the Data Text stream.

DataMemo

The DataMemo component is data-aware. This means it can display a memo field from a DataView just about anywhere on the Page layout. The main difference between the DataMemo component and the DataText component is that the DataMemo component is for printing text that may take more than one line and will thus need to be wrapped. For example, this could be used to print the remarks about a customer invoice at the bottom of each Page of an invoice.

One use of the DataMemo component is to do mail merge functions. The easiest way to accomplish this is to set the DataView and DataField property control to the source of the Memo field. Then launch the mail merge editor by clicking on the ellipsis button of the MailMergeItems property. This will allow the items to be set within that Memo that will be changed.

Note: The "Case sensitive" check box is empty (off). If case is important, then be sure to check this box.

To use the Mail Merge Editor, click on the "Add" button. Now type in the "Search Token" window the item that is in the Memo and will be replaced. After the token is entered, either type the replacement string in the "Replacement" window or click on the "Edit" button and it will start the DataText Editor that will help in selecting different DataViews and Fields.

CalcText

The CalcText component is data-aware. The main difference between the DataText component and the CalcText component is that the CalcText component is specially designed to do some form of calculation and display the results of that calculation. The CalcType property determines the type of calculation being performed and includes Average, Count, Maximum, Minimum, and Sum. For example, this can be used to print the Totals of an invoice at the top of each page of an invoice.

The CountBlanks property determines whether blank field values are included in the Average and Count calculation methods. If RunningTotal is True then the calculation will not be reset to 0 each time it is printed.

Chapter 15

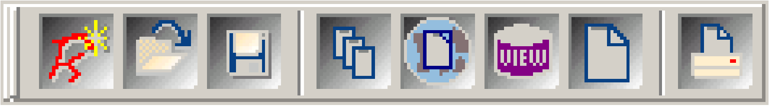
Project Components

In this Section:

- Main function of the Project Toolbar discussed.
- Project Manager and special properties covered.
- Report, Page and Global Page components and their special properties covered.
- Data Connections and Objects used to connect to Reporting Server discussed.
- Differences of Security components explained.
- Explanation of SQL and Direct DataView are given.

Overview

The Project Toolbar provides the basic functionalities for a project. These functions are essential building blocks for all reports. What makes these functions so important is the fact that these functions also provide basic building block components.



The main functions we will be concerned with the first button (Project Manager) and the second section in the toolbar (New Report, New Global Page, New DataView and New Page). These functions are used to add the supporting structure to your report design.

Each will be discussed in the following sections.

Project Manager

The Project Manager is the component from which all other components are created. Everything is placed under the Project Manager (a.k.a. RaveProject) in the Project Tree. This component is created when any new Rave file is created. There can only be one Project Manager per Rave file, this is unlike most of the other components.

For clarification, Project Manager, RaveProject, and New Project all refer to the same thing. They refer to the main Project file that contains everything.

Like every component in Rave, the Project Manager has properties. To see them, select RaveProject in the Project Tree, and then look in the Property Panel.

To quickly create a new project, simply click on the New Project button in the Project Toolbar. This will create a new file, as well as the new Project Manager.

Noted Project Manager Properties

The AdminPassword property allows the Rave Server administrator to limit who has access to the data from which the reports are created. This is important to help limit capabilities in Rave.

Parameters property allows items calculated by applications (such as Delphi) to be passed into the report to be used by other components with in the report. When clicking on the Parameters property ellipse button, the DataText Editor will allow a parameter name for each line.

PIVars Parameter is for content that is not typical, and needs to be dynamically modified within the report. This allows for content that needs to be modified in a way that is not typical of table calculation or manipulation.

SecurityControl

Report

The Report component contains the Pages of a Report. There can be multiple Reports in one Project, and each Report can have multiple Pages in that Report.

Each Report has properties. To see the properties, select the Report and view the Property Panel.

The Page component is the base visual component upon which Drawing, Reporting, Standard, and Barcode components are placed. This is where all the designing and layout of a Report are completed.

The Page also has properties which can be viewed by clicking in a blank area somewhere on the page.

Global Page

The Global Pages are located under the Global Page Catalog node in the Project Tree. These Global Page Definitions are used as Master Page definitions. These Pages can also be Mirrored. Global Pages can contain Page layouts for things like letterheads, forms, watermark designs, and other Page layouts that can serve as a foundation for several Reports in the Project. An example would be mirroring a Global Page where you wanted to print the same contents (link an "Invoice"), but you wanted to put a different caption at the bottom of the Pages like "Original", "File Copy", and "Shipping".

Global Pages also have properties. Select the Global Pages from the Project Tree and look at the Property Panel to see all the properties.

Data Objects

Data Objects are the Data Connection components used to connect to data, or components used to control who is allowed to see which Reports from the Reporting Server.

Clicking on the New Data Object button on the Project Toolbar creates each Data Connection. After clicking on the button, the Data Connection dialog will appear. From this point, one of five selections can be made. The Data Object component choices available are DataLookupSecurity Controller, Database Connection, Direct Data View, Simple Security Controller, and SQL Data View.

The details of each Data Connection component will be covered in the next few sections. Once a Data Object is selected, the Data Object component will be placed in the Data View Dictionary in the Project Tree. Selecting the component and looking in the Property Panel will reveal it's associated properties.

Database Connection

The Database Connection component is the Data Object used to connect to data. This component can be added to a Project by clicking on the New Data Object button on the Project Toolbar, then selecting Database Connection from the Data Connections dialog.

Once the Database Connection is chosen from the Data Connection dialog, the Database Connection Type dialog will appear. This is where the type of connection that will be used to connect to that data will be chosen. In this image there is only one selection, but depending on what types of connections you have, there could be many more selections. After choosing the right data connection type, click Finish.

The Database Connection component, like all other components, does have properties. Select the component from the Project Tree and see the properties in the Property Panel.

Security Components

Using a Security component can control security to individual Reports. TRaveBaseSecurity cannot be used itself, as it is an abstract. However, you can create a descendant or TRaveBaseSecurity to implement your own security scheme or use one of the pre-built TRaveBaseSecurity descendants included with Rave. Rave currently includes two TRaveBaseSecurity descendants: SimpleSecurity and LookupSecurity.

To use a Security component, create one and then set the Report's SecurityControl property to the Security component instance that you want to control access to the Report.

Security components currently only affect Reports when served via the Reporting Server. When an unauthenticated user attempts to access a Secured Report, HTTP authentication will be used to authenticate the user.

Simple Security Controller

TRaveSimpleSecurity implements the most basic form of security by using a simple list of username and password pairs in the UserList property. UserList contains one username and password pair per line in the format:

Username=password

CaseMatters is a Boolean property that controls whether or not the password is case sensitive. Username is always case insensitive.

Data Lookup Security Controller

TRaveLookupSecurity allows username and password pairs to be checked against entries in a database table.

DataView specifies the DataView to use to lookup the username and password.

UserField is the field that is used to look up the username. PasswordField is the field that contains the password to verify against.

SQL Data View

SQL Data Views are used for creating self-contained DataViews to SQL databases. A database is specified using the Database property.

Parameters can be specified using the Params property.

The SQL to use is entered into the SQL property. At design time, a property editor for the SQL property invokes a visual query builder.

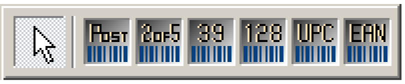
Chapter 16

Bar Code Components

In this Section:

- Describes how to place Bar Codes
- Describes how to encode Bar Codes.
- Gives brief descriptions of the Bar Code types.

Bar Code Component Basics



Bar Code components are used to create many different kinds of Bar Codes in a Report. Bar Codes are for users who know exactly what they need, as it requires background knowledge about Bar Codes and how they are used. It is not expected that the beginning user would have the background to use these components.

To place a Bar Code, click on the needed Bar Code component button and click on the Page.

To define the Bar Code value, go to the Property Panel and type the value into the Text property box. For Bar Codes containing check characters, please do not enter the check character, as it will be calculated automatically.

Brief Bar Code Descriptions

PostNetBarCode

PostNetBarCode uses the POSTNET (POSTal Numeric Encoding Technique) bar code and is specifically used by the Postal Service. It encodes ZIP Code information on letter mail for rapid and reliable sorting by bar code sorters. The PostNetBarCode can represent a five-digit ZIP code (32 bars), a nine-digit ZIP+4 code (52 bars), or an eleven-digit delivery print code (62 bars). Be aware that for the Post Office to recognize the bar code as being valid strict adherence to the guidelines must be met. Current standards require that the five digit zip plus four be used plus the two digit carrier route, which is most often obtained from the first two digits of the street address. It is recommended that the user check with the Post Office to obtain a copy of their current guidelines.

Example PostNetBarCode: 85210304119

2of5Bar Code

2of5Bar Code (interleaved 2 of 5) is a numbers-only bar code; in the Property Panel it is labeled 2of5BarCode. The symbol can be as long as necessary to store the encoded data. The code is a high-density code that can hold up to 18 digits per inch when printed using a 7.5 mil X dimension. "Interleaved" comes from the fact that the digit is encoded in the bars and the next digit is encoded in the spaces. There are five bars, two of which are wide and five spaces, two of which are wide.

Example 2of5BarCode: 2632534

Code39BarCode

Code39BarCode is an alphanumeric bar code that can encode decimal numbers, the uppercase alphabet, and the following special symbols " _ ", " . ", " * ", " $ ", " / ", " ", and " + ". The characters are constructed using nine elements, five bars and four spaces. Of these nine elements, two of the bars and one of the spaces are wider than the rest. Wide elements represent binary ones (1), and narrow elements represent binary zeros (0).

Example Code39: CODE 39

Code128Bar Code

Code128Bar Code is a very high-density alphanumeric Bar Code. The symbol will be as long as necessary to store the encoded data. It is designed to encode all 128 ASCII characters and will use the least amount of space for data of 6 characters or more of any 1-D symbology. Each data character is made up of 11 black or white modules. The stop character is made up of 13 modules. Three bars and three spaces are formed out of these 11 modules. Bar and spaces vary between 1 and 4 modules.

Example Code 128: Code 128

UPCBarCode

UPCBarCode (Universal Product Code) has a fixed length of 12-digits and can only encode numbers. UPC was designed for coding products. The format allows the symbol to be scanned with any package orientation. The check digit is calculated so there is no need to enter it when typing the value into the Text property.

Example UPCBarCode: 712345678935

EANBarCode

EANBarCode (European Article Numbering System) is identical to the UPC, except for the number of digits. EAN has a length of 13 digits - 10 numeric characters, and 2 "flag" characters that are usually country codes, and a check digit. This Bar Code is typically used for Non-U.S coding. The check digit is calculated for you so you do not need to enter it when typing the value into the Text property.

Example EANBarCode: 3847348484584

Chapter 17
Advanced Components

In this Section:

- Use of the FontMaster and PageNumInit are explained.
- Details of some advanced components are given.
- Calc Component details are given.

FontMaster

Each Text component in a Report has a Font property. By setting this property, a specific font can be assigned to the component. In many cases it may be somewhat useful and necessary to set the same font properties of more than one object. Although this could be accomplished by selecting more than one component at a time, this method has a drawback. One has to keep track of which fonts have to be of the same typeface, size and style, which is not an easy task when there is more than one report. This is where the FontMaster comes into play. Apart from allowing the user to define a global font for various components, the FontMaster also allows the user to define standard fonts for different parts of the Report, like for instance the headers, body, and footers.

The FontMaster is a non-visual component (designated by the green color of the button). To use one, simply click on the button and then click anywhere on the Page Designer. Note that being a non-visual component, there will be no visual reference of it on the actual Page, and like other non-visual components, it can be accessed using the Project Tree.

As mentioned previously, the main purpose of the FontMaster is to set fonts. It has very few properties. As most other components, it has the DevLocked, Locked, Name and Tag properties. They also contain the most important one of all, which is the Font property.

To set the FontMaster property, use the Font property on the Property panel, click on the ellipse button to get to the Font Dialog box and select the font and size settings. Click OK when done.

Once the FontMaster component is set, linking it to a body of text is simple. On the Report select a Text/Memo component, then use the down arrow button on the FontMirror property in the Property Panel to choose a FontMaster link. Any component that has the FontMirror property set to the FontMaster will be affected by and change to the FontMaster's font property. This allows the user to change fonts on various Text components at once and at the same time keep things consistent across the Report (when required).

It is important to note that by setting the FontMirror property on a component, the Font property will be overridden by the Font property of the FontMaster. This means that if a text object has a Font setting of Font A, by assigning a FontMaster to it with Font B, the Text component will automatically be assigned Font B and it's Font property will be ignored. Another side effect of using the FontMaster is that the Font Toolbar is disabled when the FontMirror property is set for that component.

There can be more than one FontMaster per Page; however, it is good practice to usefully rename a FontMaster. The Project Tree image shown previously has three FontMaster components on the Page. Two of them begin with FM, for FontMaster, and they follow with the name and size of the font that they represent. This is one naming convention that can be used to make the name descriptive and useful to the user.

PageNumInit

PageNumInit is a non-visual component that allows the restart of page numbering within a Report. Using a PageNumInit is similar to other non-visual components. It is used when more advanced formatting is required.

An example of using PageNumInit is in a CustomerStatement Report of a checking account. Account statements that customers receive every month may vary in the number of pages. In the monthly statements, the first page can define the account summary page layout, the second can define the customer's credits/deposits, and the third the withdrawals and debits. The first two pages may only be one page, but if the account activity is high for the customer then a section like withdrawals could be several pages. If the user producing the report wants each section numbered individually, the summary and deposits would have the pages marked "1 of 1" for both. For Withdrawals, an active customer account could have three pages of withdrawals and debits. Since this is a different section in the statement, it needs to be marked "1 of 3", "2 of 3", and "3 of 3". Using this kind of multiple page numbering is where PageNumInit comes in handy.

There are a couple of steps that must be completed to use the component efficiently. First define the Report Pages as usual. Add a DataText component from the Report Toolbar to the Page, placing it where the Page requires a Page number to appear.

Once it is in place correctly, in the Property Panel of the DataText component, click on the ellipse button in the DataField property.

This will open up the DataText Editor. Click on the Report Variables down arrow button and select Relative Page and click on Insert Report Var button to use the variable on the Report.

In the DataText area, "Report.RelativePage" should appear. After the text type in the following: + ' of ' +

From the ReportVariables drop-down list select TotalPages (choose it and press the Insert Report Var button). This will add the remaining text "Report.TotalPages" to the Data Text edit box area. When finished click OK.

The Property Panel now displays the sentence that was entered using the Data Text Editor.

Expanding the DataText component, the text from the editor will also appear.

To initialize the Page to a desired Page number, select PageNumInit from the Project Tree. On the Property Panel, type the desired Page number into the InitValue property box.

For every Report definition created in a Project, the PageNumInit will allow each report definition to be numbered independently of another.

DataCycle

The DataCycle component is an invisible data-aware band that would be used to control iterating information from a DataView. In general, a DataCycle component would be used to "Loop" or "Cycle" through the detail records until a change occurs at the master record level.

For example, imagine a bill being generated for multiple customers and each customer has many different purchases associated with them. For this bill you need to have each person's purchases on their own billing page, which has all and only their own listing of purchases. The table design for this might look like the following tables, where there is a master table listing of all the unique customers, and each customer has their own purchasing table, with all their own purchases listed.

The bill being created will need to have each unique customer ID number printed on one page as well as the items purchased on that page. Thus, the report will have to cycle through the table containing all the purchases made before proceeding to printing the next customer and the associated purchased items.

The main table containing the list of customer ID's would be found in what is called the MasterDataView. In the Property Panel, this master table name would be chosen from the property called MasterDataView. Once that is chosen, we will need to tell Rave what key will link the two tables together. This key is called the DetailKey. The DetailKey, in our example, would be the Customer ID's. Next, the table that will be cycled through, which is the table containing purchases to be printed, will be the DataView table. So, in essence the MasterDataView (driving table) and the DataView (details table) are connected by the Detail Key (the common unique key in each table).

The DataCycle can also be limited, or sorted while the Report is being generated. For example, supposed you just wanted to create reports for the Customers in Arizona. To limit Report creation to just the Arizona customers, the MasterKey will have to be set.

Setting the MasterKey is done by clicking on the ellipse (…) button next to the Property in the Property Panel. The Data Text Editor will appear. In the Data View area, choose the "Selected" radio button and then select the appropriate MasterDataView table, which is the Master Table in our example, by using the drop-down menu. Once you have done that, next select the field that will be used as the filter of the Master Table, or MasterDataView table. Once selected, click on Insert Field that is just underneath the Data Field drop down menu. This will place the appropriate text in the Data Text area at the bottom of the Editor. Now in the Data Text box, type in "='AZ'" to limit that field to just process the AZ customers. Click OK when done, and that will filter out non-Arizona customers.

DataMirror Section

The DataMirrorSection component is a section that will "Mirror" other "Sections" based on the contents of a "DataField". Mirroring Sections allow this component to be very flexible. Remember that Sections can contain any other component including graphics, regions, text, etc.

An example using this "DataMirrorSection" component is included in the RaveDemo project file. This example shows how to have a single report produce different envelope formats when sending to International or US addresses. The template for the International customers includes the country line and is be centered on the envelope, while the US format does not have the country line and is offset to the right of center and lower on the envelope.

This example shows several techniques on how to use Sections and Mirrors. On page 2 there are three Sections. Section 3 has the common address lines used by both templates. Section 1 and 2 contain Mirrors to Section 3. The International Section has the additional country line added in its template. Note, that "remarks" have been added to the page 2 design and they are not part of any of the sections. The "US Template" and "International Template" are just plain Text remarks that assist in the purpose of each Section shown.

Once understanding how the Master Templates were done, go to Page 1, and select the "DataMirrorSection". Notice the "DataView" and "DataField" properties have been set to the field that will be used to select which Format Template to Mirror. To examine that logic, go to the "DataMirrors" property and click on the ellipsis to open the Data Mirror Editor. Select each "DataMirror" item and note the settings in the bottom portion of the dialog box. This example has two "templates", but feel free to add more to fit more complex reporting needs.

NOTE:

Normally one of the settings will be defined as the default. If a default is NOT defined and the field value does not match any of the other settings, then the format used will be the normal contents of the DataMirror Section component.

CalcOp

The CalcOp component is a non-visual component that allows an operation (defined by the Operator property) to be performed on two values from different sources

(Src#CalcVar, Src#DataField or Src#Value). The result can then be saved in a project parameter like CalcTotal (through the DestParam and DisplayFormat properties).

For example, there could be two DataText components that need to be calculated together. Like *A+B=C*, where A and B represent the two DataText component values and C represents the result. This is where the CalcOp component would be used.

To choose the DataText components in the above example, use the Src1X and Src2X properties, where X is either CalcVar (a calculation variable), DataField, or DataValue. These are the three types of value sources that can be used for calculation in a CalcOp component. Note that the Src (source) can only use ONE of the three available source types, and there can only be two sources, Src1 or Src2.

The three source types have many different values associated with them. For a CalcVar source, the drop down menu will list all the calculation variables available in that Page available for use. This calculation variable is just that, a variable for holding a value. This value can be from another CalcOp component or from some other calculation component. For the DataField source to get available values first designate what DataView the DataField will come from. In other words the DataField is a field in a table, which is the DataView. So, in order to choose a field, the DataView must first be chosen. For a Value source, typing in a numeric value is all that is needed to fill this property. Again, remember only one of these three sources can be assigned to a source.

Once the sources are chosen the operation to be used between them has to be chosen. To choose the desired operation, use the Operator property by using the drop down menu and making the appropriate choice. In the example, *A+B=C*, the operator would be "coAdd".

There may be times when a function needs to be performed on a value before it is processed with the second value. This is where the property SrcYFunction, where Y is 1 or 2 for Src1 or Src2, will become handy. With SrcYFunction, the value can be converted (like from hours to minutes), or have a trigonometric function performed on it (like take the sin of the value), or have other functions performed on the value (like take the square root of the value, or take the absolute value).

Once the two values are chosen, it is now time to deal with the result. In the example, *A+B=C*, C is the value of the result. The result can either be written out to a project parameter (most likely a DataText component) or just held as an intermediate value. To write out the value to a parameter, use the DestParam property to choose the desired parameter to write the result write to. If the result is going to be in intermediate result, there is nothing else to do to the component. Although, it is highly suggested to rename the component, by using the Name property, to easily recognize the component for future use. This is because, as in intermediate values, you will most likely use the components in another CalcOp component, and a good reference will help to easily create the next step in the calculation process.

After setting the values and setting the result destination, it may be necessary to format the result or to even perform one last function on the result. Using the DisplayType and DisplayFormat properties to format the result into any necessary format. The DisplayType has two options, DateTimeFormat and NumericFormat. DisplayFormat has many options that must be typed into the edit box. To find these options look at the Formatting Appendix in the back of this manual. Like the two values, A and B, in the example, *A+B=C*, the result C can also have a function performed on it before being written out to a parameter, or as a holding value. To select a function, use the ResultFunction property drop down menu.

The CalcOp components can also be chained together for more complex expressions using the Src#CalcVar properties, which can be set to other CalcOp or CalcTotal components. For example, to create the complex expression shown to the right, it will be necessary to break up the expression into simple 2 value steps.

To break up the complex expression, four new expressions will need to be created and saved as CalcOp components. So the resulting components, Z, Y, X, and W will be four separate intermediate CalcOp's. But, as you can see from the flow of the expression, Z and Y will have to be completed before X can be created, as it is dependent upon the two previous operations. And finally, W will be completed last, after X, to get the final correct value.

$$\frac{(A+B)*(C*D)}{0.80} = E$$

$$\begin{aligned} &A+B=Z \\ &C*D=Y \\ &Z*Y=X \\ &\frac{X}{0.80}=W \qquad = E \end{aligned}$$

Just as it is important to do the calculations in order, it is important to make sure the components are in order in the Project Tree. When a report is executed, the report executes components down the Project Tree. For CalcOp components or any calculation component, this means that they need to be in the correct order. In the example above, if Z, Y, X, and W were in the Project Tree, Z would have to be first in the tree and W would have to be last in the tree. This would mean that at execution, Z would be processed first, then Y, and so on. It is also important to note that if Z is dependent upon any other components (like other CalcOp components or DataText components), those components must come first in the Tree before the Z component is processed. Making sure the components are in correct order is known as setting the print order. To move the components up and down within the Project Tree, use the Alignment Palette to change the print order of the components.

CalcController

CalcController is a non-visual component that acts as a controller, along with DataBands, for CalcText and CalcTotal components through their Controller properties. When the controller component is printed, it signals all calculation components that it controls to perform their summation operation. This allows totals to be performed on group bands, detail bands or whole pages depending upon the location of the CalcController component. Another feature of the CalcController component is its ability to initialize a CalcText or CalcTotal component to a specific value (through the InitCalcVar, InitDataField and InitValue properties). A CalcController component will only initialize values if it is used in the Initializer property of CalcText or CalcTotal property.

CalcTotal

The "CalcTotal" is a non-visual version of the CalcText component. When this component is "printed", its value is typically stored in a project parameter (defined by the DestParam property) and formatted according to the DisplayFormat property. This can be useful when performing totaling calculations that will be used with other calculations before being printed. Leave DestParam blank if the value of CalcTotal will only be used by other calculation components such as CalcOp.

Exercise: Using Font Master

1. Create a new page in the report. Select New Report Page from the Project window.
2. Go to the Project Tree and select the Page.
3. In the Property Panel, type in "FontMaster" in the Name property, while the Page is still selected.
4. Go to the Standard Toolbar. Find the FontMaster component and click on the button. Then click on the Page.
5. Look at the Project Tree Panel and notice that there is a new component underneath the Page called FontMaster1. But, when looking at the Page, there is no visual component. FontMaster is a non-visual component.

6. Make sure the FontMaster component is selected by clicking on it in the Project Tree. The component will be highlighted in the Project Tree to indicate that it is selected.
7. While the FontMaster component is selected, look at the Property Panel. In the Font Property, click on the ellipse button (the button with three dots).
8. The Font Dialog will appear after clicking the ellipse button. Use the scroll buttons and check mark boxes to make your desired selections. For this first FontMaster component, select Arial Font, Bold Font style, 14 size, and Underline in Effects.
9. Look at the Property Panel, with the component still selected. The Font Property will reflect the selection made in the Font Dialog.
10. Now with the Font Property still selected, scroll to the Name Property and put "FMArial14BldUndrln" in the Name property edit box.
11. Next look at the Project Tree and notice the name change. It becomes very useful and helpful to rename the components in the Project Tree in order to distinguish each component from each other. This is why we demonstrate renaming of the FontMaster component and the Page component.
12. Now, complete steps 4 to 11 three times using the following names and settings. FMArial16ItlcUndrln: Arial Font, size 16, Italic, an Underlined. FMTimesNwRmn12: Times New Roman Font, and size 12. FMCourier12: Courier Font, and size 12. To make understanding the renaming of many components, sometimes it is helpful to use a specific naming convention. In these examples we use the following naming convention for the FontMaster component names:
13. Next, drop down five Text components on the page, as well as one Memo component.
14. We will pretend to write a "letter" using components dropped on the Page.
15. Use one Text component to use for a date holder, and use the other four Text components to make an address label. The Memo component can be used for the body of the message. So, fill your components appropriately. For more information on how to fill the components with your own text, see the Property Descriptions Listing in the appendix, or see the chapter on Standard Components. Feel free to use the alignment tools to get the "letter" components to align correctly. Also, after some of the following steps it may be necessary to resize the text components to display all the text correctly.
16. Next select the Text component that has the date. While selected, change the FontMirror Property to FMCourier12 by using the drop down menu. Notice that the font of the Text component changed to the pre-set font settings of the FMCourier12.
17. Next select the four address Text components. The Property Panel will show the designation that this is a multiple selection of Text components. In the FontMirror property, choose FMTimesNwRmn12.
18. Select the Memo component, which contains the body of the "letter". While it is selected, choose FMArial16ItlcUndrln in the FontMirror drop down menu.
19. This ends mirroring of fonts to components on the Page. One last thing to cover is what to do when you change your mind about the fonts?
20. Select all the address Text components. Change the FontMirror property to FMArial14BldUndrln. Now, this would be a way to change many Text/Memo components from one font setting to another, without changing each Font property in each component.
21. Sometimes there may be many components linked to one FontMirror component, because they all relate to one specific area of the report. In this example, we can assume that all address headers would be linked to the FMArial14Bldunderln Font Mirror property. So, to change this we would have to redo the one FontMirror property.
22. Select the FMArial14BldUnderln FontMirror component in the Project Tree.
23. In the Property Panel, while the component is still selected, click on the Font property ellipse button.
24. Change the Font Dialog properties to the following: Times New Roman, size 10 font, with no other Font Effects.

25. In the Name property of the FontMirror property, put the following name: FMTimesNwRmn10.

Exercise: Setting up PageNumInit for Page Numbering

1. First create a new Page, or use what is left from the previous example, as we will do here. If this is a new Page, drop some Text components on the Page. These are just filler components in this example.
2. Go to the Report Toolbar, and find the Data Text component. Click on the Data Text component and then click on the Page.
3. Place the DataText component in an area where a Page number might appear. For example, place the DataText component at the bottom of the Page.
4. Make sure the DataText component is placed correctly, and make sure it is still selected. Check for selection by the visual appearance of the green pip surrounding the component, or by the component being highlighted in the Project Tree.
5. While the DataText component is selected, go to the Property Panel and look for the DataField property. Click on the ellipse button.
6. The Data Text Editor will next appear. Look for the *"Report Variables"* section in the Editor.
7. There will be an arrow at the end of the Report Variables selection window. Click on it to see all the selections available. Use the scroll bar to move up and down through the menu.
8. In the Report Variables section, look for *"Relative Page"*. Click on it to select.
9. Next click on the Insert Report Var button to the right of the Report Variables section. This will place the appropriate text into the Data Text area at the bottom of the Data Text Editor.
10. Go to the Data Text area and type in the following: + 'of' + . This will include spaces before and after each symbol.
11. Now return to the Report Variables drop-down list. Scroll to look for TotalPages. Select it when you find it.
12. Click the Insert Report Var button, to get the remaining text into the Data Text area. "Report.TotalPages" will be added to the Data Text area.
13. Click OK when done. Your DataText area will look like the following.
14. After clicking OK, you will be returned to the Designer and to the Property Panel. If you expand out the Property Panel and look at the DataField property, you will see the results of the DataText are from the Data Text Editor.
15. On the Page, the DataText component will probably look like the DataText component labeled A below. If you expand the borders of the DataText component (as seen in B), you can see that the results of the Data Text Editor appear. There is really no need to expand the component; it is just for you to see in this exercise.
16. There is one more thing left to do to complete the page numbering, we need to initialize the Page to the desired page number. So, go to the Project Tree and find the PageNumInit component. Select the component when you find it.
17. While PageNumInit component is still selected, go to the Property Panel and find the InitValue property.
18. In the InitValue property, type in 1. This will mean that our pages will begin with page 1.
19. That is it. That is all that is needed to setup the PageNumInit. Note that in one project, with this feature, each Report can be number independently of each other.

Chapter 18
Adaptable Reports

In this Section:
• Explains the problems related to adaptability. • Explains how to use Anchors to "fix" your components. • Shows how to work with waste areas on different printers.

Overview

One of the biggest problems that designers face when creating reports is adaptability. What is adaptability exactly? First, when a report is created, the process normally takes place on a specific computer, which has one or more printers connected to it. When that report is executed in the field, however, factors such as paper size, orientation and waste areas all come into play. Secondly, reports should allow for a certain amount of flexibility in the overall design and appearance of the layout of the report.

Rave helps overcome these problems by giving the designer access to particular properties of the report. In this chapter, these properties will be explained in detail and will allow the resulting reports to have a standard look over various platforms. This way, the designer can focus more on creating reports than worrying about deployment difficulties. The reports will also be able to adjust layouts based on external parameters passed in during execution.

Anchors

Most visual components have a common property called Anchors. This powerful feature defines how the object will move when its Parent is resized. There are two Anchor values that are set, one for the horizontal and one for the vertical. The default Anchor is set to the top left corner of the Parent control. What this means is that when the Parent (e.g. a Section component) is resized, the component will stay the same distance from the left and top corner of the Parent. Two other Anchor values, Bottom and Right, are very similar in function (they will Anchor to the bottom right corner of the Parent).

The Anchor setting of Center will Anchor the Child component to the Parent's center. Stretch will actually resize the Child component so that it's sides stay the same distance from the Parent. Stretch is most often used when you want a Child component to always match the width or height of the Parent. Two other special Anchor settings, Resize and Spread are useful for groups of components. Resize will proportionally resize the components and the spaces between them as the Parent is changed. Spread will proportionally resize the spaces only (the components will stay the same size) as the Parent changes. Drop down a Section component and place a few rectangles or Text components inside and change the values of those components to see how the Anchor property can affect things.

Anchors can be used to create adaptable Reports when combined with other Reporting features. Imagine that a Report needs to be defined that can be printed in either landscape or portrait orientation or that the Report may be run on different size papers. Setting the Anchors properly will allow one Report to adjust to these changing conditions. A typical table listing Report will be composed of a Region component; it's Band components and the Text and DataText components inside each band. If the Region component is set to Anchor Stretch on both vertical and horizontal and the Text and DataText components are all set to a horizontal Anchor of Resize, the Report will adjust to any of these changes.

Other changes, such as the printer's individual waste area, can also be solved with Anchors and will be discussed in the next section.

Waste Fit

Most printers have a Region on the paper that is called the waste area. What this represents is the portion of the Page where no printing can be done because of restrictions of the actual printing hardware (usually because the printer uses that region of the page to "grab" a hold of the paper when it is feeding it through the rollers). These values may range from 0 (common for dot-matrix printers) to 1.5 inches. Ink jet printers typically have large bottom margins (and sometimes a 0 top margin), while most ink jet and laser printers have about a 0.25 inch left and right waste area.

The red-dotted lines that run on the border of the Page represent the waste-area of the currently selected printer (or specific values if the preferences are set that way). Anything in between the red line and the border of the Page is the actual waste-area of the printer and you should avoid placing components within that area. The problem is how to know what the actual waste area of the destination printer will be. If the Report is designed with extremely large margins that will be inside the waste area of all printers, then a lot of unnecessary blank space will be on each Page. The WasteFit property is Rave's answer to this common reporting problem.

The Page has a property called WasteFit, which can have one of two values, either true or false.

By default the value is False. Setting the property to true will make the Page adjust the components it contains so that they fit within the waste-area of the destination printer. The components contained will be resized so that they all fit in and adjust accordingly.

However, it is not sufficient with setting the WasteFit property to True for all this to happen automatically. Child components should have their anchor property set accordingly so that they too can adjust accordingly to the changes of the Page.

When used properly, this property is a very powerful feature that allows the reports developed to automatically adapt to different destination printers.

Editor Anchor

Normally, ReportBands/columns/paragraphs are justified to the Left and Top of a design area. This will be fine for the majority of Reporting needs.

However, have you ever wanted to control the starting or ending position of your report components dynamically? This could be a two-column Section, where the left column is a Memo component which changes in height and the right column is a Text component, which is always a one line item. How do you make both components "float" and align to the bottom of the design block? In Rave this is done with the Anchor property.

To change the Anchor style go to the Anchor property of the desired component and click on the ellipse symbol, it will open the Anchor editor like the one shown above. This provides a method to select the Anchor style wanted for that component by using the appropriate vertical and horizontal radio button. Note that a representation appears below each Anchor selection to give a visual indication of what that setting is designed to accomplish. The last three settings, Stretch, Resize, Spread are a little difficult to explain, but view the sample and there will be a picture showing the differences between the settings.

An important point to note is that the Anchor property settings are relative to that component's Parent. So, if the Parent is a Page, then the settings are relative to the Page sides. If the Parent is a Section, then the settings are relative to the section borders. One way to visually see the parentage is to examine the component(s) on the Report Node in question in the Project Tree. Go up one level and that is the Parent.

The following combinations are not restrictive, but normally the Anchor settings will be paired as follows:

- Left/Top justified
- Right/Bottom justified
- both Center justified
- both Stretch
- both Resize
- both Spread

Chapter 19

Batch and Chain Reporting

In this Section:

- Discusses how to Batch Reports
- Covers calling and Page Chaining

Batch Pages

Probably the most common linking of Pages would be a batch processing sequence that defines a list of independent Page definitions. The first Page in the list runs to completion, then it calls the second, which runs to completion, and so on until the last Page of the defined sequence has been completed. The main thing to remember with batch Pages is that each Page definition is independent of the others and runs to completion before the other Page starts. Remember that the requirement to do batch processing is to simplify the administrative tasks when running a group of Page definitions on a recurring basis.

Define the sequence of Pages to print through the PageList property, which is available at the Report node level. When this property is selected (click on the ellipsis button), it will open a dialog window that will build the list from the Page definitions within the selected Report node. The advantage of this method is that the PageList is independent of the individual Page definitions. This means that the PageList would run the whole sequence of Pages (Reports), but individual Reports can still be selected individually and run by itself without invoking the batch link. Remember, Report Pages are not visible to other Reports, so if flexibility of calling separate Page definitions is needed, define the reusable Pages as global Pages instead of Report Pages.

WARNING
Another method to do Batch Pages is to set the first Page definition GotoPage property to the second Page definition name. Now, when the first Page is completed, it will automatically start the second Page definition. The problem with this technique is that anytime the first Page is run it will ALWAYS start the second Page as they are linked together at the Page definition level.

Calling Pages

(Page Node - GotoMode property - gmCallEach setting)

Another type of linking would be Reports where there must be a particular flow of Pages. The easiest example of this would be a Report where each record ALWAYS produces three Pages of output. This could be a "form Report" where Page 1 has a patient's demographic information, Page 2 has medical information and Page 3 has insurance information. So, when going through the database, each patient's record would produce 3 Pages of output. See the Exercises for more step-by-step instructions on how Call Pages.

Chain Pages

(Page Node-GotoMode property-gmGotoDone setting)

A chain of Pages is similar to a Batch. The Batch technique discussed earlier used the PageList property and cautioned you about using the GotoPage property. However, if you plan ahead, then the use of the GotoPage property with the Pages from the Global Page Catalog is very powerful. The exercise at the end of this chapter does a Multi-Page definition that includes an invoice, file copy, shipping document and packing slip.

Different First Page Format

(Page Node-GotoMode property-gmGotoNotDone setting)

Another type of linking would be Reports where the first Page format is different than the remaining Pages. This could be a Report that has a title layout maybe even with a company logo on Page 1, but the remaining Pages are all the same design layout. What you need to do for this is to create the Page 1 definition (first Page) that points to Page 2. Then create the Page 2 definition (all remaining Pages) that points to blank. The Exercise at the end of the chapter goes through the detail steps to complete this process.

Different Odd/Even Page format

(Page Node-GotoMode property-gmGotoNotDone setting)

Another type of linking would be Reports with a format based on an odd/even Page definition. This could be Reports that are going to be printed on both sides of the paper (duplex style) and have holes punched in one side, so that final Report could be put in a binder. This would mean that the inside margin (say 1 inch) would be larger than the outside margin (½ inch). To create a loop where the Page 1 definition (odd Page) points to Page 2 and will call it if the Report is not done when it gets to the end of the Page AND the Page 2 definition (even Page) points to Page 1 and will call it if the Report is not done at the end of that Page. This loop will need to continue until Report is completely printed. See the Exercise at the end of this Chapter to get detailed steps to complete this task.

Batch / Chain Reports

Once the Report Design is complete and working, the day-to-day routines get settled. At this point, it would not be unusual to find out there often is a need to print several Reports in some kind of sequence. This could be a group of Reports that are always generated at the end of each month, quarter, etc. Another example might be a series of executive summaries that are needed on a demand basis by upper level management. Of course, it is possible to run each required Report individually for these repetitive cases. Then when they are all done, group them together and give them to the requesting office. This often means that there is a checklist that details what repetitive Reports are required, when and for whom.

This problem of producing a repetitive sequence of Reports is solved with Rave by linking the Reports to each other. Rave has the ability to link the Report Page definitions in a wide variety of ways by setting different combinations of three properties; Page.GotoMode, Page.GotoPage and Report.PageList. It is important to note that the setting of the GotoMode property determines the behavior of the GotoPage property. The PageList property is at Report Node level and is designed to provide a way to initiate several different GotoPage property chains in a defined sequence.

Although we will give examples of how we envision achieving various Batch/Chain sequences of Pages, it will not be possible to include all of the possibilities. The secret is that one should understand and be flexible on how to "mix and match" the various parts of Rave. In particular, pay special attention to the Global Page catalog and the GotoMode, GotoPage, Mirror and PageList properties. Different combinations of these provide a wide range of output options. There is a lot of power here, so the best advice is to start with simple Reports. Then add some of these powerful extras and as they make sense.

Exercise: Calling Pages

The way to accomplish this would be:

- Complete all normal definitions for the Page 1.

- Complete all normal definitions for the Page 2.
- Complete all normal definitions for the Page 3.
- Set the GotoPage property of the first Page to point to the second Page.
- Set the GotoMode property of the first Page to gmCallEach setting.
- Set the GotoPage property of the second Page to point to the third Page.
- Set the GotoMode property of the second Page to gmGotoDone setting.
- Insure that the GotoPage property of the last Page definition is blank.

The gmCallEach setting of the Page 1 GotoMode property will activate the GotoPage property after the first physical Page has printed. So, at the end of physical Page 1, Page 2 definition will be started. Because the Page 2 definition has a gmGotoDone setting, it will go to the Page 3 definition when it has finished the printing the second Page. The Page 3 definition will print that Page's definition and then return control to the Page 1 definition because it's GotoPage property is blank. You can join any number of Pages together in this manner. The key is that a gmCallEach setting will save off the calling Page so that whenever a blank GotoPage property in the Page chain is encountered, it will continue with that calling Page.

Exercise: Chain Pages

For this example, we are going to do a Multi-Page definition that includes an invoice, file copy, shipping document and packing slip.

- Create a section on a Global Page that will be mirrored later.
Complete all of your normal definitions for the Invoice Page within this section.
- Create a section on a Global Page that will be mirrored later.
Complete all of your normal definitions for the File Copy Page within this section.
- Create a section on a Global Page that will be mirrored later.
Complete all of your normal definitions for the Shipping Page within this section.
- Create a section on a Global Page that will be mirrored later.
Complete all of your normal definitions for the Packing Slip Page within this section.
- Create a "New Report" that will hold the definitions for these Pages.
- Create a new Page definition, "Invoice"
drop a section on this Page definition and set the Left and Top properties
mirror the section to the "Global" Invoice Page section
drop a text component on the bottom of the Page "INVOICE COPY"
- Create a new Page definition, "FileCopy1"
drop a section on this Page definition and set the Left and Top properties
mirror the section to the "Global" FileCopy Page section
drop a text component on the bottom of the Page "FILE COPY 1"
- Create a new Page definition, "FileCopy2"
drop a section on this Page definition and set the Left and Top properties
mirror the section to the "Global" FileCopy Page section
drop a text component on the bottom of the Page "FILE COPY 2"
- Repeat those steps, for the "Shipping Document" and "Packing Slip"

- Now go back to the "Invoice" Page definition (NOT the global definition"
Set the PageMode setting to gmGotoDone
Set the PageGoto to point to the "File Copy 1" Page definition.
- Repeat these steps for each of the copies, remember to leave the last one blank

The mirroring of a Global Page offers a lot of "reuse" of a Master Design. This example showed that the "FileCopy" could be mirrored twice and "label" each Page definition differently.

Exercise: Different First Page

The way to accomplish this would be:

- Complete all normal definitions for Page 1.
- Create a "New Report Page" for the second Page definition.
- Set the GotoPage property of the first Page to point to the second Page.
- Set the GotoMode property of the first Page to gmGotoNotDone setting.
- Complete all normal definitions for Page 2.
- Insure that the GotoPage property of the second Page is blank.

The gmGotoNotDone setting of the GotoMode property will activate the GotoPage property after the first physical Page has printed but only when the current Page definition has not finished (for example, EOF - End Of File). So, at the end of physical Page 1, Page 2 definition will be started. Because the Page 2 definition does NOT have anything in the GotoPage property, the Page 2 definition will remain in effect for all remaining physical Pages until the Report is done.

Exercise: Different Odd/Even Page

The way to accomplish this would be:

- Make a Section on the first Page definition that is set for the "Odd" Page margins.
For example, set the properties Left = 1.0, Width = 7.0, Top = 0.5 and Height = 10.0.
- Complete all of your normal definitions for Page 1 within this section.
- Create a "New Report Page" for the second Page definition
- Drop a Section on the Page 2 and set the top and left margins for the even Page settings.
For example, set the Left property = 0.5 and Top property = 0.5.
- Set the Mirror property of Page 2 Section to point to the Section on Page 1.
- Set the GotoPage property of the second Page to point to the first Page.
- Set the GotoPage property of the first Page to point to the second Page.
- Set the GotoMode property of BOTH Pages to gmGotoNotDone setting.

The gmGotoNotDone setting of the GotoMode property will activate the GotoPage property after each physical Page has printed but only when the current Page definition has not finished (for example, EOF - End Of File). So, at the end of physical Page 1, Page 2 definition will be called. At the end of physical Page 2, Page 1 definition will be called. This loop will continue until one of the Pages is completed. If control would need to be passed to another Page at this point, use the Report components PageList property to select the next Page.

Chapter 20

Preferences

In this Section:
• Shows how to get to the Preferences Dialog • Explains each tab in the preferences dialog

Getting to the Preferences Dialog

Before getting started in Rave lets take a short detour and learn about controlling the appearance of the RAVE designer. Under the main menu, select "Edit" then "Preferences". This will open a Preferences dialog where the look and feel of the RAVE system can be customized.

Defaults Tab

"Defaults" tab provides a place to set many of the RAVE Visual Designer Project and Page settings.

Settings in the Default tab section will be used when a new Project or new Page is created. After a Project has been started, the Project properties can be changed at the Project level and then they will be saved for that Project. The same applies to the properties of Pages. For example, a Project could have a default grid of 0.25 inches, but on a special Page the settings could set the Grid Spacing to 0.1 inches.

Designer Tab

The "Designer" section controls changes of the Grid system, Alignment options, units of Measurement and Zooming.

The "Zoom Increment" controls the amount of change that is made with the in/out zoom controls on the Zoom Toolbar.

The "Alignment Options" section, controls the visibility of the Order buttons and Tap buttons. It also controls the 'speed key' assigned to the Tap Tools. The speed key is really a predetermined amount of distance that the component is allowed to move with one keystroke. To use this feature, select the component and click on any of the arrow keys on the toolbar. Or, use the arrow keys on the keyboard while pressing the Ctrl-key.

In the "Grid Settings" area, grid color and associated changes can be applied to the Page of the Report. "Snap To Grid" will cause the mouse cursor to move and size components in increments of the Grid Spacing. The "Draw Grid On Top" option allows the Grid to be seen visually on top of components that have a solid background color. To hide the Grid Lines, make sure that "Show Grid" is unchecked. Several of these preferences are controllable from the Designer Toolbar. For more information about the Designer Toolbar and other toolbars see the Utility Toolbar Chapter.

The "Waste Area" controls the visibility of the amount of excess between the area border (the red dashed line) and the edge of the Page. "Show Waste Area" hides/shows the red dashed border around the Page. Then next two selections control the Waste Area width. The Waste Area can be set to the default printer settings, or it can be set manually by using the Left, Right, Top, and Bottom edit boxes.

In the "Background Gradient" section, the three colors that make up the area between the Page and the borders of the program can be changed. Clicking on the color wheels and selecting the desired colors change the gradient of the background. To make the background a solid color, simply select the same color for all three color options.

The visibility of the Order Alignment and Tap Tools are controlled by settings in the Alignment Options section of the Designer Tab. To get to this section click Preferences in the Edit menu and choose the Designer Tab.

Also in the Alignment Options, the Tap Tools have a 'speed key' assigned to them. This speed key is really a predetermined amount of distance that the component is allowed to move in one keystroke. The "Tap Distance" is initially set at 0.01 inches. If this distance is increased it will take less time to move the component in the desired direction. To use this feature, select the component and hold the Ctrl key while clicking on any of the arrow keys in the toolbar. Or, use the arrow keys on the keyboard while pressing the ctrl-key.

Environment Tab

"Environment" contains settings for user viewed information, toolbars, and page environment options.

In "User Level", the user's level can be increased or decreased. This setting controls the amount of information to be displayed to the user, mainly dealing with the various properties that will be covered later in this manual. Do not be distracted with all the advanced properties at first. To simplify the early Rave experience, start out at either the Beginner or Intermediate User Level setting. While the Beginner and Intermediate settings are adequate for designing a Rave report, these lower settings will be missing some controls. Thus, if there are controls that are covered and it appears that Rave does not have these controls, check the User Level preference setting.

The "Options" in Environment section, controls the Band Headers, environment settings, and rulers. The "Always Show Band Headers" will have the Band Headers shown at all times. "Save Environment Only Changes When Exiting" will save all the changes made to the environment when the program is shut down. "Display Rulers" will keep the rulers visible around the Page if selected.

"Run in administrator mode," allows the user to be prompted for a password if there is a password in the file. When this selection is not selected, and there is a password in the file, the user will not be prompted for a password, the program will just run in non-administrator mode. An administrator can place a password in different areas to restrict access. Placing a password in the AdminPassword property restricts user access.

"Language" changes the language of the user interface. To have this option, the language file translators needs to be installed. Once installed simply choose a language.

Shortcuts Tab

The "Shortcuts" section allows the user to define keyboard shortcuts for a wide variety of Project actions.

It may save you some time to check the list of *"Actions"* to see if a shortcut already exists for those tasks that are repeatedly done while you are using the Rave designer. If there is no shortcut, then you may be able to create a shortcut that will be easy for you to remember.

Appendix A
Formatting

Below is a list of different format codes and what they will accomplish for each output type.

AlphaNumeric Items

Description: DisplayFormat formats the value given using the format string. The following format specifiers are supported in the format string:

	Format String	123456.78	-123.0	0.5	0.0
Examples:	#,##0.00	123,456.78	-123.00	0.50	0.00
	#.#	123456.8	-123	.5	0
	$,0.00	$123,456.78	$-123.00	$0.50	$0.00
	0.00;(0.00);'-'	123456.78	(123.00)	0.50	-----

Specifier	Represents
0	Digit place holder. If value being formatted has a digit where the '0' appears, then the digit is copied to the output string. Otherwise, a '0' is in the output string.
#	Digit place holder. If value being formatted has a digit where the '#' appears, then the digit is copied to the output string. Otherwise, nothing appears in that position.
.	Decimal point. The first '.' character in the format string determines the location of the decimal separator in the formatted value. The actual character used as a the decimal separator in the output string is determined by the Number Format of the International section in the Windows Control Panel.
,	Thousand separator. If the format string contains a ',' characters, the output will have thousand separators inserted between each group of three digits to the left of the decimal point. The actual character used as a the thousand separator in the output is determined by the Number Format of the International section in the Windows Control Panel.
E+	Scientific notation. If any of the strings 'E+', 'E-', 'e+', or 'e-' are contained in the format string, the number is formatted using scientific notation. A group of up to four '0' characters can immediately follow the 'E+', 'E-', 'e+', or 'e-' to determine the minimum number of digits in the exponent. The 'E+' and 'e+' formats cause a plus sign to be output for positive exponents and a minus sign to be output for negative exponents. The 'E-' and 'e-' formats output a sign character only for negative exponents.
'xx'/"xx"	Characters enclosed in single or double quotes are output as-is, and do not affect formatting.
;	Separates sections for positive, negative, and zero numbers in the format string.

The locations of the leftmost '0' before the decimal point in the format string and the rightmost '0' after the decimal point in the format string determine the range of digits that are always present in the output string.

The number being formatted is always rounded to as many decimal places as there are digit placeholders ('0' or '#') to the right of the decimal point. If the format string contains no decimal point, the value being formatted is rounded to the nearest whole number.

If the number being formatted has more digits to the left of the decimal separator than there are digit placeholders to the left of the '.' character in the format string, the extra digits are output before the first digit placeholder.

To allow different formats for positive, negative, and zero values, the format string can contain between one and three sections separated by semicolons.

One section: The format string applies to all values.

Two sections: The first section applies to positive values and zeros, and the second section applies to negative values.

Three sections: The first section applies to positive values, the second applies to negative values, and the third applies to zeros.

If the section for negative values or the section for zero values is empty, that is if there is nothing between the semicolons that delimit the section, the section for positive values is used instead.

If the section for positive values is empty, or if the entire format string is empty, the value is formatted using general floating-point formatting with 15 significant digits.

Date / Time items

Items that are either a date or time field can use the following format codes. The format specifiers are not case sensitive. If the format parameter is blank then the value is formatted as if a 'c' specifier had been given. The following format specifiers are supported:

Examples: dddd, mmmm d, yyyy => Monday, September 21 1998
d mmm yy => 21 Sep 98

Specifier	Displays
c	Displays date using format given by ShortDateFormat global variable, followed by time using format given by LongTimeFormat global variable. The time is not displayed if fractional part of the DateTime value is zero.
d	Displays the day as a number without a leading zero (1-31).
dd	Displays the day as a number with a leading zero (01-31).
ddd	Displays the day as an abbreviation (Sun-Sat) using the strings given by the ShortDayNames global variable.
dddd	Displays the day as a full name (Sunday-Saturday) using the strings given by the LongDayNames global variable.
ddddd	Displays the date using the format given by the ShortDateFormat global variable.
dddddd	Displays the date using the format given by the LongDateFormat global variable.
m	Displays the month as a number without a leading zero (1-12). If the m specifier immediately follows an h or hh specifier, the minute rather than the month is displayed.
mm	Displays the month as a number with a leading zero (01-12). If the mm specifier immediately follows an h or hh specifier, the minute rather than the month is displayed.
mmm	Displays the month as an abbreviation (Jan-Dec) using the strings given by the ShortMonthNames global variable.
mmmm	Displays the month as a full name (January-December) using the strings given by the LongMonthNames global variable.
yy	Displays the year as a two-digit number (00-99).
yyyy	Displays the year as a four-digit number (0000-9999).
h	Displays the hour without a leading zero (0-23).
hh	Displays the hour with a leading zero (00-23).
n	Displays the minute without a leading zero (0-59).
nn	Displays the minute with a leading zero (00-59).

s Displays the second without a leading zero (0-59).

ss Displays the second with a leading zero (00-59).

t Displays the time using the format given by the ShortTimeFormat global variable.

tt Displays the time using the format given by the LongTimeFormat global variable.

am/pm Uses the 12-hour clock for the preceding h or hh specifier, and displays 'am' for any hour before noon, and 'pm' for any hour after noon. The am/pm specifier can use lower, upper, or mixed case, and the result is displayed accordingly.

a/p Uses the 12-hour clock for the preceding h or hh specifier, and displays 'a' for any hour before noon, and 'p' for any hour after noon. The a/p specifier can use lower, upper, or mixed case, and the result is displayed accordingly.

ampm Uses the 12-hour clock for the preceding h or hh specifier, and displays the contents of the TimeAMString global variable for any hour before noon, and the contents of the TimePMString global variable for any hour after noon.

"/" Displays the date separator character given by the DateSeparator global variable.

: Displays the time separator character given by the TimeSeparator global variable.

'xx'/"xx" Characters enclosed in single or double quotes are displayed as-is, and do not affect formatting.

Appendix B
Keyboard / Mouse Shortcuts

Below is a list of different Keyboard / Mouse combinations that can be used as a shortcut. See Preferences - Shortcuts for assigning keyboard keys to your own shortcuts.

Page Designer or Project Tree

Click	on a component selects that component
Right Click	shows context menu for that component
Shift Alt Click	adds all components of the same type as the component clicked on to the selection list of the current page designer
Shift Ctrl Click	adds all children of clicked component to selection list
Shift Click	on a component toggles the selection for that component. This can be used to select multiple components.

Page Designer Only

Click	in blank area of Page Designer removes selection of all components
Ctrl + Arrow Keys	taps (moves) selected components in direction of arrow key
Ctrl C / Ctrl Ins	copies selection to clipboard
Ctrl Click	centers the design window to location clicked
Ctrl F4	unloads current global page
Ctrl V / Shift Ins	paste clipboard to page designer
Ctrl X / Shift Del	cuts selection to clipboards
Delete	deletes currently selected component(s)
Escape	changes selection to parent of current component
F9	executes the current report
F11	toggles between page designer and property panel
Shift + Arrow Keys	changes size of selected components (Up = decrement height, Down = increment height, Left = decrement width, Right = increment width)

Project Tree Only

Alt Drag	DataField component to page designer - creates text component
Alt Drag	selected component to container component in Project Tree - makes the destination component (must be a container component like sections or regions) the parent of all selected components
Ctrl Drag	DataField component to page designer - creates DataText component
Ctrl Drag	component to page designer - creates a mirror of component
Double Click	on Global Page node - loads selected page into page designer
Double Click	on Report node - actives selected report

Appendix C
Property Descriptions

Listed below is an alphabetical listing of all properties that make up the RAVE system. Properties are defined by their data type, category, components they are members of, a short description and any relationships they have with other properties. The default values are added where applicable.

AllowSplit Property

Default
False

Component/Class
Band, DataBand

Description
When set to True, the band will be allowed to split across pages.
Note:
If the band is too large to fit on a page, it will be split no matter the setting of this property.

AlwaysGenerate Property

Default
False

Component/Class
Report

Description
When set to True, generation of the complete report is forced before sending it to the output device. This is important for insuring that the report variables like TotalPages are known before the first page is printed.

Anchor Property

Default
Top / Left

Component/Class
All visible components

Description
Determines the method that will be used to align a component both vertically / horizontally within its parent's area.

See also
ExpandParent

AutoSize Property

Default

True

Component/Class

All BarCode components

Description

When set to true, BarCode dimensions will automatically resize to display all encoded text.

See also

Text

BandStyle Property

Default

'None'

Component/Class

Band, DataBand

Description

One of the powerful features of RAVE is the ability to set a band's behavior with the BandStyle property. Click on the ellipse in the BandStyle area, this will open an editor dialog window that allows the set the behavior needed for the selected band.

See also

ControllerBand, Band Style Editor

BarCodeJustify Property

Default

pjLeft

Component/Class

All BarCode components

Description

Determines where the bar code is printed relative to its bounding box.

pjLeft	Print the bar code left justified.
pjCenter	Print the bar code centered.
pjRight	Print the bar code right justified.

See also

Center, Left, Right

BarCodeRotation Property

Default

Rot0

Component/Class

All BarCode components

Description

Allows the bar code to be rotated to 4 different orientations. The pivot point for rotation is the top left corner of the bar code.

Rot0	no rotation
Rot90	rotate 90 degrees relative to page
Rot180	rotate 180 degrees relative to page
Rot270	rotate 270 degrees relative to page

See also

Left, Top

BarHeight Property

Default

0.5 (PostNet component 0.125)

Component/Class

All BarCode components

Description

Sets the height for the tallest bar.

See also

BarWidth

BarTop Property

Default

0

Component/Class

All BarCode components

Description

Sets the location of the top of the bar code. The location of the readable text is controlled by PrintReadable and PrintTop properties.

See also

PrintReadable, PrintTop, Top

Bin Property

Default

Default (Windows system settings)

Component/Class

Page

Description

Specifies the paper tray used for the document.

See also

Collate, Duplex, Orientation, PaperSize, Printer, Resolution

BorderColor Property

Default

Black

Component/Class

Circle, Ellipse, Rectangle, Square

Description

Sets the color to be used for the border of the graphic.

See also

FillColor

BorderStyle Property

Default

psSolid

Component/Class

Circle, Ellipse, Rectangle, Square

Description

Sets style of border that appears as a frame around shapes.

psClear	No border is drawn
psDash	Creates a dashed border
psDashDot	Creates an alternating dash and dot border
psDashDotDot	Creates an alternating dash and double dot border pattern
psDot	Creates a dotted border
psInsideFrame	Creates a border that is inside the frame of closed shapes
psSolid	Creates a solid border

Note:
Only psSolid can have a pen width greater than 1.

See also

BorderColor, BorderWidth

Bottom Property

Default

'None'

Component/Class

All BarCode components

Description

Sets the position for the bottom of the bar code. The value includes the readable text if it is printed.

See also

PrintReadable, PrintTop

CalcType Property

Default

ctSum

Component/Class

CalcText, CalcTotal

Description

Sets the type of calculation to be performed by the CalcText over the DataField property contents.

ctAverage	average value for a data field
ctCount	count the number of occurrences
ctMax	maximum value for a data field
ctMin	minimum value for a data field
ctSum	sum of a field

See also

CountBlanks, RunningTotal

CalcVar Property

Default

' ' (empty)

Component/Class

CalcTotal

Description

Defines the calculation component that will be used in the CalcType operation. If this property is defined, DataField will be ignored.

See also

CalcType

Categories Property

Default

' ' (empty)

Component/Class

ProjectManager

Description

Defines the available categories to which a report can belong.
For example, could define categories called 'Accounting', 'General', 'Status' and 'System'.

See also

Cursor, DevLocked, Parameters

Category Property

Default

' ' (empty)

Component/Class

Report

Description

Sets the category that a report will belong to. For example, you could define categories called 'Accounting', 'General', 'Status' and 'System'.

See also

Cursor, DevLocked, Parameters

Center Property

Default

'None'

Component/Class

All BarCode components

Description

Sets or returns the position for the horizontal center of the bar code. When a value is assigned to Center the BarCodeJustify property is set to pjCenter as well.

See also

BarCodeJustify, Left, Right

CodePage Property

Default
cpCodeA

Component/Class
I128BarCode

Description
Specifies whether Code A, Code B or Code C is being used.

cpCodeA	sets 128 output to Code A
cpCodeB	sets 128 output to Code B
cpCodeC	sets 128 output to Code C

Collate Property

Default
False

Component/Class
Report

Description
Sets the collation style of the print job for the report.

See also
Bin, Duplex, Orientation, PaperSize, Printer, Resolution

Color Property

Default
Black

Component/Class
Line and text components

Description
Used to set the color of the component's output.

See also
BorderColor, FillColor

Columns Property

Default

1

Component/Class

DataBand, Region

Description

Determines the number of columns to be used, this property is component dependent.

DataBand — Defines how many columns the band will print. The width of each column is divided evenly across the width of the band and printing progresses from the left to right column before progressing to the next row.

Region — Sets the number of columns to be use in the region. When the region is printing, it will print bands contents in all columns from left to right in a snaking fashion.

See also

Columnspacing

ColumnSpacing Property

Default

0

Component/Class

DataBand, Region

Description

Defines the width of a buffer between each column. The spacing will not be applied before the first or after the last column.

See also

Columns

ConnectionName Property

Default

' ' (empty)

Component/Class

DataView

Description

Sets the name of the data connection from which data will be retrieved for the report.

ContainsRTF Property

Default

False

Component/Class

DataMemo

Description

Indicates whether the memo contains RTF or not.

If ContainsRTF is true, then the output will be formatted according to the RTF codes contained in the memo.

Controller Property

Default

' ' (empty)

Component/Class

CalcText, CalcTotal

Description

Defines the controller component that will execute the calculation in the CalcType property when the controller is printed. Normally, the controller is tied to a particular dataview and will signal when new data is available.

See also

CalcType, ControllerBand, DataField, DataView, Initializer

ControllerBand Property

Default

' ' (empty)

Component/Class

Band, DataBand

Description

Sets the controlling band for the current Band or DataBand.

For example, a header or footer band style would assign the data of the DataBand that it is acting as a header or footer for. Detail bands in a master-detail style report would set their ControllerBand to the master DataBand.

See also

BandStyle, Controller

Copies Property

Default

1

Component/Class

Report

Description

Sets the number of copies that the report will generate when it is printed.

See also

Bin, Collate, Duplex, Orientation, PaperSize, Printer, Resolution

CountBlanks Property

Default

True

Component/Class

CalcText, CalcTotal

Description

This property sets whether the CalcText component will count blank field values for the ctAverage and ctCount calculation types.

See also

CalcType

Cursor Property

Default

crDefault

Component/Class

All drawing

Description

Will determine the type of cursor used within that item's selection zone.

crAppStart
crArrow
crCross
crDefault
crDrag
crHandPoint
crHelp
crHourGlass

See also

Categories, DevLocked, Parameters

DataField Property

Default

' ' (empty)

Component/Class

Most data aware components

Description

Defines the type of data that the component will display or process. The contents can be made up of data field names, report variables, project parameters or even string constants surrounded by quotes. It is recommended that you use the data text editor to build a DataField value.

See also

DataView

DataView Property

Default

' ' (empty)

Component/Class

Most data aware components

Description

Defines the data view that will be used if the DataField property is initialized to any field names.

See also

DataField

Description Property

Default

' ' (empty)

Component/Class

DataView, DataField, Page, Report

Description

Defines a multi-line memo that describes the component. This could be used in conjunction with the FullName property to document how the component is to be used.

See also

FullName, Name

DesignerHide Property

Default

False

Component/Class

Band , DataBand

Description

This property controls the visibility of the band contents in the designer. Reduce the "clutter" of other bands by setting their DesignerHide property to true. Then only the one(s) set to false will show. This might be needed if there are a large number of bands or a band that is occupying a large space.

Note:

This has NO effect on what will be printed, only effects what is shown on the designer page.

See also

DevLocked

DestParam Property

Default

' ' (empty)

Component/Class

CalcOp, CalcTotal

Description

value can be blank if the calculation is only going to be used as an intermediate result for other calculation components.

See also

DataField, Operator

DestPIVar Property

Default

' ' (empty)

Component/Class

Page, ProjectManager, Report

Description

Initializes the value of a PIVar (Post Initialize Variable). Any PIVars of the same name that were previously printed will show this value. PIVars are normally printed using the Data Text Editor of the DataText component. The main difference between PIVars and parameters is that PIVars will use the value that is set after (in print order) the PIVar while parameters print the value that was set before. A common use for PIVars is to print a total in a header band that would be initialized later in the footer band. This works even across multiple pages. Report.AlwaysGenerate must be true if you are using PIVars in your report.

See also

AlwaysGenerate, Editor DataText, PIVars

DetailKey Property

Default

' ' (empty)

Component/Class

DataBand , DataCycle

Description

Sets the detail key fields that will be matched to the master key fields in a master-detail report. Multiple fields should be separated with +'s.

See also

MasterKey

DevLocked Property

Default

False

Component/Class

All components

Description

Locks out the ability of anyone making changes to the property.

May be used by the developer to prevent accidental changes being made to a stable part of a complex report structure.

See also

Categories, Cursor, DesignerHide, Parameters

DisplayFormat Property

Default

' ' (empty)

Component/Class

CalcOp, CalcText, CalcTotal, All Numeric Field Types

Description

DisplayFormat formats the value given using the given format string. The various format specifiers are listed in appendix A.

See also

Appendix A

DisplayOn Property

Default

doParent

Component/Class

Most components

Description

Controls whether the component will be used during the print preview display, printer output or both.

doAll	send this item to both preview & printer
doParent	use the parent setting for DisplayOn
doPreviewOnly	item will only be displayed on the preview
doPrinterOnly	component will only be displayed on the printer

DisplayType Property

Default

dtNumericFormat

Component/Class

CalcOp, CalcText, CalcTotal

Description

Defines whether the contents represent numeric or date/time information. The DisplayFormat property will be processed as either numeric or date/time format codes depending upon this setting.

dtDateTimeFormat	sets to Date/Time format
dtNumericFormat	sets to numeric format

Duplex Property

Default

pdDefault

Component/Class

Report

Description

Will set the duplex mode for the current printer.

pdDefault	Use current mode (Duplex mode NOT changed)
pdSimplex	Simplex mode (Duplex mode NOT initialized)
pdHorizontal	Duplex mode initialized - print Head to Toe
pdVertical	Duplex mode initialized - print Head to Head

Note:
Not all printers or drivers support duplex printing.

See also

Bin, Collate, Orientation, PaperSize, Printer, Resolution

ExpandParent Property

Default

True

Component/Class

Memo

Description

When set to true, the height of the parent of the memo will be increased the same amount the height of the memo is increased.
Note:
In order to properly print dynamically sized memos; set ExpandParent to true and also set the vertical anchor to stretch.

See also

Anchor Editor, Anchor Property, DataMemo component

Extended Property

Default

False

Component/Class

Code39BarCode

Description

When set to true, Extended Code 39 format will output instead of standard Code 39 format.

FieldName Property

Default

' ' (empty)

Component/Class

All data field components

Description

Defines the field name that this field component will retrieve data from.

FileLink Property

Default

' ' (empty)

Component/Class

Bitmap, Metafile

Description

Defines a filename to initialize the bitmap or metafile with a file on the hard disk.

See also

Image

FillColor Property

Default

White

Component/Class

Circle, Ellipse, Rectangle, Square

Description

Sets the color that is used to fill the graphical shape

See also

BorderColor, Color, FillStyle

FillStyle Property

Default

fsSolid

Component/Class

Circle, Ellipse, Rectangle, Square

Description

Sets the style used to fill the graphical shape. Use the Fill Toolbar to select the fill style desired or enter it from this properties drop list box.

fsBDiagonal
fsClear
fsCross
fsDiagCross
fsFDiagonal
fsHorizontal
fsNone
fsSolid
fsVertical

Note:
Setting the FillStyle to fsClear will cause the FillColor to be set to White.

See also

BorderColor, Color, FillColor

FinishNewPage Property

Default

False

Component/Class

Band, DataBand

Description

Very similar to StartNewPage, but if set to True, it will cause a new page to begin after this band has finished printing.

Note:
The StartNewPage property would normally be used on header bands while the FinishNewPage property would normally be used on footer bands.

See also

MaxRows, StartNewPage

FirstPage Property

Default

' ' (empty)

Component/Class

Report

Description

Defines the first page that will be printed in a report if the PageList property is empty.

See also

GotoMode, GotoPage, PageList

Font Property

Default

System font

Component/Class

All text components

Description

Defines the font that will be used to draw the contents of a text component.

See also

FontJustify

FontJustify Property

Default

pjLeft

Component/Class

Most text components

Description

Sets the horizontal justification of the text data in the box.

pjBlock	block justify the text
pjLeft	left justify the text
pjCenter	center the text
pjRight	right justify the text

FontMirror Property

Default

System font

Component/Class

Most text components

Description

This property sets the FontMaster component that is used to define the font for the text. Setting this property to a font master will override the Font property.

See also

Font

FullName Property

Default

' ' (empty)

Component/Class

DataField, DataView, Page, Report

Description

Defines the full name or long name of the project item component. The full name is for single line display and may contain special characters and spaces.

See also

Description, Name

GotoMode Property

Default

gmGotoDone

Component/Class

Page

Description

This property determines the behavior of the GotoPage property.

gmGotoDone	Go to the GotoPage property setting when the page definition has completely finished printing. There may be several physical pages if there is a region defined on the page.
gmGotoNotDone	Go to the GotoPage property after a single physical page has printed, only if the current page definition has not finished printing. This option is usually only used with mirrored sections (odd/even layouts, different first page, …).
gmCallEach	Call GotoPage property after each physical page has printed whether the page definition is finished printing or not. This is useful for inserting other pages after each page of a report prints. Control is returned to the calling page when the page chain ends (i.e., a blank GotoPage property is encountered)

See also

GotoPage, PageList

GotoPage Property

Default

' ' (empty)

Component/Class

Page

Description

Defines the page that will be printed after the current page according to the GotoMode property rule.

See also

GotoMode, PageList

GridLines Property

Default

5

Component/Class

Page

Description

Controls the grid lines that are visible.

The default setting of 5 means that every fifth grid line will be visible. If GridSpacing is set to 0.1, then it means that the visible grid lines will be every 1/2 inch but snap to grid will occur every 0.1 inches.

See also

GridSpacing

GridSpacing Property

Default

0.1

Component/Class

Page

Description

Sets the spacing between grid lines.

See also

GridLines

GroupDataView Property

Default

' ' (empty)

Component/Class

Band, DataBand

Description

Defines the data view that will be used to calculate the GroupKey from.

See also

GroupKey

GroupKey Property

Default

' ' (empty)

Component/Class

Band, DataBand

Description

Defines the field(s) that will be used to calculate the group key.

When defining a report using grouping headers or footers, the GroupKey property is used to determine when a new group is encountered. Separate fields should be separated with +'s.

See also

GroupDataView

Height Property

Default

'None'

Component/Class

All visible components

Description

Defines the overall height of the component.

For bar codes this is a read only property that contains the height of the entire bar code.

If the bar code PrintReadable property is set to true, then the Height property contains the bar code height plus the line height of the current font.

See also

BarHeight, PrintReadable

HRadius Property

Default

0

Component/Class

Rectangle, Square

Description

Controls the horizontal radius of the rectangle corner. When used in combination with VRadius, these properties round the corners of rectangles or squares.

See also

VRadius

Image Property

Default

' ' (empty)

Component/Class

Bitmap, Metafile

Description

Defines the image that will be printed with a bitmap or metafile component.

See also

FileLink

InitCalcVar Property

Default

' ' (empty)

Component/Class

CalcController

Description

When this component is acting as an initializer, it defines the calculation component that will be used as the initializing value.
If this property is defined, InitDataField and InitValue will be ignored.

See also

InitDataField, InitDataView, InitValue

InitDataField {CalcController} Property

Default

' ' (empty)

Component/Class

CalcController

Description

If the InitCalcVar property is blank, then this property defines the data field or project parameter that will be used as the initial value for any component(s) using this initializer.
If this property is defined, InitValue will be ignored.

See also

InitCalcVar, InitDataView, InitValue

InitDataField {PageNumInit} Property

Default

' ' (empty)

Component/Class

PageNumInit

Description

Defines the value that the relative page number will start from when this component is printed.

If the text cannot be converted to a valid integer, a default value of 1 will be used.

See also

InitDataView, InitValue

InitDataView Property

Default

' ' (empty)

Component/Class

CalcController, PageNumInit

Description

Defines the default DataView for the InitDataField property.

See also

InitDataField

Initializer Property

Default

' ' (empty)

Component/Class

CalcText, CalcTotal

Description

Defines the initializer component. The CalcController is typically the initializer, which will initialize the calculation when the initializer is printed.

Initializers are useful for setting a calculation to a specific value or initializing it at key points in a report

See also

Controller, CalcController

InitToFirst Property

Default

True

Component/Class

DataBand, DataCycle

Description

Moves the DataSet to the Top of File or first record position.

See also

ConnectionName

InitValue {CalcController} Property

Default

0

Component/Class

CalcController

Description

If InitCalcVar and InitDataField properties are blank, then a constant value is defined that will be used as the initializing value for any components for which this is an initializer.

See also

InitCalcVar, InitDataField, InitDataView

InitValue {PageNumInit} Property

Default

1

Component/Class

PageNumInit

Description

Defines the value that the relative page number will start from when this component is printed. Only the RelativePage report variable (not CurrentPage) will reflect the new page number.

See also

InitDataField, InitDataView

KeepBodyTogether Property

Default

False

Component/Class

DataBand

Description

This property, if true, causes the data band to attempt to keep the bands from the body header to the body footer together on the same page.

See also

KeepRowTogether, OrphanRows, WidowRows

KeepRowTogether Property

Default

False

Component/Class

DataBand

Description

This property, if true, causes the data band to attempt to keep the bands from the row header to the row footer together on the same page.

See also

KeepBodyTogether, OrphanRows

Left Property

Default

'None'

Component/Class

All visible components

Description

Sets the position for the left edge of the component.

See also

Top, Width

LineStyle Property

Default

psSolid

Component/Class

All line components

Description

Sets style of line.

psClear	No line is drawn
psDash	Creates a dashed line
psDashDot	Creates an alternating dash and dot line
psDashDotDot	Creates an alternating dash and double dot line pattern
psDot	Creates a dotted pen
psInsideFrame	Creates a pen that draws a line inside the frame of closed shapes
psSolid	Creates a solid line

Note:
Only psSolid can have a pen width greater than 1 pixel.

See also

BorderStyle, BorderWidth, LineWidth

LineWidth Property

Default

1

Component/Class

Drawing

Description

Sets the width of the line. The units for this line thickness is controlled by the LineWidthType property. Line widths greater than 1 pixel can only be used with solid lines.

See also

LineStyle, LineWidthType

LineWidthType Property

Default
wtPixels

Component/Class
Drawing

Description
Determines whether the LineWidth property of the graphic shape is measure in pixels or points. Use pixels and a LineWidth of 1 (the defaults) if the thinnest line possible is needed. Also use points for all other LineWidth values for consistent thickness across devices.

WtPixels	LineWidth is measured in pixels
WtPoints	LineWidth is measured in points (1 point = 1/72nd of an inch)

See also
LineWidth

Locked Property

Default
False

Component/Class
All components

Description
Controls the state of the selected component(s) properties and all of its children (if any).
If true, then the properties cannot be selected or changed.
The color of the property names and pips (if selected) will be red when this property is true.
Note:
This can be used to a freeze part of a page design, so that the design cannot accidentally be moved while completing a design in another area.

LookupDataView Property

Default
' ' (empty)

Component/Class
DataText

Description
Specifies the data view that lookup will be performed on.

See also
DataField, LookupDisplay, LookupField, LookupInvalid

LookupDisplay Property

Default

' ' (empty)

Component/Class

DataText

Description

Specifies the field in LookupDataView that will actually be displayed in the report after the lookup is performed.

See also

DataField, LookupDataField, LookupField, LookupInvalid

LookupField Property

Default

' ' (empty)

Component/Class

DataText

Description

Specifies the field(s) in LookupDataView that will be matched to the value of the field(s) defined by DataField. Once a match is found, the value of LookupDisplay will be shown in the report.

See also

DataField, LookupDataField, LookupDisplay, LookupInvalid

LookupInvalid Property

Default

' ' (empty)

Component/Class

DataText

Description

Defines the text that will be displayed if no matches are found for the current value of DataField in the LookupDataView.

See also

DataField, LookupDataField, LookupField, LookupField

MailMergeItems Property

Default
' ' (empty)

Component/Class
All memo components

Description
Stores the tokens and replacement data text items that will be used in a search and replace during a mail merge session.

See also
Mail Merge Editor (page 129)

MasterDataView Property

Default
' ' (empty)

Component/Class
DataBand, DataCycle

Description
Defines the DataView that will be used to calculate the MasterKey property from.

See also
DetailKey, MasterKey

MasterKey Property

Default
' ' (empty)

Component/Class
DataBand, DataCycle

Description
Determines the master key field(s) for a master-detail style report. The contents of the MasterKey field(s) will be matched to the DetailKey property to set up the master-detail relationship in the detail databand. Multiple fields should be separated by +'s.

See also
DetailKey, MasterDataBand

MatchSide Property

Default

msWidth

Component/Class

Bitmap, Metafile

Description

Determines the method that the bitmap or metafile will use to resize itself.

msBoth	The image will size to match both the designed width and height.
msHeight	The image will match the designed height and adjust the width to maintain the correct proportions.
msInside	The image will be drawn proportionally inside the designed area.
msWidth	The image will match the designed width and adjust the height to maintain the correct proportions.

See also

Height, Width

MaxRows Property

Default

0

Component/Class

DataBand, DataCycle

Description

Defines the maximum number of rows that will be printed for a data band. A value of 0 means print all available rows in the data view.

See also

StartNewPage

MinHeightLeft Property

Default

0

Component/Class

Band

Description

Defines the minimum height that must remain in the region before this band will print. If the MinHeightLeft value is greater than the remaining height in the region, then band will be printed on the next page.

See also

Region

Mirror Property

Default

' ' (empty)

Component/Class

All components

Description

Will cause to currently selected component to mirror (duplicate) the properties of the component entered from the list.

See also

Global Page

Module Property

Default

None yet

Component/Class

Page

Description

This property is not implemented yet.

See also

Description, FullName

Name Property

Default

'None'

Component/Class

All components

Description

Defines the name of the component as referenced in the application's code. Use the Name property to assign a new name to the control or to find out what the name of the control is. By default, Rave assigns sequential names based on the type of the control, such as 'Rectangle1', 'Rectangle2', and so on. Change these to more meaningful names that make the code more readable. The Name must not contain any spaces or special characters. This is the name that will be used in the Project Tree Panel.

See also

Description, FullName

NullText Property

Default

' ' (empty)

Component/Class

DataField

Description

Sets the contents that will be printed if the DataField value is blank (empty).

See also

DataField, TextFalse, TextTrue

Operator Property

Default

coAdd

Component/Class

CalcOp

Description

Defines the type of operation that will be performed on the two source values. The result of this calculation can be placed in a project parameter using the DestParam property or used in other calculations as a CalcVar component.

coAdd	operation set to Source1 + Source2
coAverage	operation set to (Source1 + Source2) / 2.0
coDiv	operation set to Source1 / Source2
coExp	operation set to Source1 raised to the Source2 power
coGreater	operation set to the greater of Source1 and Source2
coLesser	operation set to the lesser of Source1 and Source2
coMod	operation set to Source1 mod Source2
coMul	operation set to Source1 * Source2
coSub	operation set to Source1 - Source2

See also

DestParam, ResultFunction, Src1Xxxxx, Src2Xxxxx

Orientation Property

Default

poDefault

Component/Class

Page

Description

Sets the orientation for a page to landscape or portrait. The value of poDefault will use the default setting for the printer to determine the orientation.

See also

Bin, Collate, Duplex, PaperSize, Printer, Resolution

OrphanRows Property

Default

0

Component/Class

DataBand

Description

Sets the minimum number of rows that can be by themselves at the bottom of a page. The default value of 0 and allows orphans (i.e. 1 row at the bottom of a page).

See also

KeepBodyTogether, KeepRowTogether, WidowRows

PageHeight Property

Default

11

Component/Class

Page

Description

Defines the height of the page. Normally this property will be modified via the PaperSize property.

See also

PageWidth, PaperSize

PageList Property

Default

' ' (empty)

Component/Class

Report

Description

Defines a list of pages to print when then report is executed. If no pages are defined in the PageList then the report will start with what is defined by the FirstPage property.

See also

FirstPage , Batch Report example on page 151

PageWidth Property

Default

' ' (empty)

Component/Class

Page

Description

Defines the width of the page. Normally this property will be modified via the PaperSize property.

See also

PageHeight, PaperSize

PaperSize Property

Default

"Letter, 8 ½ by 11 inches"

Component/Class

Page

Description

Provides a method to select the size of paper being used for a report node. Select one the report nodes, the property panel will show the properties available at the report level. Select the PaperSize and there will be a drop list where paper size can be selected.

Note:

All pages within a report must be of the same size. If they are not, the first printed page will determine the size used for all pages within that report.

See also

Orientation, PageHeight, PageWidth

Parameters Property

Default

' ' (empty)

Component/Class

Page, ProjectManager, Report

Description

Allows parameters to be defined that are available at the project, report and page level. Parameters can be used to print data that is passed from the application (e.g. ReportTitle or UserName) or to store calculation results. Parameters can be printed using the Data Text Editor of the DataText component.

See also

Editor DataText, DestParam, DestPIVar, PIVars

PIVars Property

Default

' ' (empty)

Component/Class

Page, ProjectManager, Report

Description

Allows PIVars (Post Initialize Variables) to be defined at the project, report and page level. PIVars are initialized using the DestPIVar property of the calculation components. PIVars are normally printed using the Data Text Editor of the DataText component. The main difference between PIVars and parameters is that PIVars will use the value that is set after (in print order) the PIVar while parameters print the value that was set before. A common use for PIVars is to print a total in a header band that would be initialized later in the footer band. This works even across multiple pages. Report.AlwaysGenerate must be true if you are using PIVars in your report.

See also

AlwaysGenerate, DestPIVar, Parameters, DataText

PositionMode Property

Default

pmOffset

Component/Class

Band, DataBand

Description

Determines how the position of this band will be treated relative to the previously printed band.

pmAbsolute	distances measured from top of region
pmOffset	distances measured from bottom of last band
pmOverlay	does not advance band position

See also

PositionValue

PositionValue Property

Default

0

Component/Class

Band, DataBand

Description

Sets the starting position of this band based upon the PositionMode property setting. If the setting is pmAbsolute, then this bands starting position is measured from the top of the controlling region for this band. If the setting is pmOffset, then the distance is from the bottom of the last printed band. The pmOverlay setting acts like pmOffset, however, it does not advance the "last" band printed setting.

See also

PositionMode

PrintChecksum Property

Default

'None'

Component/Class

All BarCode components

Description

Determines if the readable text includes the checksum character.

Note:

It is possible that the checksum character may not be a printable character with some of the bar code types.

See also

BarTop, UseChecksum

Printer Property

Default

' ' (empty)

Component/Class

Report

Description

Determines the printer that the report will be output to. Normally leave this field blank to print to the default printer.

See also

Bin, Collate, Duplex, Orientation, PaperSize, Resolution

PrintReadable Property

Default
True

Component/Class
All bar code components, except UPC

Description
Set this property to false, to not allow readable text to be printed along with the bar code.
Note:
For UPC bar codes, text is always printed.

See also
PrintTop, TextJustify

PrintTop Property

Default
False

Component/Class
All BarCode components

Description
Set this property to true to allow the readable text to be printed on top of the bar code. A false value means that the readable text will be printed below the bar code. This property has no effect when printing UPC codes, since the UPC text is always printed at the bottom of the bar code.

See also
PrintReadable, TextJustify

ReprintLocs Property

Default
(ALL)

Component/Class
Band, DataBand

Description
Determines whether the band reprints at the start of a new page. When a band is set to reprint on a new page, the type of band that caused the rollover to the new page will be checked against the band types in the ReprintLocs property. If they band type is found in ReprintLocs, then the band will be reprinted on the new page.

See also
BandStyle

Resolution Property

Default

prDefault

Component/Class

Report

Description

Determines the output resolution of the print job.

prDefault
prDraft
prHigh
prLow
prMedium

See also

Bin, Collate, Duplex, Orientation, PaperSize, Printer

ResultFunction Property

Default

cfNone

Component/Class

CalcOp

Description

Defines the function that will be applied to the result of the calculation after the operation has been performed.

cfAbs	result is the absolute of the value
cfArcTan	result is the ArcTan of the value in radians
cfCos	result is the cosine of the value in radians
cfDec	result is the value - 1
cfFrac	result is the decimal portion of the value
cfHoursToTime	converts the value in hours to DateTime format
cfInc	result is the value + 1
cfMinsToTime	converts the value in minutes to DateTime format
cfNeg	result is the value * -1
cfNone	result is unchanged
cfPercent	result is multiplied by 100
cfRandom	Result is a random value between 0 and the value
cfRound	Result is rounded to the nearest integer
cfRound1	Result is rounded to the 1st decimal place
cfRound2	Result is rounded to the 2nd decimal place
cfRound3	Result is rounded to the 3rd decimal place
cfRound4	Result is rounded to the 4th decimal place
cfRound5	Result is rounded to the 5th decimal place
cfSecsToTime	Converts the value in seconds to datetime format
cfSin	Result is the Sine of the value in radians
cfSqr	Result is the square of the value
cfSqrt	Result is the square root of the value
cfTimeToHours	Converts the value in datetime format to hours
cfTimeToMins	Converts the value in datetime format to minutes
cfTimeToSecs	Converts the value in datetime format to seconds
cfTrunc	Result is the integer portion of the value

See also

DestParam

Right Property

Default

'None'

Component/Class

All BarCode components

Description

Sets or returns the position for the right edge of the bar code. When a value is assigned to Right, the BarCodeJustify property is set to pjRight as well.

See also

BarCodeJustify, Center, Left

Rotation Property

Default

0

Component/Class

CalcText, DataText, Text

Description

Defines the rotation in degrees of the selected text component. The text is rotated counter clockwise through the values 0 to 359.

See also

BarCodeRotation

RunningTotal Property

Default

False

Component/Class

CalcText, CalcTotal

Description

Determines if a running total is kept when a NewPage occurs.

False	means NO and the value is reset to 0 each time it is printed
True	means Yes and the value is kept and will continue to total after it is printed

See also

CalcType, CountBlanks

Size Property

Default

'None'

Component/Class

DataField

Description

Defines the character width of the data field. This is normally used with design time activities such as dragging and dropping DataText components to determine an approximate width that it will take to print the component.

SortKey Property

Default

' ' (empty)

Component/Class

DataBand, DataCycle

Description

Defines the field(s) that will be passed to the data connection to set up a sort. Separate multiple fields with +'s.

Note:

The underlying database must support the fields being passed as a sort key.

Src1CalcVar Property

Default

' ' (empty)

Component/Class

CalcOp

Description

Defines a calculation component to use as the first source value for the calculation operation. If this property is defined, Src#DataField and Src#Value will be ignored.

See also

Src#DataField, Src#DataView, Src#Function, Src#Value

Src1DataField Property

Default

' ' (empty)

Component/Class

CalcOp

Description

If Src#CalcVar is blank, defines a data field to use as the first source value for the calculation operation. If this property is defined, Src#Value will be ignored.

See also

Src#CalcVar, Src#DataView, Src#Function, Src#Value

Src1DataView Property

Default

' ' (empty)

Component/Class

CalcOp

Description

Defines the default dataview that will be used for the Src#DataField property.

See also

Src#DataField

Src1Function Property

Default

cfNone

Component/Class

CalcOp

Description

Defines the function that will be performed on the source value before the calculation operation is performed.

Note:

see ResultFunction (for list of constants).

See also

Src#CalcVar , Src#DataField , Src#Value

Src1Value Property

Default

0

Component/Class

CalcOp

Description

If Src#CalcVar and Src#DataField are blank, defines a constant value that will be used as the first source value for the calculation operation.

See also

Src#CalcVar, Src#DataField, Src#Function

Src2CalcVar Property

Default

' ' (empty)

Component/Class

CalcOp

Description

Defines a calculation component to use as the first source value for the calculation operation. If this property is defined, Src#DataField and Src#Value will be ignored.

See also

Src#DataField, Src#DataView, Src#Function, Src#Value

Src2DataField Property

Default

' ' (empty)

Component/Class

CalcOp

Description

If Src#CalcVar is blank, defines a data field to use as the first source value for the calculation operation. If this property is defined, Src#Value will be ignored.

See also

Src#CalcVar, Src#DataView, Src#Function, Src#Value

Src2DataView Property

Default

' ' (empty)

Component/Class

CalcOp

Description

Defines the default dataview that will be used for the Src#DataField property.

See also

Src#DataField

Src2Function Property

Default

cfNone

Component/Class

CalcOp

Description

Defines the function that will be performed on the source value before the calculation operation is performed.

Note:

see ResultFunction (for list of constants).

See also

Src#CalcVar , Src#DataField , Src#Value

Src2Value Property

Default

0

Component/Class

CalcOp

Description

If Src#CalcVar and Src#DataField are blank, defines a constant value that will be used as the first source value for the calculation operation.

See also

Src#CalcVar, Src#DataField, Src#Function

Tag Property

Default

nil

Component/Class

All components

Description

Tag has no predefined meaning to Rave. The Tag property is provided for the convenience of storing additional integer value or pointer information for special needs in an application. For example, use the Tag property when implementing case statements with a component.

Text Property

Default

'None'

Component/Class

Text components and all bar code components

Description

For bar codes, do not include the check character. The check character will be automatically calculated and printed according to the state of the UseChecksum property.

Note:

For bar codes, any characters that are invalid for the bar code type will be deleted from the text property upon assignment.

See also

Font , FontJustify

TextFalse Property

Default

' ' (empty)

Component/Class

BooleanField

Description

Determines what will printed is the field value is False. A blank value for this property will print the text "False".

See also

TextTrue

TextJustify Property

Default

pjCenter

Component/Class

All BarCode components

Description

Determines how the readable text is justified in relation to the bar code.

pjBock	Block justify the text portion
pjLeft	Left justify the text portion
pjCenter	Center justify the text portion
pjRight	Right justify the text portion

See also

PrintReadable, PrintTop, Text

TextTrue Property

Default

' ' (empty)

Component/Class

BooleanField

Description

Determines what will printed is the field value is True. A blank value for this property will print the text "True".

See also

TextFalse

Top Property

Default

'None'

Component/Class

All visible components

Description

Sets or returns the position for the top edge of the component. For bar codes, the value for this property includes the readable text, if it is printed.

See also

BarTop, Left, PrintReadable, PrintTop

Truncate Property

Default

False for CalcText and Text, True for DataText

Component/Class

CalcText, DataText, Text

Description

When set to true, the text will be truncated to fit the Width property defined in the designer for that component. If the property is false, then all of the text will print without regard to the width property.

See also

Width

Units Property

Default
unInch

Component/Class
Project

Description
Sets the default units mode for this project. If the setting is unUser then units factor is determined by the value in UnitsFactor.

unCM	Units are in centimeters
unInch	Units are in inches
unMM	Units are in millimeters
unPoint	Units are in points (1/72nd inch)
unUser	Unit are custom defined in UnitsFactor

See also
UnitsFactor

UnitsFactor Property

Default
1.0

Component/Class
Project

Description
Sets or returns the current conversion factor necessary to convert units to inches. Its value should equal the number of units that equal an inch. (unCM = 2.54 since 2.54 centimeters equal an inch)

See also
Units

UseCheckSum Property

Default
False (Code128 := true)

Component/Class
All BarCode components

Description
Specifies whether a checksum character should be included in the bar code.

See also
BarHeight, BarWidth, PrintReadable, Text, Width

VRadius Property

Default

0

Component/Class

Rectangle , Square

Description

Controls the vertical radius of the rectangle corner. When used in combination with HRadius, these properties round the corners of rectangles or squares.

See also

HRadius

WasteFit Property

Default

True

Component/Class

Page, Section

Description

If true, components on the page or within the section will dynamically adjust themselves to fit within the printer's waste margins. If a component is not located within the waste area, no adjustment will occur unless it's parent component is located in the waste area.

It is important that components (within a page or section) use the "Anchor" property so that they will adjust as the margins change.

See also

Anchor, Anchor Editor, PageHeight, PageWidth, PaperSize

WideFactor Property

Default

3.0

Component/Class

All BarCode components

Description

The wide factor is the ratio of the wide bar to the narrow bar width.

See also

BarHeight, BarWidth, Width

WidowRows Property

Default

0

Component/Class

DataBand

Description

Sets the minimum number of rows that can be by themselves on the top of the next page. The default setting is 0 and allows widows.

See also

KeepBodyTogether, KeepRowTogether, OrphanRows

Width Property

Default

'None'

Component/Class

All components

Description

Sets the width of the component. For bar codes, this will return the calculated width of the entire bar code for the current value of Text.

See also

BarWidth, Height, Left, Text, WideFactor

WidthType Property

Default

wtPixels

Component/Class

Drawing components

Description

Determines how the width of lines is calculated. Generally *wtPixels* and a line width of 1 pixel should be used when the thinnest possible line is desired (typically referred to as hairline). The width type of *wtPoints* should be used on all line widths greater than one pixel to maintain consistency between devices of different DPI resolutions (i.e. Printer and Preview). When using *wtPoints*, line widths are expressed in terms of points (72 points per inch).**See also**

BorderWidth, LineWidth

Borland®

What's New in Borland® Delphi™ 7 Studio

Improve developer productivity and enhance performance

by Technical Publications
Borland Software Corp.
August 2002

Contents

Introduction

Borland® Delphi™ 7 Studio includes new features and enhancements in the following areas:

- IDE
- Web technology
- COM technology
- Database technology
- Component library
- Runtime library
- Compiler
- Support for Rave Reports
- Support for ModelMaker
- Documentation

If you are upgrading from a previous version of Delphi, see "Upgrade and compatibility issues" on page 7.

IDE

The IDE has new features in the following areas:

Compiler messages

- The new View|Additional Message Info command displays a Message Hints window from which you can download and view information about compiler messages from the Borland Web site.
- The new Project|Options|Compiler Messages page gives you greater control over which compiler warnings are generated.

Component palette

- When you open a Borland CLX™ (Component Library for Cross-platform) application in Delphi, a new CLX-only version of the System page is displayed. It includes several directory and file components. In previous releases, the System page was displayed only for VCL applications and included components for system-level access.
- The new Indy Intercepts and Indy I/O Handlers pages provide open source Internet protocol components (Professional and Enterprise editions).
- The new IW Standard, IW Data, IW Client Side, and IW Control pages provide AtoZed Software IntraWeb components for developing Web-based applications.
- The new Rave page provides components for adding report generation to your applications.
- If a component page can be scrolled horizontally to display additional icons, a new drop-down menu button can also be used to list the additional icons.

CodeInsight™

- Code completion is now faster and lets you browse to the declaration of items in the code completion list by using Ctrl+click on any identifier in the list.
- New HTML code completion automatically displays valid HTML elements and attributes in the Code editor (Professional and Enterprise editions only).
- You can create customized code completion managers by using the OpenTools API. See “Extending the IDE” in the Delphi online help for details.
- The Tools|Editor Options|Code Insight page lets you set colors for the symbols displayed in the CodeInsight™ tools.

Debugger

- The Watch List now has:
    - Multiple tabs, allowing you to organize watches into distinct watch groups for easier debugging. To add a watch group, right-click the Watch List and select Add Group.
    - A Watch Name column and a Value column. To show/hide the column headers, right-click the Watch List and select Show Column Headers.
    - A checkbox to enable or disable individual watches.
- The Tools|Debugger Options|Event Log page has the following new options:
    - Use Event Log Colors lets you display different types of event messages in color in the event log.
    - Module messages writes a message to the event log each time a module (exe, dll, ocx, etc.) is loaded or unloaded by the process that you are debugging. Previously, the Process messages option controlled whether these events were logged.
- The Run Parameters dialog box has a new option, Working Directory, that lets you specify the name of the directory to use for the debugging process.

Miscellaneous IDE improvements

- From the Project Manager, you can partially compile projects within a group by right-clicking on any project and choosing Make All from Here or Build All from Here.
- The Message view has multiple tabs for displaying different types of messages (Build, Search, and so on).
- The View|Component List command lets you multiselect components by pressing the Ctrl key.

- The new Tools|Editor Options|Source Options page lets you:
    - Set different editor options for different source types, such as Pascal, C++, C#, HTML, and XML.
    - Display tab and space characters in the Code editor.
    - Edit code templates.
    - Several of the options on the new page were formerly on the General, Display, and CodeInsight pages of the Editor Properties dialog box.
- The Tools|Editor Options|Color page has two new options, Foreground Color and Background Color, instead of a color grid, for setting colors in the Code Editor.
- Pressing Alt+Page Down and Alt+Page Up cycles through tabbed views such as the Code Editor, Watch Window, and Message view. These keyboard shortcuts are included in the Default, IDE Classic, and BRIEF key mappings.
- Delphi now displays a two-tone main menu.

Web technology

In Delphi 7 Studio Enterprise and Professional editions:

- Delphi now includes IntraWeb from AToZed Software. You can use IntraWeb to develop Web server applications using standard form tools. You can also use IntraWeb to develop pages for Borland WebBroker™ and WebSnap™ applications. For more information, see "Creating Web server applications using IntraWeb" in the *Developer's Guide* or online Help. Delphi 7 Studio Enterprise includes the complete IntraWeb product. Delphi 7 Studio Professional includes a subset of the IntraWeb product.
- Delphi now supports Apache™ 2 as a target type for WebBroker, WebSnap, and SOAP.
- Borland has deprecated Win-CGI as a target type for Web server applications and Web Services. Borland recommends using regular CGI, ISAPI/NSAPI, or an Apache target type instead. Existing Win-CGI projects can still be modified and compiled in the IDE, however, Borland does not guarantee Win-CGI compatibility for the indefinite future.

Web Services

Web Services includes the following enhancements.

New UDDI browser

The WSDL Import Wizard has a new Universal Description, Discovery, and Integration (UDDI) browser that lets you search a UDDI registry for a Web Service and import the address of its WSDL document.

SOAP headers

New classes and interfaces let you read or insert headers into the SOAP envelopes that transmit messages between clients and servers. For more information, see "Defining and using SOAP headers" and "Processing headers in client applications" in the *Developer's Guide* or online Help.

Attachments

Web Services applications (both client and server) can now handle attachments. Attachments (TSOAPAttachment descendants) are sent with SOAP-encoded messages as part of a multipart form. When an application receives the attachment, it saves it to a temporary file, which is then available to your application.

Type support

- You can now customize the conversion between remotable classes and their SOAP representation by overriding two new virtual methods that were added to TRemotable: ObjectToSOAP and SOAPToObject.
- Exception objects for exceptions that occur when responding to a Web Service request (ERemotableException instances) now contain more information from the SOAP fault packet.
- Type definitions are automatically registered with the remotable type registry when you register an invokable interface.

- TXSDecimal has a new AsBcd property for easier conversion between XML and native types. Similarly, TXSHexBinary has a new AsByteArray property. Remotable classes that represent time values now let you work with fractional seconds rather than milliseconds.

Other enhancements

- New events on THTTPReqResp let you to intercept the HTTP message before it is sent and to monitor progress while sending or receiving long messages.
- THTTPSoapPascalInvoker now publishes events that let you write code to execute before or after the invoker executes a requested method call.
- You now have more control over the mapping between invokable interfaces and WSDL documents. TWSDLHTMLPublish now publishes several events to let you control the generated WSDL. You can also identify the mapping between function return values and parameter names, the use of namespaces, and default SOAP actions. On the client side, literal encodings are now supported as well as RPC-style encoding.
- A new interface, IRIOAccess lets you access the remote interfaced object that implements an invokable interface.
- The IOPConvert interface has a new property: Encoding. This allows you to specify the character set to use for encoded messages that are passed between the client and Web Services provider.
- There are changes to Web Services that affect Borland DataSnap™ applications. For more information, see "Database technology " on page 4.
- The TLinkedRIO constructor now automatically generates separate file names for each method you call, making debugging easier.
- TOPToSoapDomConvert now has two new events that you can use when debugging the deserialization of SOAP packets.
- You can now use overloaded methods on invokable interfaces that you define.

COM technology

In Delphi 7 Studio Enterprise and Professional editions:

You can now use the Import Type Library dialog box (Project|Import Type Library) to create a CoClass wrapper for Microsoft® .NET assemblies. You can use the resulting wrapper as you would an ordinary COM server, using the interoperability features of .NET.

Database technology

In Delphi 7 Studio Enterprise and Professional editions:

- The dbExpress drivers have been updated for IBM® DB2® 7.2 and Informix® SE, Oracle9i,™ Borland InterBase® 6.5, and MySQL™ 3.23.49. A new driver is available for Microsoft SQL 2000.
- There are several new and changed database components. See "Component library " on page 5 for details.
- Borland has deprecated SQL Links; no further enhancements will be made to SQL Links, and it will not be included with Delphi after 2002. Borland recommends using dbExpress for SQL server database access in Delphi.

DataSnap™

In Delphi 7 Studio Enterprise edition only:

- In DataSnap applications, the use of IAppServer has been changed to IAppServerSOAP, which avoids some ambiguities in the IAppServer interface. The UseSOAPAdapter property of TSoapConnection can be used to write clients for servers written with earlier versions of Delphi. TSoapConnection also publishes several new events for you to customize your client applications at various points in the process of executing a Web Services request.
- You can now identify a specific SOAP data module in an application server that has multiple data modules. Use the SOAPServerIID property or add the data module's interface to the end of the URL.

- You can now use the SOAP connection component to call extensions to the application server's interface. Use the SOAPServerIID property and the GetSOAPServer method.
- DataSnap no longer supports CORBA® connections.

Component library

Support for Windows XP™ Themes

In Delphi Studio 7 Enterprise and Professional editions, Borland VCL applications now include components that enable support for Windows® common controls version 6. Your application will automatically use the new Windows controls on Windows XP™ systems if it finds a suitable manifest file. For more information, see "Common controls and XP themes" in the *Developer's Guide* or online Help.

New unit

The new DBClientActns unit contains three new action components for working with client datasets: TClientDataSetApply, TClientDataSetUndo, and TClientDataSetRevert.

New components

- The dbExpress page of the Component palette includes TSimpleDataSet for use with simple, two-tier database applications (TSimpleDataSet replaces TSQLClientDataSet).
- The Dialogs page of the Component palette includes TPageSetupDialog for providing a Windows-standard page setup dialog box.
- The Additional page of the Component palette includes TXPColorMap, TStandardColorMap, and TTwilightColorMap for colorizing menus and toolbars.
- The new CLX version of the System page of the Component palette includes new directory and file components.
- The new Indy Intercepts and Indy I/O Handlers pages on Component palette provide Internet protocols in Professional and Enterprise editions.

Changed components

- The CLX versions of TOpenDialog and TSaveDialog have been expanded to support additional features such as file previewing.
- The VCL version of TCustomForm has two new properties, ScreenSnap and SnapBuffer, which control whether a form snaps to the edge of the screen when the form is moved.
- TCustomComboBoxEx has a new AutoCompleteOptions property that enables a combo box to respond to user keystrokes.
- CLX dialog objects that descend from TOpenDialog and TQtDialog can now use Windows Common Dialogs in place of Qt Dialogs. This behavior is controlled by the UseNativeDialog property, which defaults to true.

Deprecated components

Information about deprecated components can be found in the readme.txt file in the Delphi 7 Studio directory.

Runtime library

Classes unit

- A new exception class, EFileStreamError, has been added. EFileStreamError and EFOpenError descend from this class. This new class may take a FileName parameter. As a result, the exception message text now contains the name of the file the error occurred on.
- The TStrings class has two new properties, ValueFromIndex and NameValueSeparator.
- The TThread.CheckThreadError methods have been promoted from private to protected visibility.

Math unit

The Math unit has a new default parameter, RaisePending, in the ClearExceptions procedure.

StdConvs unit

The StdConvs unit now includes stones in the supported weight units.

StrUtils unit

The StrUtils unit contains the following changes related to multi-byte character set (MBCS) support:

- Previously, LeftStr, RightStr, and MidStr each had an AnsiString parameter type and return type, and did not support MBCS strings. Each of these functions has been replaced by a pair of overloaded functions, one that takes and returns AnsiString, and one that takes and returns WideString. The new functions correctly handle MBCS strings. This change breaks code that uses these functions to store and retrieve byte values in AnsiStrings. Such code should be updated to use the new byte-level functions described below.
- New functions LeftBStr, RightBStr, and MidBStr provide the byte-level manipulation previously provided by LeftStr, RightStr, and MidStr.
- New functions AnsiLeftStr, AnsiRightStr, and AnsiMidStr are the same as the new AnsiStr LeftStr, RightStr, and MidStr functions, except that they are not overloaded with equivalent WideString functions.

The StrUtils unit has a new string-searching function called PosEx.

SysUtils unit

The SysUtils unit now includes thread-safe overloads of routines that format and parse numbers, date-time values, and currency. The new routines are thread-safe because they obtain their localization information from a TFormatSettings data structure instead of from global variables. This data structure must be populated before being used; a new function, GetLocaleFormatSettings, is provided to populate the data structure from a specified locale.

VarCmplx unit

The VarCmplx unit has new functions: VarComplexLog2, VarComplexLog10, VarComplexLogN, VarComplexTimesImaginary, and VarComplexTimesReal.

Variants unit

- The VarIsError and VarAsError functions have been added.
- The EVariantError exception is now a base class for finer grained exception classes that are thrown from variants code.
- Several new global Variant control variables have been added: NullEqualityRule, NullMagnitudeRule, NullStrictConvert, NullAsStringValue, and PackVarCreation.

Compiler

The Delphi compiler now supports three additional compiler warnings: Unsafe_Type, Unsafe_Code, and Unsafe_Cast. These warnings are disabled by default, but can be enabled with the compiler directive `{$WARN UNSAFE_CODE ON}`, compiler command line switch `dcc32 -W+UNSAFE_CODE`, and, in the IDE, on the Project|Options|Compiler Messages page.

This feature is intended to help you port your code to the managed execution environment of the .NET platform. In a managed execution environment, "unsafe" means the operation cannot be verified during the static analysis performed by the Just In Time (JIT) compiler. Such code might pose a security risk, since there is not enough information for the JIT compiler to verify its runtime behavior. Examples of unsafe code include pointer operations and memory overwrites.

Support for Rave Reports

In Delphi 7 Studio Enterprise and Professional editions:

The Delphi environment now includes Rave Reports from Nevrona. By adding Rave Reports components to your application, you can enable your users to generate reports within your application. For more information see “Creating reports with Rave Reports” in the *Developer’s Guide* or online Help.

Support for ModelMaker

In Delphi 7 Studio Enterprise and Professional editions: ModelMaker tools can help simplify the design, construction, and maintenance of classes and interfaces. ModelMaker also includes tools for creating UML™-style diagrams, which can be used to create and modify your projects' source code. For more information, see "Designing classes and components with ModelMaker" in the *Developer's Guide* or online Help.

Delphi 7 Studio Enterprise includes ModelMaker from ModelMaker software. Delphi 7 Studio Professional includes a 30-day trial version of ModelMaker. The ModelMaker functionality is the same in both editions of the Delphi environment.

Documentation

- All of the documentation files (PDF, HTML, and INT) are now distributed in the **Online+PDF Docs** folder on the Delphi Companion Tools CD instead of the installation CD. You can access the documentation directly from the CD or copy it to the folder of your choice.
- Due to size constraints for the printed *Developer's Guide*, Part V "Creating custom components," has been removed from that book to create the new *Component Writer's Guide.* The new book is available in the online Help and as a PDF file on the Delphi Companion Tools CD.
- The Object Pascal language is now called the Delphi™ language. The online Help and documentation have been updated accordingly.
- The *Object Pascal Language Guide* is now the *Delphi Language Guide*.
- To ensure the continued accuracy of the Delphi tutorials, they have been removed from the *Quick Start* and the *Developer's Guide*. The tutorials are available as PDF files on the Delphi Companion Tools CD.
- Some of the Delphi online help topics include C++ syntax and code examples for Borland Kylix™ and C++Builder™ users. For Delphi development, please disregard these examples.

Upgrade and compatibility issues

For late-breaking upgrade and compatibility issues, see the readme.txt file in the Delphi 7 installation directory.

- To upgrade a Delphi (formerly Object Pascal) language project from a previous version of Delphi, open it in the new version. The project is automatically updated to the new release.
- Details in Fault messages are now added to the <detail> node rather than as children of the <detail> node. This brings our handling of SOAP faults into accordance with the SOAP specification, but breaks backward compatibility with older code.
- Changes to the StrUtils unit LeftStr, RightStr, and MidStr functions may require you to update code that uses these functions. See "Runtime library " on page 5 for details.
- For Apache 2, the variable "ContentType" has been changed to "handler" in the ApacheApp unit.
- DataSnap no longer supports CORBA® connections.

Author: G. Beuze

Contents

Introduction

ModelMaker represents a brand new way to develop classes and component packages for Borland Delphi 1-6. ModelMaker is a two-way class tree oriented productivity**,** refactoring and UML-style CASE tool specifically designed for generating native Delphi code (in fact it was made using Delphi and ModelMaker). Delphi's Object Pascal language is fully supported by ModelMaker. From the start ModelMaker was designed to be a smart and highly productive tool. It has been used to create classes for both real-time / technical and database type applications. ModelMaker has full reverse engineering capabilities.

ModelMaker supports drawing a set of UML diagrams and from that perspective it looks much like a traditional CASE tool. The key to ModelMaker's magic, speed and power however is the active modeling engine which stores and maintains all relationships between classes and their members. Renaming a class or changing its ancestor will immediately propagate to the automatically generated source code. Tasks like overriding methods, adding events, properties and access methods are reduced to selecting and clicking.

The main difference between ModelMaker and other CASE tools is that design is strictly related to and native expressed in Delphi code. This way there is a seamless transition from design to implementation currently not found in any other CASE tool. This approach makes sure your designs remain down to earth. The main difference between ModelMaker and other Delphi code generators are it's high level overview and restructuring capabilities letting you deal with complex designs.

A unique feature, currently not found in any development environment for Delphi, is the support for design patterns. A number of patterns are implemented as 'ready to use' active agents. A ModelMaker Pattern will not only insert Delphi style code fragments to implement a specific pattern, but it also stays 'alive' to update this code to reflect any changes made to the design

As a result, ModelMaker lets you:

- Speed up development
- Produce designs and code of unequaled quality.
- Think of designing code instead of typing code.
- Design without compromising.
- Refine and experiment with your designs until they are just right.
- Create and maintain magnitudes larger models in magnitudes less time.
- Document you designs in UML style diagrams.
- Document your units in help files by clicking a single button.

- In short: *save time and money, making better software.*

Installation

For installation details, refer to the readme.txt which is part of all ModelMaker distribution archives. We suggest you read this file before installing. The readme.txt also contains the latest information available on precautions related to upgrading.

ModelMaker requires Windows 95/98/ME/2000 or Windows NT 4.0 Both Borland Delphi and ModelMaker use a lot of resources. This might lead to problems under resource limited systems as Win95/98/ME.

ModelMaker is designed to work on a high resolution monitor (800x600 or better).

Contacting ModelMaker Tools

We at find it important to support you in your use of ModelMaker all the ways we can. You can find ModelMaker on the Internet at http:\\www.modelmakertools.com or alternatively http:\\www.modelmaker.demon.nl At this web site:

- We’ll update you on the most recent news concerning ModelMaker and it’s development.
- We’ll have the latest demo versions available.
- You can consult the Tips, FAQ pages.
- You’ll find links to the web-based ModelMaker newsgroups.
- You can leave hints or requests for future versions of ModelMaker.
- You can report bugs.

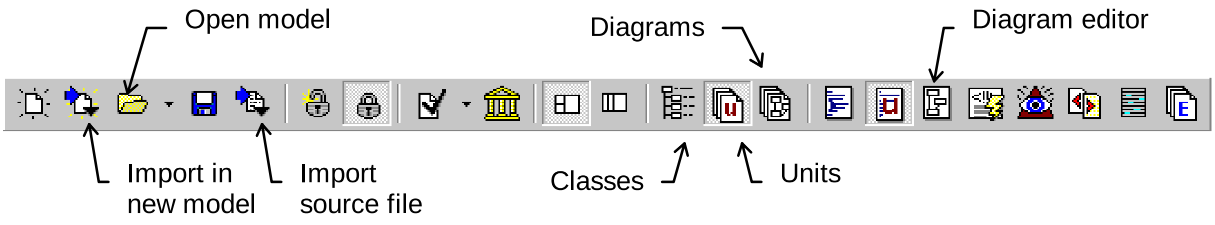
All ‘how to do this’ are best asked in the ModelMaker newsgroups. For other questions, the address to contact us is: info@modelmakertools.com or info@modelmaker.demon.nl.

Getting started

Getting a first impression

Here are some examples to get you started without reading lots of text. The development model will be explained in detail in the next chapters.

Loading an example model



To get a first impression of what ModelMaker is capable of, load the model ..\ModelMaker\6.0\Demos\MMToolsApi.mpb. It contains the interfaces making up ModelMaker's open tools API. In diagrams the relations between the interfaces defining this API are visualized. The Classes view shows the inheritance relations of this unit.

Then, to see how ModelMaker treats classes and units, use the 'Import source file in new Model' command from the toolbar. This will create a new model and import a Delphi unit (such as a form unit or a VCL unit). The model is named after the unit: Importing unit1.pas will create model unit1.mpb. Note the use of source aliases in the popup menu associated with the tool button. Source aliases are used to locate the source file and will be explained in chapter Source Aliases, page 52

Visualizing existing code

Visualizing existing code is a also good way too of getting started with ModelMaker. To visualize code:

1. Import the units containing the classes to visualize. Use the 'import source file" tool button in the main toolbar or drag drop source files on the 'unit's view' (View|Units)
2. Create or select a new class diagram in the 'diagrams' view (View|Diagrams)
3. In the Diagram editor (View|Diagram Editor) select the visualization wizard from the Wizard popup-up sub-menu.
4. Use this wizard to select the classes and interfaces to visualize and the kind of relations to visualize (inheritance, uses, supports etc.)
5. Completing the wizard gives you an instant diagram of the code just imported.

You might want to move around classes or interfaces (Drag move) or select different display options for classes or interfaces (Double click on the symbol) or the diagram as a whole

(Double click in empty space). Try to turn on and off member display, select interface style etc.

Creating code with ModelMaker, overview

A ModelMaker model contains a Code Model and Diagrams. The Code Model contains the classes, class members (properties, methods), units etc. that map to the corresponding entities in Delphi's Object Pascal. Diagrams are used to visualize aspects of the code model or entities that do not exists in the code model at all such as use cases. This 'Getting started' example will focus on the code model and demonstrate creating a new unit containing a new component class.

To create code for a new (component) class (or interface) in ModelMaker you will at a minimum need to,

1. Create a new model in which you want to put related classes, if you don't want to add the new class to the current model.
2. Add a new class to the model defining it's class name and ancestor.
3. Add (or override) properties, methods and events to the class's interface.
4. Implement the new methods.
5. Add the new class to a (new) unit.
6. Generate the unit to actually create or update a source file on disk.
7. In Delphi, debug the unit, and if it contains components, add it to the VCL.
8. While debugging, keep editing your code in ModelMaker, switching between Delphi and ModelMaker using ModelMaker's integration experts

An alternative way is to import existing files into a new model to either maintain these units in ModelMaker or to derive new classes from. This will be explained in detail in the Import demo.

The more advanced features of ModelMaker demonstrated in this example include:

9. Creating documentation for your component.
10. Generating a Help file.
11. Creating a class diagram to document your design.

The demo component: TIntLabel

Let's examine these steps a little closer by creating an new component class `TIntLabel` which is a `TLabel` descendant. `TIntLabel` adds a property `NumValue` of type integer which simple converts the `Caption` property to an Integer. We'll store this class in a new file `INTLABEL.PAS` and register it on page '*MM Demo*' in the VCL. We'll also create the help file `INTLABEL.HLP` and integrate it with Delphi's on line help.

This demo project is also shipped with ModelMaker. You can load the `GETSTART.mpb` in the `[installdir]\DEMOS` folder. The source file `INTLABEL.PAS` is also in this folder.

The ModelMaker Class Creation Wizard

If you start up ModelMaker the first time you'll see the Class Creation Wizard. This wizard makes it easy to create new classes and add them to a (new) unit. This wizard can be found at the main menu 'Tools|Create Class wizard'.

The wizard is great for adding classes, but for demonstrating the ModelMaker development model it's more instructive to create a new class manually. Therefore, if you started ModelMaker and the wizard is automatically started, abort the wizard by clicking 'Cancel'. You might also want to uncheck the option 'Show at start up' which will stop the wizard from appearing each time you run ModelMaker.

Creating a new project

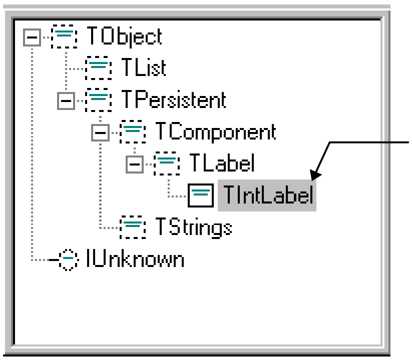
There are three ways to create a new project (or model):

- Select 'File|New', you'll get a clean project just containing the default ancestors `TObject` and `IUnknown`.
- Select 'File|New from default', you'll get a new project loaded from the default template.
- Select 'File|New from template', you'll select a template other than the default to create a new project.

In this case select 'File|New from default' to create a project which at least contains the `TComponent` class, if you didn't modify the default project shipped with ModelMaker `[installdir]\BIN\DEFAULT.mpb`.

Creating new classes

We'll use the Classes view to create a new class. In this view you add a new class as a descendant to another class in the model. The Classes view is depicted here.



Class tree containing place holder TLabel and real class TIntLabel

The ancestor class must *always* be part of the model since ModelMaker needs it to correctly generate the class declaration. In our case this implicates that before adding the `TIntLabel` class, it's ancestor `TLabel` must exist in the model. This raises a problem. If you started with the same default model, or with a template model that did not contain the class

`TLabel`, you will have to add the `TLabel` class first. But, in order to correctly add a class `TLabel` to your model, you now need to add it's ancestor first, and before that, etc.... help!

Since you do not intend to create code for `TLabel`, but only use it as an ancestor, there is no need to have the correct ancestor for `TLabel`. In our example the ancestor for `TLabel` could be anything, for example `TObject`. A better fitting ancestor is of course `TComponent`. Classes like `TLabel` in our example are called 'placeholder' classes as opposed to 'real' classes such as `TIntLabel`. Other examples of placeholders are `TObject`, Delphi's default class ancestor and `TComponent`.

What we have to do now, is add two classes `TLabel` ('placeholder') and then add `TIntLabel` ('real' class).

To do so:

1. Make the Classes view visible by selecting 'View|Classes' (or press F3)
2. Select `TComponent` by clicking it.
3. Press the "Ins" key or select add 'Add descendant' from the popup menu.
4. Enter `TLabel` as class name. You might want double click the class and in the class editor dialog check the option 'placeholder' to make it clear that `TLabel` is just a substitute for the real `TLabel` (which is in unit `StdCtrls`).
5. Now add the class `TIntLabel` using the `TLabel` as it's ancestor the same way. Of course you don't check 'placeholder' here.

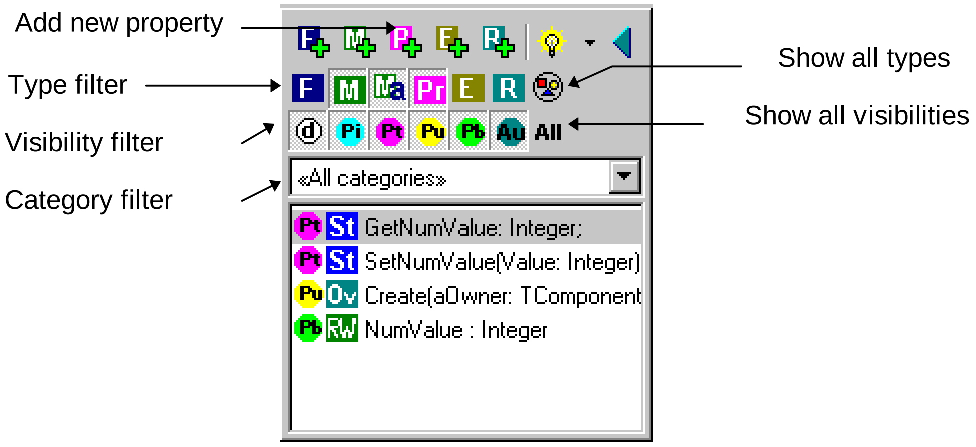
In the Classes view you'll see a tree or list based overview of all classes (and interfaces) in the model. Use the popup menu to toggle between tree and list style.

Adding properties and methods to a class

In our example we now need to add a new property and a read and write access method to the interface of the class `TIntLabel`, to get something like:

```
type
  TIntLabel = class (TLabel)
  protected
    function GetNumValue: Integer;
    procedure SetNumValue(Value: Integer);
  published
    property NumValue: Integer read GetNumValue write SetNumValue;
  end;
```

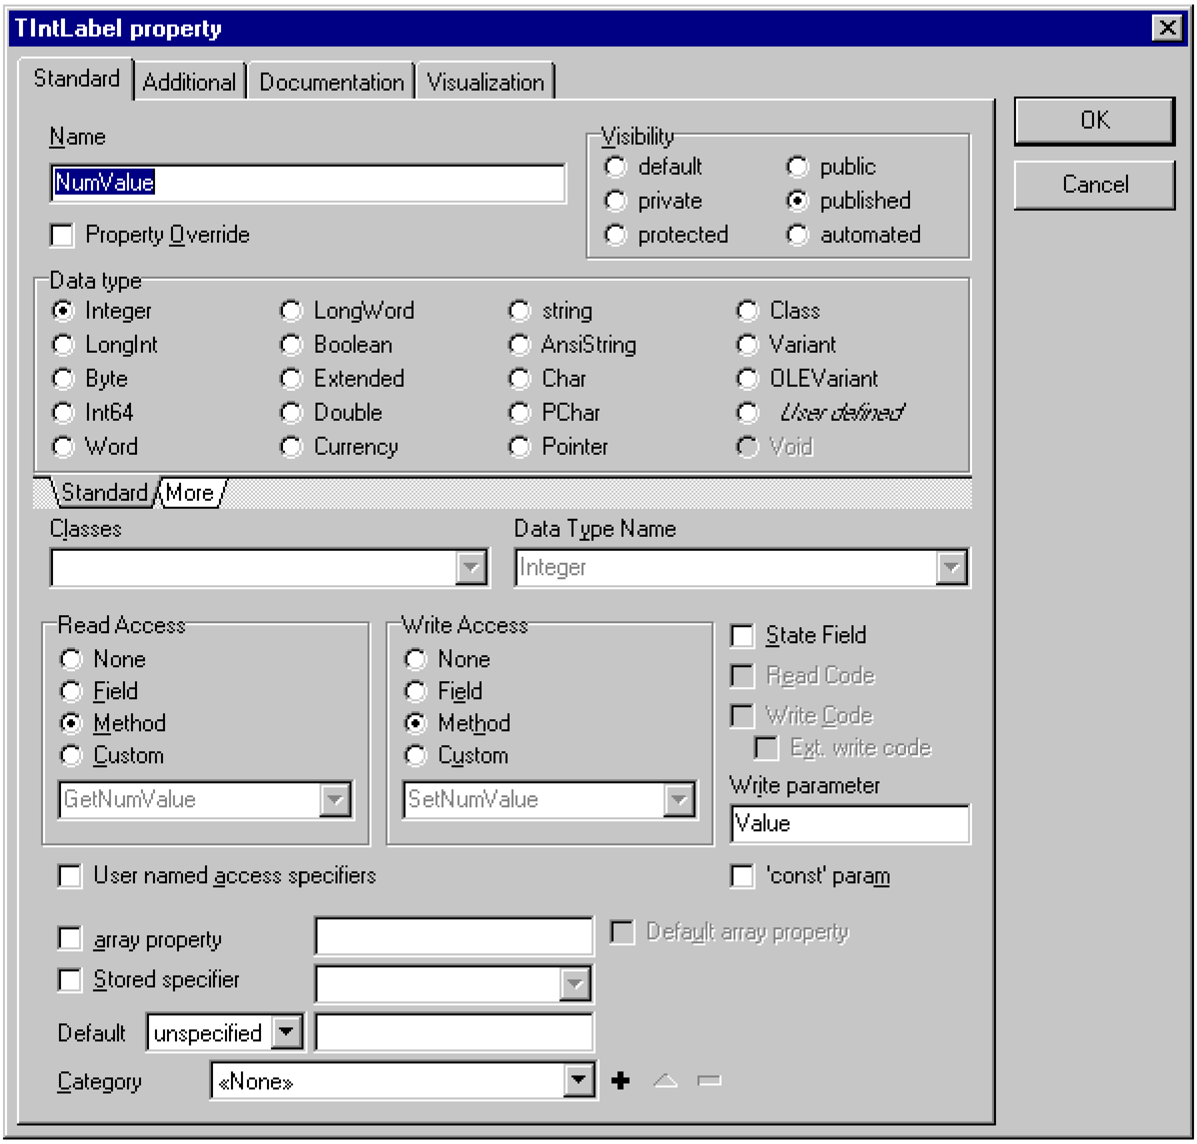
To do this we'll use the Class Members view - the bottom left window in the main window. Class Members are the fields, methods, properties (and event type properties) that make up a class's interface. The Class Members view is depicted here.



«All categories»

Pt St GetNumValue: Integer;
Pt St SetNumValue(Value: Integer)
Pu Ov Create(aOwner: TComponent
Pb RW NumValue : Integer

1. In this view all members for the currently selected class are displayed. Filters on *type* (Field, Method etc.), *visibility* (private, protected etc.) and *category* let you filter which members are displayed. Reset the filters by selecting ‘Reset Filter’ from the pop-up menu or by clicking the buttons ‘Show all types’ and ‘Show all visibilities’. All filter buttons should be in a ‘down’ state now, except of course the ‘Show all..’ buttons which do nothing but (p)reset the filters. Make sure the category filter shows <all categories>. The member list is still empty because we didn’t create any new Class Members yet. Note that the filter layout can be toggled using the popup menu ‘filter layout or double clicking on the filter area.
2. Click the ‘Add property’ button.
3. The property editor dialog will appear. See picture below.
4. Enter `NumValue` as the property’s name.
5. Select the visibility ‘published’.
6. Make sure the property’s data type is ‘Integer’.
7. Select for Read Access ‘Method’. This defines that the property has read access and you want to use a method to access it, rather than a field.
8. Select for Write Access ‘Method’ This defines that the property has write access and you want to use a method to access it, rather than a field.
9. Leave the other settings in their default values and click OK. In the property editor’s picture below the correct settings are displayed.



Name: NumValue

□ Property Override

Visibility
○ default ○ public
○ private ● published
○ protected ○ automated

Data type
● Integer ○ LongWord ○ string ○ Class
○ LongInt ○ Boolean ○ AnsiString ○ Variant
○ Byte ○ Extended ○ Char ○ OLEVariant
○ Int64 ○ Double ○ PChar ○ *User defined*
○ Word ○ Currency ○ Pointer ○ Void

Classes:

Data Type Name: Integer

Read Access
○ None
○ Field
● Method
○ Custom
GetNumValue

Write Access
○ None
○ Field
● Method
○ Custom
SetNumValue

□ State Field
□ Read Code
□ Write Code
□ Ext. write code

Write parameter: Value

□ User named access specifiers

□ 'const' param

□ array property

□ Default array property

□ Stored specifier

Default: unspecified

Category: «None»

Now have a look again in your Class Members view:
You’ll not only see a property `NumValue`, but also two property access methods `GetNumValue` and `SetNumValue`. This is because properties create and update their access fields and methods automatically. Now that saves time!

The `TIntLabel` class’s interface is now defined, but the methods `GetNumValue` and `SetNumValue` still need to be implemented.

Implementing methods

In our example we will need to add code to the implementation of the methods `GetNumValue` and `SetNumValue`. This code should be something like:

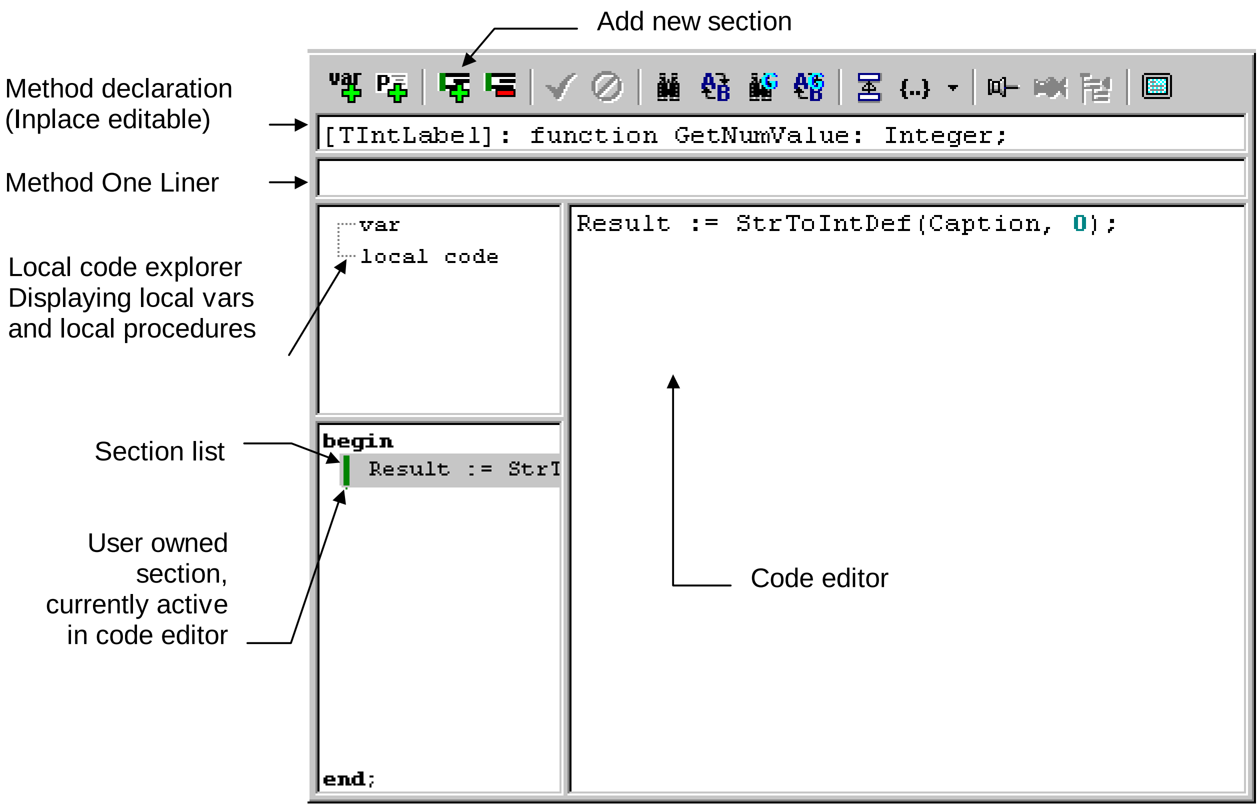
```
function TIntLabel.GetNumValue: Integer;
begin
```

```
  Result := StrToIntDef(Caption, 0);
end;

procedure TIntLabel.SetNumValue(Value: Integer);
begin
  Caption := IntToStr(Value);
end;
```

To add code to a method’s implementation you use the (Method) Implementation view.

1. Select the method you want to implement in the Class Member view, in this case the method `GetNumValue`.
2. To make the Method Implementation view visible, select ‘View|Implementation’.



```
[TIntLabel]: function GetNumValue: Integer;
```

```
Result := StrToIntDef(Caption, 0);
```

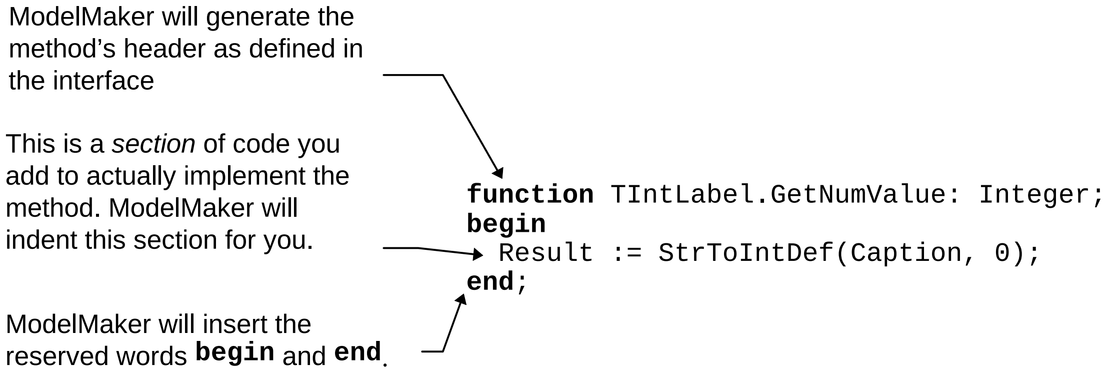
```
var
local code
```

```
begin
  Result := StrT
end;
```

Add new section
Method declaration (Inplace editable)
Method One Liner
Local code explorer Displaying local vars and local procedures
Section list
User owned section, currently active in code editor
Code editor

The picture above shows the Method Implementation view. This editor is perhaps the element of ModelMaker that is the most different from other editors. To understand how this editor works you need to know a little more about how ModelMaker generates code for a method’s implementation.

Let’s have a closer look at the `GetNumValue` method. This is just a simple method, not containing any local variables or local procedures.



ModelMaker will generate the method’s header as defined in the interface

This is a *section* of code you add to actually implement the method. ModelMaker will indent this section for you.

ModelMaker will insert the reserved words **begin** and **end**.

```
function TIntLabel.GetNumValue: Integer;
begin
  Result := StrToIntDef(Caption, 0);
end;
```

The body of a method’s implementation consists of a list of local variables, local procedures and *sections* of code which implement the block between **`begin..end`**. A section can take up any number of lines of code. All sections together make up the actual implementation. Using sections, ModelMaker is able to identify certain lines of code within the body. This is for example used to automatically add and update a call to the inherited method, as we’ll see later.

On the left side of the method code editor the complete method’s code is displayed, although maybe *collapsed* if necessary. On the right we find the actual code editor. It is used to edit the section of code selected in the sections list. The same editor is also used to edit the local procedures code.

As we see in the above picture, the only thing we need to do, is add a section of code containing the statement:

```
Result := StrToIntDef(Caption, 0);
```

To do this, first create a new section. If you didn’t change the code options settings in ‘Options|Code options’ a new section is automatically created if the method does not contain any sections yet.

1. If necessary, add a new section by clicking the ‘Add section’ button.
2. Enter the statement in the code editor. There’s no need to indent the code with spaces since this will be done automatically by ModelMaker.
3. Click the ‘save code’ button. This is not really necessary, since ModelMaker will automatically save the section as soon as you select a new section or a new method.

Notice that the section is now also displayed in the section list, and is marked with a green line. This green line informs you that *you* created this section and are it’s *owner*. Red lines indicate that a section is not owned by you, but, for example, is inserted by a pattern which has the only rights to update it. If a section contains more lines than the current ‘Fold height’ (adjustable in the Environment options tab Editors), the section will be collapsed. Collapsed sections are marked with a second purple line with a mark on the collapsing position. More about this later.

Now you should be able to implement the `SetNumValue` method the same way: select the method in the Class Members view, add a section if necessary and enter your code.

Although we have finished implementing the class `TIntLabel` for now, all code exists only in the ModelMaker model, so the next thing to do is to generate a source file.

Creating a source file

Units are the gateways to source files on disk. They provide a link between all data in a ModelMaker project such as classes, method implementations etc. and an Object Pascal style unit file which Delphi is able to compile.

Creating a Unit

In this example we need to create a unit which, after it has been generated, should look something like:

```
unit IntLabel;

interface

uses
  SysUtils, Windows, Messages, Classes, Graphics, Controls,
  Forms, Dialogs, StdCtrls;

type
  TIntLabel = class (TLabel)
  protected
    function GetNumValue: Integer;
    procedure SetNumValue(Value: Integer);
  published
    property NumValue: Integer read GetNumValue write SetNumValue;
  end;

procedure Register;

implementation

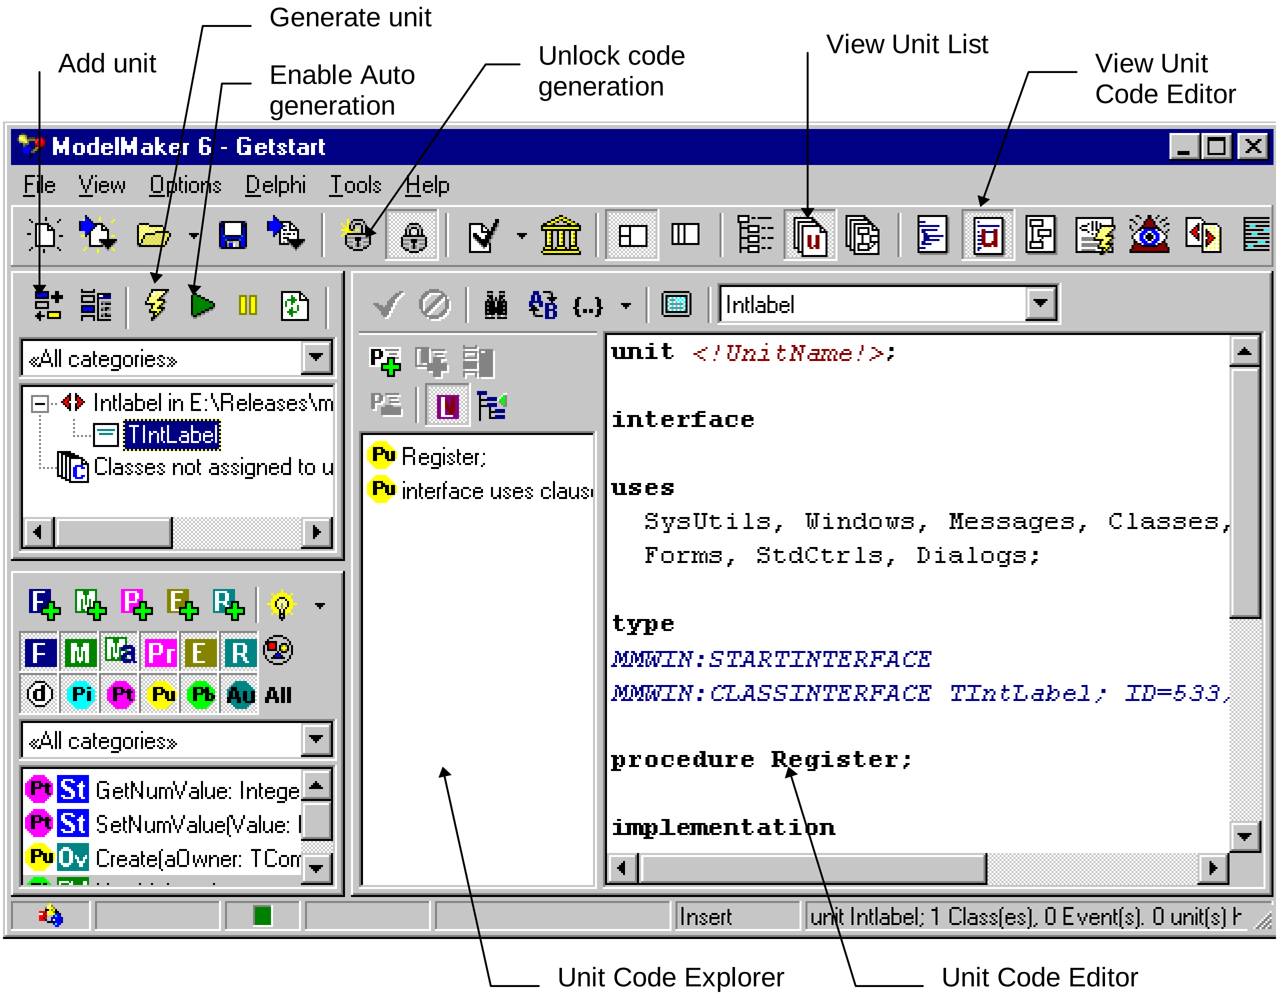
procedure Register;
begin
  RegisterComponents(’MM Demo’, [TIntLabel]);
end;

function TIntLabel.GetNumValue: Integer;
begin
  Result := StrToIntDef(Caption, 0);
end;

procedure TIntLabel.SetNumValue(Value: Integer);
begin
  Caption := IntToStr(Value);
end;

end.
```

To create a new unit we use the Unit List view which is depicted below,



Pt St GetNumValue: Intege
Pt St SetNumValue(Value: I
Pu Ov Create(aOwner: TCom

```
unit <!UnitName!>;

interface

uses
  SysUtils, Windows, Messages, Classes,
  Forms, StdCtrls, Dialogs;

type
MMWIN:STARTINTERFACE
MMWIN:CLASSINTERFACE TIntLabel; ID=533;

procedure Register;

implementation
```

unit Intlabel; 1 Class(es), 0 Event(s), 0 unit(s) I

1. To make the Unit list view visible, select ‘View|Units’. Repeat this for the Unit Code editor.
2. In the Unit list click the ‘Add unit’ button, a unit properties dialog will now appear.

In the Unit editor dialog you define:

1. Leave the source path alias `<no alias>` unchanged.
2. The source file name (the full path including drive and folders), to define the path you could use an source alias, but for now just click the browse button and locate the `\ModelMaker\6.0\TEST` folder (or `ModelMaker\6.0\Test` depending on the base path you installed ModelMaker in) and enter the file name `IntLabel.PAS`.
3. On the tab sheet ‘Classes’ add the class `TIntLabel` to the list on the right either by dragging or by selecting it and clicking the ‘Add selected’(▸) button or by double-clicking.
4. Change the ‘VCL page’ from `<unregistered>` to ‘`MM Demo`’ by entering this name in the string grid.
5. Click OK.

We’ll see the newly created unit now listed in the unit list on the left. In this editor unit’s code containing a text which should look something like:

```
unit <!UnitName!>;
```

```
interface

uses
  SysUtils, Windows, Messages, Classes, Graphics,
  Controls, Forms, Dialogs;

type
MMWIN:STARTINTERFACE
MMWIN:CLASSINTERFACE TIntLabel; ID=7;

procedure Register;

implementation

procedure Register;
begin
MMWIN:CLASSREGISTRATION TIntLabel; ID=7; Page='MM Demo';
end;

MMWIN:STARTIMPLEMENTATION
MMWIN:CLASSIMPLEMENTATION TIntLabel; ID=7;

end.
```

For now, it is enough to understand that ModelMaker uses tags (like `MMWIN:CLASSINTERFACE`) to insert the interface, VCL registration and implementation of a class in otherwise ‘plain’ text that you define. There is one problem however: if you look at the **`uses`** clause in the interface, you’ll see that the unit `StdCtrls` which defines the ancestor class `TLabel`, is missing. That is because the default unit template we are using does not contain this unit. For changing this template refer to ‘Customizing ModelMaker’. For now, we will have to add `StdCtrls` manually.

To do this,

1. In the unit code editor add `StdCtrls` to the uses clause.
2. Click the ‘Save code’ button in the toolbar above the editor.

Generating the source file

To generate the source file and create or update a file on disk,

1. Make sure that code generation is not locked. Locking is explained later, for now make sure the button ‘unlock code generation’ in the ModelMaker toolbar is pressed down.
2. Click the ‘Generate current unit’ button in the unit list view.
3. Start Delphi (if it was not running already).
4. Either manually switch to Delphi or - much more instructive - click the ‘Locate in Delphi’ button in the main tool bar - or simply press Ctrl+F11. This will open the unit and locate the entity currently selected in ModelMaker.

The generated source file should look pretty much the same as we wanted it to be. (Differences may occur if you modified your file `DEFUNIT.PAS` in ModelMaker’s `\BIN` folder.)

We’re ready to debug the `TIntLabel` now, and install it in our VCL.
Before doing this it’s a good idea to save our model. This is very much like in other windows applications, so it won’t be explained here. We could use the `[installdir]\TEST` folder to

save this project. Practice shows that it is convenient to name your model after the main source file you create with it, or the main set of components. In this case `INTLABEL.mpb` seems an obvious name.

Adding the component to the VCL

Debugging your component

A good practice, is to debug your new component before adding it to the VCL. Do this for example by adding the source file to the current Delphi project (e.g. by using Delphi's project manager) and re-compile the project. This should at least filter out all syntax errors. Either use 'Compile' or 'Syntax Check' since Delphi does not always correctly manage the file's date/time and modified status if you just 'Run' the project.

Compiling errors

If you didn't make any mistakes, the unit should compile all right. If it doesn't: change the code in the appropriate place in ModelMaker. That is:

- For missing units in the unit's uses clause: the unit code editor.
- For any code not part of the class: the unit editor.
- For errors in the class's name or ancestor name: the Class view.
- For errors in the class's interface declaration: the Class Members view.
- For errors in a method's implementation: the Method Implementation view.

Switch to ModelMaker and fix the code. Use the integration expert's menu 'Jump to ModelMaker' to jump straight from Delphi's code editor to the corresponding position in ModelMaker. Finally, in the Unit list view click the button 'Generate' again and re-compile the Delphi project. If you are having trouble with this: look ahead where we are adding new behavior and editing code is explained.

Adding the component to the VCL

After debugging your new file, add it to the Delphi's VCL.
In *Delphi 1.0*: select menu 'Options|Install Components', select 'Add' and browse to find the unit `INTLABEL.PAS` in folder ..`\ModelMaker\6.0\TEST\`.
In *Delphi 2.0*: Select menu 'Component|Install', select 'Add' and browse to find the unit `INTLABEL.PAS`. Refer to your Delphi User guide for more information about installing components.
In *Delphi 3 and higher*: you must install the new component in a package. Select a new package called MMtest in the ..ModelMaker\6.0\Test folder. Please refer to your user guide for installing packages.

After recompiling the VCL the new TIntLabel component should be on the palette page where you registered it: *MM Demo*. To test it, add a TIntLabel component to a (new) form.

You can use the Object Inspector now to set the 'NumValue' property and see the caption change. But the component can be improved!

Improving the component in ModelMaker

If you watch carefully, you'll see that a TIntLabel when dropped on a form, initially has the caption 'IntLabel1' rather than '0'. The NumValue however is 0. This is conflicting and not very nice. To improve the component we'll have to override the constructor Create like this: (refer to Delphi's on-line help for the TControl.ControlStyle property)

```
constructor TIntLabel.Create(AOwner: TComponent);
begin
 inherited Create(AOwner);
  { Don't let the Object Inspector set a caption }
  ControlStyle := ControlStyle - [csSetCaption];
  { Instead pre-set the Caption ourselves }
  NumValue := 0;
end;
```

To do this we need to return to ModelMaker.

Keep editing your code in ModelMaker

We could of course change TIntLabel's code in Delphi, but then the ModelMaker model and the modified source file would be out of sync. The next time we would (re-)generate the file from within ModelMaker, the changes made in the Delphi Editor will be lost. Of course, if we do not intend to maintain our code any longer in ModelMaker that's fine, but we won't benefit the advantages ModelMaker offers during maintenance and documentation. And although it may seem a burden at first, after getting used to it, the benefits of keeping the master code in ModelMaker are much higher than the costs. So resist the itch in your fingers and return to ModelMaker now.

Overriding the constructor Create

To override the constructor Create, we could add a method in the Class Members view clicking 'Add method', name it 'Create' adjust it's other attributes such as parameters 'AOwner: TComponent', method kind 'constructor', etc. but overriding methods can be done far more easy. The only thing is: in order to override a method (or property) the method to be overridden must exist in the model. If you used the default project template as was shipped with ModelMaker (which also contains the class TComponent), the virtual constructor TComponent.Create is in your model with the correct attributes, ready to be overridden.

To do so:

1. In the Members view tool bar click the 'Wizards' button, and

2. Select ‘Method override wizard’. Alternatively use the same function from the Wizards popup sub menu.
3. In the ‘Override Methods’ dialog select the ‘`Create`’ method.
4. Make sure the option ‘Call inherited method’ is checked. This will instruct ModelMaker to add a section of code containing a call to the inherited method.
5. Click OK.

In the Class Members view we’ll see that a method called `Create` is added to the list. Just for your information you may check the methods attributes by selecting it in the member list and clicking the ‘Edit Member’ button, or double clicking it in the member list.

Notice that all relevant attributes are copied from `TComponent.Create`:

- The methods name is `Create`.
- The parameter list is `AOwner: TComponent`.
- The method is ‘public’.
- The data type is ‘void’.
- The method type is ‘constructor’.
- The binding kind is ‘override’ (since `TComponent.Create` is virtual).
- The option ‘Call inherited’ is checked because we checked the option ‘Call inherited method’ running the override wizard.
- The option ‘Inheritance restricted’ is checked. If this option is checked, the method will automatically be updated to reflect any changes applied to the overridden method in the ancestor class.

Click Cancel to leave the method in it’s original state.

Implementing Create, non-user sections in code

To implement the method `Create` switch to the Method Implementation view again. Notice that in the section list on the left, already one section is added containing the code:

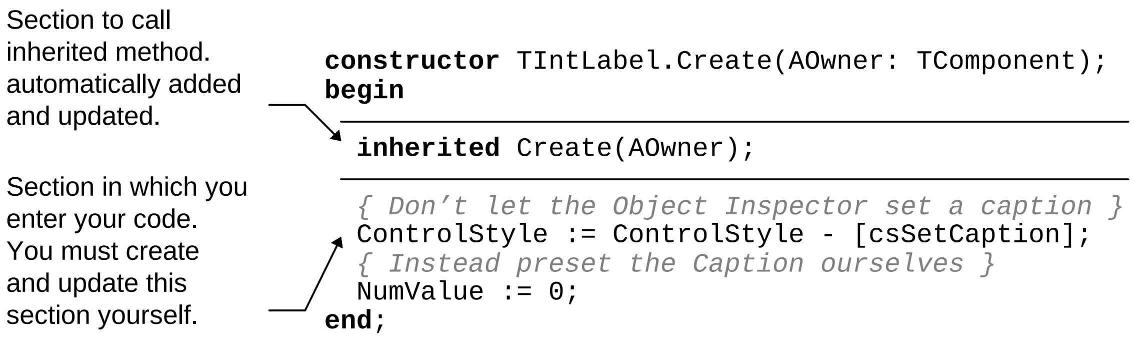
```
  inherited Create(AOwner);
```

This section is marked with a red line, indicating that we cannot edit it’s contents. The section was added because the method’s option ‘Call inherited’ is checked.

To add the other lines of code,

1. Add a new section by clicking the ‘Add section’ button.
2. Enter the code in the code editor on the right.
3. Click the ‘Save code’ button

In the section list on the left we'll see the complete implementation of `Create`.



Section to call inherited method. automatically added and updated.

Section in which you enter your code. You must create and update this section yourself.

```
constructor TIntLabel.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);
  { Don't let the Object Inspector set a caption }
  ControlStyle := ControlStyle - [csSetCaption];
  { Instead preset the Caption ourselves }
  NumValue := 0;
end;
```

Instant code generation

If we have a look in the Delphi editor, we'll see that the source file has not been updated yet. To do this we need to regenerate the unit. Therefore switch to the Unit list view again.

Regenerating the unit could be done by clicking the 'Generate' button again, but it is more instructive to demonstrate ModelMaker 's *instant code generation* feature. Rather than having to manually regenerate a source file whenever something has changed, it is possible to '*Enable Auto generation*' for a unit. The source file will then be regenerated each time anything changes in the Model that affects the source file. It is a nice feature that ModelMaker not only regenerates the source file, but also instructs Delphi to reload the file if it's opened in Delphi's code editor. Refer to Integration with Delphi.

To watch this:

1. Make sure you have the `INTLABEL.PAS` file loaded and is on top in the Delphi code editor.
2. Click the 'Enable auto generation' unit button in the Unit view tool bar.
3. See how the Delphi editor now reflects the last changes in your file.

Now return to ModelMaker again, and let's play around:

1. Switch to the Class Members view.
2. Edit the Create Method (Double click or click the Edit button).
3. Now uncheck the 'Call inherited' option and click OK.
4. Watch the code being updated in Delphi.
5. Now check the 'Call inherited' option again.

To have a closer look at the Method Code editor,

1. In the Create method's section list you can drag sections up and down, do this and see how Delphi's code editor follows your changes.

Lets have play around with the units view:

1. Make sure the units view is in ‘display as tree mode’ (popup menu)
2. Select the class `TIntLabel` by clicking it.
3. Press the Del key once, this will remove the class from the unit. The class is still in the code model. In fact, the class is listed under the ‘classes not assigned to units’ node. Check the code in the IDE: you’ll see that the entire interface and declaration have been removed.
4. Drag the class on the IntLabel unit. This will add the class to the unit again. Note that the VCL Component registration page is now reset to ‘none’. Edit the unit (double click unit or use toolbar) to change this back to ‘MM Demo’.

After you have played around with the instant code generation feature, make sure the `TIntLabel` class still is as you want it to be. In order to actually see the improved behavior,

1. Rebuild your VCL in Delphi.
   Delphi 1: menu ‘Options|Rebuild library’.
   Delphi 2: menu ‘Component|Rebuild library’.
   Delphi 3 and higher: recompile the package MMtest.dpk.
2. Remove any old `TIntLabel` components from forms.
3. Add a new `TIntLabel` to a form and notice how the Caption is set to ‘0’ now.

Documenting your component

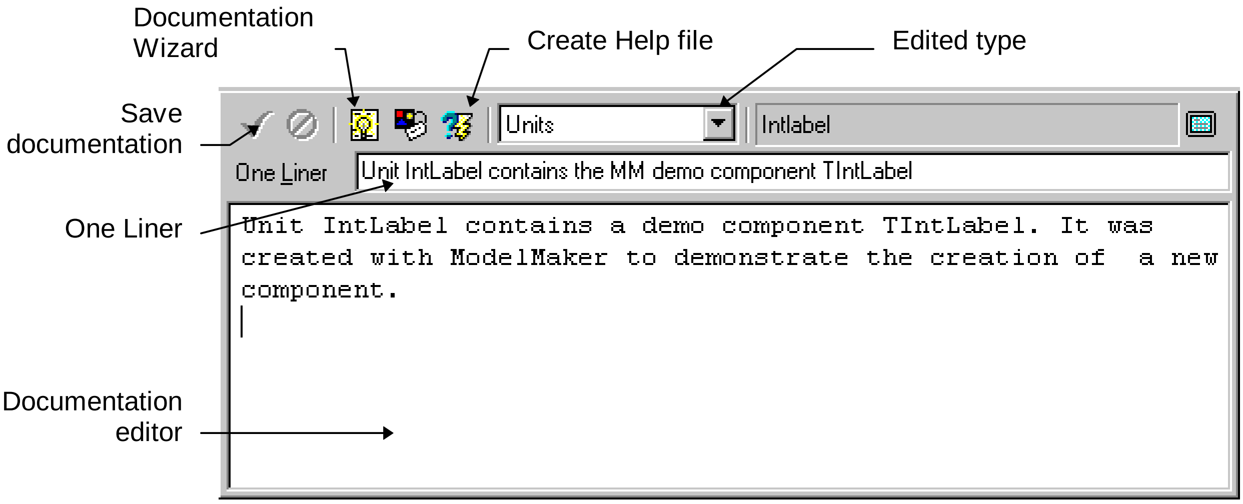
ModelMaker not only supports source code generation for your component, but it has also advanced wizards and generators to document your component. These include

- Documentation wizard which inserts basic standard documentation for all members in a class.
- In source documentation.
- Help file generation.
- Instant visualizing in class diagrams. Although creating diagrams is usually done in the design process, it is also possible to create diagrams from existing code.

To demonstrate these features we will now create a help file and a class diagram for the `TIntLabel` component.

Adding documentation to your component

Each unit, class, all members of a class, ebent types and symbols in diagrams can be documented with a short description named One Liner and a longer text named Documentation. For editing One Liner and documentation we’ll use the Documentation view. Alternatively we could have used the floating documentation window which is available from the main menu “Views”.



Unit IntLabel contains the MM demo component TIntLabel

Unit IntLabel contains a demo component TIntLabel. It was created with ModelMaker to demonstrate the creation of a new component.

To make this view visible: Select menu ‘View|Documentation Editor.

With this Documentation editor you add a One Liner and a more descriptive text to each unit, class and member (method, property etc.). That can be quite a job, so ModelMaker includes a documentation wizard, which does some of the nasty work for you. This wizard will insert pieces of documentation in the currently selected class.

To demonstrate this:

1. Select the class `TIntLabel` in the Classes or Units view.
2. In the Documentation view click the button ‘Documentation Wizard’.
3. Click OK to confirm creation of standard documentation.
4. In the drop-down box ‘Edited type’ select ‘class members’.
5. In the Class Members view select the `GetNumValue` method.

What you see now in the documentation editor is that the wizard inserted text like:
GetNumValue is the read access method for the NumValue property.
Usually this is sufficient to document `GetNumValue`, since you will be documenting the exact meaning of the property `NumValue` and this avoids redundancy.

Selecting the method `SetNumValue` in the Class Members view makes the documentation for `SetNumValue` visible:
SetNumValue is the write access method of the NumValue property.
Again this is usually sufficient to document the `SetNumValue` method.

What remains to be done is documenting the constructor `Create` and the property `NumValue`. But here too, the wizard inserted already some useful text.

Select the documentation for the constructor `Create` and change this to:
Constructor Create overrides the inherited Create. First inherited Create is called, then the Caption is pre-set to 0, reflecting the initial NumValue state. ControlStyle is modified to exclude csSetCaption.

Now select the `NumValue` property’s documentation and change this to:
Property NumValue is read/write at run time and design time.

It reads and writes the Caption property as an Integer.

To edit the documentation for the class `TIntLabel`:

1. Make sure class `TIntLabel` is selected in the Classes or Units view,
2. In the Documentation view, select ‘classes’ in the drop-down box ‘Edited type’.

Enter the text:
TIntLabel is a simple TLabel descendant created with ModelMaker.
It adds the property NumValue which reads and writes the Caption property
as an Integer.

To edit the documentation for unit IntLabel which contains the `TIntLabel` class:

1. Make sure the unit `IntLabel` is selected in the Units view.
2. In the Documentation view, select ‘units’ in the drop-down box ‘Edited type’.

Enter the text.
Unit IntLabel contains a demo component TIntLabel. It was created with
ModelMaker to demonstrate the creation of a new component.

The unit `IntLabel` is now completely documented. Documentation is typically used to create a helpfile or for in-source documentation. Third party plug-in experts use the ModelMaker ToolsApi to output documentation to other formats.

You add One Liners (short, single line descriptions) the same way. In the Views menu you’ll find a ‘Floating documentation’ view. This view can be used to insert One Liners and documentation too. This view can be docked or stay floating. The edited entity type in this view is automatically updated to reflect the last focused view in ModelMaker.

Creating a help file

ModelMaker can create a Borland style help file from your documentation. This includes the generation of the Borland `/B` keywords which are necessary for interaction with Delphi’s on-line context sensitive Help. Help files are generated from unit’s. In our example we’ll create a help file for unit `INTLABEL`.

ModelMaker let’s you select the visibilities you want to include in your help file. These are:

- ‘User’ (public, published, automated and default)
- ‘Component writer’ (user visibilities plus protected)
- ‘Developer’ (all visibilities)

The default visibility ‘User’ is the most restricted, since this will include only help for the public, published or automated interface of a class. Use this filter to create a help file you distribute with your components. Selecting the ‘Component writer’ visibilities will also include help for the protected interface. This is the type of help file you would typically distribute with components if other developers should be able to derive a descendant class from your component. The last selection includes also the private details (typically fields and or property access methods etc.) which you might want to have documented internally.

To create a help file for the `TIntLabel` component,

1. Make sure the unit `IntLabel` is selected in the Units view.
2. In the Documentation view, click the button ‘Create help file’.
3. In the ‘Create help file’ dialog you’ll be prompted to enter a file name for the unit’s RTF file. A help project file with the same name and extension `.HPJ` will automatically be created. In our example enter `[installdir]\TEST\INTLABEL.RTF.`
4. In the same dialog, select the visibilities you want to include in your help file. In this example we’ll go for the ‘Component writers’ visibility.
5. Leave the reformat paragraphs option checked and Click OK.
6. Open the explorer (file manager) and notice that both `INTLABEL.RTF` and `INTLABEL.HPJ` have been created.
7. Run your Delphi help compiler with the `INTLABEL.HPJ` project. Be aware that you need to use the help compiler that was shipped with the Delphi version you want to create help for. For *Delphi 1.0*: Use `DELPHI\BIN\HC31.EXE` in a DOS box and run it from the folder your HPJ file is in. For example: `DELPHI\BIN\HC31.EXE INTLABEL.HPJ`
For *Delphi 2, 3 and higher*: Use the `Delphi 2(or 3 / 4/5/6).0\HELP\TOOLS\HCW.EXE` to compile your project: double clicking the `INTLABEL.HPJ` file in the explorer should be enough.

The help files have been created now. You might want to have a look at them, using windows help. Double clicking the newly generated `INTLABEL.HLP` starts help.

The Help File Generator source is available as plug-in expert on request. It can be extended to create help for multiple units at once etc.

Integrating your help files with Delphi’s on line help

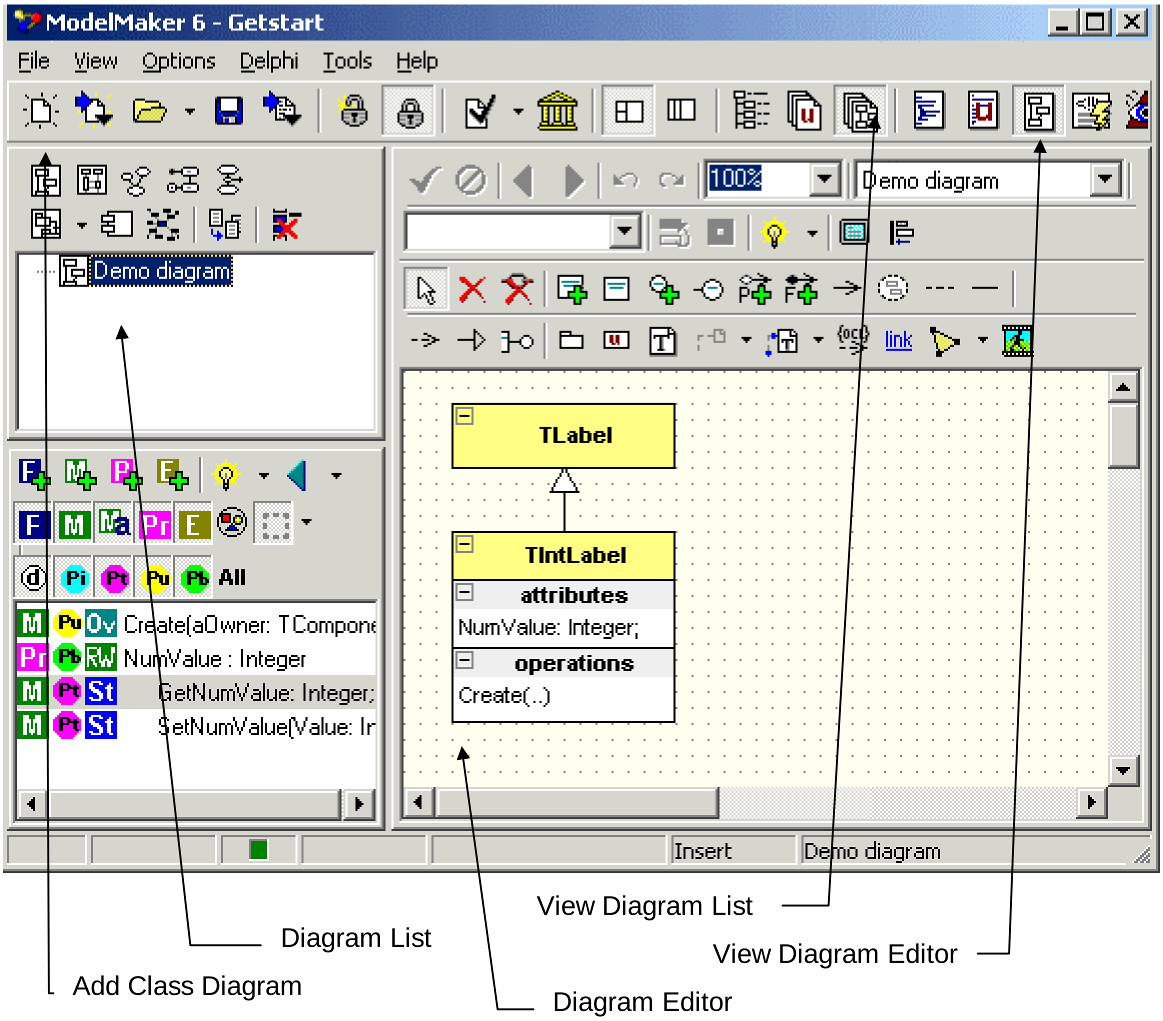
To be able to invoke Delphi’s help on your `TIntLabel` component you must integrate your `INTLABEL.HLP` help file with the Delphi 1 and 2 on line help. To do this:

1. Generate key words using `KWGEN.EXE`
2. Install help using `HELPINST.EXE`

Installing help in Delphi 3 and higher is documented in Delphi’s Component Writers Guide / User’s Guide.

Documenting the design in a diagram

Although creating diagrams is usually done in the first stages of the design process, it is also possible to create diagrams from existing models using ModelMaker’s instant visualization feature. A list of diagrams in the model is edited in the Diagram List view. The actual diagrams are edited in the Diagram Editor.



Make the Diagrams List view and Diagram Editor visible:

1. Select menu 'View|Diagrams'. This will make the diagram list visible in the top left window.
2. Select menu 'View|Diagram Editor'. This will make the diagram editor visible in the editor pane on the right
3. In the Diagram list create a new class diagram by clicking the 'Add Class diagram' button.
4. You can inplace edit the diagram's name. Enter 'Demo diagram'. The name is intended only to distinguish different diagrams.

In the newly created diagram we'll demonstrate ModelMaker's instant visualization feature:

1. Make sure the Classes or Units view is visible (View|Classes or Units)
2. Drag the class `TLabel` from the Classes or Units view and drop it on the diagram editor.
3. Do the same with `TIntLabel`.
4. Save the Class diagram by clicking the 'Save diagram' button.

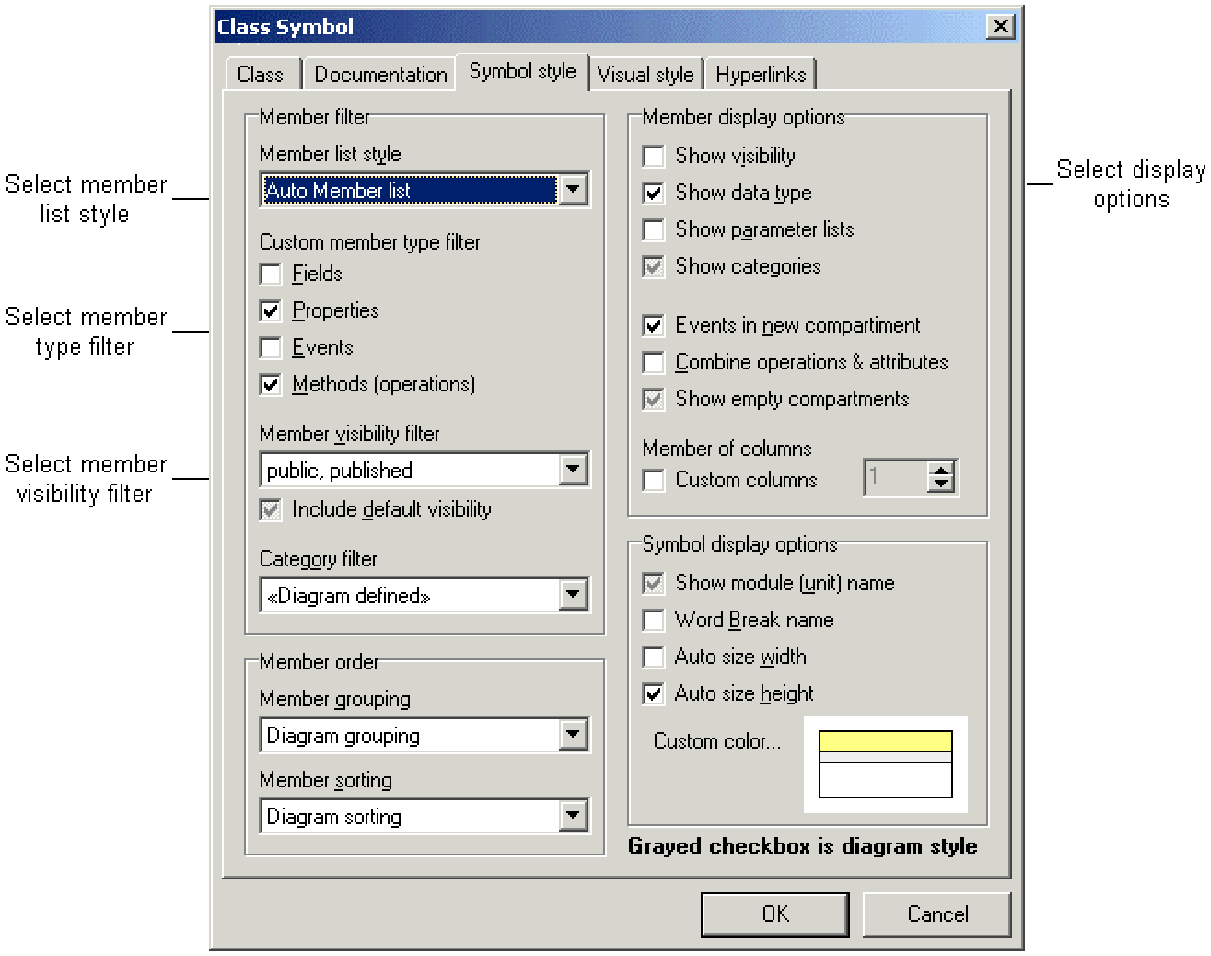
Notice how the inheritance relation `TIntlabel = class (TLabel)` is automatically visualized. If appropriate, ModelMaker will also visualize 'uses' relations if a class is dragged onto a diagram.

You can copy the current selected diagram to the clipboard (in WMF format) and paste it in your word processor to document your design. To do this: press `Shift+Ctrl+C` or use the local menu ‘Export as Image’|‘Clipboard’. Alternatively you could export the image to a file (bmp, wmf and jpg). To print the diagram, press `Ctrl+P` or use the pop-up menu.

Symbol styles in Diagrams: displaying members

ModelMaker supports many UML styles of displaying classes and interfaces: show module (unit) names, show members, collapse interfaces etc. To demonstrate a few and give you an idea of what is possible we’ll change the symbol style for the `TIntLabel` class symbol. Symbol styles define how a symbol is displayed in a diagram. Note: the visual appearance (colors, fonts etc) is controlled by the visual style which is not part of the symbol style; check this manual for details. Default all symbol styles are “as defined in current diagram”. The diagram symbol style defaults to “as defined in the current project”. This gives you the possibility to change style on any level you like: just a single class symbol, all class symbols in a diagram or all diagrams in a project.

Here we’ll change the symbol for TIntLabel only. Double click on the TIntLabel class symbol. This will show the class symbol editor.



Select member list style

Select member type filter

Select member visibility filter

Select display options

Class Symbol

Member filter

Member list style: Auto Member list

Custom member type filter
- ☐ Fields
- ☑ Properties
- ☐ Events
- ☑ Methods (operations)

Member visibility filter: public, published
- ☑ Include default visibility

Category filter: «Diagram defined»

Member order

Member grouping: Diagram grouping

Member sorting: Diagram sorting

Member display options
- ☐ Show visibility
- ☑ Show data type
- ☐ Show parameter lists
- ☑ Show categories
- ☑ Events in new compartment
- ☐ Combine operations & attributes
- ☑ Show empty compartments

Member of columns
- ☐ Custom columns 1

Symbol display options
- ☑ Show module (unit) name
- ☐ Word Break name
- ☐ Auto size width
- ☑ Auto size height

Custom color...

Grayed checkbox is diagram style

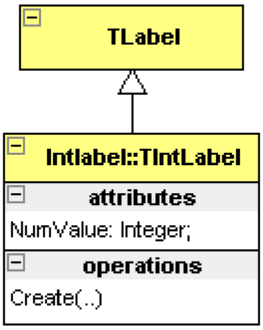
First you define ***which*** members are displayed. In this dialog change the Member list style from “Diagram Auto Member list” to “Auto Member list”. This style will automatically add all members defined by the member filter in this editor. In the Member filter check

“Properties” and “Methods”. Change the visibility filter to public and published members only. This will suppress display of the protected property access methods GetNumValue and SetNumValue.

Then you define ***how*** members are displayed. Use the Member display options to modify this. Check “Show Data type” and “Events in new Compartment”. Note that a grayed option reverts the option to the parent (diagram) style.

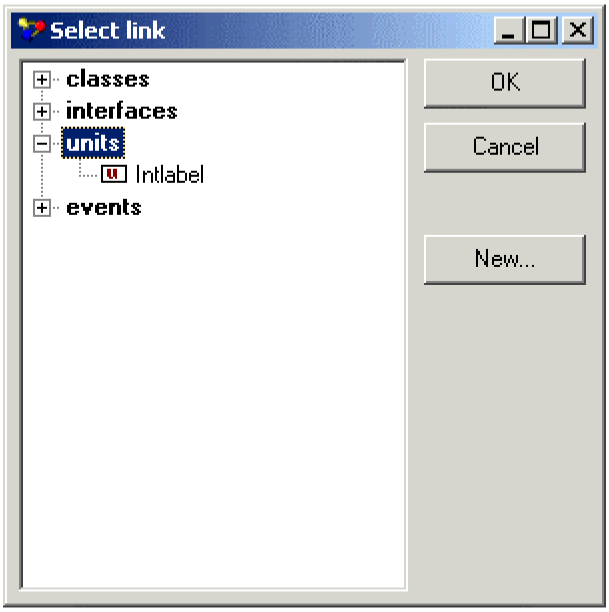
To display the name of the unit that contains this class in the symbol name compartment, check the “Show module name” option.

After clicking OK you should have a diagram that looks something like this (you can stretch a class symbol as needed depending on the Auto Size options – check the class symbol dialog). The property NumValue is displayed in the ‘attributes’ compartment and the method Create is displayed in the ‘operations’ compartment. Likewise events can be displayed in a separate compartment or combined with the attributes. If you wish you could even combine all members into a single compartment.

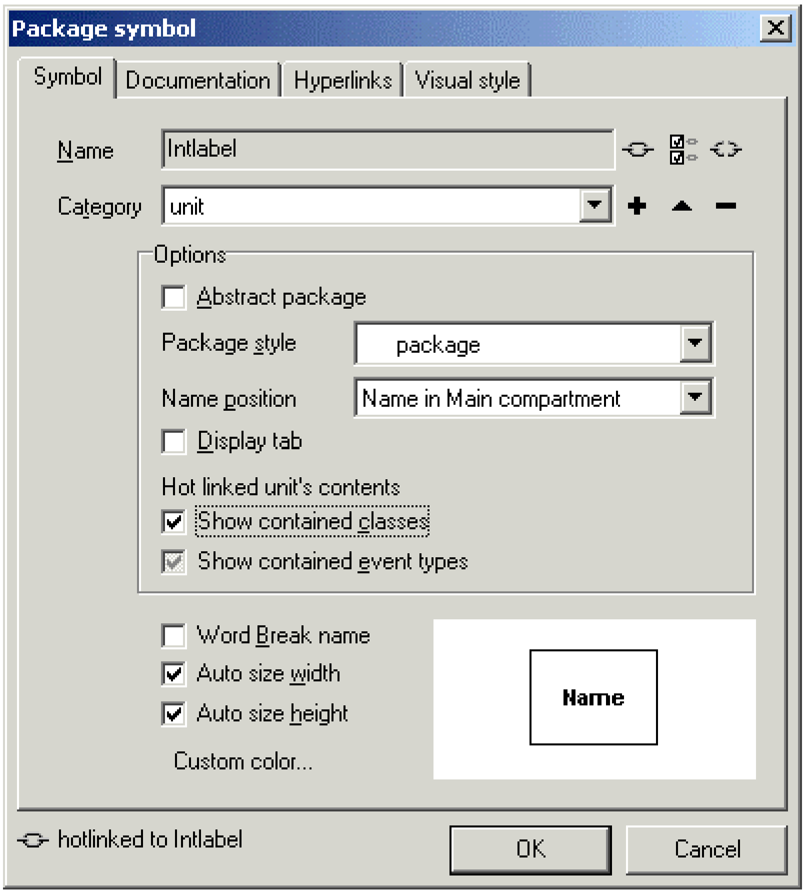


Visualizing the unit IntLabel.pas

Just like classes can be visualized by class symbols, the unit IntLabel which contains TIntLabel can be visualized. To do this, click the “Add Unit Package” tool on the diagram editor tool bar and then click on the diagram. The following dialog will appear which lets you select the unit to visualize in the package. In this dialog, select “IntLabel” and click OK.



Now the Package Symbol editor will be visible, which is used to edit the visualization of the linked unit.



Name: Intlabel

Category: unit

□ Abstract package

Package style: package

Name position: Name in Main compartment

□ Display tab

☑ Show contained classes

☑ Show contained event types

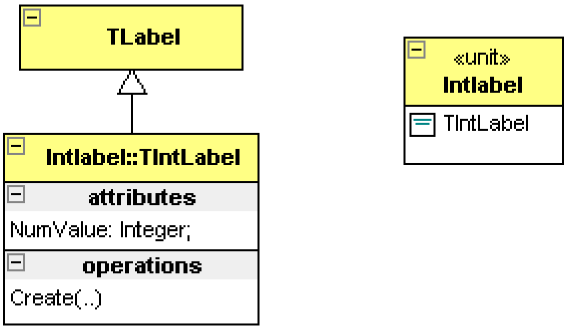
□ Word Break name

☑ Auto size width

☑ Auto size height

hotlinked to Intlabel

In this dialog, Make sure the “Show contained classes” option is checked (not grayed) and click OK. Your diagram should now look something like the picture below.

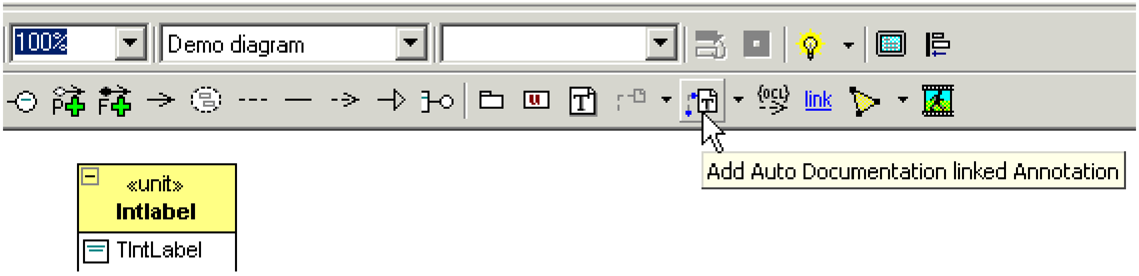


The package symbol displays it's contained classes (TIntLabel) and has a stereotype (category) named <<unit>>. Of course, if you add more classes to the unit, the symbol will be updated automatically.

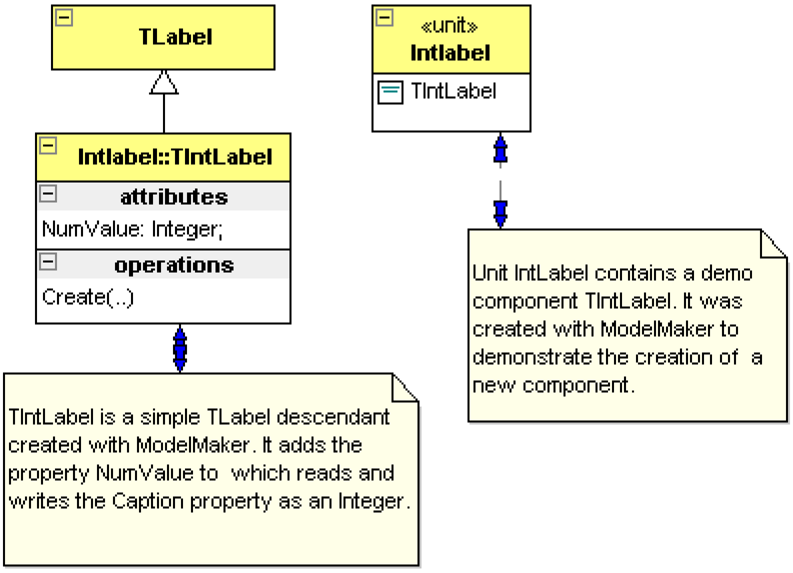
Visualizing the Documentation

The UML uses Annotation symbols to add notes to diagrams. ModelMaker supports hotlinking annotations to symbol documentation (or OneLiners). This is a two way hot link: the annotation text will automatically show the symbol's documentation and editing the annotation text will update the symbol's documentation. To demonstrate this, we'll add a linked annotation to the class symbol TIntLabel and to the unit package symbol IntLabel.pas.

On the diagram editor toolbar select the "Add Auto Documentation linked Annotation" tool. This tool allows three link styles which can be selected with the drop down button next to it. Links styles are: passive (not linked), documentation and one liner. Make sure the Documentation style is selected.



Then after selecting this tool, click on the class symbol and drag the mouse below it. This will create the link and annotation. Repeat this for the package symbol that is linked to unit IntLabel. Your diagram will now look something like this.



TLabel
«unit»
Intlabel
TIntLabel
Intlabel::TIntLabel
attributes
NumValue: Integer;
operations
Create(..)
Unit IntLabel contains a demo component TIntLabel. It was created with ModelMaker to demonstrate the creation of a new component.
TIntLabel is a simple TLabel descendant created with ModelMaker. It adds the property NumValue to which reads and writes the Caption property as an Integer.

Now try to edit the documentation for TIntLabel in the annotation and see it change in the class dialog and the diagram. To do this, click TIntLabel's annotation and press F2. This invokes the annotation's inplace editor. Change the text to your liking and after pressing the Enter key, check the documentation tab in the class editor dialog (classes view). Similar to linking the documentation, a symbol's One Liner can be linked to an annotation.

Summary

In this chapter you got a first glimpse of some basic features in ModelMaker.

- ModelMaker is all about creating classes.
- It is important to start with the right project template especially if you want to override methods or properties.
- The interface of a class consists of Class Members (fields, methods and properties).
- Properties create and update their access fields and methods.
- Method code consists of sections, which can either be created automatically or manually.
- A Unit provides a link with a source file. Units can have 'auto generation' enabled to instantly reflect any change in the model to the source file.
- ModelMaker's IDE integration experts will take care of reloading units in Delphi's code editor.
- To jump from ModelMaker to the IDE and back, use the Locate in Delphi and Locate in ModelMaker commands.
- It's easy to document a design using the documentation wizard.
- Help files can be created for a unit, which are ready to integrate with Delphi's on-line help.
- Instant visualization in class diagrams can be used to document your design.
- Class symbols can automatically display contained members, package symbols can automatically display classes contained by a unit (source module).

- Symbols can be hotlinked to annotations, which will then display documentation or One Liners.
- Diagrams support multiple symbol styles that can be defined at different levels.

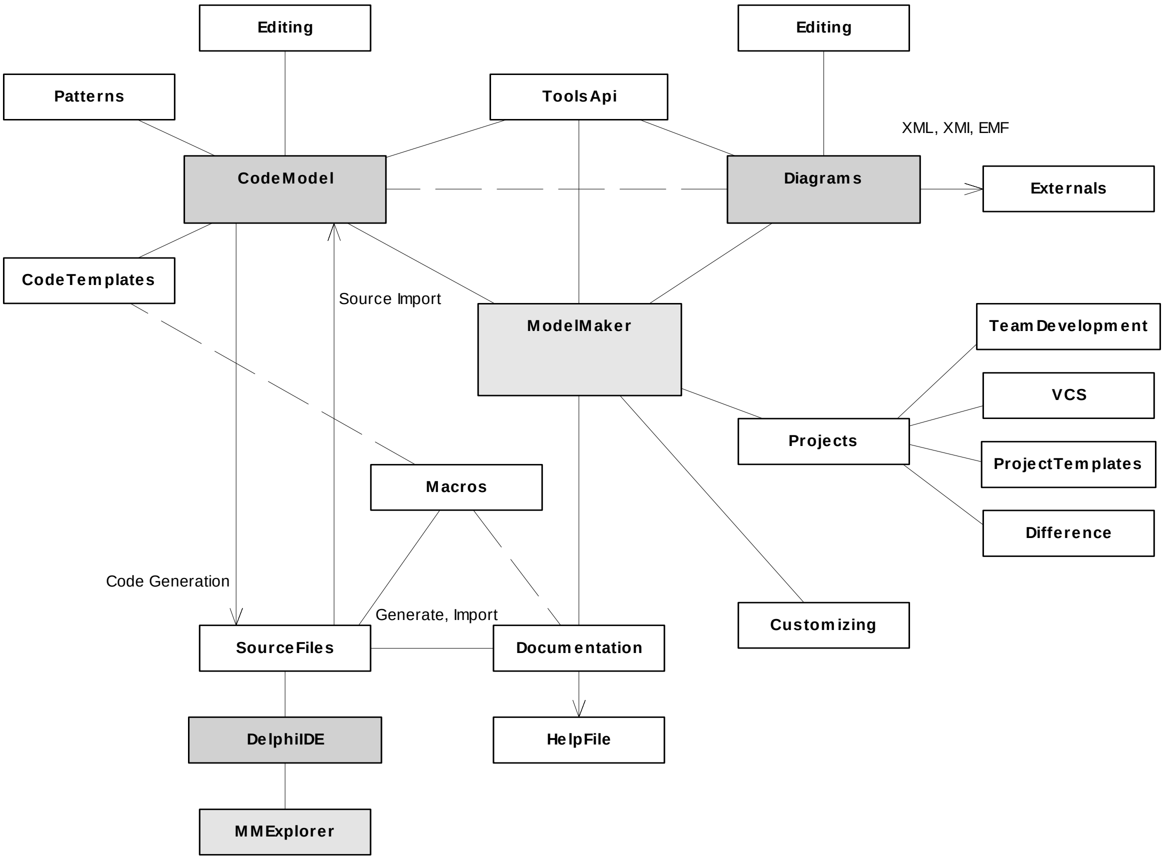
Where to now?

Now you’ve seen ModelMaker’s basic mechanisms. You can have a look at the following topics:

- There is another step-by-step example in the Design Patterns manual that demonstrates the use of design patterns. You should have enough background now to work through this demo.
- ModelMaker’s *Basic Concepts* page 36.
- The other chapters in this manual focus in greater detail on common aspects of ModelMaker such as diagrams, code generation and import.

Basic Concepts

Overview



This picture gives an impression of ModelMaker’s main parts and how they relate.

The two main entities are the Code Model and the Diagrams. Around them you’ll find importing and generating source code, interaction with the Delphi IDE, saving models etc. Going around this picture more or less anti-clockwise we’ll see:

The ***Code Model*** contains the classes, members, units etc. that map to the corresponding concepts in Delphi’s Object Pascal. The Classes view, Members view, Method Implementation view and Units (Code) view all deal with visualizing and manipulating the code model directly.

Code Generation is the process of creating an Object Pascal source file containing classes, members and unit code. ***Units*** provide the link between the Code Model and a source file. A unit contains classes and/or event type declarations plus user defined ***unit code*** such as module procedures. Refer to Code Generation, page 45, for a more detailed description of source code generation. Code generation is typically, but not only, controlled from the Units view.

Code Import is the process of reverse engineering an Object Pascal source file into entities that make up the *Code Model*. This can be initial importing - the unit and / or classes it contains did previously not exist in the Code Model - or ***refresh import*** - re-importing an existing unit and / or the classes it contains in order to synchronize the Code Model and source file. Code Import is typically controlled from the Units view. It is amongst others also available in the classes view and difference view. Code Import is described in detail in chapter Importing Source Code, page 56

Design patterns are proven solutions for a general design problem. It consists of communicating classes and objects that are customized to solve the problem in a particular context. In ModelMaker patterns are active agents that will insert code into the model and stay *alive* to *reflect changes* in the model to the pattern related code. Design patterns currently only relate to the *Code Model*. Patterns are manipulated in the Patterns view. There is more on patterns in the Design Patterns manual.

Code Templates are user definable and parameterizable snippets of related code. They are like user definable patterns. Code templates can be created form the Members view and applied from the Patterns view or Members view. There's more in Code Templates page 71

ModelMaker's ***Delphi IDE integration*** takes care of synchronizing the Delphi IDE editor buffers whenever a file is (re-)generated by ModelMaker. Depending on the Delphi version there are other functions available like: add IDE editor file to model, refresh IDE editor file etc. There's more in chapter Integration with the IDE page 105

The ***ModelMaker Code Explorer*** is a separate *ModelMaker Tools* product that brings basic ModelMaker Code Model related functionality into the Delphi IDE. With this explorer you can navigate and add, edit, copy properties, methods or even entire classes with the same ease and concepts as in ModelMaker, usually even with the same dialogs.

A ***Macro*** is a fragment of text that is identified by a macro identifier. While generating source code and in-source documentation, ModelMaker will expand the text, replacing macro identifiers with the macro's text. Macros are also used to customize certain parts of the generation process (custom class separator, method section separator etc.). Macros are maintained in the Macros view. Macros are described in detail in chapter Macros, page 74 Macros are also used to parameterize *Code Templates* as described in chapter Code templates, page 71

All Code Model entities and Diagram symbols can be documented with ***Documentation*** and a ***One Liner***. In all relevant editors you'll find a Documentation tab. The Documentation view and Floating Documentation view are dedicated to editing One Liners and Documentation. Emitting "in-source documentation" during code generation is controlled by macros. You can redefine these macros to customize the documentation format.

Documentation can be converted to a unit based ***Help File***. This is done in the Documentation view. Other documentation output formats can be created with (third party) plug-in experts that use the ***MMToolsApi*** to access the model.

The ***Diagrams*** contains multiple types of diagrams. Some diagrams visualize aspects of the Code Model in UML-style. Others visualize entities such as Use Cases that only exist in Diagrams. Most symbols can be ‘HotLinked” to entities in the code model. Class symbols for example are linked strictly to classes in the Code Model: changing the class in a diagram will also change the class in the code model. Messages in sequence diagrams can be weak linked: they can or cannot be linked to a class member. If they are not linked the message name is just text. Symbols such as Use Case symbols only exist in the Diagram model and have usually no relation with the code model. It is important to realize that symbols linked to the code model (for example Class symbols in class diagrams) only *visualize* an entity (class) in the code model. The same class can be visualized many times in multiple diagrams in different styles depending on the context. Diagrams are created and maintained in the Diagram list view. The actual diagrams are edited in the Diagram Editor view. There’s more in chapter Diagrams, page 39

Diagrams can be ***exported*** as image, native XML format or in XMI format (third party plug-in expert).

The Environment and Project options are a first means to ***Customizing*** ModelMaker to your taste or coding style.

In Chapter “Customizing” page 80 there’s more on customizing ModelMaker.

ModelMaker ***Projects*** or ***Models*** contain both Code Model and Diagrams. In ModelMaker you work on a single model at a time. Opening a different model will close the model you were working on.

Working with models requires care in the areas ***team development*** and model (system) ***boundaries*** as described in chapter Team development. Model boundaries and Version Control, page 43

The ***Difference*** view is used to compare a model unit to the associated file on disk. Most powerful is the structured difference that does a syntactical comparison rather than a plain file based comparison. Also use the Difference view to compare any disk file or model unit with any other file or model unit or to compare two classes.

Code Model contents

A ***Class*** is the most important entity in the Code model, it matches the corresponding concept in Delphi and it is a container of Class Members. Classes always have an ancestor (super) class and sometimes have descendent (sub) classes. The default class ancestor `TObject` is always present in the model.

An ***Interface*** is similar to a class, as it matches the corresponding concept in Delphi. It is also a container of a restricted set of Class Members. Interfaces always have an ancestor (super) interface and sometimes have descendent (sub) interfaces. From Delphi 6 onwards there are two interface roots; IUnknown and IInterface. These default interface ancestors are always present in the model. Because classes and interfaces are so similar, in the remainder of this manual usually where you read class you can also read interface. Both are

Class Members are the fields, methods, properties and events making up a class's interface. They always belong to a class (or interface).

Fields, Methods and ***Properties*** match the corresponding concepts in Delphi. Fields are used to store a class's state and/or data. Methods are used to implement behavior. A method's implementation consists of ***sections*** of code. This allows ModelMaker to locate specific code within the method's body. Properties let you have controlled access to a class's attributes as though they were fields. ***Events*** are a special kind of properties. They are used to represent method pointer type properties (delegates). This way ModelMaker makes the same distinction as Delphi's Object Inspector does. It is possible to create a *property* of type `TNotifyEvent` and ModelMaker will generate the correct code for the property, but ModelMaker will not recognize this property as an event. Therefore: use Events rather than properties to model event types.

Event type definitions are used to define the signature of event type properties. ModelMaker relies on these definitions to create and update event handler methods and event dispatch methods. The most used event type `TNotifyEvent` is automatically inserted in each model. Event types are maintained in the Events view.

Design patterns and ***Units*** as described earlier complete the code model contents.

Diagrams

ModelMaker supports a set of UML diagrams:

1. Class diagram or static structure diagram
2. Sequence diagram
3. Collaboration diagram
4. Use case diagram
5. Robustness analyses diagram (not defined in the UML)
6. Activity diagram
7. State chart diagram
8. Package diagram or Unit dependency diagram, a static structure diagram, just showing unit package symbols.
9. Implementation diagrams: Deployment diagram and Component Diagram
10. Mind Map diagram (not defined in the UML)

The basic elements of diagrams are ***symbols*** and ***associations***. The meaning and attributes of the symbols and association used are according to the UML specification. This manual will not explain the meaning and details of each symbol. In the ModelMaker on-line help you'll find a short description for each symbol and association and it's attributes. There are a number of good books available on the UML. Alternatively you could download the latest version of the UML specification as available for free on the Rational web site.

The Chapter "Diagrams" contains a detailed description of organization and editing of diagrams in ModelMaker.

Working with models

In this chapter, a model is the equivalent of a ModelMaker project that contains both Code Model and Diagrams.

Model files

Native ModelMaker will save a model into set of files:

1. <model>.mpr; contains the project settings.
2. <model>.mma; contains the project related macros.
3. <model>.mmb; contains the code model data
4. <model>.mmc; contains the documentation for the model.
5. <model>.mmd; contains the diagrams.
6. <model>.mme; contains the event type definitions.
7. <model>.mmf; contains the project messages.

If you manage your source files using a version control system, you should add these model files to version control too.

However, ModelMaker is able to bundle the project files into a single project bundle: *.mpb. To enable this, check the option 'Bundle project files' in “Options|Environment|General”. This option is checked by default. If this option is checked, the file Open and Save dialogs will have the *.mpb file type as well as the *.mpr. Using single file bundles makes it easier to work with ModelMaker projects. To convert existing projects to single file project bundles, use File|Save as and manually change the .mpr extension to an .mpb for the project. In very large projects you may find that saving and loading bundles takes some more time than the multi file projects. When using project bundles it is sufficient to add the <model>.mpb file to version control.

ModelMaker cooperates with version control systems by not allowing you to save a project that exists with read-only file attributes. Note that only the file <model>.mpr or .mpb is checked for read only attributes. In an unbundled project file the *.mma.*.mme files are not checked.

Model templates

As you probably have noticed (for example in the Getting Started demo), one of ModelMaker’s powerful features is that it’s easy to override methods and properties and that changes are automatically propagated down the inheritance tree. But to let this work, the ancestor class and the methods and properties to override must be part of the model. So it is important with which (new) model you start.

Now you may ask: why didn't I get the complete VCL as default model? This would contain all classes I ever need! The answer is that this would result in very large models, through which it is hard to navigate. We have been working with ModelMaker for quite a few years now, and it shows that it is most practical if models contain classes of a single domain only. Classes contained in a single component package typically reside in single model too. Generally this result in models typically containing 5 to 20 classes or may be up to 50 for really large models.

And that's where you need templates. Templates are just ordinary models containing classes for a certain domain that you use to derive new classes with in a certain domain. Since it's possible to have as many templates as you like, you can create nice compact templates for each relevant sub-domain: like a template for creating simple components, one for simple TCustomPanel descendants etc.

You load a template by selecting 'File|New from template' which will load the template model and then reset the model's name to 'untitled'. Any model can be used as a template, but by design ModelMaker looks in the `[installdir]\TEMPLATE` folder for template models.

ModelMaker has one special template that it uses as default. This is the model `[installdir]\DEFAULT.mpb`. You may open this model and change it to your needs or overwrite it with another template model.

Editing a model

To edit a model, ModelMaker has multiple views on the model. Most of these views are interlinked: selecting something in one view will show related information in another. Interlinking is based on:

- The current *class*, selected in the Classes view or Diagrams view. For example, the Class Members view displays the members of the current class.
- The current *class member* (if any), selected in the Class Members view.
- The current *method* (if any), equal to the current class member if that is a method. For example, the Method Implementation view displays the implementation of the current method.
- The current *unit*, selected from the Units view.

The other view like the Macros view and the Event Library view are (more or less) independent from these selections.

In the Environment options Navigation tab you'll find options to synchronize and activate views on certain events.

Ownership in ModelMaker

ModelMaker assigns an *owner* to each entity in the model. Entities can be anything from classes to methods or a section of code in a method. The owner of an entity created the entity and has exclusive rights to update or delete it whenever suitable. Usually you, ‘User’ will be the owner since you create most classes, class members etc. ModelMaker does not discriminate between users: it does not remember that John created this class and Mary that property.

Deleting an entity will automatically delete all entities it owns too. For example: a property owns it’s read access method. You cannot delete or edit these methods, other than by deleting or editing the property.

Team development, Model boundaries and Version Control

In ModelMaker team development support and model boundaries are related issues as they both deal with the question: what should and what should not be in a model. There are a few important reasons to use multiple relative small models according to logical boundaries rather than one big model containing all classes and diagrams you have.

1. It enables team development: while one developer works on one model that is part of a larger project, the other can work on another. There are limited possibilities to merge changes made to the same model. Therefore only one developer can work on a single model at the time.
2. It improved ease of navigation and overview
3. It improves performance.

Usually you'll find logical boundaries to split up models - and usually well-designed modules (as in units or classes) have low coupling and dependencies. Boundaries could be: units in a certain Delphi package, units containing classes that perform a related task etc. In ModelMaker itself for example, we have lots of models, sometimes only containing a single unit. Large models for example contain all classes related to diagrams, the entire code engine or the source importer. And yet other models contain units that are used in many projects: timers, filters etc.

Although we have some happy customers that have models containing 300+ classes in 150+ units, practice shows that a good model size is about 1 to 30 classes in 1..10 units.

The drawback on having multiple smaller models is that ModelMaker maintains active relations only within the same model and not beyond model boundaries. As a result you occasionally might need to re-import a unit after it has been altered in another model.

It’s a good idea to use a version control system and put the model files under version control too. Although a model contains everything that is needed to (re-)generate the source files it contains, you should ***always*** store the actual source files under version control too. It's from the source files that you build your product, not the model.

Merging models is only partly supported: source code can be generated and imported and diagrams can be exported/imported. However no code model meta-information can be exported/imported. Because ModelMaker stores its data in a native binary format, you cannot use the merging capabilities of a Version Control System without corrupting the model.

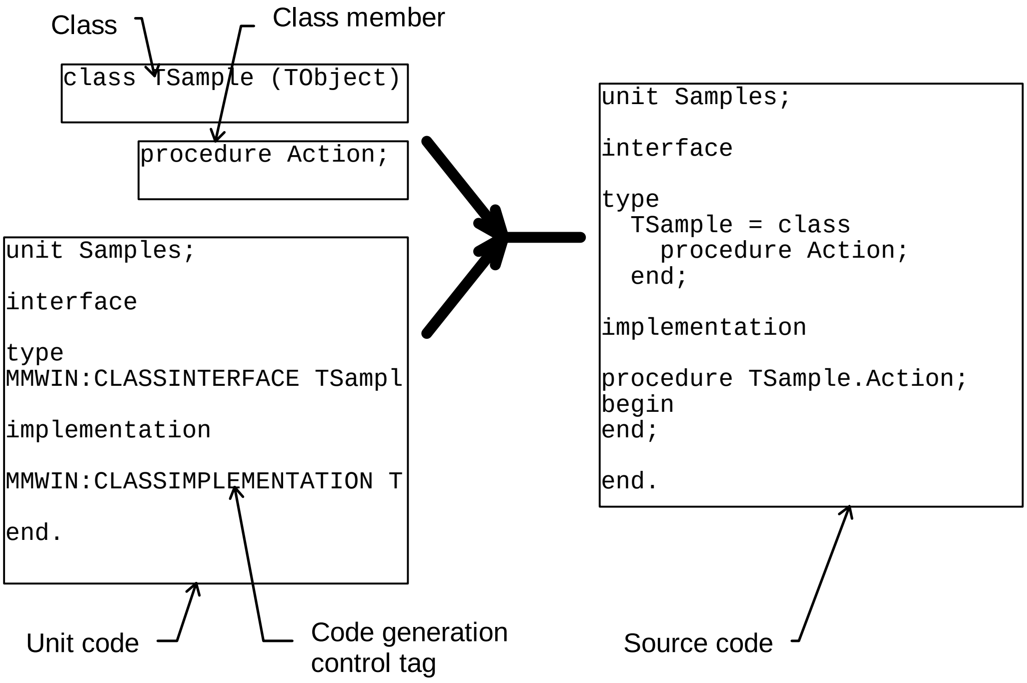
If models do get out of sync with the source code or other models you've always got the Difference View with it's powerful structural difference function to help getting the model synchronized with source or other models.

Using source aliases rather than hard coded directories is a must in team development. Check chapter Source Aliases, page 52 on source aliases.

Generation source code

Overview

In ModelMaker units are the gateways to source files on disk. During code generation, unit code, classes and class members from the code model are combined into a source file. A unit’s unit code contains (can contain) code generation control tags. At the position of a tag ModelMaker will insert the associated entity such as class interface or implementation. Here is a picture that visualizes this process.



```
class TSample (TObject)
```

```
procedure Action;
```

```
unit Samples;

interface

type
MMWIN:CLASSINTERFACE TSampl

implementation

MMWIN:CLASSIMPLEMENTATION T

end.
```

```
unit Samples;

interface

type
  TSample = class
    procedure Action;
  end;

implementation

procedure TSample.Action;
begin
end;

end.
```

The unit code is read line-by-line and scanned for code generation control tags. If a line contains a code generation control tag, the entity as defined by that tag is inserted instead of the tag. Any lines not containing code tags are just copied to the source file.

During code generation macros in both unit code and method implementation code will be expanded using the predefined macros and the project and environment macros you define yourself. Macro expansion and line formatting are the last stages in the source code generation process for both text generated from code tags and text just copied from a unit’s unit code. Macros are explained in detail in chapter Macros, page 74

During generation of the implementation section, class separators, method separators and method section separators can be emitted. This is controlled by code generation settings and macros.

Insertion of in-source documentation can also be part of the generation. This is explained in detail in chapter “In source Documentation” , page 67.

Code generation control tags

ModelMaker uses code generation control tags to control source file generation. Only code generation control tags placed in the unit code are interpreted. Tags in a method’s implementation are not interpreted. Here are the rules that apply to code generation control tags:

1. Code generation control tags are *case insensitive*.
2. All code generation control tags start with `MMWIN:` at the *first* position of a line.
3. Code generation control tags must reside on a *single line*.
4. Any *semi-colons* or *equal* signs defined in a tag are obligatory.
5. Code generation control tags can contain any white space after the `MMWIN:` definition. For example: `MMWIN:STARTINTERFACE` is the same as tag `MMWIN: START INTERFACE`

Class related tags

These code generation control tags are used to define the insertion position of class and interface related code:

```
MMWIN:CLASS INTERFACE classname ;ID=###;
MMWIN:CLASS IMPLEMENTATION classname ;ID=###;
MMWIN:CLASS REGISTRATION classname ;ID=###;PAGE=vcl page name
MMWIN:CLASS INITIALIZATION classname;ID=###; // OBSOLETE
```

These class related tags are automatically inserted and maintained by ModelMaker whenever you add a class to a unit or remove it again. Normally you would use the Unit editor dialog or drag and drop in the Units view to insert or delete classes in/from a unit or change the relative position within a unit. However, in special cases you can manually move these tags to any other position in the unit code. This is for example useful if you want the interface of a class to reside in the unit’s implementation.

In these tags ModelMaker ignores the ‘`classname`’ and just uses the ‘`ID=###`’ tag to identify the class. The class name is inserted just for your convenience. Modifying it will have no effect.

Normally, for classes both the `CLASS INTERFACE` and `CLASS IMPLEMENTATION` tags should be put in the unit code. If either one is missing after you’ve edited the unit code manually, you’ll get a warning. In special cases - for example in include or documentation files - you may manually remove either the interface or implementation tag. Interfaces (as opposed to classes) ignore the `IMPLEMENTATION` tag.

The `CLASS REGISTRATION` tag is optional and is used to insert a snippet of code to register the class as component. You may manually remove them from the unit code. You can manually edit the 'vcl page name=...' text in the registration tag to change the VCL registration page. However, usually you would do this in the unit editor dialog. If you remove the registration tag or the page name, no registration code will be generated for the class.

When importing a unit containing a procedure Register, the registration code is automatically converted to tags.
The tag CLASS INITIALIZATION is obsolete from version MMv6.0 onwards. This tag is maintained for backward compatibility only. The tag is used to insert initialization code for TStreamable descendants: RegisterStreamable(..); If you remove the initialization tag, no initialization code will be generated for the class.

Event type declaration tag

This code generation control tag is used to define the insertion position of an event type declaration.

```
MMWIN: EVENT DEFINITION eventname type declaration; ID=###;
```

This declaration is maintained by ModelMaker and is obligatory for each event definition in a unit. Normally you use the unit editor dialog or drag and drop from the Events and Units view to insert or remove event type definitions in/from a unit, or change their relative positions within a unit. However, you may manually move these tags to any other position. If you remove them, the event type definition is also removed from the unit. The 'eventname' and 'type declaration' texts are ignored, only 'ID=###' is used to identify an event type definition.

Editing marker tags

These code generation control tags are used to mark the positions at which you want ModelMaker to insert the first class or event type declaration in a unit.

```
MMWIN:STARTINTERFACE
MMWIN:STARTIMPLEMENTATION
```

These tags are for editing purposes only and they have no role in the code generation process. There's one exception to this. The MMWIN:STARTINTERFACE tag is also used to determine the insertion position of class forward declarations - if any. If this MMWIN:STARTINTERFACE tag is absent, class forward declarations will be inserted before the first event type declaration or class interface, which ever comes first.

Macro expansion control tags

These code generation control tags are used to switch on and off macro expansion during code generation:

```
MMWIN:START EXPAND
MMWIN:END EXPAND
```

By default the expansion is switched ON. You need these tags if your unit or method code contains the text “`<!`” (“” not included). The macro expander will interpret the sequences

```
“<!” + Identifier + “!>” on a single line
“<!” + Identifier + “(“ param list + “)” + “!>”
```

as a macro. “Identifier” (the macro name) can consist of characters ['0'..'9', 'a'..'z', 'A'..'Z', '_']. Which is similar to Object Pascal identifiers, although macro names can start with a number. White space surrounding the identifier is ignored.

Because macros can be in any text including comments and strings, this would make it impossible to generate code for units that contain a valid macro sequence <!ident!>.

There are a few workarounds for this problem. The most sensible uses these control tags in the unit code - remember the tags do not work in method code!

```
MMWIN:ENDEXPAND
const
  HTMLCommentStart = ‘<!’;
  HTMLCommentEnd = ‘!>’;
MMWIN:STARTEXPAND
```

In the rest of the code you can now use the constants and still leave the macro expansion on.

Note that these tags do not affect generation of in-source documentation, which is also based on macros. Documentation related macros are always expanded regardless of the setting of these switches.

Unit documentation tag (obsolete)

This code generation control tags defines the insertion position of a unit’s documentation. Because inserting unit documentation is much better controlled with the ‘In-source documentation generation’ options, we recommend avoiding the use of this tag although it’s still supported for backward compatibility.

```
MMWIN:INCLUDE UNITDOC;INDENT=##;
```

The tag ‘`INCLUDE UNIT DOC`’ defines the position at which ModelMaker will insert the unit’s documentation. The unit’s documentation can be edited in the Documentation view. The ‘`INDENT=##;`’ extension is optional and may be omitted. This defines an indention for the documentation of `##` spaces. A typical use would be:

```
{
MMWIN:INCLUDE UNIT DOC;INDENT=2;
}
unit <!UnitName!>
```

Obsolete tags

These code generation control tags are obsolete from MMv6.0 onwards.

```
MMWIN:STARTREGISTRATION
MMWIN:STARTINITIALIZATION
```

On loading a model, ModelMaker will remove these tags from the unit code. If you add them manually they will simply be ignored.

Code generation options

In the Project options|Code Generation tab you will find options that control code generation:
1. Formatting the layout of source code
2. Sorting of class members and method implementations
3. Inserting a (custom) class header to that precedes the class’s method implementations
4. Inserting a (custom) method separator to that precedes each method’s implementation
5. Inserting a (custom) method section divider in between each section.

The on-line help file explains the meaning of these options.

The Project options|Source Doc generation tab controls the generation of in-source documentation. This is explained in detail in the chapter on “In source Documentation”, page 67.

Maintaining Code Order / Custom member order

ModelMaker supports a user definable custom member interface and method implementation order.
These custom orders can be assigned during import used during code generation. When that is done, the effect is that ModelMaker will maintain the imported code order during generation.

This is how it works:
In the Project options Code Generation tab you define a member sorting scheme in class interface and implementation generation. In these sorting schemes Custom orders can be used as a grouping or additional sorting property.

When ***grouped*** on custom order, members will be sorted according to the (original) custom code order. Members that have been added later with an unspecified custom order, will be placed after all members with a specified order.
When using the custom order to perform ***additional sorting***, the default sorting scheme will be applied and within each 'section' (visibility etc.), the custom order will be applied.
If class members have an unspecified order (which is the default for new members), the effect of enabling Custom Order during Generation or in the Members list is null.

Custom orders can be assigned during Import. In the Project options|Code Import tab you’ll find settings to enable / disable assigning the custom order during import. The import dialog allows temporarily overruling these settings.

If the Importer assigns custom orders and Generation uses grouping on Custom Order ModelMaker will effectively maintain the original code order during ’refresh import’ and append new members at the end.

Additionally Custom orders can manually be defined - per class - with the "Members custom order" dialog or with the Members view ‘Rearrange mode’.

The Rearrange dialog is available from the Members and Classes view 'Wizards' local sub menus and from the Units view 'classes' local sub menu. In this dialog you either you drag and drop to rearrange a class interface and method order or use one of the predefined sorting schemes. The dialog can be also used to clear an interface or implementation custom order. Note that manually defining a custom order will erase an imported code order.

The Members view has a 'Rearrange mode' (members local menu). In this mode an interface custom order can be assigned using drag and drop in the members view itself. For method implementation order you must use the Rearrange dialog. In the in the rearrange mode the Members view filter settings (visibility, type, category) are ignored to make sure all members are displayed. Also Members view grouping is implicitly set to "Custom Order" and sorting is predefined and cannot be changed. As a visual feedback, the background of the members is changed to a silver color in this mode.

Adjusting the unit template

Whenever you add a new unit to a model, ModelMaker looks for the file `DEFUNIT.PAS` in the folder `ModelMaker\6.0\BIN`. The default unit may also be (re-)defined when adding a new unit. This text file is used as a template for the newly created unit code. You may edit this file to your needs. You can use these code generation control tags to mark the insertion position for the first class ModelMaker will insert in the unit:

```
MMWIN:START INTERFACE
MMWIN:START IMPLEMENTATION
```

You might want to adjust the default unit template in order to:

- Customize the **`uses`** clauses in the unit **`interface`** and **`implementation`**.
- Add a company-defined header.
- Control macro expansion.

As an example: here’s a unit template we use for freeware units. In the chapter Macros the same template extensively using macros is shown.

```
{
  File      : <!UnitName!>
  Version   : <!Version!>
  Comment   : <!Comment!>
  Date      : <!Date!>
  Time      : <!Time!>
  Author    : <!Author!>
  Compiler  : <!Compiler!>
+-------------------------------------------------------------------------+
| DISCLAIMER:                                                             |
| THIS SOURCE IS FREEWARE. YOU ARE ALLOWED TO USE IT IN YOUR OWN PROJECTS |
| WITHOUT ANY RESTRICTIONS. YOU ARE NOT ALLOWED TO SELL THE SOURCE CODE.  |
| THERE IS NO WARRANTY AT ALL - YOU USE IT ON YOUR OWN RISC. AUTHOR DOES  |
| NOT ASSUME ANY RESPONSIBILITY FOR ANY DAMAGE OR ANY LOSS OF TIME OR MONEY |
| DUE THE USE OF ANY PART OF THIS SOURCE CODE.                            |
+-------------------------------------------------------------------------+
}

unit <!UnitName!>;

interface

uses
  SysUtils, Windows, Messages, Classes, Graphics, Controls,
  Forms, Dialogs;

type
MMWIN:START INTERFACE

procedure Register;

implementation

uses StrUtils, NumUtils;

procedure Register;
begin
end;

MMWIN:START IMPLEMENTATION

initialization
end.
```

Notice how this template contains (from top to bottom):

- A simple standard header and a free ware disclaimer.
- Some statistics macros, like `<!Date!>` and `<!UnitName!>`
- The basic unit structure: **`unit..interface..uses..implementation..uses..initialization..end.`**
- A macro `<!UnitName!>` to define the unit's name.
- The **`procedure`** `Register;` definition and implementation for registering components.
- A default uses clause in the unit's implementation to include some often-used units `StrUtils` and `NumUtils`.

Unit Time Stamp Checking

The ModelMaker code generator by default uses Time Stamp checking to prevent overwriting source files that may have been changed outside ModelMaker. It checks if the file on disk is newer than the last time a unit was generated. If this is the case you'll be warned that you are about to overwrite that modified file.

You can switch on and off time stamp checking in the Environment options|General tab.

There is a limitation on time stamp checking you must be aware of:

1. If you rename a unit in ModelMaker the time stamp is not reset to 'unknown', so if you have an existing file on disk which is NEWER than the last time the unit was generated (with the old name) you will NOT get a warning. The Unit editor dialog warns you for this (file xxxx already exists, overwrite?), but the in place editor in the Units view does NOT.

The Unit difference View displays the time stamp comparison on activation. The function "Check Time stamps" refreshes this comparison.

Source Aliases

ModelMaker supports source path aliases in units to avoid hard-coded directories and make your models machine-independent. An alias is associated with an aliased directory, similar to database aliases. In the model a unit's alias is saved rather than the aliased directory. On each machine aliased paths can be defined differently. This allows you to transport models to other machines.

Source aliases are a must in team development.

Example:

Suppose on machine A you have a source directory:
`C:\DATA\PROJECTS\COMMON`
An alias defining this directory could be COMMON.
On machine B, COMMON could de defined as
`\\PROJECTDATA\COMMON`

You add aliases from the main menu "Options|Source aliases", or from the Units view popup menu.

To avoid that you need to mimic a large directory structure in aliases, unit names can be relative to an alias. That way you only need to define a few aliases for root paths.

Here's an example:
Suppose you have a directory structure which looks like this:

C:\Project1\App_a\source
C:\Project1\App_a\components
C:\Project1\App_a\utils
C:\Project1\App_b\source
C:\Project1\App_b\components
C:\Project1\App_b\utils
C:\AllProjects\source
C:\AllProjects\components
etc.

You could define three aliases
App_a = C:\Project1\App_a

App_b = C:\Project1\App_b
AllProjects = C:\AllProjects

A unit named C:\Project1\App_a\source\Samples.pas could then use

Alias = “App_a” (omit the “”)
Relative unit name = “source\Samples.pas” (omit the “”)

Source code aliases are also used to offset the Import source code dialog's initial directory. If you define an alias VCL Source for C:\Program files\Borland\Delphi 3.0\Source\Vcl, the import dialog can be offset to this directory by simply selecting this alias from the drop down menu.

Source aliases also participate in Version Control integration. See next chapter.

Version Control support and Aliases

By using a plug-in VCS Expert you can add Version Control capabilities to ModelMaker. Check the ModelMaker Tools web site for ready available third party VCS Experts or create your own using the MMToolsApi VCS interface.

If a VCS expert is installed, in the units view popup menu and main file menu VCS related menu items are available to manually check-in/out a model or unit. Also each time a read-only unit is about to be generated an attempt is made to check the unit out (after your confirmation). VCS Experts can add more VCS related commands to the popup menu such as ‘Add to project’, ‘History’ etc.

Usually VCS systems usually need a VCS project name to perform an operation. In ModelMaker Source aliases are used to store the user definable VCS projects.

Each source alias can (but does not need to) store a Version Control project. This string is passed on to an installed VCS integration expert whenever a VCS file related action is performed.

If you install a VCS expert in ModelMaker, the ModelMaker IDE integration experts will use the same expert to integrate VCS in the Delphi IDE.

For details, refer to your VCS system and MM VCS expert provider.

Using ModelMaker to generate Instrumentation code

ModelMaker supports generating Method instrumentation. This feature makes ModelMaker suited for generating instrumentation code for CodeSite, GpProfile and other tools instrumenting source code on a method base for profiling, tracing etc.

Method instrumentation generation is controlled with the option 'Instrumented' in the Method editor dialog. If this option is checked instrumentation code will be generated for the method. Instrumentation can be (de-) activated for all units at once with "Project options|Code generation|Instrumentation". The actual instrumentation code is defined by two macros you must add manually to the environment or project macro list: “MethodEnterInstrumentation” and “MethodExitInstrumentation” (omit the “”). These macros are expanded before the first and after the last section in a method's main body. For example (note the use of the predefined macros ClassName and MemberName in these macros)

macro MethodEnterInstrumentation=

```
CodeSite.EnterMethod(’<!ClassName!>.<!MemberName!>’);
try
```

macro MethodExitInstrumentation=

```
finally
  CodeSite.ExitMethod(’<!ClassName!>.<!MemberName!>’);
end;
```

When this is applied to:

```
procedure TSample.DoSomething;
begin
  ShowMessage(’Doing something’);
end;
```

This will result in the following code:

```
procedure TSample.DoSomething;
begin
  CodeSite.EnterMethod(’TSample.DoSomething’);
  try
  ShowMessage(’Doing something’);
  finally
    CodeSite.ExitMethod(’TSample.DoSomething’);
  end;
end;
```

To avoid creep when re-importing instrumented methods you can use the code remove tags. Check chapter “START and REMOVE tags, page 59 for details:

```
MMWIN:>>STARTREMOVE
MMWIN:>>ENDREMOVE
```

These tags may be part of a comment. Depending on the setting in the Project options|Code import tab the importer will filter out any code in between a start remove / end remove pair.

The macro MethodEnterInstrumentation using these tags would for example look like:

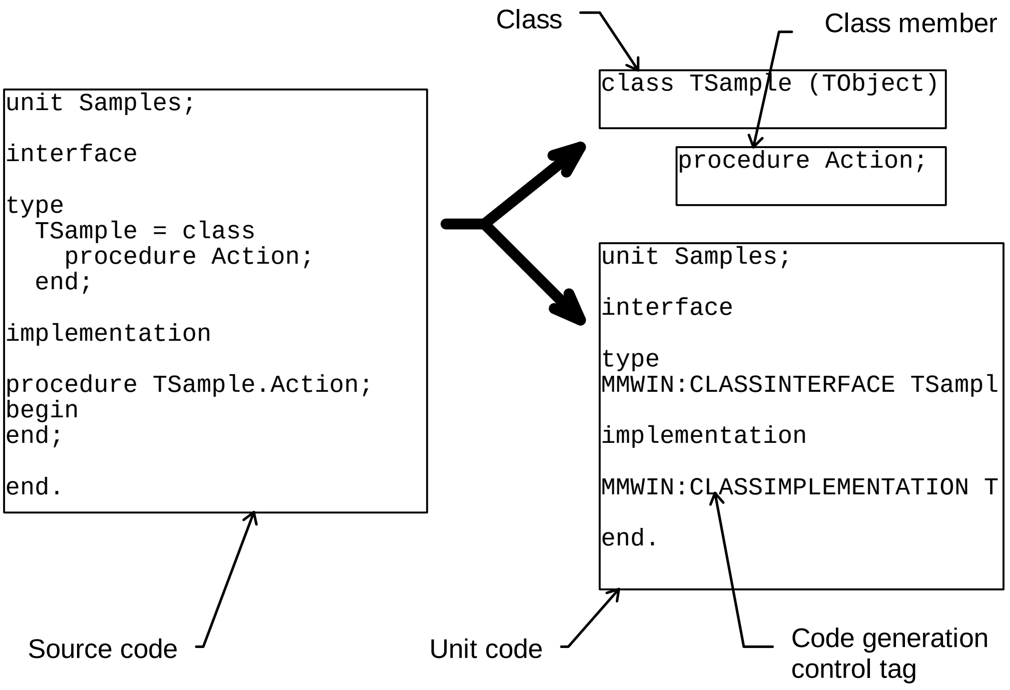
```
//MMWIN:>>STARTREMOVE
CodeSite.EnterMethod('<!ClassName!>.<!MemberName!>');
try
//MMWIN:>>ENDREMOVE
```

The Member Manipulator can be used to switch on and off Instrumentation for multiple methods at once. On the ModelMaker Tools web site you'll find a third party plug-in Instrumentation expert. This expert is dedicated to controlling method instrumentation code.

Importing source code

Background

ModelMaker imports Delphi Object Pascal source files. This process is basically the inverse from generating a source file from classes, members and unit code. The class related code is converted into Code Model entities such as classes, interfaces, members and method implementations. All non-class or interface related code is moved into a ModelMaker unit's unit code.
This process is called reverse engineering.



```
unit Samples;

interface

type
  TSample = class
    procedure Action;
  end;

implementation

procedure TSample.Action;
begin
end;

end.
```

```
class TSample (TObject)
```

```
procedure Action;
```

```
unit Samples;

interface

type
MMWIN:CLASSINTERFACE TSampl

implementation

MMWIN:CLASSIMPLEMENTATION T

end.
```

It is important to realize that if an imported class is not currently existing in the model, members and code sections are inserted as 'User created/owned" and no attempt is made to extract meta information, such as applied patterns, inherited calls etc. The only exception to this, are the read and write access members of properties, which are restored and linked to the property. For example: all code inserted by patterns is read back, but marked as "user" and the patterns itself is not recreated. The same applies for inherited method calls etc. In general you loose the meta information.

However, if an imported class already occurs in the model it is 'refreshed' and all meta-information is restored. Even applied design patterns can be traced back.

Therefore importing source code is great for:

- Importing (an interface of) a class you want to inherit from or use as a client.
- Importing existing code originally not developed with ModelMaker
- Updating an existing class from source code

However it is advised that once imported, you keep editing your code in ModelMaker. The only exceptions to this are form and (other resource module's) source files which by their nature you (partially) need to edit in Delphi.

Importing a source file

The main toolbar and units view pop-up menu contain buttons and commands to

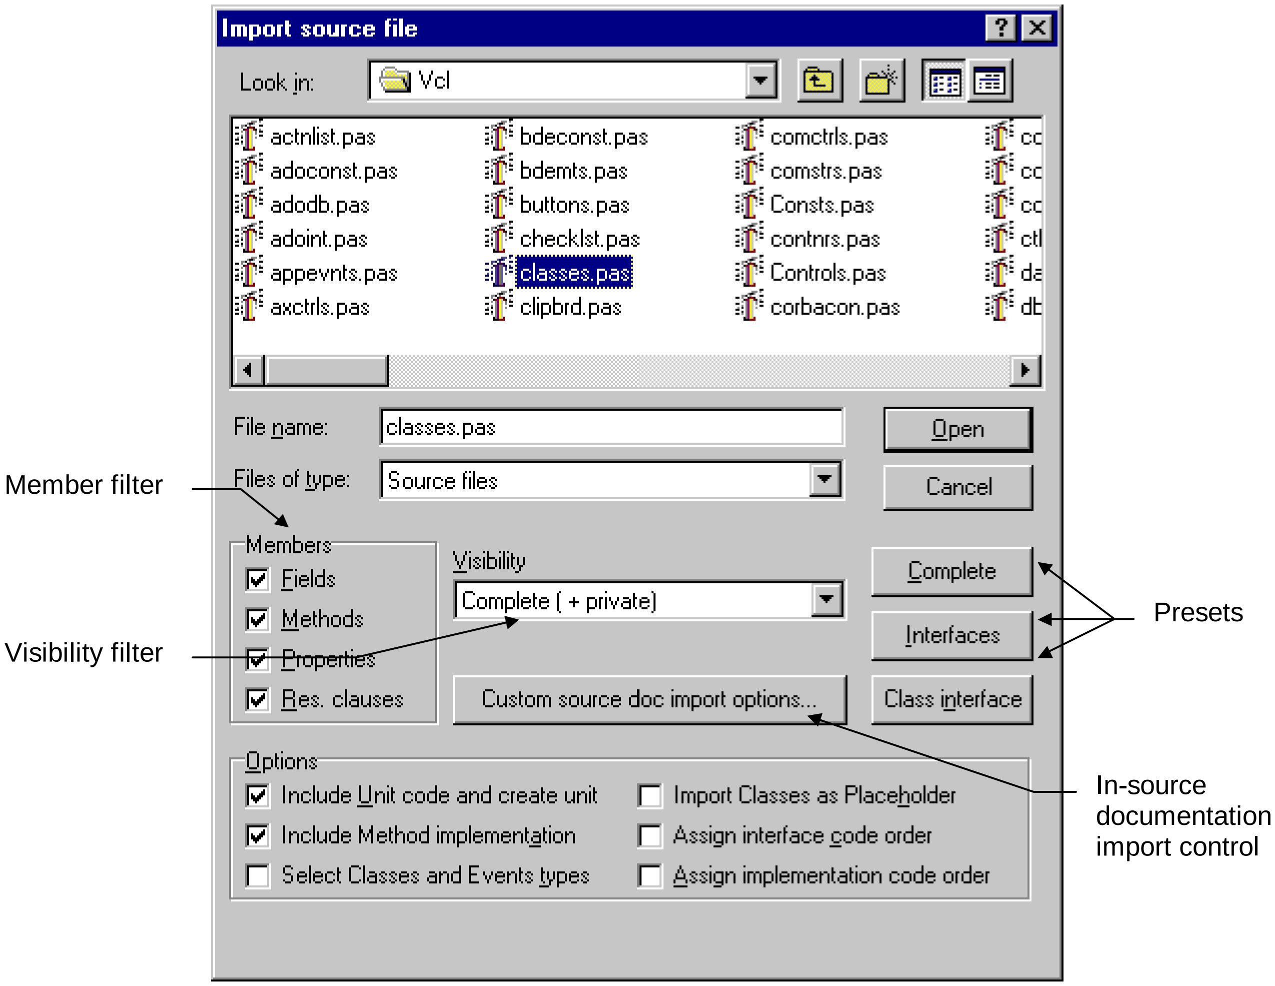
- Import a source file (in the current model or a new model).
- Refresh import source file.

Additionally you'll find import functions in the Classes view (refresh class or associated unit) and the Difference view (refresh unit, class or method).

In the Project options|Code Import tab you'll find the options to control source code import. Check the on-line help file for a detailed description on each option. The project options are used for all (refresh) imports except when you use the Import dialog to interactively import a file. The import dialog allows temporarily overruling some project import control options. The import dialog has some other options that by their nature are not in the project options, typically related to initial first time import. The options in the import dialog are preset (each time!) to the project options.

The import dialog's initial directory is pre-set by selecting a source code alias. You'll find more on (defining) Source code aliases on page 52.

When importing a source file using the import dialog, you enter a source file name and set filters and options to control the import. Most options are rather self-explanatory.



Import source file

Look in: Vcl

File name: classes.pas

Files of type: Source files

Members

☑ Fields

☑ Methods

☑ Properties

☑ Res. clauses

Visibility: Complete (+ private)

Options

☑ Include Unit code and create unit

☑ Include Method implementation

□ Select Classes and Events types

□ Import Classes as Placeholder

□ Assign interface code order

□ Assign implementation code order

If the option “Include Unit code and create unit” is checked, not only the classes will be imported, but also the non-class related unit code. Check this option if you want a complete import. If you just need a class’s interface this option can be unchecked.

If the option “Select Classes and Events to import” is checked, you may select which of the classes or events found in the source file will actually be imported in the model. Useful if you’re not interested in all classes and events contained by a unit.

If the option “Import Classes as Placeholder” is checked all imported classes will be marked placeholder. If it is unchecked classes will remain their current state or ‘real’ if not found in the current model.

There are three pre-set buttons, which set the filters to a “complete”, “interfaces only” “class interfaces” mode. The default settings (as displayed) are those for a complete import.

The In-source documentation import control settings are explained in detail in chapter “Importing a source file” page 57.

Importing (adding) versus Refreshing

‘Refresh Import’ and Import as in ‘Add to Model’ act similar - the difference is how existing units and classes are treated.

Importing with the ‘Add to Model’ function (in the IDE or ModelMaker) will add non-existing units or classes contained in the added unit. If either unit or class already exists in the model it will be refreshed.

‘Refresh Import’ issued from the IDE integration expert will only refresh the unit if already existed in the model and will not add a unit not currently in the model. In ModelMaker you can only refresh an existing unit.

Avoiding creep - removing code during import

ModelMaker supports removing certain fragments of code during import to avoid creep in a full generation / re-import cycle.

ModelMaker generated default class separators such as

```
{
***************************** TSample *****************************
}
```

and ModelMaker generated default category markers such as
{<<Category>>: Model linking}

are automatically removed.

Additionally ModelMaker will remove the following code:

1. All code marked by a MMWIN:>>STARTREMOVE and MMWIN:>>ENDREMOVE pair.
2. All comments with the ‘removal signature’ as defined in the Code Import options.
3. Matched (and optionally unmatched) comments according to the documentation style comment.

For importing “In source documentation” and removing comments with the documentation signature(s), refer to chapter on “Importing in source Documentation”, page 68.

STARTREMOVE and ENDREMOVE tags

You can use these tags in any code, comment or string to instruct ModelMaker to remove all code between the tags including the tags themselves:

```
MMWIN:>>STARTREMOVE
MMWIN:>>ENDREMOVE
```

The corresponding setting in the Project options|Code import tab will enable/disable filtering based on these tags.

These tags are commonly used to remove (part of) a macro that was generated by ModelMaker from the input file. Check the chapter on generating Method Instrumentation code for an example.

Comments with remove signature

If you want to remove certain comments from the source file you can use comments with the Removal Signature. This signature is defined in the Project options|Code import tab which also enables and disables removing comments with this signature.

You will need to use this type of comment remove filter if you
1. Define a custom class separator,
2. Define a custom method separator,
3. Define a custom method section separator
4. Redefine the category expansion macros 'IntfCategory' or 'ImplCategory'

Assuming {- } to be the removal style comment, a custom class header should look like

```
{-
****************************
*
*           <!Classname!>
*
****************************
}
```

Similar, a custom category expansion tag could look like
`{- Category: <!Category!> }`

Note that Method End Documentation is automatically removed due to the fact that the importer will remove the method including the line containing the method's final **`end;`**.

Import restrictions and limitations

ModelMaker usually imports in about 99.9 % of all cases without problems. If ModelMaker generated the source file, the imported code is usually 100 % correct. ModelMaker uses a combination of syntactical analyses and line based extraction to support importing of code that is not entirely syntactically correct.

ModelMaker's import mechanism imposes the following restrictions on source files in order to be imported correct. ModelMaker's importer uses the same parser as the ModelMaker Code Explorer. The ModelMaker Code Explorer that integrates in the Delphi IDE will display a list of parse errors. That way it acts more or less as tool to check code before importing into ModelMaker.

Class and Interface interfaces

Restrictions in class and interface declarations.

Any comments, compiler directives and white space in a class's interface are/is ignored except in method parameter lists.

Comma separated Field declarations are converted into separate fields:

```
FA, FB: Integer;
```

is imported as

```
FA: Integer;
FB: Integer;
```

Procedure or method pointers that are not defined as an type are not imported correct. The work around is to use a type definition.

The following code causes import errors.

```
TSample = class(TObject)
  FEvent: procedure of object;
end;
```

Which can be replaced by this code that will import correct:

```
TMyEvent = procedure of object;

TSample = class(TObject)
  FEvent: TmyEvent;
end;
```

Method implementation

Restrictions in method declarations.
Any comments, compiler directives and white space in are/is ignored except in parameter lists.

Local variables immediately following the method declaration will be converted to ModelMaker method variables. If local variables for example are preceded by a **`type`** or **`const`** declaration, they will be added to the method's local code section, just like all other local code for that method.

In the following example the local vars. I, J and S will be converted to ModelMaker local vars., the const declaration and procedure CheckIt will be placed in the method's local code section.

```
procedure TSample.Action;
var
  I, J: Integer;
  S: string;
  const CheckSum = $AAAA; // this will go into local code
  procedure CheckIt;
  begin
  end; // this is the end of the local section
begin
  CheckIt;
end;
```

In the following example the local vars. I, J and S will be placed in the method's local code section together with the const declaration:

```
procedure TSample.Action;
const CheckSum = $AAAA; // this will go into local code including the vars
var
  I, J: Integer;
  S: string;
  procedure CheckIt;
  begin
  end; // end of local code section
begin
  CheckIt;
end;
```

During refresh import of a method already existing in the model, the importer will leave the code sections intact wherever possible. If the importer cannot locate a non-user owned section of code, it will simply leave the section in the method and give a warning.

Comments and white space

The following table shows how ModelMaker treats comments and compiler directives

Comment or compiler directive in:	Import result
Class interface	Ignored
Method header	Ignored except in parameter list
Local vars.	Ignored
Method local code and body	Copied to method
All other code	Copied to unit code

Check the ModelMaker generated default class separators such as

```
{
***************************** TSample *****************************
}
```

and ModelMaker generated default category markers such as
{<<Category>>: Model linking }

are automatically removed.

If you define a custom class separator, method section separator, or redefine for example the category expansion macro TODO, you should use the remove style comments to avoid creep during import. Check paragraph " Comments with remove signature", page 60.

Unsupported language constructs

Include files are not read during import, so if you find yourself thinking: "where's my method implementation gone?" you probably need to add the included files to the imported unit using a text editor and re-import the file.

Compiler directives in class interfaces are not supported and are a potential problem source. Using inheritance may sometimes solve this. Worst case you need to create two units.

Compiler directives *around* method implementations are not supported. Placing the directives inside the method can solve this:

```
{$IFDEF DEMO}
procedure TSample.Action;
begin
end;
{$ELSE}
procedure TSample.Action;
begin
  { actually do something useful }
end;
{$ENDIF}
```

Won't be imported correct, but can be replaced by the following code which will be imported fine:

```
procedure TSample.Action;
begin
{$IFDEF DEMO}
{$ELSE}
{ actually do something useful }
{$ENDIF}
end;
```

The importer matches **`begin..end try..end, case..end`** pairs etc. to locate methods. Because conditional defines are not interpreted, using conditional defines you can create code that will compile correct but will not import correct. In fact The Delphi IDE background compiler uses a similar mechanism and will not be able to function properly either when inserting new methods in code completion or creating a new event handler.

This code for example will confuse the importer's begin end matching. The method will not be imported correct.

```
procedure TSample.Action;
{$IFDEF DEMO}
var
  S: string;
begin
  S := 'Demo';
  ShowMessage(S);
{$ELSE}
begin
{$ENDIF}
end;
```

You can replace the previous code by the following code that will import correct and as a side effect allows the Delphi IDE to stay on track too:

```
procedure TSample.Action;
{$IFDEF DEMO}
var
  S: string;
{$ENDIF}
begin
{$IFDEF DEMO}
```

```
S := ‘Demo’;
  ShowMessage(S);
{$ENDIF}
end;
```

Pure assembler methods are not supported:

```
procedure TSample.Fast; assembler;
asm
end;
```

Expressions in an indexed property’s index specifier are not supported:

```
property FirstPicture: TBitmap index BM_USER + 0 read GetPicture;
property SecondPicture: TBitmap index BM_USER + 1 read GetPicture;
property ThirdPicture: TBitmap index BM_USER + 2 read GetPicture;
```

This can be solved like:

```
property FirstPicture: TBitmap index BM_FIRST read GetPicture;
property SecondPicture: TBitmap index BM_SECOND read GetPicture;
property ThirdPicture: TBitmap index BM_THIRD read GetPicture;
```

Conversion errors

Any import conversion errors or warnings will be displayed in the Message View. The messages may be printed, saved etc.

Not reported conversion errors are:
1. Minor changes in property access method parameters lists.
2. Positioning of code generation tags in the unit code.

The best thing to do after importing a complex unit, is to perform a Delphi syntax check on the re-generated unit. From our experience it shows that if there are any remaining errors, they will evolve here.

Another option is to make a file based difference in the Difference view between the imported unit and the original source file. You should make sure that Code generation sorting scheme matches the scheme used in the original file. You might need to import Custom Code order and use the same order during generation to maintain code order. Check chapter “Maintaining Code Order / Custom member order” on page 49.

Note that to build a *structured* difference the same importer is used that will hide the same type of errors!

Auto Refresh Import

The Auto Refresh Import feature is only available together with the Delphi 4 and higher. This function will automatically refresh a unit in ModelMaker if you save the unit in the Delphi IDE. This improves synchronization of code developed both in ModelMaker and the Delphi IDE at the same time. However there are some serious warnings.

How it works

If you change a unit in the IDE editor that is also maintained in a ModelMaker model, the model and source file will be out of sync. Normally you have to 'refresh import' the unit to synchronize the model with the changes on disk. The auto-refresh import feature will do this automatically each time you save a unit in the IDE.

How it is activated and controlled

In the ModelMaker menu in the Delphi 4 (and higher) IDE check the item 'Enable Auto Refresh'. If this option is set, each time you save a unit (or project) in the IDE, the 'Auto Refresh command is send to ModelMaker which checks if:

1. The Environment option 'Auto refresh Import' is checked
2. The unit is in the current model
3. Unit generation is not (user) locked
4. The unit has 'auto code generation' enabled

If all above conditions are met, ModelMaker will do a refresh import and unlike after a manual 'refresh import' leave the unit in 'auto generation enabled' mode and - this is ***very important*** - *regenerate* the unit.

Effectively Auto Refresh improves synchronization between ModelMaker and the Delphi IDE: whenever you change something in ModelMaker, the auto-generation enabled unit will regenerate the file and reload it in the IDE. Whenever you change and save a file in the IDE, ModelMaker will resynchronize it in the model.

Warnings

In the normal, non-auto refresh development model you always have one master and slave: either ModelMaker refreshes the IDE using automatic code generation or you manually refresh the ModelMaker model with the IDE if you want to resynchronize again. With this feature there's no master or slave anymore. This can seriously damage your work as may be clear from the following example: When refreshing the unit, ModelMaker assumes it's reading a 'compilable unit'. If you for example have omitted a single begin or 'end;' or worse, comment out something, have unterminated strings etc. class and method import will be in trouble and not detect your error but simply remove all 'unwanted' methods. Since ModelMaker detected a change the unit is auto-generated and immediately after you saved the unit is reloaded with disastrous results. Experience shows that it's easy to loose lots of work instantly. Auto Refresh must be used with great care. Note that if Auto Save is enabled in the IDE, the Compile / Run command will auto save modified units depending on your IDE environment settings.

If you want more control, rather than just save in the IDE invokes auto refresh, you can use the ‘Refresh Import’ command from the ModelMaker IDE expert to save a file. This command will not only generate a manual refresh import command but also automatically save your unit in the IDE. Therefore you could use this command with shortcut Ctrl+Shift+H rather than the conventional Ctrl+S to save and refresh. You can add the ModelMaker Refresh command to the IDE tool bar. Check chapter (Integration in) Delphi IDE page 106.

Editing Form source files

ModelMaker Tools developed the ModelMaker Code Explorer to help editing Form, Data Module and other resource module source files. Due to the nature of these resource module files the IDE editor is more suitable for editing them. The ModelMaker Code Explorer will dock into the IDE editor and bring basic Code Model editing and navigation actions right into the IDE.

If you do not have the ModelMaker Code Explorer installed, you *can* edit form (and other resource module) source files with ModelMaker. This offers many advantages:

1. Use ModelMaker’s high level view and filters to navigate through your form code.
2. Automatically *restructure* your source files by regenerating them.
3. Improve your form code quality by adding methods and (array) properties with the same ease as for “normal” non form classes. Especially when you turn your forms into components, you want them to have nice and clean code to improve maintainability.
4. In general speed up form implementation.

For a smooth cooperation between Delphi and ModelMaker, stick to these rules:

In Delphi,

- Create and rename the form and unit.
- Add, delete and rename components.
- Set component properties.
- Create, rename and delete event handler methods.

Delphi adds all it’s components and event handler methods with the default visibility, so they are easy recognized in ModelMaker (use the members filter to filter out default visibility).

In ModelMaker,

1. Import your form file in an (empty) ModelMaker model.
2. Add, edit and delete all other members
3. Add additional classes to the unit.

To synchronize between Delphi and ModelMaker,

1. Regenerate the ModelMaker unit whenever you changed your code in ModelMaker. The auto-generate feature will help you doing this automatically.
2. Refresh the ModelMaker unit whenever you changed your code in Delphi, the integration experts will help you doing this automatically.

In source documentation

Overview

ModelMaker supports generating and importing "in-source” documentation. That is: the documentation and One Liner attributes of Code Model entities can be inserted during code generation and / or read (back) during import. Generation and importing of in-source documentation is controlled by the Project options tab “Source Doc Generation” and “Source Doc Import”. The Import source dialog allows temporarily overruling the import settings.

"In-source" documentation must be marked with special (user definable) documentation and one liner signature tags, more or less like in Java Doc. These signatures must be an Object Pascal comment symbol followed by one or more letters, Common used signatures are:

Documentation tags:

```
{{
{:
(**
(*:
```

One liner tags:
{1
//:
//1

Generation is internally based on macros. To customize the generated format, you can redefine these macros. To ensure a correct round trip (generation followed by a re-import) the generation and import settings must match. Normally ModelMaker enforces a correct match by using the essential import settings for generation. If you redefine the documentation generation macros, you must ensure correct matching.

Generating in-source documentation

ModelMaker supports generating and importing ‘in-source’ documentation in source files. Generation is controlled by the Project options on tab ‘Source Doc Generation’ and some macros (refer to Macros). You do not need to define these macros, as ModelMaker will on the fly insert the required macros. You can however redefine them either as environment or as project macro to customize the generated format.

Documentation macros

Macro name	Description	Example

ModuleDeclDoc	Used to expand Module (unit) documentation. Check Module related macros	`{{ module`
		`<!ModuleDoc!>`
		`}`

EventDoc	Used to expand Event Type documentation	`{{ event type`
		`<!MemberDoc!>`
		`}`

ClassIntDoc	Used to expand Class documentation in the class declaration	`{{ class <!ClassName!>`
		`<!ClassDoc!>`
		`}`

ClassImpDoc	Used to expand Class documentation in the class implementation (emitted just before the first method implementation)	`{{ class <!ClassName!>`
		`<!ClassDoc!>`
		`}`

MemberIntDoc	Used to expand member documentation in the class interface	`{{ <!ClassName!>.<!MemberName!>`
		`<!MemberDoc!>`
		`}`

MemberImpDoc	Used to expand method implementation documentation	`{{ <!ClassName!>.<!MemberName!>`
		`<!MemberDoc!>`
		`}`

MemberEndMacro	used to expand method termination documentation	`{ <!ClassName!>.<!MemberName!>`
OneLinerMacro	Used to expand one liners in classes, members, units and event types	`//: Summary: <!OneLiner!>`

In the examples it is assumed that {{ is the documentation signature and //: is the One Liner signature.

As you see in the examples, you can use any of the predefined macros such as <!ClassName!> inside the documentation macros.

However, ModelMaker is only able to import certain styles of source documentation. This is important if you want to ‘Refresh Import’ a unit.

Importing in-source documentation

ModelMaker supports importing "in-source" documentation. Importing source documentation is controlled by settings in the Project options tab “Source Doc Import” and the Import source dialog. As explained: "In-source" documentation and One Liners must be marked with special (user definable) documentation signature tags. More or less like in Java Doc.

An example:

```
//1 SomeMethod does something useful.
{{
procedure TSample.SomeMethod
This method does something useful
It would take pages to tell what.
}
procedure TSample.SomeMethod;
begin
end;
```

In the above example the OneLiner signature is defined as //1 and the documentation signature is defined as {{. The whole comment until the matching comment end symbol is treated as documentation for the first entity defined following or preceding it - depending on the documentation import options. In the example above the comment will be assigned to TSample.SomeMethod. You cannot use multiple line // style comments for documentation.

In the Source documentation options there are three documentation import modes:

1. Import: enables source documentation import and replaces documentation in the model with that in the source file,
2. Clean up: leaves the documentation in the model unaffected, but removes documentation from the unit-code
3. Inactive: which does nothing and leaves the documentation in the unit code.

The option ‘Remove unmatched documentation determines if only matched documentation should be removed or just any comment with the documentation signatures.

When assigning the comment to the Documentation attribute, the first and last #n lines are ignored. Defining any other value than 1 (one) is only useful if you redefine the documentation generation macros. The standard macros assume a value of 1.

You could use the fact that the first n lines (user definable) are ignored and place there the additional macros you'd like to generate. For example:

```
{{
<!ClassName!>.<!MemberName!>
(<!Visibility!>)
<!MemberDoc!>
}
```

This macro would require the first three (3) lines and the last one (1) to be skipped. Using this technique the member documentation won't grow each time you (refresh) import a unit. Another option is to use the Import "clean-up" import mode after in-source documentation has been imported once.

Alternatively you could leave the number of lines to be skipped at 1, and use additional removal style comments to customize your in-source documentation format.

For example:

```
macro ClassIntDoc =
{- ************
<!ClassName!>
```

```
**************}
{{
<!ClassDoc!>
}
```

Note the removal style comment in the first part of this macro. Check chapter “Comments with Remove signature”, page 60.

Related to this is the use of a custom ClassSeparator or MethodSeparator to emit more than just the documentation preceeding the class or a method implementation. Refer to Code Generation options. Using custom separators has the advantage of not needing the redefine the documentation macros and that way ensuring that all expanded documentation looks similar.

For example, defining a MethodSeparator macro like this:

```
{- <!ClassName!>.<!MemberName!>
  (<!Visibility!>) }
```

Combined with enabling the method implementation in source documentation (without redefining the related macro), this behaves as if the entire macro were:

```
{- <!ClassName!>.<!MemberName!>
  (<!Visibility!>) }
{{
<!MemberDoc!>
}
```

Which would be emitted for example like this:

```
{- TSample.SomeMethod
  (public) }
{{
This is the documentation for the method
}
```

Note the use of removal style comments for the MethodSeparator that avoids creep when re-importing the generated code.

Code templates

ModelMaker supports the use of code templates. They are like user definable patterns and consist of a (usually consistent) set of members that is put in a code template source file. This template can then be applied whenever needed again. The template file acts like a structured persistent copy / paste buffer. The powerful aspect is that templates can be parameterized using user definable macros. ModelMaker will extract the macros, let you edit them and expand the macros before importing the template file. The template files can be edited in Delphi, but should not be imported in ModelMaker directly.

Creating a Code template

To create a code template, in the Members view select the members you want the template to contain use the popup menu 'Create code template’. You'll be prompted for a file name. ModelMaker then generates the selected members as part of a stand-in class named `TCodeTemplate`. Here's an example of a simple template file containing a simple `Items` property with a standard `TList` implementation

```
unit SimpleItems;

  TCodeTemplate = class (TObject)
  private
    FItems: TList;
  protected
    function GetItems(Index: Integer): TObject;
  public
    property Items[Index: Integer]: TObject read GetItems;
  end;

function TCodeTemplate.GetItems(Index: Integer): TObject;
begin
  Result := TObject(FItems[Index]);
end;
```

Applying a Code template

To apply a previously created template, select the popup menu 'Apply template’ from the Members view. You'll be prompted for a template file name. ModelMaker will import the members contained by the first class in the template unit and add them to the currently selected class. Other classes and all other code in the unit are/is ignored. There's one exception: event type definitions can also be added to a code template, they will automatically be added to the event library when applying the template.

Registering a Code template

Code Templates can be registered on the patterns palette (patterns view) and Code Template palette (members view popup menu). These palettes that look like the Delphi component palette make it even easier to apply a Code Template. To (un)register a template use the popup menu functions in the palettes or select the corresponding option when you create a Code Template. Code Templates are shared with the ModelMaker Code Explorer.

Parameterize a Code template using macros

You can parameterize a code template by adding macros to the template unit. When applying a template, ModelMaker will first extract the macro parameters, let you edit them, expand the code template and finally apply the template. This allows you to create more generic templates. A macro definition should be formatted as

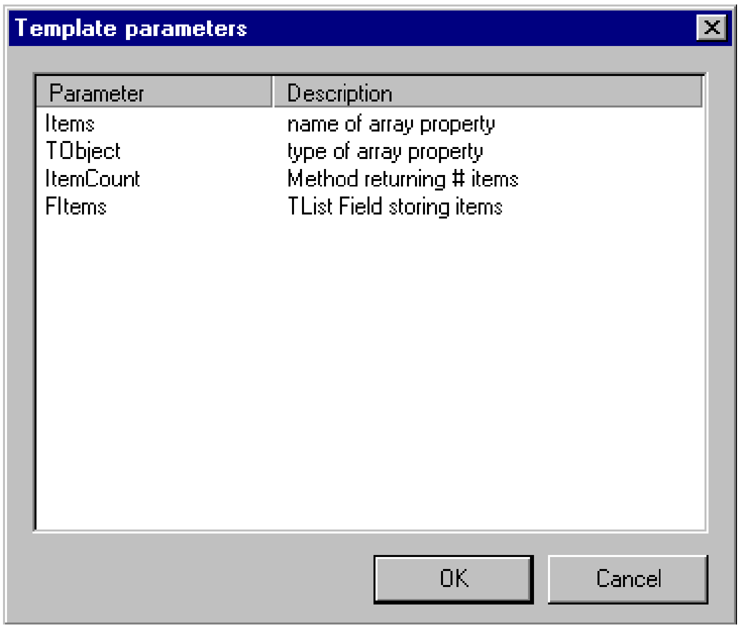
```
//DEFINEMACRO:macroname=macro description
```

The standard ModelMaker macro rules apply. For example: macroname must be an identifier. Parameterizing the above example could for example be done like this.

```
unit SimpleItems;
//DEFINEMACRO:Items=name of array property
//DEFINEMACRO:TObject=type of array property
//DEFINEMACRO:ItemCount=Method returning # items
//DEFINEMACRO:FItems=TList Field storing items

  TCodeTemplate = class (TObject)
  private
    <!FItems!>: TList;
  protected
    function Get<!Items!>(Index: Integer): <!TObject!>;
  public
    property <!Items!>[Index: Integer]: <!TObject!> read Get<!Items!>;
  end;

function TCodeTemplate.Get<!Items!>(Index: Integer): <!TObject!>;
begin
  Result := <!TObject!>(<!FItems!>[Index]);
end;
```



Parameter	Description
Items	name of array property
TObject	type of array property
ItemCount	Method returning # items
FItems	TList Field storing items

If you apply this template, ModelMaker will show a dialog with the list of parameters you defined: Items, TObject, ItemCount and FItems allowing you to change them for example in Members, TMember, MemberCount and FMembers. This way the template can be added multiple times in different contexts. ItemCount is not used in this example, but in the sample code template that is shipped with ModelMaker method ItemCount is part of the template.

ModelMaker predefines one macro: “ClassName” contains the name of the class the macro is applied to. You can redefine ClassName when parameterizing a template. Use ClassName for example to create a singleton implementation macro:

```
function TCodeTemplate.Instance: <!ClassName!>;
begin
  // return the single instance.
end;
```

When applied to a class named TMySample this will expand to:

```
function TMySample.Instance: TMySample;
begin
  // return the single instance.
end;
```

Macros

Overview

A macro in ModelMaker is an identifier placed between <! and !> tags. They may also include an optional parameter list. When the macro is expanded, the macro identifier and tags are substituted by the text associated to the macro. For example macro <!UnitName!> will (in unit Samples) be expanded to the actual unit's name 'Samples'.

Macros are used in

- Code Generation.
- Customizing certain aspects of code generation such as a custom class separator, inserting categories etc.
- Generating in-source documentation.
- Parameter zing Code Templates
- ModelMaker Code editor.

During code generation ModelMaker predefines some model statistics macros at run time. Such as <!`UnitName!>, <!Date!>` etc.

You define your own macros in the Macros view. Macros are defined per desktop (environment) and per project. If a macro is both in the project and the environment macros, the project macro overrules (redefines) the environment macro.

For Parameterizing Code Templates using Macros, refer to chapter Parameterize a template using macros , page 72. To expand a Code Template the predefined macros and project and environment macros are not used.

Macros in Code generation

When generating a source file from a ModelMaker unit (refer to chapter Code Generation page 45), ModelMaker will expand macros in all text that is send to the output file. Therefore macros can be placed in any code: in unit code, in a section of a method's implementation or even in a local var definition. Macro expansion is switched on and of with the generation control tags `MMWIN:START EXPAND` and `MMWIN:END EXPAND` By default the expansion is switched ON. Check chapter "Macro expansion control tags", page 47 for an example.

When expanding a macro, first the list with predefined macros is checked, then the Project macros and finally the environment macros. If an identifier is not found, the macro text is either just removed or generation is aborted depending on the setting of '`Ignore undefined macros`' in the Project options Code Generation tab.

Predefined macros

This table shows the macros ModelMaker predefines when generating a source code file. Some macros may be redefined - especially the documentation expanders, others such as Date and ClassName are fixed.

Macro Name	Allows override	Description	Example
Generic predefined macros			
`Date`	No	Generation date, for example: `19-02-2003`	
`Time`	No	Generation time, for example: `12:34:56`	
`LineNr`		The 1-based line number in the resulting source file at which the macro is defined.	
Documentation expanders			

`ModuleDeclDoc`	Yes	Used to expand Module (unit) documentation. Check Module related macros	`{{`
			`<!ModuleDoc!>`
			`}`

`EventDoc`	Yes	Used to expand Event Type documentation	`{{`
			`<!MemberDoc!>`
			`}`

`ClassIntDoc`	Yes	Used to expand Class documentation in the class declaration	`{{`
			`<!ClassDoc!>`
			`}`

`ClassImpDoc`	Yes	Used to expand Class documentation in the class implementation (emitted just before the first method implementation)	`{{`
			`<!ClassDoc!>`
			`}`

`MemberIntDoc`	Yes	Used to expand member documentation in the class interface	`{{`
			`<!MemberDoc!>`
			`}`

`MemberImpDoc`	Yes	Used to expand method implementation documentation	`{{`
			`<!MemberDoc!>`
			`}`

Customization Macros			

`ClassSeparator`	Yes	Custom Class separator, Only active if corresponding option is activated in Project Code	`{-********************`
			`** Class: <!ClassName!>`
			`** Category: <!Category!>`
			`**********************}`

		Generation options.	assuming {- is the comment remove style
`MethodSeparator`	Yes	Custom Method implementation separator. Only active if corresponding option is activated in Project Code Generation options.	`{- <!MemberName!> -}` assuming {- is the comment remove style
`SectionSeparator`	Yes	Custom Method section separator. Only active if corresponding option is activated in Project Code Generation options.	`{------- section --------}` assuming {- is the comment remove style
`IntfCategory` `ImplCategory`	Yes	Wrappers for Category emission in class or member interface and implementation.	`{- Category: <!Category!>}`
`OneLinerMacro`	Yes	Used to expand one liners (class, member, unit event type)	`//: Summary: <!OneLiner!>}`
`MethodEndMacro`	Yes	Used to expand method end documentation. Only active if corresponding option is set in Project Source documentation Generation options	`{<!ClassName!>.<!MethodName!>}`
Entity specific Macros			
`OneLiner`	No	All entities: for Modules only during Module documentation generation.	
`OneLiner` `Category`	No	All entities: for Modules only during Module documentation generation.	

`ModuleDoc`
`ModuleName`
`ModulePath`
`Alias`
`UnitName`
`UnitPath`
	No	Module specific macros (units). Always available (not only in module documentation). The UnitXYZ macros exist for backward compatibility. Use the ModuleXYZ macros in new projects	

`ClassDoc`
`ClassName`
`TrimmedClassName`
`Ancestor`
	No	Class specific macros. Valid in class and members of that class. Valid in unit code after the first class has been generated. TrimmedClassName contains the class name with the first character (’T’ / ’t’) removed.	In unit code use this to insert auto updated global variables or class pointer types:
			
			`var <!TrimmedClassName!>: <!ClassName!>;`
			`type <!ClassName!>Class = class of <!ClassName!>;`

`MemberDoc`
`MemberName`
`Visibility`
`DataType`
	No	Member specific macros. Valid during generation of declaration, documentation and method	

		implementation code.	

`Parameters`
`CallParams`
`MethodKind`
	No	Method specific macros. Valid during generation of declaration, documentation and method implementation code.	

		Event Types use the same macros as methods. Except: Category and Visibility which are undefined	

The Documentation Expander macros are used to generate in-source documentation. To customize the generated format, you must redefine these macros, either in the project or environment macros. Refer to chapter “Generating in source documentation”, page 67.

The Customization macros can be (re)defined to customize the format of the related aspect. ClassSeparator, MethodSeparator and SectionSeparator are only active if the corresponding options are checked in the project Code Generation options. Refer to chapter “Code Generation Options”, page 49.

Using Macros in code

Some rules that apply to using macros:

- An entire macro including start and end tags must reside on a single line.
- Macro identifiers can contain characters ['0'..'9', 'a'..'z', 'A'..'Z', '_']. This is similar to Object Pascal identifiers, although macro names can start with a number.
- White space surrounding the macro identifier is ignored.
- A start tag not followed by a valid identifier is not considered to be a macro
- If the macro identifier is not followed by either the end tag or the parameter list, the macro is not considered to be a macro.

Rather than presenting the macro syntax diagram, an example will demonstrate the use and definition of macros.

Assume these (user) macros to be defined, in either the project macro list or in the environment macro list.

Name: `Author`
Parameters:
Text:

```
S.M.A.R.T. Programmer
```

Name: `Assert`
Parameters: `Cond, Msg`
Text:

```
{$IFOPT D+}
if not (<!Cond!>) then
  raise Exception.Create(’Assertion error in line <!LineNr!> of unit <!UnitName!>’ +
                         #13 + Msg);
{$ENDIF}
```

This is how you could use these macros:

```
procedure SomeAction(Index: Integer; C: Char);
begin
  <!Assert(Index >= 0, ‘Index out of range’)!>
  <!Assert(C in [‘a’, ‘b’], ‘Char out of range’)!>
  <!Assert(ValidPair(Index, C), ‘Additional checks failed’)!>
  ShowMessage(‘<!Author!> created this code’);
end;
```

Assuming the procedure was placed on line 100 in unit Demos, this text would expand to:

```
procedure SomeAction(Index: Integer; C: Char);
begin
  {$IFOPT D+}
  if not (Index >= 0) then
    raise Exception.Create(‘Assertion error in line 102 of unit Demos’ +
    #13 + ‘Index out of range’);
  {$ENDIF}
  {$IFOPT D+}
  if not (C in [‘a’, ‘b’]) then
    raise Exception.Create(‘Assertion error in line 107 of unit Demos’ +
    #13 + ‘Char out of range’);
  {$ENDIF}
  {$IFOPT D+}
  if not (ValidPair(Index, C)) then
    raise Exception.Create(‘Assertion error in line 112 of unit Demos’ +
    #13 + ‘Additional checks failed’);
  {$ENDIF}
  ShowMessage(‘S.M.A.R.T. Programmer created this code’);
end;
```

The basic rules that apply to the use of macros are:

- When using macros in text, the complete macro including its parameter list must reside on a single line. So this won’t work:
  ```
  <!Assert((A > B) and (B > C),
           ‘This is bad input’)!>
  ```
- Arguments in the parameter list are comma delimited, such as in the use of `Assert`.
- Arguments can contain even pairs of () , [] and ‘’ characters, such as in sets, arrays and string literals.
- If no parameters are defined, as in <!Author!>, you omit the brackets when using the macro.
- Macros can use other macros in their macro text. In fact even parameters can be macros. Nesting is allowed up to 15 levels.
- Circular macro definitions are illegal.
- Macros expand to plain text. See for example the use of the predefined LineNr and UnitName macros in the Assert macro’s text. The expanded macro LineNr is not an Integer, and the expanded macro UnitName is not a string.

Using macros in the code editors

An entirely different use of macros is to expand a macro in the code editor. To do this, press Ctrl+Space after typing the macro name - or Shift+Space, depending on your Environment Options|Editors settings. This is convenient if you create macros like: **tryf** that could expand to:

```
try
  >< // >< in macro text positions cursor after expansion.
finally
  .Free;
end;
```

Using macros in your default unit template

To demonstrate the use macros, here's the effect of using macros on the default unit which was described in "Adjusting the unit template" page 50.

```
{
<!UnitHeader!>

<!FreeWareDisclaimer!>
}

unit <!UnitName!>;

interface

// rest of the unit template is unchanged
end.
```

Notice how this template differs from the previous template:

- The company header is now placed in a macro `UnitHeader`. This saves a lot of redundant text.
- The macro `UnitHeader` contains other macros like unit name, model name, etc.
- The disclaimer is now placed in the macro `FreeWareDisclaimer`.

Diagrams

Diagrams, Diagram List view

ModelMaker supports a set of diagram types as defined by the UML. Currently the UML v1.3 style is implemented. A model can contain any number of diagrams of any type. The Diagram list view (Main menu View or F5) contains a list of all diagrams in the model. Diagrams contain symbols and associations that can be, but do not need to be linked to entities in the code model.

The Diagrams list View is used to create, rename and delete diagrams. Select a diagram in the Diagrams list view to open it in the diagram editor.

Diagrams are named. Names do not need to be unique.

Hierarchy

Diagrams can be organized hierarchically in the Diagrams view. This organization is pure visual and has no further meaning in the model. Any diagram can serve as a parent for any other diagram. To rearrange parent child relations, make sure the list’s “Order by” is set to Hierarchy (Diagram list Popup menu). Then use drag and drop to rearrange diagrams. If the Ctrl key is pressed while dropping, the hierarchy is edited; else the order within the current parent is changed.

Styles

Each diagram has a visual style and a symbol style that define the default styles for the symbol inside that diagram. Editing these styles (diagram editor popup menu Diagram attributes), affects the appearance of all symbols in that diagram. Refer to chapter “Visual styles” for more information.

Default properties

Whenever a new diagram is created (except a Cloned diagram), the format (size) and orientation (portrait or landscape) are set to the defaults as defined in the project options.

Symbols and visual containment

Symbols can visually contain other symbols. For example package symbols can contain class symbols or other package symbols; and Nodes in a deployment diagram can contain Component symbols. Visual containment implicates visual ownership only. Visual containment is not linked to the code model. Inserting a class symbol into a package that is linked to a unit will not actually move that class to that unit. It is just visualized as being part of that unit.

After a symbol is created, visual containment is fixed and cannot be changed in the diagram editor. The only way to change a symbol’s parent is to cut the symbol and paste it on the new parent. Take care: connected associations are only copied if both ends of the association are copied.

Symbol names and other visual adornments

Most symbols have a symbol name text adornment. Depending on the visual style options, the name will display a hotlink status icon, a navigation icon and the hyperlink status. Check chapters Hyperlinks and Hotlinks. The stereotype (category) of a symbol is also displayed in the name adornment.

Other visual adornments are depending on the type of symbol. For example: a state region for a concurrent state contains a state region divider and icons, a sequence diagram role symbol contains a lifeline etc.

Associations

Basics

Associations are used to model relations between symbols. Some associations such as “documentation link” and “constraint” can also be connected to other associations. An association that is not connected to both ends is invalid and will automatically be removed from the diagram.

All associations have a direction: they lead from a source symbol to a target symbol. Usually a navigation arrow is displayed is appropriate. These arrows can be suppressed in the visual style on project, diagram or association level.

Usually the visual path of an association is formed by the two association end points. Shape nodes can be inserted to create more complex paths.

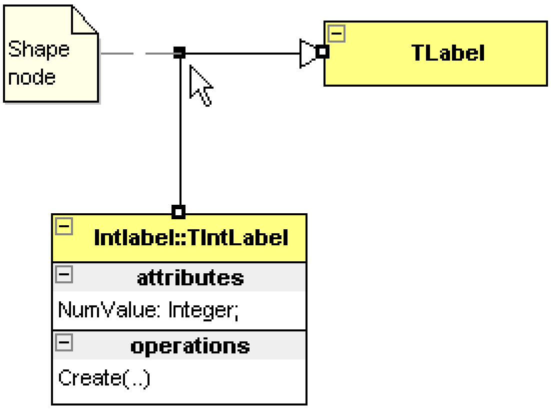
Associations are created by clicking the mouse on the source symbol and while keeping the mouse down, drag to the target symbol where the mouse is released. Once created, associations can be connected to different symbols by moving one of the endpoints to the new source or target symbol.

Anchors

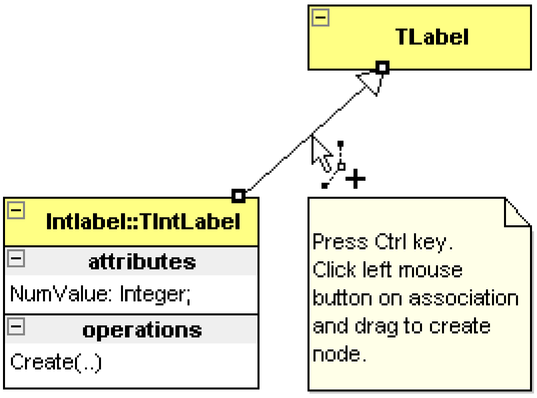
Associations are connected with an anchor point to symbols. Usually the anchor is connected to the center of a symbol. You can however drag-move the connection anchor point within the bounds of the connected symbol. This will change the intersection point of symbol and association. The diagram editor’s popup menu has a function ‘Reset Anchors” which will reset both anchors to the symbol’s center.

Shape Nodes

Shape nodes can be inserted to change the visual path of an association. Shape nodes allow bending associations visually. The association anchor points (connection points on the connected symbols) and the association’s shape nodes make up the actual visual path of the association. The picture below shows an generalization association from TIntLabel to TLabel with one shape node.



To insert a shape node into an association, press the Ctrl-key and drag on a line segment of an association. After the mouse is released, a new node is inserted. Alternatively, use Insert Shape Node from the diagram editor "Association" popup sub menu. This command is available if you invoke the popup menu on an association.

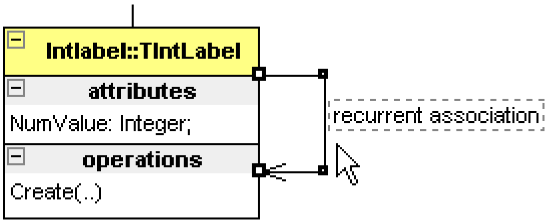


Shape nodes can be moved by selecting the association and then drag them with the mouse.

A shape node can be deleted by aligning it with the two surrounding nodes and is basically the reverse of creating a new shape node. Alternatively, use Delete Shape Node from the diagram editor "Association" popup sub menu. This command is available if you invoke the popup menu on a shape node. The command 'Clear shape nodes" in the same popup menu will clear all shape nodes in all selected associations.

Recurrent associations

Normally associations connect two different symbols. If both ends of an association are connected to the same symbol, the association is recurrent. Most associations can be made recurrent. Some recurrent associations will display a rounded curve rather than a square path. The rounded curve is a bezier that is controlled by two shape nodes. Inserting another shape node will turn the bezier curve into normal straight lines.



To create a new recurrent association, simply make the target symbol the same as the source symbol. Two shape nodes will automatically be inserted that allow control of the visual path.

An existing non-recurrent association can be made recurrent by moving on of the endpoints to the same symbol as the other endpoint. Again, two shape nodes will be inserted automatically.

To convert a recurrent association into a non-recurrent association, move either source or target endpoint to another symbol. The shape nodes will be removed.

Association Name, Qualifiers, Roles and other adornments

Most associations can be named and have an association name adornment. If the name is currently not visible, select the association and press F2 to invoke the in place editor. Depending on the visual style options, the association name will display a hotlink status icon, a navigation icon and the hyperlink status. Check chapters Hyperlinks and Hotlinks. The stereotype (category) of the association is also displayed in the name text adornment.

Other adornments include

1. Qualifiers in qualified association such as class associations. To reduce visual space, the qualifier's type can automatically be suppressed. This is controlled with the visual style options.
2. Role name, both source and target endpoint can be named in for example class associations and object links.
3. Multiplicity (cardinality), both source and target endpoint can have a multiplicity in for example class associations and actor communications.
4. Conditions, usually only in the source endpoint of sequence diagram messages and state transitions.

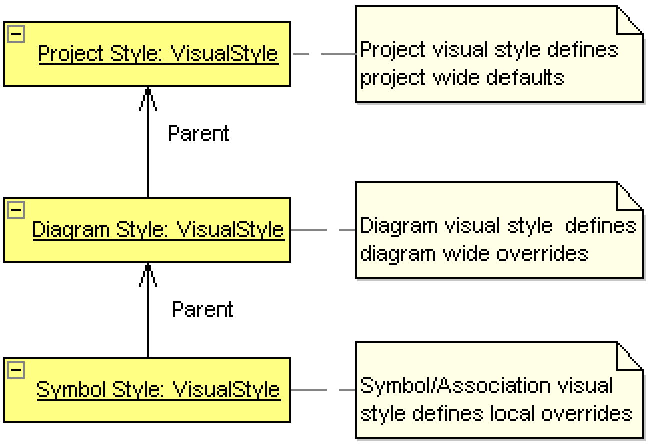
These adornments are all texts and can be moved freely in the diagram. The word break property of text adornments is controlled with the Word break functions on the "Align and Size" palette.

Visual styles

All symbols, associations and diagrams have a visual style. It is this visual style that defines how a symbol appears. A visual style contains font settings, a color palette and some options that control display of icons. The symbol styles, that are discussed in the next chapter, control *what* is displayed; the visual styles control *how* a symbol is displayed.

Style hierarchy

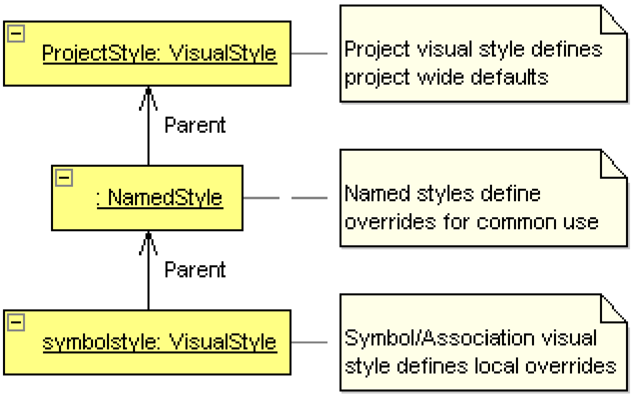
All visual styles are linked in a lookup hierarchy. A style normally looks up an attribute in the parent style but can also override "parent" attributes. By default symbol and association styles are linked to the diagram visual style and have all properties set to "lookup from parent"; that is override or change nothing. As a result, all symbols will appear as defined by the diagram visual style. On their turn, all diagram visual styles are linked to the project visual style and also have all properties set to "lookup from parent".



Project Style: VisualStyle
Project visual style defines project wide defaults
Parent
Diagram Style: VisualStyle
Diagram visual style defines diagram wide overrides
Parent
Symbol Style: VisualStyle
Symbol/Association visual style defines local overrides

This hierarchical structure allows easy adjusting of visual appearance on any level. To change the appearance of an entire project: change the project style. You can even save the project settings as default, and new projects will have the same project style. Change the diagram style to modify the appearance of all symbols a single diagram. To change the appearance of a single symbol, edit the symbol's style.

To make reuse of visual styles easy, the visual style manager allows creation of "Named styles". Named styles can be used to define a specific appearance that can be reused. A named style is applied making it the parent of a diagram or symbol style. Named styles can have other named styles or the project visual style as their parent. The diagram editor tool bar contains a parent style combo which is used for this.



ProjectStyle: VisualStyle
Project visual style defines project wide defaults
Parent
: NamedStyle
Named styles define overrides for common use
Parent
symbolstyle: VisualStyle
Symbol/Association visual style defines local overrides

Visual style properties

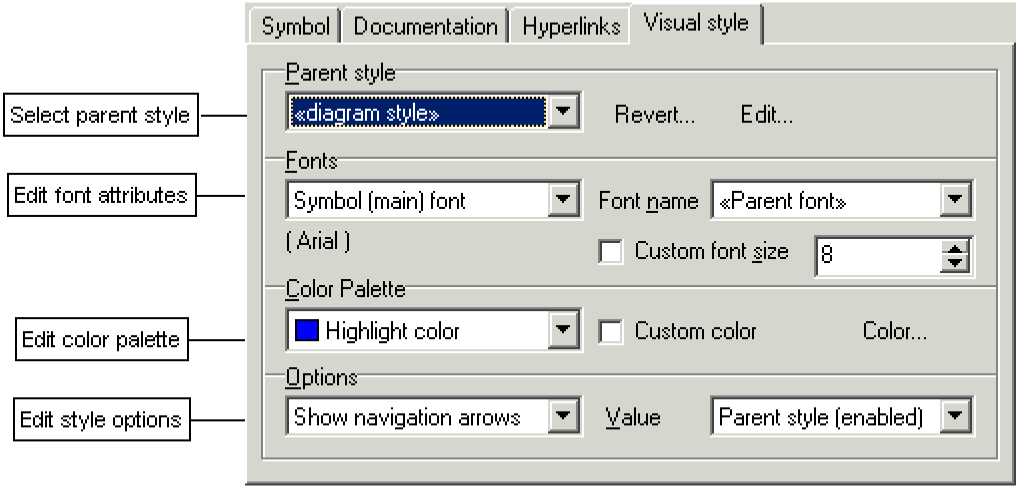
A visual style consists of a set of properties. Not all symbols / associations use all properties.

1. A main font name and size. The main font is used for symbol and association names. The font's style, bold, italic and underline, cannot be defined because that is usually has a syntactical meaning in the symbol as defined in the UML specifications: classifier names are bold, instances named are underlined etc.
2. An adornment or text font. Used for all other texts. For example the members in a class symbols and the roles in an association.
3. A color palette defining the colors for basic drawing entities such as main font, symbol compartment, symbol pen, symbol tab, association line etc. Which entries on this palette are used is dependent on the type of symbol.
4. Options that control display of some visual elements, such as: navigation arrows in associations, hotlink icons, navigation (hyperlink) icons etc.

Most symbols properties dialogs and the diagram properties dialog contain a 'visual style' tab that allows editing a style. Refer to next paragraph.

Controlling & assigning styles

Most symbols properties dialogs and the diagram properties dialog contain a 'visual style' tab that allows editing the symbol's visual style. In this tab you change and or edit the parent style and the style's attributes.



Parent style: «diagram style»

Fonts: Symbol (main) font (Arial) Font name: «Parent font»

□ Custom font size: 8

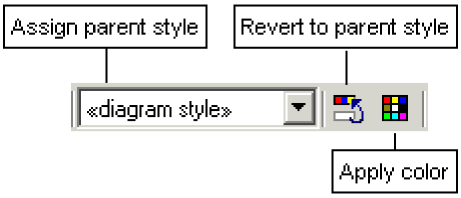
Color Palette: Highlight color

□ Custom color

Options: Show navigation arrows Value: Parent style (enabled)

To entirely revert to the parent style, erasing all overridden / redefined attributes, click the 'Revert' button.

The diagram editor's tool bar contains some visual style specific tools.

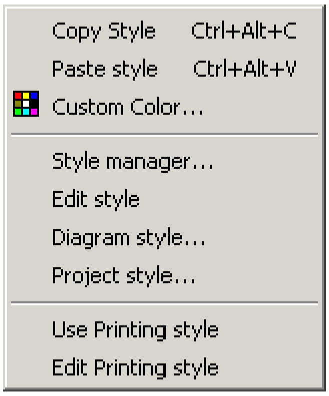


The "parent style" combo displays the parent style for the selected symbols and associations. It is blank if selected symbols have different parents. It allows assigning a new parent for the selected symbols.

The “Revert to parent style” tool will reset the visual styles for all selected symbols and associations. Useful to erase any local redefined style attributes.

The Apply color tool will let you select a color and apply it to the selected symbols and associations. The color is applied as the “main” feature color. Usually this is the symbol color palette entry, but for tabbed symbols like class symbols and package symbols, the symbol tab color is changed.

The Diagram editor contains a ‘Visual style’ sub popup menu that contains some additional visual style related functions.



Most striking functions in this popup menu are:

1. Copy / Paste a visual style. This is useful in case you have redefined the style of a symbol and want to apply the same visual style to a selection of other symbols. Note that similar functions exist for the symbol style that controls the display of members etc.
2. Show the Style Manager and it’s named styles, which is described in the next paragraph.
3. Toggle (and Edit) “Printing Style”. The printing style is described in the next paragraphs.

Style Manager

The visual Style Manager is used to create and maintain named visual styles. Named styles can be assigned as parent style for symbols and diagrams. They allow creating a predefined set of appearances that can be applied by simply assigning the style.

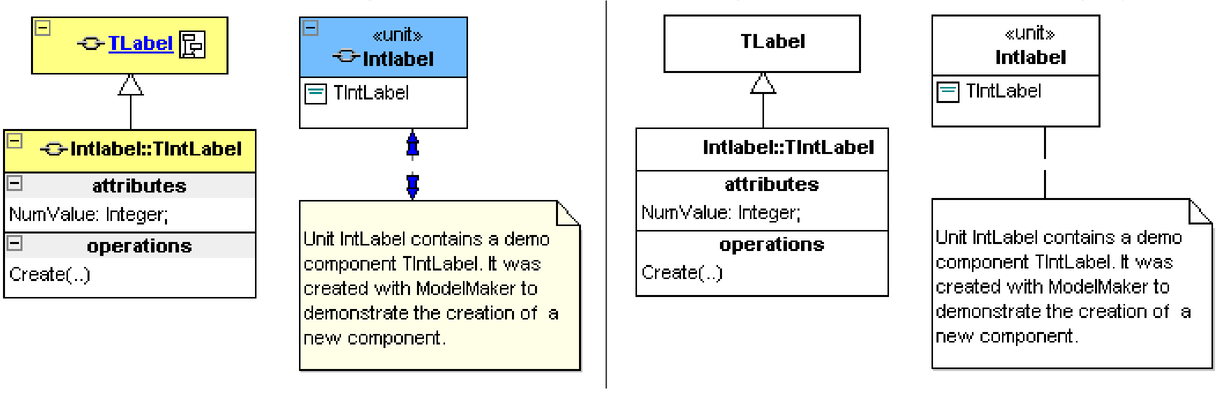
For example, you could create a style named “System components” which specifies a specific blue palette to paint symbols. Another style could be named “GUI components” and define a yellow palette to paint symbols.

In class diagrams, you can then easily change the visual appearance of a class symbol by assigning “System components” as parent style for the class symbol using the diagram editor’s tool bar parent combo.

Named Visual styles can be imported or exported with the Style Manager. This allows synchronizing named styles in projects.

Printing Style

ModelMaker allows suppressing a specific set of graphical features when printing diagrams. These include: printing in black and white (suppressing colors), no navigation icons, no hotlink icons etc. While these features can help while designing, they may be unwanted in printed output. The following picture shows the same diagram in normal and printing style.



Unit IntLabel contains a demo component TIntLabel. It was created with ModelMaker to demonstrate the creation of a new component.

Unit IntLabel contains a demo component TIntLabel. It was created with ModelMaker to demonstrate the creation of a new component.

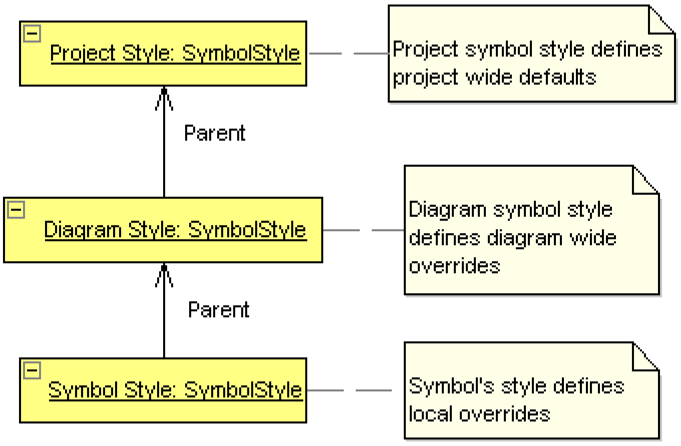
The printing style is defined in the diagram environment options. It is automatically superimposed on all other styles when printing, and can also be manually activated in the diagram editor. The diagram editor popup menu “visual style” menu contains an item that toggles the “Use Printing style” state. If the printing style is active in the diagram editor, it will also be effective when creating visual exports as image file or to the clipboard.

Symbol (contents) style

Just like visual styles hierarchically control the visual appearance of diagrams and symbols, symbol styles control the contents of displayed symbols. For example: which members are displayed in a class symbol and in which format is controlled by the class symbol “symbol style”. The symbol styles control *what* is displayed; the visual styles control *how* it is displayed. The symbol styles are only applicable for a specific set of symbols such as class, interface and (unit) package symbols. In classes the symbol style controls which members are displayed and how they are displayed. In unit packages they control whether contained classes are automatically displayed.

Style hierarchy

Just like visual styles, all symbol styles are linked in a lookup hierarchy and can override parent style attributes. Symbol styles are linked to the diagram symbol style and have all properties set to “lookup from parent” that is: override or change nothing. As a result, all symbols will appear as defined by the diagram symbol style. On their turn, all diagram symbol styles are linked to the project symbol style and also have all properties set to “lookup from parent”.



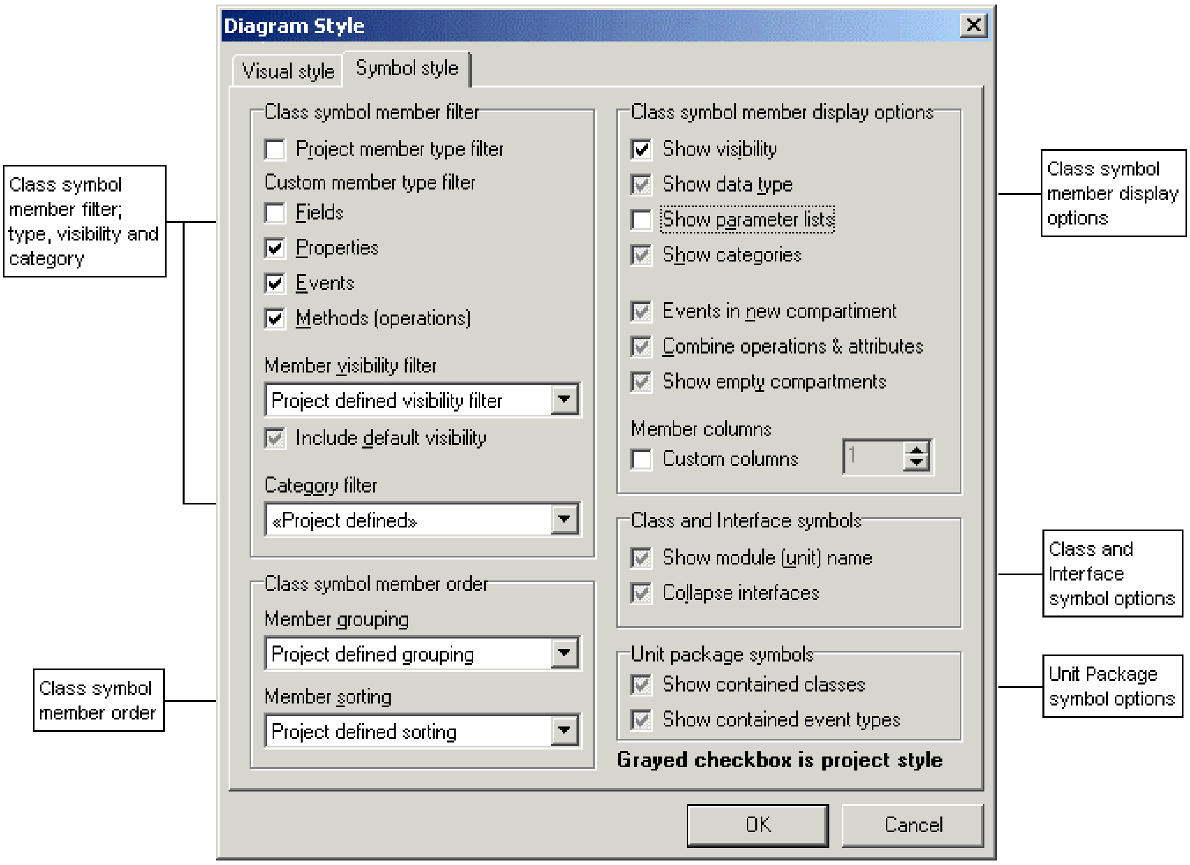
Project Style: SymbolStyle
Project symbol style defines project wide defaults
Parent
Diagram Style: SymbolStyle
Diagram symbol style defines diagram wide overrides
Parent
Symbol Style: SymbolStyle
Symbol's style defines local overrides

This hierarchical structure allows easy adjusting of what is displayed within symbols. To change the style of an entire project: change the project style. You can even save the project settings as default, and new projects will have the same project style. Change the diagram style to modify all symbols a single diagram. To change the contents of a single symbol, edit the symbol’s style.

Unlike the visual style, the symbol style cannot be linked to named styles.

Controlling & assigning styles

The diagram properties dialog contains a ‘symbol style’ tab that allows editing the symbol style. The project options “symbol style” tab is similar. In these tabs you control how class and interface symbols display members and unit packages display contained classes.



Class symbol member filter; type, visibility and category
Class symbol member order
Class symbol member display options
Class and Interface symbol options
Unit Package symbol options

Diagram Style

Visual style | Symbol style

Class symbol member filter

□ Project member type filter

Custom member type filter

□ Fields

☑ Properties

☑ Events

☑ Methods (operations)

Member visibility filter: Project defined visibility filter

☑ Include default visibility

Category filter: «Project defined»

Class symbol member order

Member grouping: Project defined grouping

Member sorting: Project defined sorting

Class symbol member display options

☑ Show visibility

☑ Show data type

□ Show parameter lists

☑ Show categories

☑ Events in new compartment

☑ Combine operations & attributes

☑ Show empty compartments

Member columns

□ Custom columns 1

Class and Interface symbols

☑ Show module (unit) name

☑ Collapse interfaces

Unit package symbols

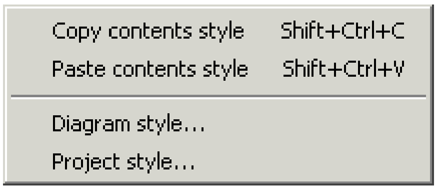
☑ Show contained classes

☑ Show contained event types

Grayed checkbox is project style

OK | Cancel

The Diagram editor contains a ‘Symbol style’ sub popup menu that contains some symbol style related functions.



Copy contents style Shift+Ctrl+C
Paste contents style Shift+Ctrl+V
Diagram style…
Project style…

Most striking functions in this popup menu are Copy / Paste a symbol style. This is useful in case you have redefined the style of a for example a class symbol and want to apply the same visual style to a selection of other class symbols.

Class & Interface symbols

The symbol style in class and interface symbols is edited on the “member style” tab of the symbol’s dialog. These are basically the same tabs as the diagram symbol style tab, except that fixed or non-appropriate elements have been removed.

Package symbols (units)

The symbol style in a package symbol is incorporated in the main symbol tab. Here you control if contained classes and events are displayed. This feature is only available for units and classes that are (imported) in the model.

Size and Alignment

The Drawing Grid

The diagram editor's drawing grid is defined in the project options diagram style tab. It helps aligning symbols. All symbols are automatically snapped to the drawing grid. And for most symbols, the extent (bounds) is automatically adjusted to fit on the grid too. The MindMap node symbol allows enabling/disabling this "Bounds on Grid".

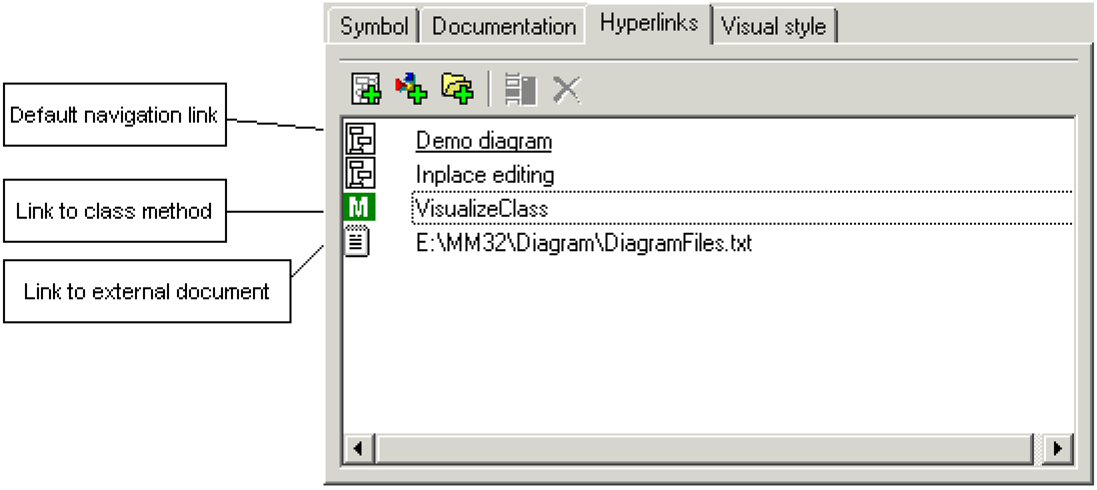
If you change the grid size, all symbols will most likely resize too. Because the grid it affects all diagrams and symbols, it is defined and saved per project.

Align & Size Palette

The Alignment palette, which is available from the diagram editor tool bar, contains a set of functions to control alignment, auto sizing, text alignment and word break properties. These functions are similar to those in other applications such as Delphi, and are not explained in detail.

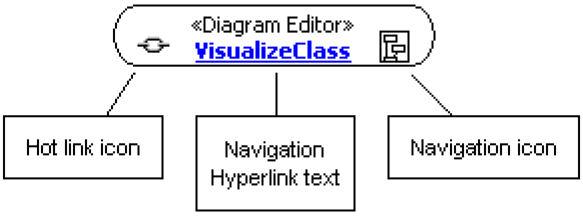
Hyperlinks, navigation

Virtually all symbols can contain hyperlinks. Hyperlinks can point to other diagrams, code model entities (class, member, event, unit) or to external documents. Hyperlinks are created and maintained in the "hyperlinks" tab of a symbol's dialog. Although there can be many hyperlinks, only one is the default navigation link. This is the first link that supports navigation. The default navigation link is underlined in the hyperlinks list. Only HotLinks to code model entities usually have navigation disabled. Check chapter HotLinks to Code Model.



Demo diagram
Inplace editing
VisualizeClass
E:\MM32\Diagram\DiagramFiles.txt

Most symbols will show a navigation icon next to their name if a navigation hyperlink is available. This is shown in the picture below. These icons can be suppressed by the visual style or the printing style. Also, if a symbol has a default navigation link, the symbol's name will appear underlined and in the hyperlink color as defined in the visual style's palette. The picture below shows this. The Hotlink icon is explained in Paragraph "Hotlinks to the code model".



If the navigation icon is clicked, ModelMaker will follow the link and navigate to the object. If this is another diagram, the current diagram is saved and the referenced diagram is opened in the diagram editor.

If the link refers to a code model entity, ModelMaker will select the entity (class, member) and make the classes and members views visible. If the entity is a method, the method editor will also be made visible.

If the link refers to an external document, ModelMaker will perform a default "open" command on the filename or URL.

Clicking the hotlink icon (left of the symbol name) will edit the hot linked entity rather than the symbol.

If a symbol contains more than one hyperlink, you can navigate to the non-default hyperlinks by using the diagram editor's popup menu Navigate function. This contains a dynamic submenu with all hyperlinks available in the focused symbol.

External documents

External documents are defined with the same alias / relative name mechanism as used for source files. Check chapter 'source aliases' in this manual for details. The use of aliases avoids the use of hard coded, machine dependent paths.

The standard shell "open" command is performed to navigate to an external document. This accepts all kinds of external documents such as executables or files that are associated with an application. For example "c:\temp\manual.doc" will be run MS word and open the document.

URLs to web pages or web sites are also valid. For example:
Alias=""
Relative filename = "http://www.modelmakertools.com"
will open a web browser and navigate to the ModelMaker Tools site. This can be used to navigate to html documentation etc.

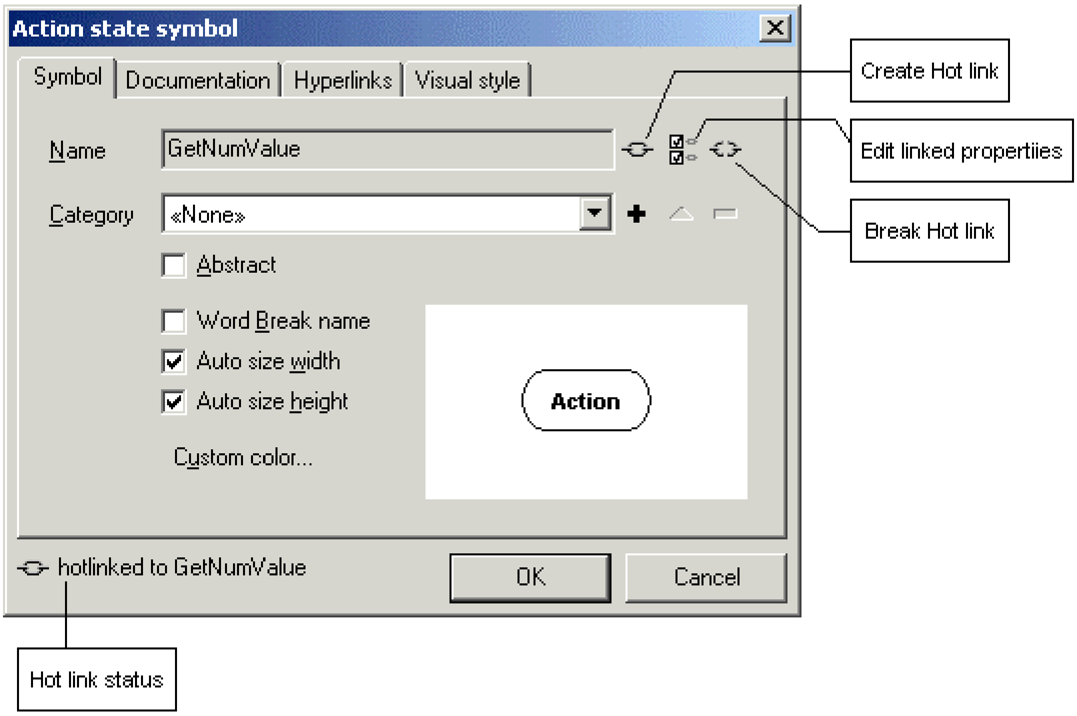
To refer to another ModelMaker model and start another ModelMaker instance, associate the ModelMaker project bundle extension *.mpb with the ModelMaker executable in the Windows shell.

Coupling Symbols to the Code Model

Most symbols and associations are linked or can be linked to entities in the code model. This is either hard coded or can be done manually by creating a HotLink. A hotlinked symbol will share name, documentation, one liner, “abstract” state and stereotype (category) with the linked entity. Modifying one of these properties in the symbol reflected to the linked entity and vice versa.

HotLinks

HotLinks are used to link a symbol or association to another entity, usually a code model entity like a class or a method. A hotlink is basically a navigation hyperlink that is (internally) marked as “hot”. Most symbol dialogs contain a set of buttons next to the name that allow creating and editing the hotlink. Here is an example from the Action State editor dialog.



Name: GetNumValue

Category: «None»

☐ Abstract

☐ Word Break name

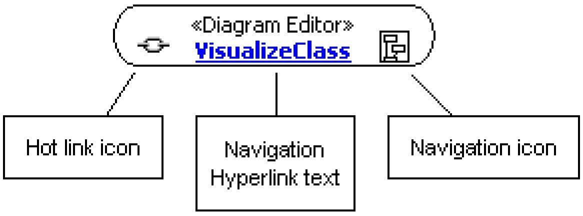
☑ Auto size width

☑ Auto size height

hotlinked to GetNumValue

Normally, action states are not coupled to any other entities. If you for example wanted to link an action state symbol to the TIntLabel.GetNumValue method, click the “Create HotLink” button and select the entity to link to. To break the hot link, click the Break hot link button. The icon at the bottom left of the dialog displays the hot link status. Not all properties need to be linked. To edit the linked properties, click “Edit linked properties”. The linked properties dialog lets you select which properties are linked.

If a symbol is hot linked, a hot link icon is displayed at the left of the symbol’s name. The following picture shows this. Hot link icons can be suppressed in the visual style and/or in the printing style.



If you click at the hot link icon in the symbol's name, the linked entity will be edited rather than the symbol.

If a symbol is hot linked to a code model entity, that entity will be selected if you click on the symbol or any of its (text) adornments. Unlike navigation through hyperlinks, this will not ensure that the associated view is made visible.

Delete HotLinked entity

The Diagram Editor toolbar contains two delete tools: one to delete the symbol from the diagram, one to delete the symbol and the hotlinked entity. The last one will not only delete the symbol from the diagram but also remove the linked entity. You will be asked for confirmation before the linked entity is deleted.

Specialized symbols and associations

Some symbols are linked to the code model by design. These symbols do not allow any other linking than the built in one.

Class and Interface symbols
Class and Interface symbols are implicitly linked to a class in the code model. If the class is deleted from the code model, all class symbols linked to that class are removed from all diagrams.

Property and Field associations
Similar to class symbols, property and field associations are hard linked to properties and fields in a class. The data type of these members must match the association target class.

Shared Class Association
Shared class associations are associations between class symbols that allow greater flexibility than field and property associations. They do not need to be linked to existing code model members or classes. Because they are shared, they can be auto visualized if both source and target classes are being visualized on a diagram.

Generalization relation

Generalization (inheritance) relations can be created between all symbols that are generalizable. In most cases they are not coupled the code model. Only if they connect two class or interface symbols, they are implicitly linked to the code model. Therefore, changing a generalization between two use cases does not affect the code model. But creating or changing a generalization between classes will be reflected in the code model by changing the class hierarchy.

Realization relation

Realization relations (such as interface support) can be created between most symbols that allow realization. In most cases they are not coupled the code model. Only if they connect a class and an interface symbol, they are implicitly linked to the code model. Therefore, changing a realization between a package and interface does not affect the code model. But creating or changing a realization between a class and interface will be reflected in the code model by adding or removing interface support to that class.

Package (units)

Units can be visualized as package symbols. Normal hot linking is used to achieve this. However, unit packages can display the contained classes and events. This is controlled by the diagram symbol style and the related options in the package editor dialog. The displayed content is read-only.

Documentation & OneLiners

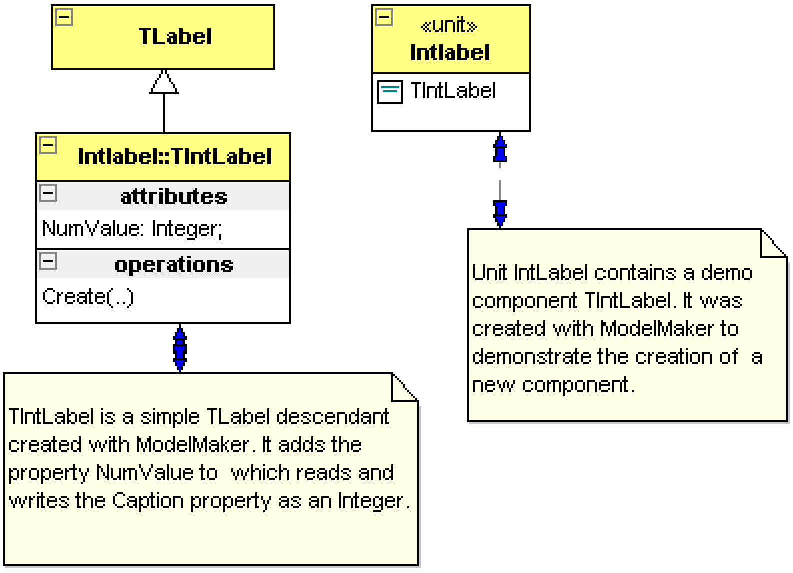
Floating Documentation view

All symbols can be documented with a One Liner and multi line documentation. Most symbol editor dialogs contain a “documentation” tab. The standard documentation view cannot be used to edit the symbol’s documentation because the diagram editor and documentation view cannot be visible at the same time. The floating documentation view however is coupled to the diagram editor’s focused symbol. This view can conveniently be used to edit symbol documentation.

If a symbol is hotlinked to a code model entity, the symbol’s documentation and one liner will be linked to that of the entity. Changing it in the entity will change it in the symbol and vice versa. This is controlled by hot links and the hot linked properties.

Linked Annotations

Annotations can visually be linked to symbols with documentation links. These links can be either passive or automatically link documentation or one liner. Here is an example from the Getting started demo in this manual.



TLabel
«unit»
Intlabel
TIntLabel
Intlabel::TIntLabel
attributes
NumValue: Integer;
operations
Create(..)
Unit IntLabel contains a demo component TIntLabel. It was created with ModelMaker to demonstrate the creation of a new component.
TIntLabel is a simple TLabel descendant created with ModelMaker. It adds the property NumValue to which reads and writes the Caption property as an Integer.

The annotations in this example are coupled in auto documentation style; the blue double arrows on the link paths show this. Changing the annotation text (for example by in place editing) will change the symbol's documentation. In the example the class symbols are implicitly linked to the code model classes. This means that editing the annotation text will modify both the symbol and class documentation. This also works the other way round: if the code model class's documentation is changed, the annotation text will be updated.

To change the style of a documentation link, double click on the link path.

Diagram Editor

Properties

The environment options "diagrams" tab controls the diagram editor's properties. These include: printing style, hint feed back, background color, grid style and color etc.

Keyboard and Mouse control

The diagram editor's keyboard short cuts are:

Scroll and Move	
Up/Down/Left/Right	Scroll
PageUp/PageDown/Home/End	Scroll one page up/down
Ctrl+PageUp/PageDown	Scroll to top/bottom
Home/End	Scroll one page left/right
Ctrl+Home/End	Scroll to left, right side of page

Zooming	
Numeric + / -	Zoom In/Out by 10%

Ctrl+Shift+I	Zoom in
Ctrl+Shift+U	Zoom out

Editing	
Escape	Cancel operation or select containing (parent) symbol
Ctrl+Z	Undo
Ctrl+Shift+Z	Redo
F2	Rename (invoke inplace editor)
Ctrl+Up/Down/Left/Right	Move selected symbols
Ctrl+C/V/X	Copy/Paste/Cut selection
Ctrl+Alt+C/V	Copy / Paste visual style
Ctrl+Shift+C/V	Copy / Paste symbol style
Del	Delete selection
Ctrl+Del	Delete All (clear diagram)
Ctrl+A	Select All
Ctrl+P	Print Diagram
Ctrl+Alt+P	Print Preview Diagram
F12	Toggle full screen mode

Navigation	
Ctrl+U	Navigate Up; select parent diagram
Ctrl+B	Navigate Backward
Ctrl+F	Navigate Forward

Mouse selection	
Click	Select exclusive
Shift+Click	Toggle selected state, incluse in selection
Drag	Multiple Select(lasso selection)
Shift+Drag	Extend selection by lasso selection
Ctrl+Drag	Parent selection (only select symbols within parent, excluding the parent). Similar to Delphi IDE from designer

Mouse Wheel control	
Wheel	Scroll up/down
Shift+Wheel	Scroll left/right
Ctrl+Wheel	Zoom in/out

Drag & Drop and conversions

ModelMaker extensively supports drag and drop between the main model views (classes, members, units, diagrams etc). Each major model view can act as a drag source of entities and as drop target for entities dragged from most other views. The details of each combination are described in the next paragraphs. Since there are always two views cooperating in a drag /drop operation (source and target) the details of conversions are described for the target view only.

Classes view

Internal (tree mode)

- Change inheritance.
- Apply interface support, press Control to invoke interface wizard

Internal (list mode)

- Apply interface support, press Control to invoke interface wizard

Source

Acts as a source for classes (and interfaces)

- Drag a class or interface to **diagram editor** for instant visualization.
- Drag a class to a **code editor** to insert its name as text.

Target

Accepts members, local vars, procedures and event types:

- Drop **members** from the **members view** on a class to copy them to the target class. Press Shift (before releasing) to Move rather than copying the members. If a property is copied or moved, it’s read and write access members are also copied, even if not included in the dragged members. Restrictions that apply for interfaces are automatically applied: fields are ignored, property write access is restricted and visibility is made default when dropping a class’s members on an interface.
- Drop **procedures** from **Method Local Code Explorer** to convert them to new methods.
- Drop **procedures** from **Unit Code Explorer** to convert them to new methods.
- Drop l**ocal vars** from the **Method Local Code Explorer** to convert them to new fields. Press shift on dropping to move rather than copy the var. Since interfaces cannot contain fields, local vars cannot be dropped on interfaces.

- Drop **event type definitions** from **Event library** view and **Units view** (tree mode) to add an event handler or event property using the dragged event as a template. On dropping a popup menu offers the available options.

Members view

Internal

- In custom order rearrange mode (Ctrl+R toggles this mode), member custom order can be arranged.

Source

Acts as a source of members.

- Drag members the **classes view** to copy them to a class or interface.
- Drag members to a **class** in the **units view** (tree mode only). Similar to dragging members to the classes view
- Drag a field or method to the **Method Local Code Explorer** to convert it to a local var.
- Drag a method to the **Unit Code Explorer** to converted it to a local procedure.
- Drag a method to the **Method Implementation view** (toolbars, or tabs) to “pin” the method.
- Drag a method(s) to the **Event Library view** to create new event types using the methods as template.
- Drag a member to a **code editor** to insert its name as text.

Target

Accepts code sections, local vars, (local) procedures, text, event type definitions and text.

- Drop **code sections** from the **Method Implementation Section list**. The dropped section is copied to the target method. Only if dropped on a method.
- Drop a **Local var** from the **Method Local Code Explorer.** If a var is dropped on a method, the var will be copied to the target method. Press shift to move the var rather than copying it. If a var is dropped on any other member or empty space in the member list, the var is converted to a new field. Drag the vars root node in the method local code explorer instead of a single var to drag all all vars at once.
- Drop a **local procedure** from the **Method Local Code Explorer.** If a local procedure is dropped on a method, it will be copied to that method. Press shift to move rather than copy it. If a local procedure is dropped on any other member or empty space in the member list, the local procedure is converted to a new method.
- Drop a **local procedure** from the **Unit Code Explorer**. Acts similar as local procedures dragged from the Method Local Code Explorer.

- Drop **Event type definitions** from **Event Library View** and **Units view (tree mode)**. A popup menu will let you select between adding an event handler for an event type or creating an event property. Multiple event types may be dragged at once.
- Drop **Text** from the **code editors** on the “add field” “add method” “add property” and “add event” buttons in the toolbar. The corresponding member type will be created and its name will be set to the dragged text. Method parameters are extracted from the dropped text.
- Drop **Text** from **code editors** dropped on the member list acts similar as text dropped on the“add method” button.

Units view

Internal (tree mode only)

- Classes and Event types can be copied or moved between units and “Classes not assigned to any units”. Pressing Ctrl will copy rather than Move (default). Within the same unit classes and event types can be rearranged using drag and drop.

Source

In tree mode acts as source for units, classes and event types. In list mode acts as source for units only.

- Drag a unit to the **diagram editor** to visualize that unit as a package.
- Dragging a class or interface to any other view is similar to dragging a class from the classes view.
- Dragging an **event type** is similar to dragging an event type from the event library view.
- Drag a unit, class or event to a **code editor** to insert its name as text.

Target

Accepts members, members, (local) procedures, local vars (all in tree mode only) and event types (both modes).

- Drop an **event type** from the **Event Library view**. If dropped on a unit, this will add the event type definition to the unit. If dropped on a class this will add an event handler or event property using the dragged event as a template or alternatively add the event type to the unit. On dropping a popup menu offers the available options. Applies to both tree and list mode.
- Dropping entities on a class is similar to dropping on a class in the classes view (tree mode only).
- Event types contained by units do not accept dropped entities.

Method Implementation view

Method Local Code Explorer

Internal

- Rearrange local vars
- Rearrange local procedures

Source

Acts as a source for **local vars**. Dragging the vars root node will drag all vars at once. Press shift to move rather than copy / convert a local var.

- Drag a Local var (or the root "Vars" node) to a class in the **classes view** to convert it to a field.
- Dragging a Local var to a **class** in the **units view** (tree mode) is similar as dragging it to a class in the classes view.
- Drag a local var to the **members view** to copy it to a method or add a new field in the class.
- Drag a local var to a **code editor** to insert its name as text.

Acts as a source for **(local) procedures**. Press shift to move rather than copy/convert a procedure

- Drag a local procedure to a class in the **classes view**. The procedure will be converted to a method.
- Dragging a local procedure to a **class** in the **units view** (tree mode) is similar as dragging it to a class in the classes view.
- Drag a procedure to the **members view** to copy it to a method or add a new method.
- Drag a procedure to a **code editor** to insert its name as text.

Target

Accepts members, local vars, procedures and event types:

- Drop a **field** or **method** from **members view**. A field will be converted to a local var, a method will be converted to a local procedure. This is usually only relevant for "pinned" methods as selecting a member to drag it will automatically change the "current method".
- Drop **text** from a code editor containing an "`ident + ":" + type`" list to convert the text to local vars.

Method Implementation Section list

Internal

- Rearrange sections (drag up/down)
- Indent / unindent sections (drag left/right)

Source

Acts as a source for code sections.

- Drag a section to a method in the **members view** to copy it to that method. Press shift to move rather than copy the section.

Target

Does not act as external drop target.

Method Implementation Code Editor

Internal

- Rearrange text inside editor copy or move.

Source

Acts as a source for text.

- Drag a **text** to the members view to add a new member, using the text as name (plus parameter list for methods).
- Drag a **text** containing an "`ident + ":" + type`" list to the Local Code Explorer to convert the text to vars.

Target

Accepts all dragged entities and inserts the associated name at the drop point.

Unit Code view

Unit Code Explorer

Internal

No internal drag and drop support.

Source

Acts as a source for (local) procedures. Press shift to move rather than copy/convert a procedure.

- Drag a local procedure to a class in the **classes view** to convert it to a method.
- Dragging a local procedure to a **class** in the **units view** (tree mode) is similar as dragging it to a class in the classes view.

- Drag a procedure to the **members view**. This is similar to dragging a local procedure from the Method Local Code Explorer.
- Drag a procedure to a **code editor** to insert its name as text.

Target

Accepts methods and procedures.

- Drop a **method** from the **members view** to convert it to a module procedure.

Unit Code Editor

Similar to Method Implementation view Code Editor.

Event Library view

Internal

Does not support internal drag and drop.

Source

Acts as a source for event type definitions.

- Drag an event to the **members view** or on a class in the **classes view**. This will add an event handler or event property.
- Drag an event to the **units view**. If dropped on a unit, this will add the event type definition to the unit. If dropped on a class in the units view (tree mode) this is similar as dropping it on a class in the classes view.

Target

Accepts methods.

- Drop a **method** from the **members view**. For each dropped method an event type will be created that takes the method's signature (name, parameter list, result type etc) as a template.

Diagrams view

Internal (tree mode only)

- In "sort hierachical" mode, diagrams can be rearranged. Pressing Shift will change diagram hierarchy relations. Other modes: no internal drag drop support.

Source

Does not act as external drag source.

Target

Does not act as external drop target.

Diagram Editor

Internal

The selected editor tool controls the extensive internal drag drop support.

Source

Does not act as external drag source.

Target

Accepts classes and units, depending on the opened diagram.

- A **class** or **interface** dragged from the **classes view** or **units view** will be visualized as class or interface symbol, object flow symbol or role symbol. For class diagrams relations with other classes are automatically visualized. If three or more classes are dropped on a class diagram the “drop visualization wizard” will be invoked. This wizard allows selecting the visualization scheme and relations to visualize.
- A **unit** dragged from the **units view** will be visualized as package symbol. Relations with classes (contained) and other packages (uses and used dependencies) are automatically visualized.

Customizing ModelMaker

Here are some links to customizing ModelMaker to your wishes. Most of them you'll find in the Environment and Project options dialogs. For details refer to the GUI reference, here are just a few:

- To adjust the appearance of ModelMaker use the Environment options
- To adjust prefixes of property access methods and fields: use Project Options|Coding style.
- To adjust the layout of the generated source code, use Project Options|Code Generation.
- To adjust the way ModelMaker imports source code: use Project options|Code Import tab.
- To adjust the in-source documentation generation and import settings, check the corresponding tabs in the project options.
- To define a basic diagram visual style: Project options|Diagram Style
- To define a basic symbol style (displayed members etc): Project options|Diagram Style
- For defining the code editor's shortcut keys, Use Environment Options|Shortcuts.

Here are some other links to customization:

- Add Version Control capabilities by using a plug in expert. (Check ModelMaker web-site for ready available third party VCS Experts)
- To adjust the unit template used for new units, refer to Adjusting the unit template, page 50.
- Create Parameterizable Code Templates for pattern like groups of members that appear in multiple classes and models.
- For creating model templates, refer to Model templates page 41.
- Define and use your own macros for use in code generation or in the code editor.
- Most views have special display settings that are controlled in their popup menu: In Members view you modify toolbar layout and sorting. In the Classes view you adjust navigation order and history etc.
- Use the MM OpenToolsApi to create you own experts.

Integration with the Delphi IDE

ModelMaker is a stand-alone application and you don't need Delphi to run it. Integrating ModelMaker with Delphi's IDE will enable some additional features.

- ModelMaker will automatically update Delphi's code editor whenever a source file is (re) generated.
- You'll be able to access Delphi's on-line context sensitive help from within ModelMaker.
- Call Delphi's 'Syntax Check' "Compile" or "Build" commands from within ModelMaker.
- Open source files and locate the member selected in ModelMaker in the Delphi IDE from within ModelMaker

Inside the Delphi IDE integration experts add several features that enable smooth integration:

- Synchronize ModelMaker with the IDE: refresh import a unit and locate the current member.
- Add (multiple) files to a ModelMaker project

Although it is possible to integrate ModelMaker with all versions of Delphi and run multiple instances or versions of Delphi at the same time, it is recommended that only one is running when working with ModelMaker, as integration is a based on a one-to-one connection.

For the same reason we suggest that you do not run multiple instances of ModelMaker. In the environment options General tab you'll find an option that will ensure this.

Integration with Delphi 3 and higher

ModelMaker is integrated with Delphi 3 and higher by use of an integration expert. These experts are automatically installed by the setup program for the IDE versions you have installed on your PC. You can manually (un)install an IDE expert later using the ModelMaker environment options "Delphi IDE" tab.

The experts add a ModelMaker main menu item to the IDE's menu bar. The ModelMaker menu contains:

- Run ModelMaker, (if not already running)
- Jump to ModelMaker (Ctl+F11 in D3, Ctrl+Shift+M in D4 or higher) - this will activate ModelMaker and select the unit, class and member corresponding to the IDE's topmost editor's position. Note that inside MM the inverse command 'Locate in Delphi' - main menu "Delphi" or main tool bar 'Locate in Delphi' - which locates the member selected in ModelMaker in the Delphi editor. ModelMaker's 'Locate in Delphi' command also has shortcut Ctl+F11.
- Add to Model, adds the topmost unit in the Delphi editor to the current MM model.
- Add files to model, lets you select which files to import in a model. In D4 and higher you may select files contained in a project or files opened in the editor.
- Refresh in Model, will re-import the topmost unit just like add to model, but only if the unit is already in the model. If the unit is not in the model, the command is silently ignored.

- Convert to Model, creates a new model and adds the topmost unit to this new model.
- Convert project to Model, which creates a new model and adds all files in the current Delphi project to the new model.

Note that the file in the IDE editor will be SAVED prior to performing the actual command. Therefore these commands won't work on read-only (project) files.

Delphi 4 and higher

The Delphi 4 and higher integration experts have additional commands in the IDE's ModelMaker menu.

- Open Model, opens the model associated with the top most file in the IDE editor. Check the web-site 'Tips' page for details.
- 'Enable Auto refresh' and 'Lock Auto refresh on Run'. These control the Auto refresh feature that is described in detail in chapter Auto Refresh Import, page 65.
- Version Control. This menu item is enabled if you integrated a Version Control system in ModelMaker using a (third party) VCS expert. The available commands depend on this VCS-expert. They usually include at a minimum Check-in and Checkout. Check the ModelMaker Tools web site for available VCS-experts.

Some additional tools and utilities

- Unit Dependency analyzer. This is the same tool as available inside ModelMaker. For a description, check the ModelMaker on-line help by pressing F1 in this tool in ModelMaker.
- Resource string wizard. This will scan a unit for hard coded strings and help in converting them to a section of resource strings or string constants.
- String to Resource string, similar to the Resource string wizard, but only handles the current string token in the editor.
- Shortcut wizard: checks the active form for duplicate keyboard hot keys in control captions like "&Apply this" and "&Surprise me" and suggests alternatives in case of conflicts.

In Delphi 4 and higher you can also add commands to the IDE toolbars. In Delphi's toolbar 'Customize...' dialog, you'll find these commands in the ModelMaker category - right click on Delphi's toolbar, go to 'all commands'.

Delphi 4 and higher syntax highlighting scheme

In ModelMaker you can specify the syntax-highlighting scheme to mimic your settings in the Delphi IDE. Unlike Delphi 1/2/3, Delphi 4 and higher do not define the default color scheme in the registry unless you manually (re-)define it. If the syntax highlighting scheme in ModelMaker is set to "Delphi 4" or higher, it might display strange settings: anything could happen such as underlined, blue colored normal text.

In order to solve this problem, in Delphi 4+ go to environment options and on the Colors tab define all fore-and background colors you want by explicitly selecting them rather than relying on the 'use default' check boxes. The same applies for the font styles: you must explicitly select them. After applying these settings and restarting ModelMaker, you should have the highlighting scheme you selected. The following entries should be explicitly defined: "Comment"," Identifier", "Number", "Plain text", "Reserved word", "String", "Symbol", "White space" and "Marked block".

Uninstalling IDE integration experts

If after uninstalling ModelMaker you still get a message when starting Delphi 3 or higher saying: can't find ..\\..MMEXPT.DLL or similar, you must manually uninstall the ModelMaker integration experts.

To do this:
Either use the ModelMaker environment options 'Delphi IDE' tab to uncheck the IDE version you want uninstall, or
Run RegEdit.exe from the "Start" menu and go to
HKEY_CURRENT_USER\Software\Borland\Delphi\3.0\Experts
There should be an entry called ModelMakerExpert, to uninstall the expert you must manually remove that entry. Higher versions of Delphi have a similar registry entry

Integration with Delphi 1 and 2

Integration with Delphi 1 and 2 does not offer the same functions as the Delphi 3 and higher integration experts. Only basic synchronization functions are supported. And the installer cannot activate the integration - you must install the integration yourself. Integration consists of two aspects:

1. Installing the unit MMINTF.PAS (in directory [installdir]\mmintf in your component library. Installing this unit will enable ModelMaker to:
    - Automatically update Delphi's code editor whenever a source file is (re)generated.
    - Access Delphi's on-line context sensitive help.
    - Call Delphi's 'Syntax Check' command from within ModelMaker.
2. Installing the utility UNITJMP.EXE in your Delphi Tools menu. This will enable you to jump from Delphi's code editor to the corresponding code in ModelMaker and perform some basic file related commands.

Installing the integration unit in Delphi 1 /2

1. Start Delphi 1 /2
2. Add the unit `ModelMaker\6.0\Mmintf\MMIntf.pas` to your component library, just like you would do with any other component (refer to your Delphi user manual).
   In Delphi 1: Select menu 'Options|Install Components',
   In Delphi 2: Select menu 'Component|Install',
   select Add and browse to find the unit `MMINTF.PAS` in folder `ModelMaker\6.0\MMintf\`.

3. Don’t be surprised that you won’t see any changes in your VCL component palette after Delphi recompiled the VCL: there is no new component installed, just an integration link, which is not a component.

Installing UNITJMP.EXE as a DELPHI 1 /2 IDE tool

Installation of UNITJMP is basically the same for Delphi 1 and 2. To install the UNITJMP.EXE utility, (refer to your Delphi user manual)

1. Start Delphi
2. Select menu ‘Options|Tools...’. (*Delphi1.0*)
   Select ‘Add’ and add a new tool, title it ‘Jump &to MM’. (D*elphi 1.0*)
   Select ‘Add’ and add a new tool, title it ‘Jump to &MM’. (D*elphi 2.0*
3. Select ‘Browse’ to locate the UNITJMP.EXE file in the `ModelMaker\6.0\BIN` folder.
4. Select ‘Macros’ to pass the parameters ‘`$ROW $EDNAME`’, the space is required; the single quotes (‘’) should not be entered.
5. Select OK and Close to add this utility.

Now you’ll be able to jump from Delphi’s code editor to ModelMaker (which should be running) by pressing `Alt+T+T` (D1) or `Alt+T+M (D2)`

UnitJump can be installed more than once as a tool to perform different integration tasks, each time passing different parameters.

1. For automatic refreshing of the top most file in the IDE editor, pass parameters '-1 $EDNAME', refer to “Refresh Import” for details. You could enter ‘&Refresh Import” as title.
2. To add the topmost in the Delphi editor to the current model, use parameters '-3 $EDNAME'.
3. To create a new model and add the topmost in the Delphi editor to this model, use parameters '-2 $EDNAME'. You could enter ‘&Convert to Model’ as title.

Yes: you have identical “tools” `UNITJMP` now; the only difference is the parameters passed.

MMToolsApi primer

This chapter is a introduction on COM interfaces and using the MMToolsApi to create your own experts to ModelMaker's functionality. You should also check the MMExptDemo.dpr that demonstrates most aspects of an expert. If you have not noticed yet: in the ..\ModelMaker\demos directory there's a model MMToolsApi.mpb that contains two diagrams showing relations of the API. Do not use this model to re-create the MMToolsApi.pas, this file will be changed in future versions.

Interfaces basics

Interfaces are like classes in the way that once you've got a pointer to an interface, you can call methods and read/write properties.

Assume for example you have an interface pointer CodeModel: IMMCodeModel. From the MMToolsApi unit you can see that this interface supports the ClassCount and Classes[idx] properties. Also you can see that Classes[idx] returns IMMClass interface pointers. You could now for example iterate the code model for classes and list their names in a list box

```
for I := 0 to CodeModel.ClassCount do
  ListBox.Items.Add(CodeModel.Classes[I].Name);
```

Expert DLL basics

The big thing is now: how do you get the first interface pointer CodeModel, because once you've got hold of that, everything is easy. In the MMToolsApi there is a central access point called MMToolServices: IMMToolServices that is declared as a global var in unit MMToolsApi. This interface var is initially nil but gives access to all major aspects of the MM engine such as the CodeModel in the above example. ModelMaker Experts are dll's which are loaded dynamically (all experts must be placed in directory ..\[installdir]\experts.) After loading the library MM looks for a procedure called MMExpertEntryProc, as defined in MMToolsApi.pas and calls this procedure passing the interface pointer of the actual MMToolServices object. You should store this interface pointer as it provides your central access the tools API. You can access this interface and read the CodeModel: IMMCodeModel interface as shown in this example

```
procedure EntryProc(const Srv: IMMToolsServices); stdcall;
begin
  // here you get passed the interface pointer, store it to use later.
  MMToolServices := Srv;
end;
```

The entry procedure should be exported named SMMExpertEntryProc (MMToolsApi.pas). There's also an exit procedure, which is called upon termination of ModelMaker. In this procedure we use the previously stored MMToolServices as central access point:

```
for I := 0 to MMToolServices.CodeModel.ClassCount do
  ListBox.Items.Add(CodeModel.Classes[I].Name);
```

MMToolsApi version control

The unit MMToolsApi is continuously under construction and version control is governed by an ExpertVersionProc. This is the first procedure ModelMaker attempts to call when loading the expert. In your expert you must export this function and return the MMToolsApiVersion constant as defined in unit MMToolsApi.pas. ModelMaker will reject any expert not exporting this procedure or experts that do not match the version of the MMToolsApi with which ModelMaker was created.

```
function ExpertVersion: LongInt; stdcall;
begin
  Result := MMToolsApiVersion;
end;

exports
  ExpertVersion name SMMExpertVersionProc;
```

Interfaces and memory management

Memory management for interfaced classes is controlled by reference counting which is automatic done for you by the compiler. Even assigning an interface to a local var will increase the reference count automatically, as will assigning nil to the var or going out of scope (exiting a procedure) will decrease the reference-count again. This means you don't have to worry about freeing classes after creating them. In general all interfaces passed on from ModelMaker to you are objects existing in MM.exe space. All interface pointers you pass on to ModelMaker are objects you create (such as an expert) and ModelMaker will only have access through the interface pointer. Since these objects are reference counted the objects will disappear after MM and the expert both drop all references to it.

For example if you retrieve an IMMClass interface pointer from ModelMaker and use it in your expert code, the actual interface object will exist as long as you keep a reference to it for example by assigning to a global var. The actual class the IMMClass refers to, may be gone in ModelMaker due to user actions (delete the class, open a new model) but the interface object remains live until the expert drops all references. To check whether an interface is actually connected to a real class you could /should check the Valid property. If Valid is False, the actual class object does not exist anymore, just the interface object. The interface object will return default values in all functions (such as GetName =”).

Adding an expert and menu items

After reading the COM interface basics, you might want to create something useful which initiates on user action. The MMToolsApi provides the IMMExpert mechanism for this. You can create an object implementing IMMExpert and register it in ModelMaker, again using the MMToolServices. The fun about IMMExpert is that it allows you to insert menu-items in the ModelMaker main menu bar Tools menu and some predefined pop-up menus. Each expert should support properties Verbs, VerbCount and MenuPositions. VerbCount defines the number of menu-items you want inserted and Verbs are the actual menu item Captions. MenuPositions[..] defines where to which menu an item should be added. If the user clicks one of these menu-items, the Execute(Idx) method of the expert will be called, where Idx is [0..VerbCount -1]

There are some more methods supported by IMMExpert, but these are the basics. In the MMExptDemo.dpr you'll find an object implementing IUnknown and IMMExpert. If you go through the associated code you'll see that it has only one Verb and does only one thing in Execute. This demo expert could serve very well as a base for all other experts.

How do you inform ModelMaker that you want such an expert to be installed? Well create it (instantiate the class) and register the interface pointer with ModelMaker using MMToolServices.AddExpert(..). Reference counting will again take care of memory management. On shutdown you should remove your expert again using the index that was passed by AddExpert.

```
var
  ExptIndex: Integer = -1;

procedure MMExpertEntryProc(Srv: IMMToolServices); stdcall;
begin
  MMToolServices := Srv;
  ExptIndex := MMToolServices.AddExpert(TMyExpert.Create);
end;

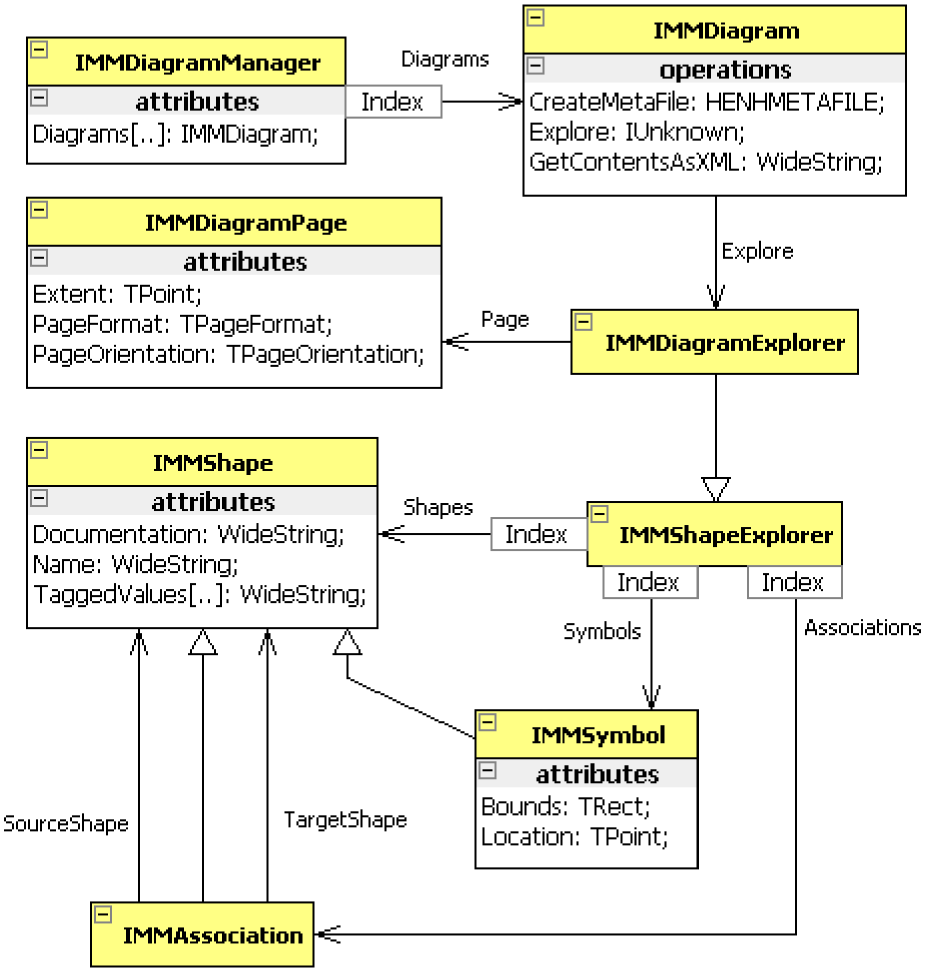
procedure MMExpertExitProc; stdcall;
begin
  if ExptIndex <> - 1 then MMToolServices.RemoveExpert(ExptIndex);
end;
```

Suppose you want to create an expert that does two reports "Simple" and "Extended", you should create an object that returns VerbCount = 2 and Verb[0] = 'Simple', Verb[1] = 'Extended'. To add the items to the Tools menu, return mpToolsMenu in GetMenuPositions. Then in Execute(Idx) you check whether Idx = 0 or 1 to either create the Simple (0) or extended (1) report. The actual report creation could be something like:

- Create a form containing a list box
- use
  ```
      for I := 0 to MMToolServices.CodeModel.ClassCount do
        ListBox.Items.Add(CodeModel.Classes[I].Name);
  ```
  to fill the list box, and
- Call the Form's ShowModal method to show the current class list

Accessing Diagrams through the API

The following picture explains how to access the Diagrams and their contents through the MM ToolsAPI.



The IMMDiagramManager property of the MMToolsServices is the entry point that gives access to all diagrams. The IMMDiagram interfaces are life pointers to the actual diagrams as displayed in the diagram list view. To get at the contents of a diagram, use the IMMDiagram.Explore method. This will create a Diagram Explorer similar to the diagram editor. The interface this method returns can be cast as an IMMDiagramExplorer. The definition of IMMDiagramExplorer and the symbols can be found in MMDiagramAPI.pas.

Note that each time you call Explore, as new explorer is created. And that the contents of two explorers are not linked. If you create two explorers and modify a diagram in explorer_1, in explorer_2 you won’t see the change made in explorer_1.

An explorer gives access to a diagram’s symbols and associations. The Shapes property simply concatenates the symbols and associations properties. An IMMShape gives access to basic shape behavior: name, documentation and hyperlinks. An IMMymbol gives acsess to symbol specific properties like Bounds and Location (which associations do not have). IMMAssociation defines the association specific properties like SourceShape and TargetShape.

There are many ways to manipulate a diagram, the ModelMaker Tools demo expert shows a few examples like: create a sequence diagram and create an image containing a single class.

Accessing Experts through scripting

ModelMaker 6 is a self-registering COM server that allows access to plug-in experts that support IDispatch. The ModelMaker type library can be found in the [installdir]\experts directory. It contains interface IApp that contains a single method: GetExpert.

```
  IApp = interface(IDispatch)
    ['{D077CEC1-83F0-11D5-A1D2-00C0DFE529B9}']
    function  GetExpert(const ExpertID: WideString): IDispatch; safecall;
  end;
```

The parameter ExpertID is used to locate the expert based on the value returned by IMMExpert.ExpertID.

If your expert supports IDispatch and inherits from TAutoObject, you can access it for example in a java script like this (assuming your expert has a method named TestMethod which takes a single WideString parameter).

```
// Java script
var mm = new ActiveXObject("ModelMaker.App");
var api = mm.GetExpert("ModelMakerTools.ScriptingDemoExpert_10");
api.TestMethod("Hello World");
```

The above example will start ModelMaker or locate the active instance. Then locate the test expert and call it’s method named “TestMethod”.

This mechanism can be used to expose specific interfaces to scripting. For example, assume you have a reporter plug-in that supports this interface:

```
type
  IMyReporter = interface(IDispatch)
    procedure CreateReport(const ModelName, ReportName: WideString); safecall;
end;

  IMyReporterDisp = dispinterface
    ['{F9BA1301-84EB-11D5-A1D2-00C0DFE529B9}']
    procedure CreateReport(const ModelName, ReportName: WideString); dispid 1;
  end;
```

You could then call this expert from a script to load a model and create a report.
To learn more about disp interfaces and IDispatch, please check the Borland Delphi developers guide.

ModelMaker Training

ModelMaker is an extremely powerful tool; as a result, like all powerful and extensive products, ModelMaker is complex and can be quite daunting to a new user. With that in mind, I've prepared this document as a starting place for those who see the potential in ModelMaker and wish to get up and running faster.

ModelMaker is often billed as a UML diagramming tool or a Delphi CASE tool. However, it is far more than a diagramming tool and the label "CASE tool" sometimes brings to mind some AI attempting to write code for you. A more accurate description of ModelMaker is that of a full-featured, extensible two-way code management tool with support for UML diagramming, design patterns, reverse engineering, refactoring, etc.

At its core, ModelMaker features an "active code model" — all your classes and associated elements (units, diagrams, documentation, event types, etc.) are objects within the model. ModelMaker provides various views into this active model, allowing you to manipulate it from within a class list, member list or a diagram… When you're ready, you can generate source code units from the model to be compiled by Delphi. Since the units are generated afresh each time (rather than MM working in the extant units), you can change various settings (such as code commenting options, code order, method instrumentation, etc.) and regenerate the units for a variety of purposes (instrumented code for debugging, heavily commented code for automated documentation generation, etc.).

Note that these tutorials are in no way comprehensive; there is more than one way to do most operations; and there are many, many options in the environment. But the following topics should give you a small taste of what ModelMaker is capable of. For more information or assistance, visit www.modelmakertools.com for downloadable documents. You can also request ModelMaker training services via Thoughtsmithy; see our Training Services page for details or contact us at info@thoughtsmithy.com.

Tutorial 10

ModelMaker Training

Warning: *in order to avoid overwriting some of your production code, make a copy of the unit or units you are going to import before continuing.*

The fastest way to see ModelMaker in action is to import some of your existing code.

Open ModelMaker and create a new model by selecting the New button or File|New.

At this point we are going to tell ModelMaker to import a source file — it will reverse engineer the code it finds and add it to the model. Keep in mind that while ModelMaker's parsing engine is good, it can only deal with so much obfuscated code formatting before it chokes. For most people, this is not an issue — if MM encounters problems while importing your code, it will tell you.

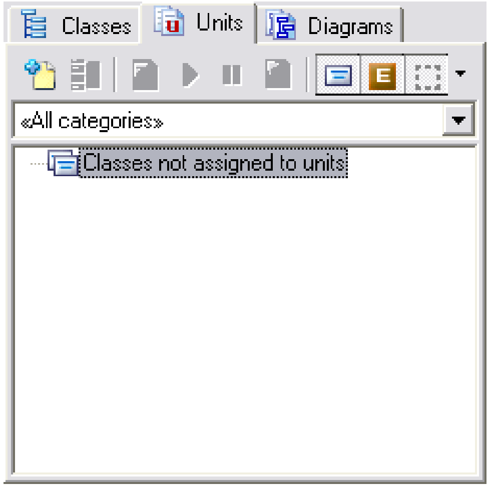

Figure 1 — the empty Units View.

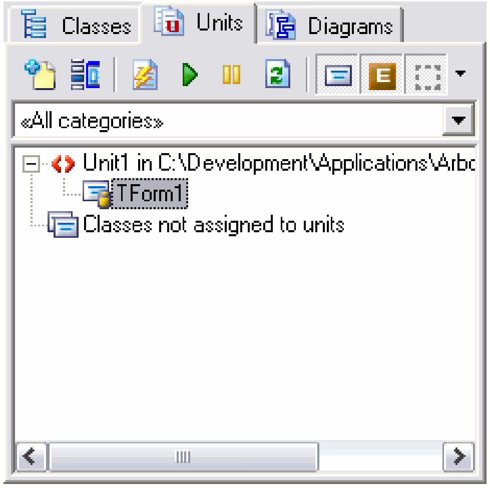
There are multiple ways to import a file, but the quickest way is via drag & drop.

In ModelMaker, select the Units View by pressing F4 or by selecting its tab.

Find the unit you wish to import in Windows Explorer and then position ModelMaker so that you can drag the file into MM's main window.

Drop the unit into the Units View — if you're in a new project that is empty, the Units View should look like figure 1.



Classes
Units
Diagrams
«All categories»
Unit1 in C:\Development\Applications\Arbc
TForm1
Classes not assigned to units

Figure 2 — Units View with imported unit.

Once you have dropped the unit, it will be reverse-engineered. The unit and any classes it contains will be added to the Unit List, which should now look something like Figure 2.

Don’t worry if your icons look a little different — I’ve got some ModelMaker extensions installed that can change the appearance of my screens.

The top-level node in the Unit View treeview represents the unit you’ve just imported. Any child nodes are the classes, interfaces or event types that reside in that unit. You can double-click these nodes to bring up their editors.

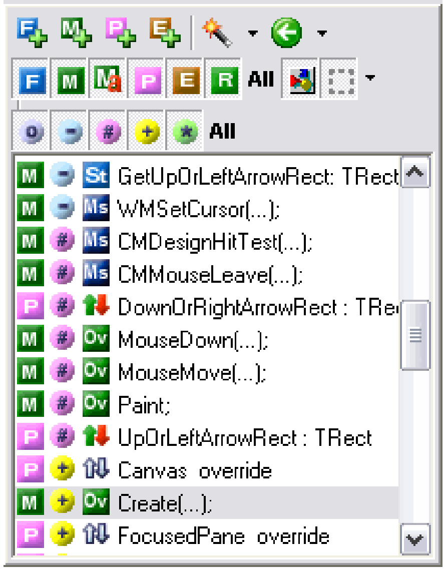


Figure 3 — the Member List.

Note that if you select a class in the Unit View, all of its members (properties, methods, etc.) will be displayed in the Member List, which looks something like figure 3.

We’ll cover the Member List in Tutorial 5; for now it’s enough to notice that your class’ members are enumerated here.

Press F3 to switch to the Classes View. You should notice here a hierarchical representation of the classes you’ve imported. Figure 4 is an example.

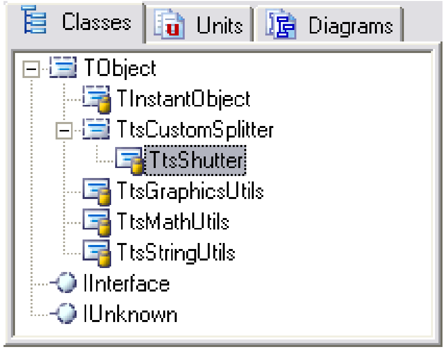

Figure 4 — the Classes View.

Notice that TObject, IInterface and IUnknown are always present. Note also the appearance of my TtsCustomSplitter class in Figure 4 — this is the ancestor of TtsShutter, which I’ve imported. However because I did not (yet) import the unit containing TtsCustomSplitter, this class must be represented as a “placeholder” (note the dotted lines around the class icon which denote placeholder status.) ModelMaker knows that TtsShutter descends from TtsCustomSplitter, but that’s all it knows. If I wish to be able to use ModelMaker’s features involving inheritance, I’d have to import TtsCustomSplitter’s unit.

ModelMaker is also capable of importing your in-source comments and attaching them to their associated entities, but only if the comments and/or ModelMaker are properly set up to do so. If MM’s Unit Code Editor (F7) shows a mass of unassociated code comments, fear not — we’ll cover importing comments in Tutorial 7.

This is an extremely abbreviated example of how to import existing code. You can also perform imports using one of the two import buttons on the main toolbar.

– this button will import your code into a new model.

– this button will import your code into the existing model.

In both cases, the buttons will give you the option of importing from a specific path or from a Source Path Alias (which we have not covered here). See Source Path Aliases in the ModelMaker help file for more information.

Generating Code

Obviously our ultimate goal is to create code which can be compiled in Delphi. ModelMaker uses its internal code model and applies the various formatting options you've selected to generate the specified units.

— the *Unlock Code Generation* button.

— the *Lock Code Generation* button.

— the *Generate* button.

— the *Enable Auto Generation* button.

— the *Disable Auto Generation* button.

In its default configuration, ModelMaker will not generate source code until you tell it to. To do so now, switch to the Units View by pressing F4 or by selecting the Units tab. Assuming you have one or more units containing classes (if you don't, go back, use your new-found skills and import some units), first, make sure that code generation is enabled by clicking the Unlock Code Generation button in the main toolbar (see sidebar), then select a unit to generate and press the Generate button (found in the Units View toolbar — see sidebar.) You should find that the specified unit has been regenerated by ModelMaker. If the unit was open in Delphi, you'll see that Delphi has already reloaded the new version of the file. This method is handy if you don't want to generate the code until you are ready.

However, if you wish, ModelMaker can be set to automatically regenerate a unit every time you make a change to that unit. This is called Auto Generation. You can enable or disable Auto Generation for each unit in your model by clicking either the Enable or Disable Auto Generation buttons in the Units View toolbar (see sidebar). Now, anytime you make a change to an Auto Generated unit, ModelMaker will regenerate the file. For that reason, care should be taken when enabling Auto Generation.

There are several other options and Delphi integration features which can effect when and how code is generated; we'll take a look at these options in Tutorial 6.

Return to the Introduction.
Go on to the next tutorial.

Getting Started with ModelMaker

Tutorial 2 — Visualizing Imported Classes

by Robert Leahey of Thoughtsmithy

To get an initial taste of ModelMaker‘s diagramming capabilities, let‘s visualize one of the classes we imported in the last tutorial.

ModelMaker‘s split screen design allows you to choose from three different possible views on the left of the screen and eight on the right. The views on the left (“master views” I‘ll call them) are:

Classes View (F3)
Units View (F4)
Diagrams View (F5)

The views on the right (“detail views” or editors) are:

Method Implementation Editor (F6)
Unit Code Editor (F7)
Diagram Editor (F8)
Macro Editor (Shift + F6)
Design Patterns (Shift + F7)
Differencing (Shift + F5)
Documentation (Shift + F8)
Event Types (Ctrl + F8)

The various views can, of course, be accessed via their tabs, so you don‘t have to remember the keyboard shortcuts.

For our demonstration, first we‘ll want the Diagrams View, so press F5.

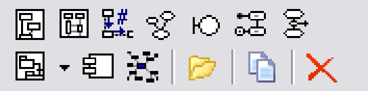

Figure 5 — the Diagram View toolbar.

From the Diagrams View toolbar, (figure 5) click the Add Class Diagram button. Now that we have a new class diagram open, we‘ll want to see the Classes View on the left while editing the diagram on the right, so press F3. Depending on how ModelMaker‘s environment options are set, sometimes changing the master view can change the active editor, so if your diagram goes away, press F8 to bring it back.

There are several ways to add a class to a diagram, but again, the easiest way is to drag it from the Classes View and drop it into the diagram. So select a class from the Classes View, click-and-drag it into the class diagram and drop it there. With the default settings, ModelMaker will display only the class name in the symbol, like in figure 6.

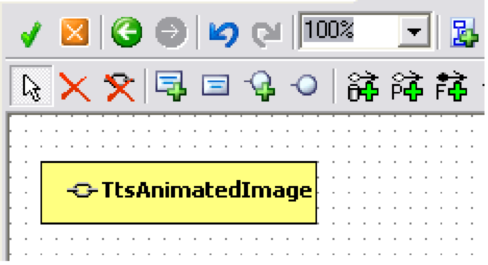

Figure 6 — a visualized class.

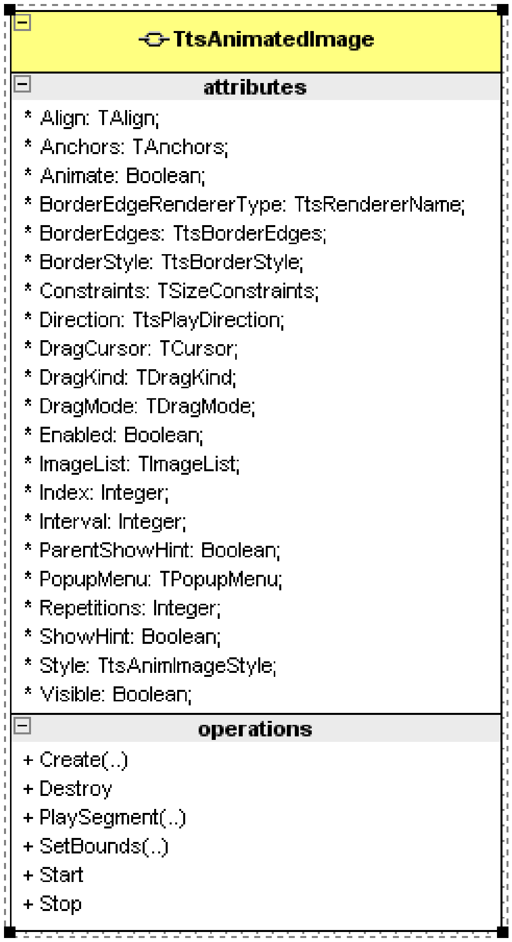
To cause the diagram to display some or all of the members of your class, we‘ll need to change the display style properties. ModelMaker‘s diagram display styles use an inheritance scheme. You can set properties for a symbol, but by default it will inherit the display properties of the diagram. The diagram will inherit a project‘s styles unless you override them, and likewise, a project will inherit the environment‘s styles.



TtsAnimatedImage

attributes

* Align: TAlign;
* Anchors: TAnchors;
* Animate: Boolean;
* BorderEdgeRendererType: TtsRendererName;
* BorderEdges: TtsBorderEdges;
* BorderStyle: TtsBorderStyle;
* Constraints: TSizeConstraints;
* Direction: TtsPlayDirection;
* DragCursor: TCursor;
* DragKind: TDragKind;
* DragMode: TDragMode;
* Enabled: Boolean;
* ImageList: TImageList;
* Index: Integer;
* Interval: Integer;
* ParentShowHint: Boolean;
* PopupMenu: TPopupMenu;
* Repetitions: Integer;
* ShowHint: Boolean;
* Style: TtsAnimImageStyle;
* Visible: Boolean;

operations

+ Create(..)
+ Destroy
+ PlaySegment(..)
+ SetBounds(..)
+ Start
+ Stop

Figure 7 — the class with attributes and operations.

In the interest of time, let‘s adjust the symbol display properties for the whole diagram. Double-click the diagram anywhere outside your class‘ symbol. This will bring up the Diagram Style dialog. Select the Symbol Style tab and uncheck the Project Member Type Filter checkbox. We‘re telling ModelMaker that we want to override the project‘s display style for this diagram. Now that the checkboxes under Custom Member Type Filter are enabled, check the Properties and Methods checkboxes. We‘ve told the diagram we want it to display any class symbol‘s properties and methods. Click OK.

Your class symbol should now resemble something like figure 7 — a class with attributes and operations displayed. You should note that the class symbol has some active hot spots — the tiny minus sign in the upper left hand corner of each section will collapse that section (these appear when the class is selected); the little linked chain icon next to the class name will open the class editor if clicked.

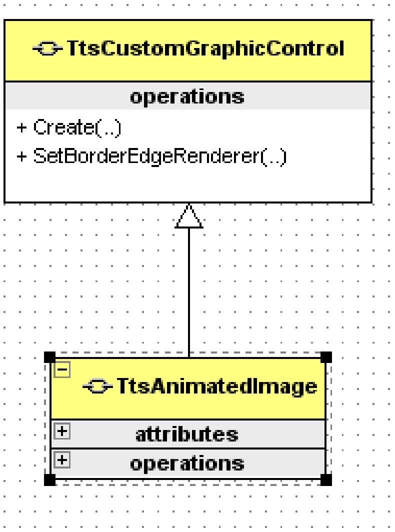


Figure 8 — automatically visualized generalization relation.

If your model contains an ancestor for the class you‘ve just visualized, drag the ancestor to the diagram and drop it there. Notice that ModelMaker automatically visualizes the generalization relation between the two classes as in figure 8.

This topic describes how to visualize an existing class from the code model. It is also possible to add a new class to the code model by adding it to the diagram. For more information, read the next tutorial.

Getting Started with ModelMaker

Tutorial 3 — Creating Classes Within Diagrams

by Robert Leahey of Thoughtsmithy

Introduction

Tutorial 1

Tutorial 2

Tutorial 3

Tutorial 4

Tutorial 5

Tutorial 6

Tutorial 7

Tutorial 8

Tutorial 9

Tutorial 10

ModelMaker Training

Now that we‘ve visualized existing classes, we can examine how to create a new class within a diagram. As we mentioned earlier, the master views in ModelMaker (Classes View, Units View and Diagrams View) are all just different views into the same active model. This means that we can add a model element in any of these views — adding those elements is just a slightly different process in each view.

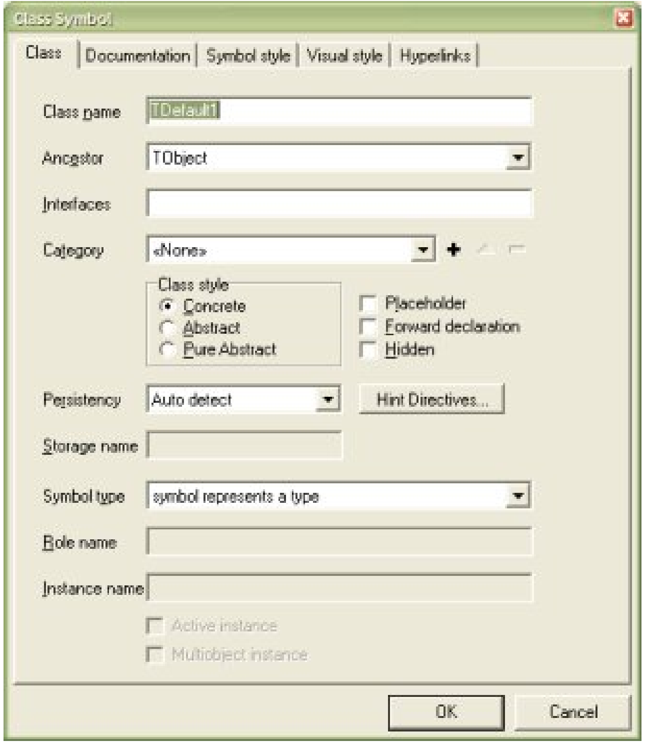
For our purposes, you can either use the class diagram from the previous topic or create a new one. As a point of convention, it‘s important to note the differences between a few of the tool buttons on the Class Diagram Editor toolbar (see figure 9). There are some buttons here that are common to all diagrams and we‘ll discuss these in the next tutorial.

Figure 9 — part of the Class Diagram Editor toolbar.

These four buttons are used to add classes and interfaces to the diagram. The first button will create a new class, adding it to the model and the diagram — we‘ll discuss that in a moment. The second button allows you to choose a class that already exists in the model, and add it to the diagram. The third creates a new interface, adding it to both the model and the diagram while the fourth button will add an existing interface to the diagram. For this topic, we‘ll focus on the first button.

Click this first button (actually the fourth from the left). The cursor will change to indicate that you‘re adding a class.

Click on the diagram where you would like to add the class. The Class Symbol editor will be displayed (see figure 10).



Class Symbol

Class name: TDefault1

Ancestor: TObject

Interfaces:

Category: «None»

Class style: ● Concrete ○ Abstract ○ Pure Abstract

□ Placeholder □ Forward declaration □ Hidden

Persistency: Auto detect

Storage name:

Symbol type: symbol represents a type

Role name:

Instance name:

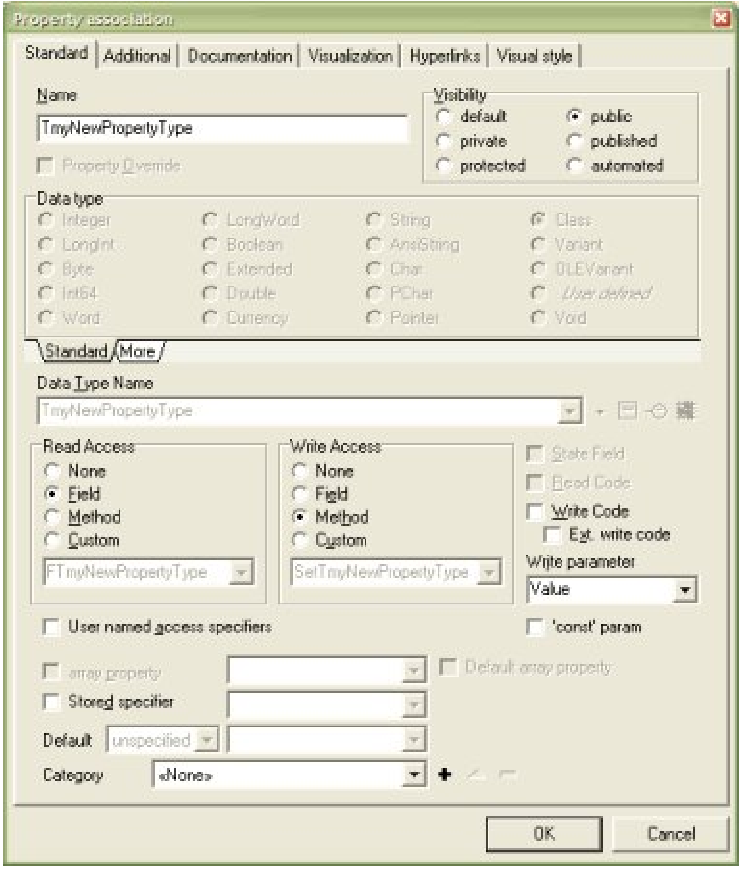
□ Active instance □ Multiobject instance

Figure 10 — the Class Symbol editor.

This editor allows you to define most every facet of a class — its role, appearance, documentation, etc. The Class Name field should be self-explanatory — enter your class‘ name here. Use the Ancestor drop-down to select an ancestor class. The other fields on this tab and the other tabs are optional; for now just set the first two fields and click OK. Your new class will appear in the diagram.

Press F3 (or select the Classes tab) to switch to the Classes View. If your diagram only contains the one class, drag some classes from the Classes View to the diagram to add them. Now notice that, as you select the various classes in your diagram, they become selected in the Classes View as well. In addition, their members are displayed in the Member List.

Your new class is rather empty, so let‘s add some properties. We need the Member List to add methods, events and simple properties and we‘ll be discussing that in Tutorial 5, but we can easily add class-type properties and fields in the Diagram Editor, so let‘s try that now. In the Class Diagram Editor, click the Add Property to Model tool button (8th from the left). Now click-and-hold in the class symbol to which you are adding the property, and drag to the class symbol whose type the property will be. For example, if you have a diagram containing the classes TmyClass and TmyNewPropertyType, to add a property to TmyClass of type TmyNewPropertyType, select Add Property to Model, then click on the TmyClass symbol and drag to the TmyNewPropertyType symbol. The Property Association dialog will appear (see figure 11).



Name: TmyNewPropertyType

□ Property Override

Visibility: ○ default ○ private ○ protected ● public ○ published ○ automated

Data type: ○ Integer ○ LongInt ○ Byte ○ Int64 ○ Word ○ LongWord ○ Boolean ○ Extended ○ Double ○ Currency ○ String ○ AnsiString ○ Char ○ PChar ○ Pointer ● Class ○ Variant ○ OLEVariant ○ *User defined* ○ Void

Data Type Name: TmyNewPropertyType

Read Access: ○ None ● Field ○ Method ○ Custom — FTmyNewPropertyType

Write Access: ○ None ○ Field ● Method ○ Custom — SetTmyNewPropertyType

□ State Field
□ Read Code
□ Write Code
□ Ext. write code

Write parameter: Value

□ User named access specifiers
□ 'const' param
□ array property
□ Default array property
□ Stored specifier

Default: unspecified

Category: «None»

Figure 11 — the Property Association dialog.

This is a complex dialog, but don‘t be daunted. Most the fields on this tab are the values you‘re used to entering in Delphi by hand: Name is the name of the new property, this defaults to the name of the properties class type. Use the Visibility group box to set the new property‘s visibility. The Data Type fields are disabled since, by adding a class-type property in the diagram, we already know the data type. The Read and Write Access group boxes allow you to set the methods of access for this new property. This is a very powerful and timesaving feature of ModelMaker; any accessor methods or state fields needed by this property are added automatically and are always kept up-to-date by ModelMaker. If you change the name of this property, ModelMaker will automatically update its accessors and/or state field.

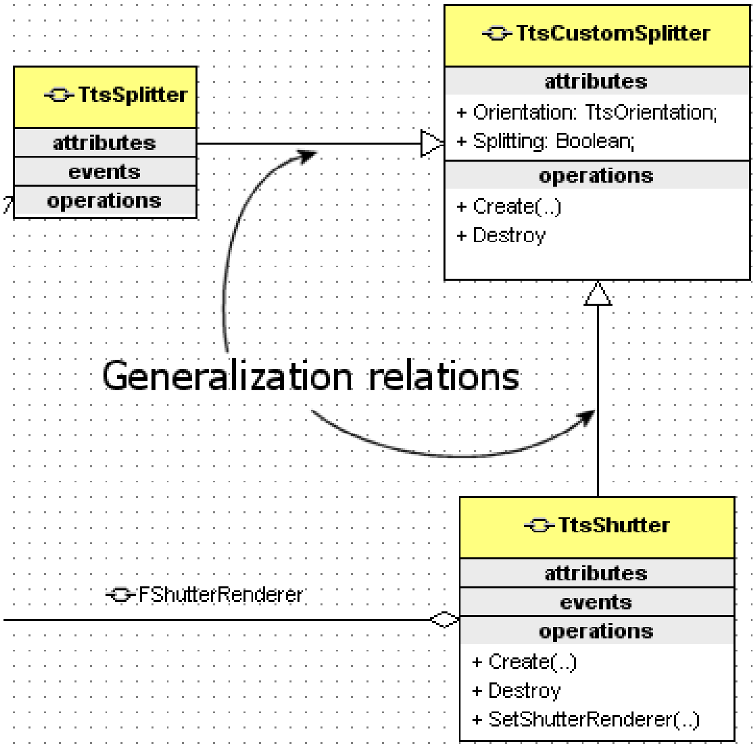


Figure 12 — Automatically visualized Generalization relations.

Changing Relations in a Diagram

You may have noticed that when visualizing your classes, if a class is added to a diagram and that class‘ ancestor is also in the diagram, the Generalization relation is automatically visualized (see figure 12).

There are a great many options and wizards for advanced handling and automation of visualizations, but the Generalization relation is pertinent to our current topic, so for our final thought here, notice the following:

You can change the ancestor of a class, not just within the diagram but also for the whole model, from within a class diagram. Make sure you are editing a class diagram that contains 3 classes, one of which is descendant of another in the diagram. Open the Classes View (so you can see the results) by pressing F3. Click the Generalization arrow to select it. A “grabber” should appear at each end of the arrow (see figure 13).

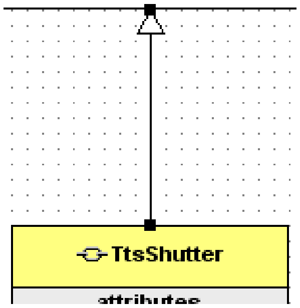

Figure 13 — A Generalization arrow, selected.

To change the class‘ ancestor, click the grabber at the arrowhead, and drag the arrowhead to a different class. Notice in the Classes View that the ancestor of your class has changed. This is a good example of the interconnectedness of the various editors — they are all looking into the same active code model. Note that this same method can be used to change the class type of a class‘ property within a diagram; drag the Property relation to a new class to change the property‘s type.

This has been an incomplete view of diagramming and the class creation process. See Tutorial 4 for an overview of diagramming in ModelMaker and Tutorial 5 for an overview of the class implementation process.

Getting Started with ModelMaker

Tutorial 4 — Diagramming Overview

by Robert Leahey of Thoughtsmithy

Before we begin our discussion of diagrams, remember the following: ModelMaker maintains an internal active code model from which all source code units are generated. The various views (including the Diagram Editor) are simply different ways of looking into that model. The diagrams are not static, stand-alone images; they are graphical representations of the internal model, thus diagram symbols that represent code entities are actually showing us a representation of the entity in the model not just a graphic symbol. It‘s important to remember that distinction lest you try to delete a class from a diagram and wonder why the class still exists in the model.

ModelMaker currently offers the ability to create and manage 10 different types of diagrams, most of which are UML compliant. While most of the diagrams have toolbars and concepts that are specific to their types, there is some common ground with which I will acquaint you here.

There are two parts to the diagramming interface; the Diagrams View (F5) and the Diagram Editor (F8). The reason that these are mentioned separately is that it is possible to view the Diagram Editor while displaying any of the three main views (Classes, Units or Diagrams). See tutorial 2 for a listing of possible views and keystroke shortcuts. For the moment, display both diagramming views by pressing F5 (and if the Diagram Editor is not subsequently displayed, F8). If you are in a new project, with no diagrams, the Diagrams View should be blank and the Diagram Editor and toolbar should be grayed.

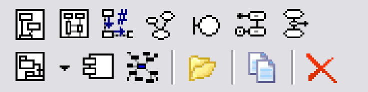

Figure 14 — the Diagrams View toolbar.

The Diagrams View toolbar (figure 14) contains buttons which will add each of the supported diagram types (Class, Sequence, Collaboration, Use Case, Robustness, State, Activity, Unit Dependency, Implementation and Mind Map).

To begin, let‘s add a new class diagram. Click the Add Class Diagram button (the upper-left button) in the Diagrams Views toolbar. Note that a new diagram is added to the Diagrams View tree and the diagram editor is activated with the new class diagram. You can rename the diagram by selecting its node and pressing F2. It‘s always possible to simply add a new diagram to the diagram list by clicking one of the “Add...” buttons. Try clicking some of the other “Add...” buttons now to add some other diagrams to the tree. Notice that as the various diagram types are added, the Diagram editors toolbar displays tool buttons specific to that diagram type. You also see some tool buttons that are common to all diagram types and we‘ll discuss these in a bit.

The Diagrams View is hierarchical; we can add some diagrams and rearrange them to be children of other diagrams. Right-click the Diagrams View and select Advanced Add... from the context menu. The resulting dialog allows you to specify a name for your diagram, select a diagram type and assign a parent diagram all in one step. Select one of your existing diagrams as the parent for your new creation and click OK. Note that the new diagram is added to the tree as the child of the existing diagram. This is a nice organizational feature and comes in handy in projects that contain numerous diagrams. For existing diagrams, it‘s possible to “re-parent" them within the Diagrams View by simply holding down the Ctrl key and dragging the diagram to its new parent.

Figure 16.

Figure 15.

Next we'll look at some of the design elements common to all diagrams. Select any of the diagrams you have added and have a look at the toolbar of the Diagram Editor. For any diagram you select, you should see figure 15 at the far left of the toolbar and figure 16 at the far right.

Moving from left to right, these common tools are as follows:

– Select. Use this tool to select diagram elements.

– Delete from Diagram. This tool will delete a symbol from a diagram, but will not delete the entity it represents from the model.

– Delete Symbol and Linked Entity. This tool will delete a symbol from the diagram and will also delete the entity it represents from the model.

– Add Package. Use this tool to create a package symbol in your diagram. This symbol is "container" and can hold other symbols, much like TPanel in Delphi.

– Add Unit Package. Similar to the Add Package tool, this tool adds a symbol representing a physical Delphi unit to your diagram. The symbol automatically displays the entities contained within the unit.

– Add Annotation. This tool will create a standard UML annotation symbol in which you can enter text of any sort.

– Add Documentation Link. This tool and the next, Add Linked Annotation, have some subtle differences, but they can be summed up as follows: the three options in this drop-down button allow you to connect a symbol and an existing annotation symbol. Whereas the next tool, Add Linked Annotation, will create a new annotation symbol and link it to the selected symbol. The three options in the drop-down menu allow you to add your own annotation text, display the linked entity's documentation or its One Liner comment.

– Add Linked Annotation. This tool, like the one above, links documentation to a diagram symbol. Using this tool will add a new annotation symbol and link it to the selected symbol. The three options in the drop-down menu allow you to add your own annotation text, display the linked entity's documentation or its One Liner comment.

– Add Constraint Relation. This is rather self explanatory; use this tool to add a constraint relation between two symbols to the diagram.

– Add Hyperlink. This is a powerful tool. This symbol, when added, will allow you to add a hyperlink to your diagram which can link to another diagram, a code model entity and/or an external document.

– Add shape. Use this tool to add simple geometric shapes to your diagram.

– Add Image. This tool allows you to add an image from an external file to your diagram.

When trying to alter the appearance of your diagrams, keep in mind that double-clicking on a diagram symbol (including associations and relations) will display that symbol‘s editing dialog where you can change the visual attributes of the diagram symbol. However, before you start trying to format your diagrams one symbol-at-a-time, keep in mind the following: ModelMaker provides access to the display styles of diagrams and their symbols using an inheritance model. It is possible to set styles for diagrams at an environment level via the Diagrams tab in the Environment Options dialog; to override these settings for a particular project, you would do so in the Project Options dialog, available from the Options menu. To override the settings for a diagram, double-click the diagram to display the Diagram Style dialog. Likewise, double-click a symbol to display its Symbol Style dialog.
This should provide enough of a basic overview of diagramming in ModelMaker to get you started. See the online help for information about specific diagram types.

Figure 17 — the Member List.

Given the wide range of options available in adding class members, this step is more informative than tutorial.

Ok, we’ve looked around enough — it’s time to get serious about implementing our classes.

The pane that you’ll need to get to know well is the Member List (see figure 17). This window is found below the triumvirate of the Classes View/Units View/Diagrams View.

The Members List allows you to manage the members (fields, methods, properties and events) of your classes. Note that there are many options that control the appearance of the Member List so my screen shots may not look the same as the Member List in your copy of ModelMaker.

The first thing to notice is that the Member List is just that — a list of a class‘ members. Remember that ModelMaker keeps an active model of your code internally and that all of the various editors are simply different views into the model; the Member List is another example of that. Any changes you make here are simply changing the model, not the physical source code files (unless you have Auto Generation Enabled) until you generate the source from the model.

On the General tab of the Environment Options dialog (available from the Options menu) is a group box entitled Members Appearance. If you check the first three items, Display Type Bitmaps, Display Visibility Bitmaps and Display Info Bitmaps, you will see all three columns of graphics in your Member List (as shown in figure 17). Select all three options and we’ll have a look at the various icons presented in the Member List.

The first two columns in the Member List represent the member type and visibility:

F — Field	d — default visibility
M — Method	Pi — private
Pr — Property	Pt — protected
E — Event	Pu — public
R — Method Resolution Clause	Pb — published

The third column displays a contextual icon depending on the member type. For methods, the icons represent bindings as follows:

St — static	Vr — virtual	Ov — override
Ab — abstract	Dy — dynamic	Ms — message

If the member is a property, the icons are as follows:

RW — Read/write	R — Read-only	No — Property override

The Member List allows you to add and edit members as well. Here we will take a general look at that process.

Figure 18 — Add Members toolbar.

Near the top of the Member List, you should see the toolbar in figure 18. The first four buttons on this toolbar are for adding members; they are, from left to right, Add Field, Add Method, Add Property and Add Event. Clicking one of these buttons will display the appropriate editor for the memeber type you selected. You should notice some similarities in each of the editors: Name, Visibility and Type. Also common to each editor is the Documentation tab where you can add documentation for your new member. The documentation you add is attached to the member within ModelMaker‘s internal model and can be used in a variety of ways. For example, you can emit the documentation with your code as comments (see Tutorial 7) or link to it within a diagram as an annotation (see Add Documentation Link and Add Linked Annotation in Tutorial 4). It is also available via the ModelMaker OpenTools API (see Tutorial 10).

In addition to the common elements, each editor contains settings specific to its member type. For instance, in the Property Editor, you can control the property‘s read and write access while the Event Editor allows you to generate a dispatch method.

Here are some quick thoughts on each of the member types which should help you to get more comfortable with ModelMaker:

Fields and Methods

If you‘re trying to add a propert‘s state field or an access method, stop. One of the key advantages of ModelMaker is its automation, and the automation surrounding the creation of properties is high. See the next section for more information.

Make sure you visit the ModelMaker online help by pressing F1 in the editor dialogs. Some items of note are the Owned and Initialized options for fields and the Inheritance Restricted option for methods.

Properties

As mentioned in the previous section, ModelMaker can greatly simplify the process of adding a property through its automation features. This is one of the reasons many people choose to work in ModelMaker as their code editor (as a Delphi IDE replacement); when adding a property by hand in Delphi, you write the declaration code for the property, its access methods, perhaps a state field and the implementation code for the access methods. When adding a proprty in ModelMaker, you add the property. Period.

Within the Property Editor you will find options for specifying the read/write access for the property (state field, method or none) as well as for generating some rudimentary read/write access code. Once you have set these options and clicked OK, ModelMaker adds not only the property, but the related access code. The generated code is “owned” by the property — if you change the name of the property or delete it, all the generated code is automatically renamed or deleted as well. Try experimenting with these settings and read in the online help for more information.

Events

Adding an event is somewhat similar to adding a property; most of the overhead is managed for you by ModelMaker. In the Event Editor dialog, you select a name, event type (event types are managed in the Event Type Library, available in the Events tab) and visibility. You can also specify a dispatch method by checking the Dispatch checkbox. The generated method will be owned by the event similar to the way a property owns its access methods.

Note that if you wish your dispatch methods to automatically be prefixed (with “Do”, for example) you can specify this and other coding style options in the *Coding Style* tab of the *Project Options* dialog under the *Options* menu.

Getting Started with ModelMaker

Tutorial 6 — Delphi Integration

by Robert Leahey of Thoughtsmithy

While some developers use ModelMaker as a complete Delphi IDE replacement, most seem to prefer to use ModelMaker and Delphi simultaneously — switching back and forth as needed. To support this, ModelMaker offers extensive Delphi integration features, which we will examine here.

Delphi Controls ModelMaker

ModelMaker installs a Delphi integration expert into the Delphi IDE, which allows you to control ModelMaker somewhat from within Delphi.

First, start Delphi if it is not running, and have a look at the ModelMaker menu in the main Delphi menu bar. Notice that the first menu item allows you to launch ModelMaker. Also notice that most of the items in the ModelMaker menu require ModelMaker to be running — if it is not, those items will be disabled.

Launch ModelMaker now, if it is not running, by selecting the first menu item.

Warning: *in order to avoid overwriting some of your production code, make a copy of the unit or units you are going to import before continuing.*

The first thing we'll do is to create a new project and import into it some existing classes, all from within Delphi. Open, in Delphi, a project that you'd like to import into ModelMaker. From the ModelMaker menu, select *Convert Project to Model*. The ModelMaker window should come to the front, most likely asking whether to save your current model. After you answer that dialog as appropriate, ModelMaker will create a new project and import the Delphi project's units.

Some of the other menu items that operate similarly are *Add to Model*, which causes the active unit in Delphi to be imported into the current model in ModelMaker; *Add Files to Model*, which allows you to select units to be added to the current model in ModelMaker and *Convert to Model*, which will create a new model in ModelMaker and import the active Delphi unit into it.

Two other noteworthy menu items in the Delphi ModelMaker menu are *Jump to ModelMaker* and *Refresh in Model*. *Jump to ModelMaker* will bring ModelMaker to the front and attempt to find the current code block within the model. *Refresh in Model* will cause ModelMaker to re-import the active unit into the current model.

ModelMaker Controls Delphi

If you find that you like editing your code in ModelMaker, and prefer to have ModelMaker control Delphi, you have that option. Make sure that you are familiar with the process of generating code from within ModelMaker, by reading tutorial 1, then examine the Delphi portion of ModelMaker's main toolbar (see figure 19).

Figure 19 — Delphi control buttons.

The first button, *Generate*, you should already be familiar with.

The second button, *Generate and Perform Default Compile Action*, will cause the current unit to be generated, and will request that Delphi perform one of three actions: Syntax Check, Compile or Build. This default compile action can be set on the next button's drop-down menu.

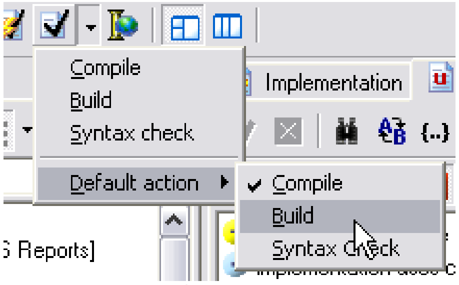

Figure 20 — Default Compile Action drop-down menu.

The third button (its hint will vary depending on the default compile action), will cause Delphi to perform the currently selected default action. This default is set in this button's drop-down menu (see figure 20); after setting a default, that action will be taken any time this button or the previous button is clicked. Note: these Delphi actions will be enacted upon whatever the currently loaded Delphi project may be.

The fourth button, *Locate in Delphi*, will bring Delphi to the front and attempt to locate the current code block in the code editor. It will open the current unit in Delphi if necessary.

Two-way Integration

The most complete integration can be achieved through ModelMaker's two-way integration, although a warning must be issued here: normally ModelMaker works with a safety net of allowing you to determine when code will be generated and when it will be refreshed into the model. Even if you enable auto-generation (see tutorial 1), you still have control over when code is re-imported if it has been changed outside of ModelMaker. If you enable the two-way integration, you will lose this control and code will automatically be generated and refreshed without warning. If there are changes to the code you do not wish to overwrite without warning, you should be careful using this option.

Enabling this feature basically causes ModelMaker to generate your units any time they change in ModelMaker and to re-import them any time they change outside of ModelMaker. To use this feature, do the following:

In ModelMaker, unlock code generation. Select one or more units to auto-generate and select the *Enable Auto-Generation* button for each.

Select *Environment Options* from the *Options* menu in ModelMaker. In the General tab, under Code Generation and Import, check the *Auto Refresh from IDE* and *Refresh Keeps Units Enabled* check boxes.

In Delphi, select *Integration Options* from the ModelMaker menu. In that dialog, select *Enable Auto Refresh*.

Open one of your auto-generated units in Delphi by clicking ModelMaker's Locate in Delphi button. If you want, arrange your ModelMaker and Delphi code editor windows so that you can see both at the same time. Now go back to ModelMaker and change something in that unit, then save the model. You should see the unit update in Delphi automatically. Now change something in the unit in the Delphi code editor, then save the unit. The unit will be refreshed in ModelMaker. Viola! Two-way code editing integration.

Another warning: if your code comment importing options are not correctly set up, you may see "comment creep" or worse, you might see comments deleted without warning. Be very careful using this two-way feature until you understand how to set up code comment importing options. For more information on that, see the next tutorial.
