Marco Cantù's Essential Pascal

Introduction

October 1, 1999: Book is on Delphi 5 Companion CD.
Source Code available. Examples list added.

Book Cover. Apollo, the god worshipped at Delphi,
in an Italian 17th century fresco.

The first few editions of Mastering Delphi, the best selling Delphi book I've written, provided an introduction to the Pascal language in Delphi. Due to space constraints and because many Delphi programmers look for more advanced information, in the latest edition this material was completely omitted. To overcome the absence of this information, I've started putting together this online book, titled **Essential Pascal**.

This is a detailed book on Pascal, which for the moment will be available for free on my web site (I really don't know what will happen next, I might even find a publisher). This is a work in progress, and any feedback is welcome. The first complete version of this book, dated July '99, has been published on the Delphi 5 Companion CD.

Copyright

The text and the source code of this book is copyrighted by Marco Cantù. Of course you can use the programs and adapt them to your own needs, only you are not allowed to use them in books, training material, and other copyrighted formats. Feel free to link your site with this one, but please do not duplicate the material as it is very subject to frequent changes and updates.

The Book Structure

The following is the current structure of the book:

Source Code

The source code of all the examples mentioned in the book is available. The code has the same Copyright as the book: Feel free to use it at will but don't publish it on other documents or site. Links back to this site are welcome.

Download the source code in a single zip file, **EPasCode.zip** (only 26 KB in size) and check out the **list of the examples**.

Feedback

Please let me know of any errors you find, but also of topics not clear enough for a beginner. I'll be able to devote time to the project depending also on the feedback I receive. Let me know also which other topics (not covered in Mastering Delphi 4) you'd like to see here. Again, hook onto the newsgroup, listed on my web site, and look for the books section, or mail to **marco@marcocantu.com** (putting **Essential Pascal** in the subject (and your request or comment in the text).

Acknowledgements

If I'm publishing a book on the web for free, I think this is mainly due to Bruce Eckel's experience with Thinking in Java. I'm a friend of Bruce and think he really did a great job with that book and few others.

As I mentioned the project to people at Borland I got a lot of positive feedback as well. And of course I must thank the company for making first the Turbo Pascal series of compilers and now the Delphi series of visual IDEs.

I'm starting to get some precious feedback. The first readers who helped improving this material quite a lot are Charles Wood and Wyatt Wong. Mark Greenhaw helped with some editing the text. Rafael Barranco-Droege offered a lot of technical corrections and language editing. Thanks.

Author

Marco Cantù lives in Piacenza, Italy. After writing C++ and Object Windows Library books and articles, he delved into Delphi programming. He is the author of the Mastering Delphi book series, published by Sybex, as well as the advanced Delphi Developers Handbook. He writes articles for many magazines, including The Delphi Magazine, speaks at Delphi and Borland conferences around the world, and teaches Delphi classes at basic and advanced levels.

You can find more details about Marco and his work on his web site, **www.marcocantu.com**.

Marco Cantù's Essential Pascal

Appendix B: Examples

This is a list of the examples which are part of Essential Pascal and available for download:

Chapter 3

ResStr: resource strings
Range: ordinal types ranges
TimeNow: time manipulation

Test

Chapter 4

GPF: general protection faults with null pointers

Chapter 5

IfTest: if statements
Loops: for and while statements

Chapter 6

OpenArr: open array parameters
DoubleH: simple procedures
ProcType: procedural types
OverDef: overloading and default parameters

Chapter 7

StrRef: strings reference counting
LongStr: using long strings
FmtTest: formatting examples

Chapter 8

DynArr: dynamic arrays
WHandle: Windows handles
Callback: Windows callback functions
StrParam: command line parameters

Chapter 10

VariTest: simple variant operations
VariSpeed: the speed of variants

Marco Cantù's Essential Pascal

Chapter 1 Pascal History

The Object Pascal programming language we use in Delphi wasn't invented in 1995 along with the Borland visual development environment. It was simply extended from the Object Pascal language already in use in the Borland Pascal products. But Borland didn't invent Pascal, it only helped make it very popular and extended it a little...

This chapter will contain some historical background on the Pascal language and its evolution. For the moment it contains only very short summaries.

Wirth's Pascal

The Pascal language was originally designed in 1971 by Niklaus Wirth, professor at the Polytechnic of Zurich, Switzerland. Pascal was designed as a simplified version for educational purposes of the language Algol, which dates from 1960.

When Pascal was designed, many programming languages existed, but few were in widespread use: FORTRAN, C, Assembler, COBOL. The key idea of the new language was order, managed through a strong concept of data type, and requiring declarations and structured program controls. The language was also designed to be a teaching tool for students of programming classes.

Turbo Pascal

Borland's world-famous Pascal compiler, called Turbo Pascal, was introduced in 1983, implementing "Pascal User Manual and Report" by Jensen and Wirth. The Turbo Pascal compiler has been one of the best-selling series of compilers of all time, and made the language particularly popular on the PC platform, thanks to its balance of simplicity and power.

Turbo Pascal introduced an Integrated Development Environment (IDE) where you could edit the code (in a WordStar compatible editor), run the compiler, see the errors, and jump back to the lines containing those errors. It sounds trivial now, but previously you had to quit the editor, return to DOS; run the command-line compiler, write down the error lines, open the editor and jump there.

Moreover Borland sold Turbo Pascal for 49 dollars, where Microsoft's Pascal compiler was sold for a few hundred. Turbo Pascal's many years of success contributed to Microsoft's eventual cancellation of its Pascal compiler product.

Delphi's Pascal

After 9 versions of Turbo and Borland Pascal compilers, which gradually extended the language, Borland released Delphi in 1995, turning Pascal into a visual programming language.

Delphi extends the Pascal language in a number of ways, including many object-oriented extensions which are different from other flavors of Object Pascal, including those in the Borland Pascal with Objects compiler.

Chapter 2 Coding in Pascal

Before we move on to the subject of writing Pascal language statements, it is important to highlight a couple of elements of Pascal coding style. The question I'm addressing here is this: Besides the syntax rules, how should you write code? There isn't a single answer to this question, since personal taste can dictate different styles. However, there are some principles you need to know regarding comments, uppercase, spaces, and the so-called pretty-printing. In general, the goal of any coding style is clarity. The style and formatting decisions you make are a form of shorthand, indicating the purpose of a given piece of code. An essential tool for clarity is consistency-whatever style you choose, be sure to follow it throughout a project.

Comments

In Pascal, comments are enclosed in either braces or parentheses followed by a star. Delphi also accepts the C++ style comments, which can span to the end of the line:

```
{this is a comment}
(* this is another comment *)
// this is a comment up to the end of the line
```

The first form is shorter and more commonly used. The second form was often preferred in Europe because many European keyboards lack the brace symbol. The third form of comments has been borrowed from C++ and is available only in the 32-bit versions of Delphi. Comments up to the end of the line are very helpful for short comments and for commenting out a line of code.

> In the listings of the book I'll try to mark comments as italic (and keywords in bold), to be consistent with the default Delphi syntax highlighting.

Having three different forms of comments can be helpful for making nested comments. If you want to comment out several lines of source code to disable them, and these lines contain some real comments, you cannot use the same comment identifier:

```
{  ... code
{comment, creating problems}
... code }
```

With a second comment identifier, you can write the following code, which is correct:

```
{  ... code
//this comment is OK
... code }
```

Note that if the open brace or parenthesis-star is followed by the dollar sign ($), it becomes a compiler directive, as in {$X+}.

> Actually, compiler directives are still comments. For example, {$X+ This is a comment} is legal. It's both a valid directive and a comment, although sane programmers will probably tend to separate directives and comments.

Use of Uppercase

The Pascal compiler (unlike those in other languages) ignores the case (capitalization) of characters. Therefore, the identifiers Myname, MyName, myname, myName, and MYNAME are all exactly equivalent. On the whole, this is definitely a positive, since in case-sensitive languages, many syntax errors are caused by incorrect capitalization.

> Note: There is only one exception to the case-insensitive rule of Pascal: the Register procedure of a components' package must start with the uppercase R, because of a C++Builder compatibility issue.

There are a couple of subtle drawbacks, however. First, you must be aware that these identifiers really are the same, so you must avoid using them as different elements. Second, you should try to be consistent in the use of uppercase letters, to improve the readability of the code.

A consistent use of case isn't enforced by the compiler, but it is a good habit to get into. A common approach is to capitalize only the first letter of each identifier. When an identifier is made up of several consecutive words (you cannot insert a space in an identifier), every first letter of a word should be capitalized:

```
MyLongIdentifier
MyVeryLongAndAlmostStupidIdentifier
```

Other elements completely ignored by the compiler are the spaces, new lines, and tabs you add to the source code. All these elements are collectively known as white space. White space is used only to improve code readability; it does not affect the compilation.

Unlike BASIC, Pascal allows you to write a statement on several lines of code, splitting a long instruction on two or more lines. The drawback (at least for many BASIC programmers) of allowing statements on more than one line is that you have to remember to add a semicolon to indicate the end of a statement, or more precisely, to separate a statement from the next one. Notice that the only restriction in splitting programming statements on different lines is that a string literal may not span several lines.

Again, there are no fixed rules on the use of spaces and multiple-line statements, just some rules of thumb:

- The Delphi editor has a vertical line you can place after 60 or 70 characters. If you use this line and try to avoid surpassing this limit, your source code will look better when you print it on paper. Otherwise long lines may get broken at any position, even in the middle of a word, when you print them.
- When a function or procedure has several parameters, it is common practice to place the parameters on different lines.
- You can leave a line completely white (blank) before a comment or to divide a long piece of code in smaller portions. Even this simple idea can improve the readability of the code, both on screen and when you print it.
- Use spaces to separate the parameters of a function call, and maybe even a space before the initial open parenthesis. Also keep operands of an expression separated. I know that some programmers will disagree with these ideas, but I insist: Spaces are free; you don't pay for them. (OK, I know that they use up disk space and modem connection time when you upload or download a file, but this is less and less relevant, nowadays.)

Pretty-Printing

The last suggestion on the use of white spaces relates to the typical Pascal language-formatting style, known as pretty-printing. This rule is simple: Each time you need to write a compound statement, indent it two spaces to the right of the rest of the current statement. A compound statement inside another compound statement is indented four spaces, and so on:

```
if ... then
  statement;

if ... then
begin
  statement1;
  statement2;
end;

if ... then
begin
  if ... then
    statement1;
  statement2;
end;
```

The above formatting is based on pretty-printing, but programmers have different interpretations of this general rule. Some programmers indent the begin and end statements to the level of the inner code, some of them indent begin and end and then indent the internal code once more, other programmers put the begin in the line of the if condition. This is mostly a matter of personal taste.

A similar indented format is often used for lists of variables or data types, and to continue a statement from the previous line:

```
type
  Letters = set of Char;
var
  Name: string;
begin
   { long comment and long statement, going on in the
     following line and indented two spaces }
   MessageDlg ('This is a message',
     mtInformation, [mbOk], 0);
```

Of course, any such convention is just a suggestion to make the code more readable to other programmers, and it is completely ignored by the compiler. I've tried to use this rule consistently in all of the samples and code fragments in this book. Delphi source code, manuals, and Help examples use a similar formatting style.

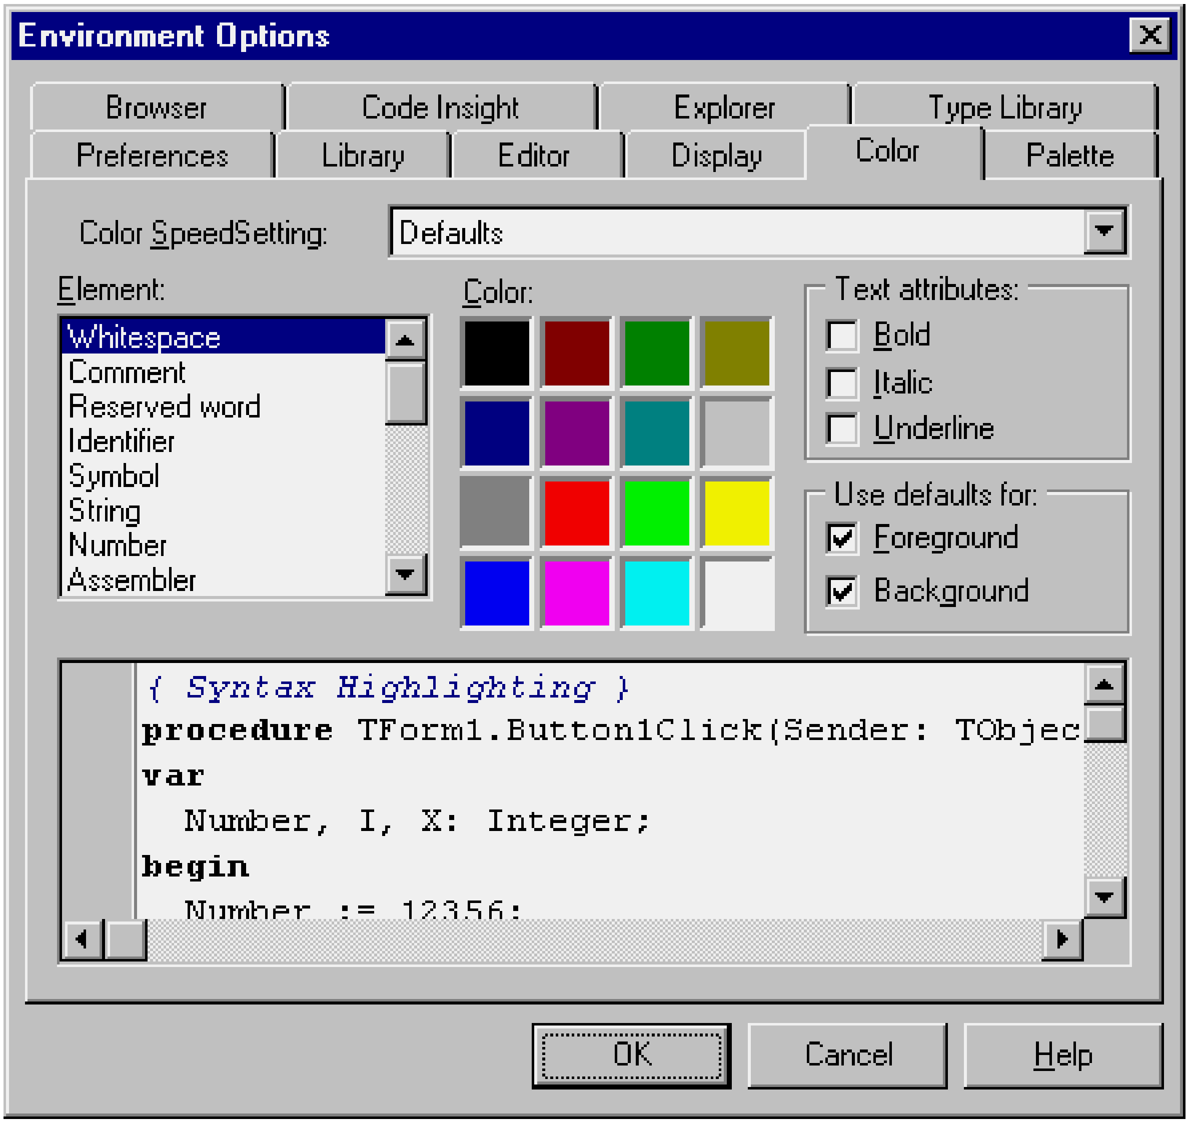
Syntax Highlighting

To make it easier to read and write Pascal code, the Delphi editor has a feature called color syntax highlighting. Depending on the meaning in Pascal of the words you type in the editor, they are displayed using different colors. By default, keywords are in bold, strings and comments are in color (and often in italic), and so on.

Reserved words, comments, and strings are probably the three elements that benefit most from this feature. You can see at a glance a misspelled keyword, a string not properly terminated, and the length of a multiple-line comment.

You can easily customize the syntax highlight settings using the Editor Colors page of the Environment Options dialog box (see Figure 2.1). If you work by yourself, choose the colors you like. If you work closely with other programmers, you should all agree on a standard color scheme. I find that working on a computer with a different syntax coloring than the one I am used to is really difficult.

FIGURE 2.1: The dialog box used to set the color syntax highlighting.



Color SpeedSetting: Defaults

Element:
- Whitespace
- Comment
- Reserved word
- Identifier
- Symbol
- String
- Number
- Assembler

Text attributes:
- □ Bold
- □ Italic
- □ Underline

Use defaults for:
- ☑ Foreground
- ☑ Background

```
{ Syntax Highlighting }
procedure TForm1.Button1Click(Sender: TObjec
var
  Number, I, X: Integer;
begin
  Number := 12356;
```

Note: In this book I've tried to apply a sort of syntax highlighting to the source code listings. I hope this actually makes them more readable.

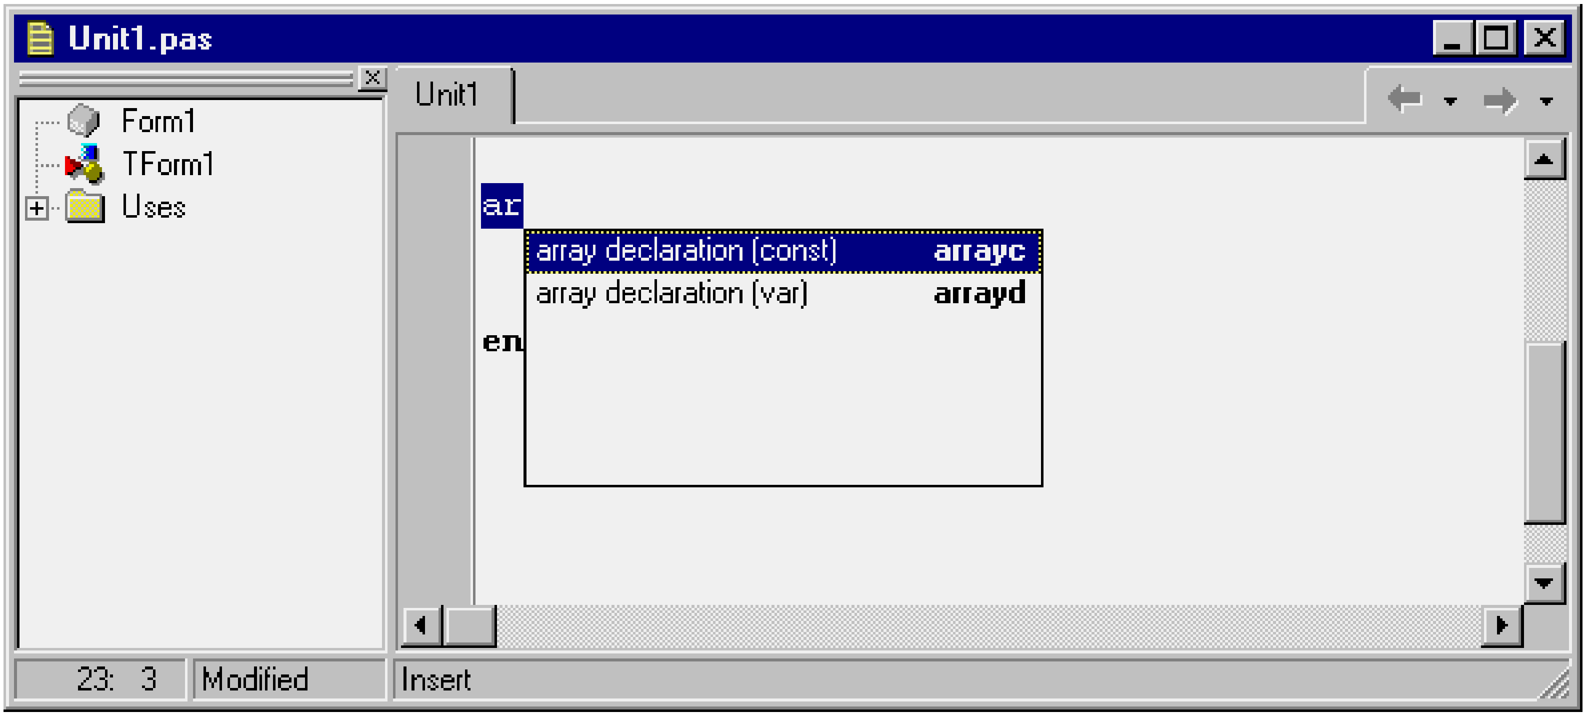
Using Code Templates

Delphi 3 introduced a new feature related to source code editing. Because when writing Pascal language statements you often repeat the same sequence of keywords, Borland has provided a new feature called Code Templates. A code template is simply a piece of code related with a shorthand. You type the shorthand, then press Ctrl+J, and the full piece of code appears. For example, if you type arrayd, and then press Ctrl+J, the Delphi editor will expand your text into:

```
array [0..] of ;
```

Since the predefined code templates usually include several versions of the same construct, the shortcut generally terminates with a letter indicating which of the versions you are interested in. However, you can also type only the initial part of the shortcut. For example, if you type ar and then press Ctrl+J, the editor will display a local menu with a list of the available choices with a short description, as you can see in Figure 2.2.

Figure 2.2: Code Templates selection



Unit1.pas
Form1
TForm1
Uses
Unit1
ar
en
array declaration (const) arrayc
array declaration (var) arrayd
23: 3
Modified
Insert

You can fully customize the code templates by modifying the existing ones or adding your own common code pieces. If you do this, keep in mind that the text of a code template generally includes the '|' character to indicate where the cursor should jump to after the operation, that is, where you start typing to complete the template with custom code.

Language Statements

Once you have defined some identifiers, you can use them in statements and in the expressions that are part of some statements. Pascal offers several statements and expressions. Let's look at keywords, expressions, and operators first.

Keywords

Keywords are all the Object Pascal reserved identifiers, which have a role in the language. Delphi's help distinguishes between reserved words and directives: Reserved words cannot be used as identifiers, while directives should not be used as such, even if the compiler will accept them. In practice, you should not use any keywords as an identifier.

In Table 2.1 you can see a complete list of the identifiers having a specific role in the Object Pascal language (in Delphi 4), including keywords and other reserved words.

Table 2.1: Keywords and other reserved words in the Object Pascal language

Keyword	Role
absolute	directive (variables)
abstract	directive (method)

and	operator (boolean)
array	type
as	operator (RTTI)
asm	statement
assembler	backward compatibility (asm)
at	statement (exceptions)
automated	access specifier (class)
begin	block marker
case	statement
cdecl	function calling convention
class	type
const	declaration or directive (parameters)
constructor	special method
contains	operator (set)
default	directive (property)
destructor	special method
dispid	dispinterface specifier
dispinterface	type
div	operator
do	statement
downto	statement (for)
dynamic	directive (method)
else	statement (if or case)
end	block marker
except	statement (exceptions)
export	backward compatibility (class)
exports	declaration
external	directive (functions)
far	backward compatibility (class)
file	type
finalization	unit structure
finally	statement (exceptions)
for	statement
forward	function directive
function	declaration
goto	statement
if	statement
implementation	unit structure
implements	directive (property)
in	operator (set) - project structure
index	directive (dipinterface)
inherited	statement
initialization	unit structure
inline	backward compatibility (see asm)
interface	type

is	operator (RTTI)
label	declaration
library	program structure
message	directive (method)
mod	operator (math)
name	directive (function)
near	backward compatibility (class)
nil	value
nodefault	directive (property)
not	operator (boolean)
object	backward compatibility (class)
of	statement (case)
on	statement (exceptions)
or	operator (boolean)
out	directive (parameters)
overload	function directive
override	function directive
package	program structure (package)
packed	directive (record)
pascal	function calling convention
private	access specifier (class)
procedure	declaration
program	program structure
property	declaration
protected	access specifier (class)
public	access specifier (class)
published	access specifier (class)
raise	statement (exceptions)
read	property specifier
readonly	dispatch interface specifier
record	type
register	function calling convention
reintroduce	function directive
repeat	statement
requires	program structure (package)
resident	directive (functions)
resourcestring	type
safecall	function calling convention
set	type
shl	operator (math)
shr	operator (math)
stdcall	function calling convention
stored	directive (property)
string	type
then	statement (if)

threadvar	declaration
to	statement (for)
try	statement (exceptions)
type	declaration
unit	unit structure
until	statement
uses	unit structure
var	declaration
virtual	directive (method)
while	statement
with	statement
write	property specifier
writeonly	dispatch interface specifier
xor	operator (boolean)

Expressions and Operators

There isn't a general rule for building expressions, since they mainly depend on the operators being used, and Pascal has a number of operators. There are logical, arithmetic, Boolean, relational, and set operators, plus some others. Expressions can be used to determine the value to assign to a variable, to compute the parameter of a function or procedure, or to test for a condition. Expressions can include function calls, too. Every time you are performing an operation on the value of an identifier, rather than using an identifier by itself, that is an expression.

Expressions are common to most programming languages. An expression is any valid combination of constants, variables, literal values, operators, and function results. Expressions can also be passed to value parameters of procedures and functions, but not always to reference parameters (which require a value you can assign to).

Operators and Precedence

If you have ever written a program in your life, you already know what an expression is. Here, I'll highlight specific elements of Pascal operators. You can see a list of the operators of the language, grouped by precedence, in Table 2.1.

> Contrary to most other programming languages, the and and or operators have precedence compared to the relational one. So if you write a < b and c < d, the compiler will try to do the and operation first, resulting in a compiler error. For this reason you should enclose each of the < expression in parentheses: (a < b) and (c < d).

Some of the common operators have different meanings with different data types. For example, the + operator can be used to add two numbers, concatenate two strings, make the union of two sets, and even add an offset to a PChar pointer. However, you cannot add two characters, as is possible in C.

Another strange operator is div. In Pascal, you can divide any two numbers (real or integers) with the / operator, and you'll invariably get a real-number result. If you need to divide two integers and want an integer result, use the div operator instead.

Table 2.2: Pascal Language Operators, Grouped by Precedence

Unary Operators (Highest Precedence)

@	Address of the variable or function (returns a pointer)
not	Boolean or bitwise not
Multiplicative and Bitwise Operators	
*	Arithmetic multiplication or set intersection
/	Floating-point division
div	Integer division
mod	Modulus (the remainder of integer division)
as	Allows a type-checked type conversion among at runtime (part of the RTTI support)
and	Boolean or bitwise and
shl	Bitwise left shift
shr	Bitwise right shift
Additive Operators	
+	Arithmetic addition, set union, string concatenation, pointer offset addition
-	Arithmetic subtraction, set difference, pointer offset subtraction
or	Boolean or bitwise or
xor	Boolean or bitwise exclusive or
Relational and Comparison Operators (Lowest Precedence)	
=	Test whether equal
<>	Test whether not equal
<	Test whether less than
>	Test whether greater than
<=	Test whether less than or equal to, or a subset of a set
>=	Test whether greater than or equal to, or a superset of a set
in	Test whether the item is a member of the set
is	Test whether object is type-compatible (another RTTI operator)

Set Operators

The set operators include union (+), difference (-), intersection (*),membership test (in), plus some relational operators. To add an element to a set, you can make the union of the set with another one that has only the element you need. Here's a Delphi example related to font styles:

```
Style := Style + [fsBold];
Style := Style + [fsBold, fsItalic] - [fsUnderline];
```

As an alternative, you can use the standard Include and Exclude procedures, which are much more efficient (but cannot be used with component properties of the set type, because they require an l-value parameter):

```
Include (Style, fsBold);
```

Conclusion

Now that we know the basic layout of a Pascal program we are ready to start understanding its meaning in detail. We'll start by exploring the definition of predefined and user defined data types, then we'll move along to the use of the keywords to form programming statements.

Marco Cantù's Essential Pascal

Chapter 3 Types, Variables, and Constants

The original Pascal language was based on some simple notions, which have now become quite common in programming languages. The first is the notion of data type. The type determines the values a variable can have, and the operations that can be performed on it. The concept of type is stronger in Pascal than in C, where the arithmetic data types are almost interchangeable, and much stronger than in the original versions of BASIC, which had no similar concept.

Variables

Pascal requires all variables to be declared before they are used. Every time you declare a variable, you must specify a data type. Here are some sample variable declarations:

```
var
  Value: Integer;
  IsCorrect: Boolean;
  A, B: Char;
```

The var keyword can be used in several places in the code, such as at the beginning of the code of a function or procedure, to declare variables local to the routine, or inside a unit to declare global variables. After the var keyword comes a list of variable names, followed by a colon and the name of the data type. You can write more than one variable name on a single line, as in the last statement above.

Once you have defined a variable of a given type, you can perform on it only the operations supported by its data type. For example, you can use the Boolean value in a test and the integer value in a numerical expression. You cannot mix Booleans and integers (as you can with the C language).

Using simple assignments, we can write the following code:

```
Value := 10;
IsCorrect := True;
```

But the next statement is not correct, because the two variables have different data types:

```
Value := IsCorrect; // error
```

If you try to compile this code, Delphi issues a compiler error with this description: Incompatible types: 'Integer' and 'Boolean'. Usually, errors like this are programming errors, because it does not make sense to assign a True or False value to a variable of the Integer data type. You should not blame Delphi for these errors. It only warns you that there is something wrong in the code.

Of course, it is often possible to convert the value of a variable from one type into a different type. In some cases, this conversion is automatic, but usually you need to call a specific system function that changes the internal representation of the data.

In Delphi you can assign an initial value to a global variable while you declare it. For example, you can write:

```
var
  Value: Integer = 10;
  Correct: Boolean = True;
```

This initialization technique works only for global variables, not for variables declared inside the scope of a procedure or method.

Constants

Pascal also allows the declaration of constants to name values that do not change during program execution. To declare a constant you don't need to specify a data type, but only assign an initial value. The compiler will look at the value and automatically use its proper data type. Here are some sample declarations:

```
const
  Thousand = 1000;
  Pi = 3.14;
  AuthorName = 'Marco Cantù';
```

Delphi determines the constant's data type based on its value. In the example above, the Thousand constant is assumed to be of type SmallInt, the smallest integral type which can hold it. If you want to tell Delphi to use a specific type you can simply add the type name in the declaration, as in:

```
const
  Thousand: Integer = 1000;
```

When you declare a constant, the compiler can choose whether to assign a memory location to the constant, and save its value there, or to duplicate the actual value each time the constant is used. This second approach makes sense particularly for simple constants.

> Note: The 16-bit version of Delphi allows you to change the value of a typed constant at run-time, as if it was a variable. The 32-bit version still permits this behavior for backward compatibility when you enable the $J compiler directive, or use the corresponding Assignable typed constants check box of the Compiler page of the Project Options dialog box. Although this is the default, you are strongly advised not to use this trick as a general programming technique. Assigning a new value to a constant disables all the compiler optimizations on constants. In such a case, simply declare a variable, instead.

Resource String Constants

When you define a string constant, instead of writing:

```
const
  AuthorName = 'Marco Cantù';
```

starting with Delphi 3 you can write the following:

```
resourcestring
  AuthorName = 'Marco Cantù';
```

In both cases you are defining a constant; that is, a value you don't change during program execution. The difference is only in the implementation. A string constant defined with the resourcestring directive is stored in the resources of the program, in a string table.

To see this capability in action, you can look at the ResStr example, which has a button with the following code:

```
resourcestring
  AuthorName = 'Marco Cantù';
  BookName = 'Essential Pascal';

procedure TForm1.Button1Click(Sender: TObject);
begin
  ShowMessage (BookName + #13 + AuthorName);
end;
```

The output of the two strings appears on separate lines because the strings are separated by the newline character (indicated by its numerical value in the #13 character-type constant).

The interesting aspect of this program is that if you examine it with a resource explorer (there is one available among the examples that ship with Delphi) you'll see the new strings in the resources. This means that the strings are not part of the compiled code but stored in a separate area of the executable file (the EXE file).

> Note: In short, the advantage of resources is in an efficient memory handling performed by Windows and in the possibility of localizing a program (translating the strings to a different language) without having to modify its source code.

Data Types

In Pascal there are several predefined data types, which can be divided into three groups: ordinal types, real types, and strings. We'll discuss ordinal and real types in the following sections, while strings are covered later in this chapter. In this section I'll also introduce some types defined by the Delphi libraries (not predefined by the compiler), which can be considered predefined types.

Delphi also includes a non-typed data type, called variant, and discussed in Chapter 10 of this book. Strangely enough a variant is a type without proper type-checking. It was introduced in Delphi 2 to handle OLE Automation.

Ordinal Types

Ordinal types are based on the concept of order or sequence. Not only can you compare two values to see which is higher, but you can also ask for the value following or preceding a given value or compute the lowest or highest possible value.

The three most important predefined ordinal types are Integer, Boolean, and Char (character). However, there are a number of other related types that have the same meaning but a different internal representation and range of values. The following Table 3.1 lists the ordinal data types used for representing numbers.

Table 3.1: Ordinal data types for numbers

Size	Signed Range	Unsigned Range
8 bits	ShortInt -128 to 127	Byte 0 to 255
16 bits	SmallInt -32768 to 32767	Word 0 to 65,535
32 bits	LongInt -2,147,483,648 to 2,147,483,647	LongWord (since Delphi 4) 0 to 4,294,967,295
64 bits	Int64	
16/32 bits	Integer	Cardinal

As you can see, these types correspond to different representations of numbers, depending on the number of bits used to express the value, and the presence or absence of a sign bit. Signed values can be positive or negative, but have a smaller range of values, because one less bit is available for the value itself. You can refer to the Range example, discussed in the next section, for the actual range of values of each type.

The last group (marked as 16/32) indicates values having a different representation in the 16-bit and 32-bit versions of Delphi. Integer and Cardinal are frequently used, because they correspond to the native representation of numbers in the CPU.

Integral Types in Delphi 4

In Delphi 3, the 32-bit unsigned numbers indicated by the Cardinal type were actually 31-bit values, with a range up to 2 gigabytes. Delphi 4 introduced a new unsigned numeric type, LongWord, which uses a truly 32-bit value up to 4 gigabytes. The Cardinal type is now an alias of the new LongWord type. LongWord permits 2GB more data to be addressed by an unsigned number, as mentioned above. Moreover, it corresponds to the native representation of numbers in the CPU.

Another new type introduced in Delphi 4 is the Int64 type, which represents integer numbers with up to 18 digits. This new type is fully supported by some of the ordinal type routines (such as High and Low), numeric routines (such as Inc and Dec), and string-conversion routines (such as IntToStr). For the opposite conversion, from a string to a number, there are two new specific functions: StrToInt64 and StrToInt64Def.

Boolean

Boolean values other than the Boolean type are seldom used. Some Boolean values with specific representations are required by Windows API functions. The types are ByteBool, WordBool, and LongBool.

In Delphi 3 for compatibility with Visual Basic and OLE automation, the data types ByteBool, WordBool, and LongBool were modified to represent the value True with -1, while the value False is still 0. The Boolean data type remains unchanged (True is 1, False is 0). If you've used explicit typecasts in your Delphi 2 code, porting the code to later versions of Delphi might result in errors.

Characters

Finally there are two different representation for characters: ANSIChar and WideChar. The first type represents 8-bit characters, corresponding to the ANSI character set traditionally used by Windows; the second represents 16-bit characters, corresponding to the new Unicode characters supported by Windows NT, and only partially by Windows 95 and 98. Most of the time you'll simply use the Char type, which in Delphi 3 corresponds to ANSIChar. Keep in mind, anyway, that the first 256 Unicode characters correspond exactly to the ANSI characters.

Constant characters can be represented with their symbolic notation, as in 'k', or with a numeric notation, as in #78. The latter can also be expressed using the Chr function, as in Chr (78). The opposite conversion can be done with the Ord function.

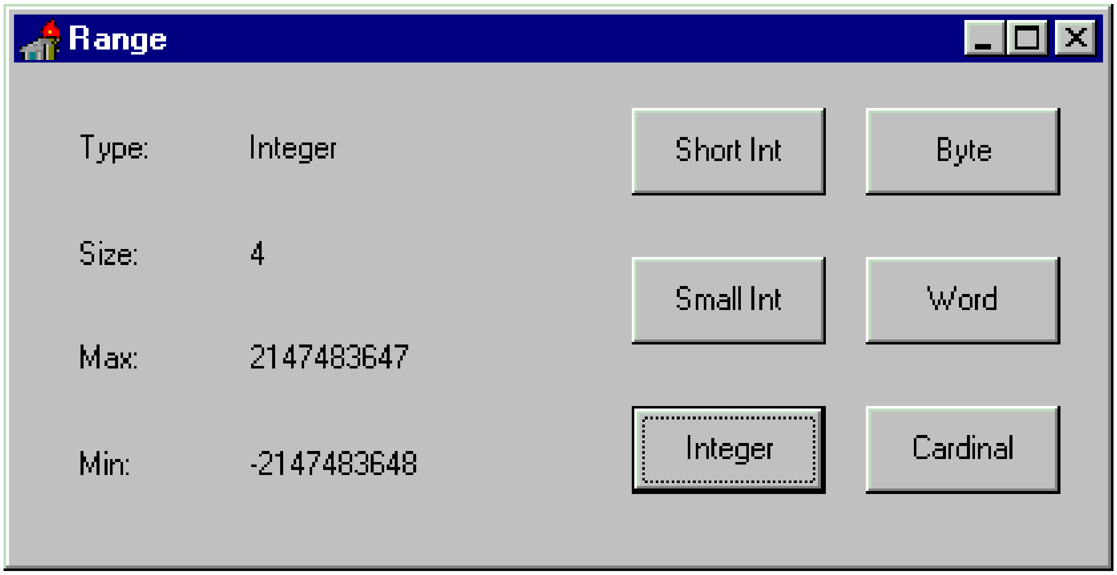
It is generally better to use the symbolic notation when indicating letters, digits, or symbols. When referring to special characters, instead, you'll generally use the numeric notation. The following list includes some of the most commonly used special characters:

- #9 tabulator
- #10 newline
- #13 carriage return (enter key)

The Range Example

To give you an idea of the different ranges of some of the ordinal types, I've written a simple Delphi program named Range. Some results are shown in Figure 3.1.

FIGURE 3.1: The Range example displays some information about ordinal data types (Integers in this case).



Type: Integer

Size: 4

Max: 2147483647

Min: -2147483648

The Range program is based on a simple form, which has six buttons (each named after an ordinal data type) and some labels for categories of information, as you can see in Figure 3.1. Some of the labels are used to hold static text, others to show the information about the type each time one of the buttons is pressed.

Every time you press one of the buttons on the right, the program updates the labels with the output. Different labels show the data type, number of bytes used, and the maximum and minimum values the data type can store. Each button has its own OnClick event-response method because the code used to compute the three values is slightly different from button to button. For example, here is the source code of the OnClick event for the Integer button (BtnInteger):

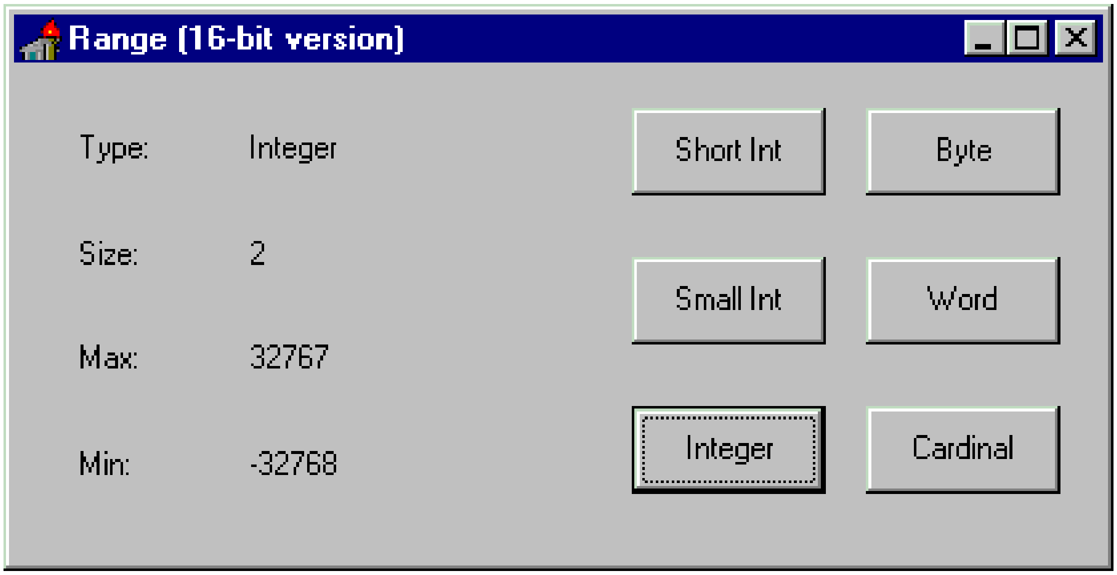
```
procedure TFormRange.BtnIntegerClick(Sender: TObject);
begin
  LabelType.Caption := 'Integer';
  LabelSize.Caption := IntToStr (SizeOf (Integer));
  LabelMax.Caption := IntToStr (High (Integer));
  LabelMin.Caption := IntToStr (Low (Integer));
end;
```

If you have some experience with Delphi programming, you can examine the source code of the program to understand how it works.

For beginners, it's enough to note the use of three functions: SizeOf, High, and Low. The results of the last two functions are ordinals of the same kind (in this case, integers), and the result of the SizeOf function is always an integer. The return value of each of these functions is first translated into strings using the IntToStr function, then copied to the captions of the three labels.

The methods associated with the other buttons are very similar to the one above. The only real difference is in the data type passed as a parameter to the various functions. Figure 3.2 shows the result of executing this same program under Windows 95 after it has been recompiled with the 16-bit version of Delphi. Comparing Figure 3.1 with Figure 3.2, you can see the difference between the 16-bit and 32-bit Integer data types.

FIGURE 3.2: The output of the 16-bit version of the Range example, again showing information about integers.



Range (16-bit version)

Type: Integer

Size: 2

Max: 32767

Min: -32768

The size of the Integer type varies depending on the CPU and operating system you are using. In 16-bit Windows, an Integer variable is two bytes wide. In 32-bit Windows, an Integer is four bytes wide. For this reason, when you recompile the Range example, you get a different output.

The two different representations of the Integer type are not a problem, as long as your program doesn't make any assumptions about the size of integers. If you happen to save an Integer to a file using one version and retrieve it with another, though, you're going to have some trouble. In this situation, you should choose a platform-independent data type (such as LongInt or SmallInt). For mathematical computation or generic code, your best bet is to stick with the standard integral representation for the specific platform--that is, use the Integer type--because this is what the CPU likes best. The Integer type should be your first choice when handling integer numbers. Use a different representation only when there is a compelling reason to do so.

Ordinal Types Routines

There are some system routines (routines defined in the Pascal language and in the Delphi system unit) that work on ordinal types. They are shown in Table 3.2. C++ programmers should notice that the two versions of the Inc procedure, with one or two parameters, correspond to the ++ and += operators (the same holds for the Dec procedure).

Table 3.2: System Routines for Ordinal Types

Routine	Purpose
Dec	Decrements the variable passed as parameter, by one or by the value of the optional second parameter.
Inc	Increments the variable passed as parameter, by one or by the specified value.

Odd	Returns True if the argument is an odd number.
Pred	Returns the value before the argument in the order determined by the data type, the predecessor.
Succ	Returns the value after the argument, the successor.
Ord	Returns a number indicating the order of the argument within the set of values of the data type.
Low	Returns the lowest value in the range of the ordinal type passed as its parameter.
High	Returns the highest value in the range of the ordinal data type.

Notice that some of these routines, when applied to constants, are automatically evaluated by the compiler and replaced by their value. For example if you call High(X) where X is defined as an Integer, the compiler can simply replace the expression with the highest possible value of the Integer data type.

Real Types

Real types represent floating-point numbers in various formats. The smallest storage size is given by Single numbers, which are implemented with a 4-byte value. Then there are Double floating-point numbers, implemented with 8 bytes, and Extended numbers, implemented with 10 bytes. These are all floating-point data types with different precision, which correspond to the IEEE standard floating-point representations, and are directly supported by the CPU numeric coprocessor, for maximum speed.

In Delphi 2 and Delphi 3 the Real type had the same definition as in the 16-bit version; it was a 48-bit type. But its usage was deprecated by Borland, which suggested that you use the Single, Double, and Extended types instead. The reason for their suggestion is that the old 6-byte format is neither supported by the Intel CPU nor listed among the official IEEE real types. To completely overcome the problem, Delphi 4 modifies the definition of the Real type to represent a standard 8-byte (64-bit) floating-point number.

In addition to the advantage of using a standard definition, this change allows components to publish properties based on the Real type, something Delphi 3 did not allow. Among the disadvantages there might be compatibility problems. If necessary, you can overcome the possibility of incompatibility by sticking to the Delphi 2 and 3 definition of the type; do this by using the following compiler option:

```
{$REALCOMPATIBILITY ON}
```

There are also two strange data types: Comp describes very big integers using 8 bytes (which can hold numbers with 18 decimal digits); and Currency (not available in 16-bit Delphi) indicates a fixed-point decimal value with four decimal digits, and the same 64-bit representation as the Comp type. As the name implies, the Currency data type has been added to handle very precise monetary values, with four decimal places.

We cannot build a program similar to the Range example with real data types, because we cannot use the High and Low functions or the Ord function on real-type variables. Real types represent (in theory) an infinite set of numbers; ordinal types represent a fixed set of values.

> Note: Let me explain this better. when you have the integer 23 you can determine which is the following value. Integers are finite (they have a determined range and they have an order). Floating point numbers are infinite even within a small range, and have no order: in fact, how many values are there between 23 and 24? And which number follows 23.46? It is 23.47, 23.461, or 23.4601? That's really hard to know!

For this reason, it makes sense to ask for the ordinal position of the character w in the range of the Char data type, but it makes no sense at all to ask the same question about 7143.1562 in the range of a floating-point data type. Although you can indeed know whether one real number has a higher value than another, it makes no sense to ask how many real numbers exist before a given number (this is the meaning of the Ord function).

Real types have a limited role in the user interface portion of the code (the Windows side), but they are fully supported by Delphi, including the database side. The support of IEEE standard floating-point types makes the Object Pascal language completely appropriate for the wide range of programs that require numerical computations. If you are interested in this aspect, you can look at the arithmetic functions provided by Delphi in the system unit (see the Delphi Help for more details).

Note: Delphi also has a Math unit that defines advanced mathematical routines, covering trigonometric functions (such as the ArcCosh function), finance (such as the InterestPayment function), and statistics (such as the MeanAndStdDev procedure). There are a number of these routines, some of which sound quite strange to me, such as the MomentSkewKurtosis procedure (I'll let you find out what this is).

Date and Time

Delphi uses real types also to handle date and time information. To be more precise Delphi defines a specific TDateTime data type. This is a floating-point type, because the type must be wide enough to store years, months, days, hours, minutes, and seconds, down to millisecond resolution in a single variable. Dates are stored as the number of days since 1899-12-30 (with negative values indicating dates before 1899) in the integer part of the TDateTime value. Times are stored as fractions of a day in the decimal part of the value.

TDateTime is not a predefined type the compiler understands, but it is defined in the system unit as:

```
type
  TDateTime = type Double;
```

Using the TDateTime type is quite easy, because Delphi includes a number of functions that operate on this type. You can find a list of these functions in Table 3.3.

Table 3.3: System Routines for the TDateTime Type

Routine	Description
Now	Returns the current date and time into a single TDateTime value.
Date	Returns only the current date.
Time	Returns only the current time.
DateTimeToStr	Converts a date and time value into a string, using default formatting; to have more control on the conversion use the FormatDateTime function instead.
DateTimeToString	Copies the date and time values into a string buffer, with default formatting.
DateToStr	Converts the date portion of a TDateTime value into a string.
TimeToStr	Converts the time portion of a TDateTime value into a string.
FormatDateTime	Formats a date and time using the specified format; you can specify which values you want to see and which format to use, providing a complex format string.
StrToDateTime	Converts a string with date and time information to a TDateTime value, raising an exception in case of an error in the format of the string.
StrToDate	Converts a string with a date value into the TDateTime format.
StrToTime	Converts a string with a time value into the TDateTime format.
DayOfWeek	Returns the number corresponding to the day of the week of the TDateTime value passed as parameter.

DecodeDate	Retrieves the year, month, and day values from a date value.
DecodeTime	Retrieves out of a time value.
EncodeDate	Turns year, month, and day values into a TDateTime value.
EncodeTime	Turns hour, minute, second, and millisecond values into a TDateTime value.

To show you how to use this data type and some of its related routines, I've built a simple example, named TimeNow. The main form of this example has a Button and a ListBox component. When the program starts it automatically computes and displays the current time and date. Every time the button is pressed, the program shows the time elapsed since the program started.

Here is the code related to the OnCreate event of the form:

```
procedure TFormTimeNow.FormCreate(Sender: TObject);
begin
  StartTime := Now;
  ListBox1.Items.Add (TimeToStr (StartTime));
  ListBox1.Items.Add (DateToStr (StartTime));
  ListBox1.Items.Add ('Press button for elapsed time');
end;
```

The first statement is a call to the Now function, which returns the current date and time. This value is stored in the StartTime variable, declared as a global variable as follows:

```
var
  FormTimeNow: TFormTimeNow;
  StartTime: TDateTime;
```

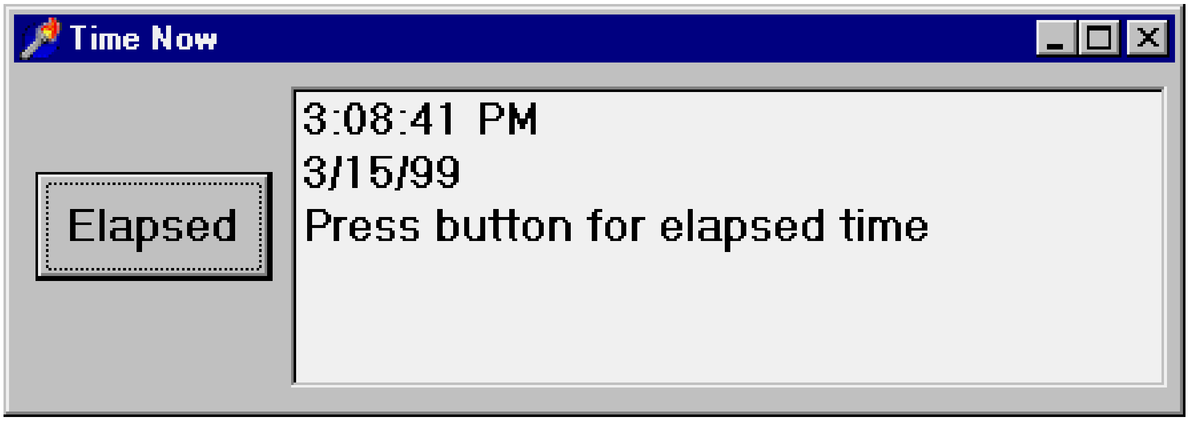
I've added only the second declaration, since the first is provided by Delphi. By default, it is the following:

```
var
  Form1: TForm1;
```

Changing the name of the form, this declaration is automatically updated. Using global variables is actually not the best approach: It should be better to use a private field of the form class, a topic related to object-oriented programming and discussed in Mastering Delphi 4.

The next three statements add three items to the ListBox component on the left of the form, with the result you can see in Figure 3.3. The first line contains the time portion of the TDateTime value converted into a string, the second the date portion of the same value. At the end the code adds a simple reminder.

FIGURE 3.3: The output of the TimeNow example at startup.



3:08:41 PM
3/15/99
Press button for elapsed time

This third string is replaced by the program when the user clicks on the Elapsed button:

```
procedure TFormTimeNow.ButtonElapsedClick(Sender: TObject);
var
  StopTime: TDateTime;
begin
  StopTime := Now;
  ListBox1.Items [2] :=  FormatDateTime ('hh:nn:ss',
    StopTime - StartTime);
end;
```

This code retrieves the new time and computes the difference from the time value stored when the program started. Because we need to use a value that we computed in a different event handler, we had to store it in a global variable. There are actually better alternatives, based on classes.

> **Note:** The code that replaces the current value of the third string uses the index 2. The reason is that the items of a list box are zero-based: the first item is number 0, the second number 1, and the third number 2. More on this as we cover arrays.

Besides calling TimeToStr and DateToStr you can use the more powerful FormatDateTime function, as I've done in the last method above (see the Delphi Help file for details on the formatting parameters). Notice also that time and date values are transformed into strings depending on Windows international settings. Delphi reads these values from the system, and copies them to a number of global constants declared in the SysUtils unit. Some of them are:

```
DateSeparator: Char;
ShortDateFormat: string;
LongDateFormat: string;
TimeSeparator: Char;
TimeAMString: string;
TimePMString: string;
ShortTimeFormat: string;
LongTimeFormat: string;
ShortMonthNames: array [1..12] of string;
LongMonthNames: array [1..12] of string;
ShortDayNames: array [1..7] of string;
LongDayNames: array [1..7] of string;
```

More global constants relate to currency and floating-point number formatting. You can find the complete list in the Delphi Help file under the topic Currency and date/time formatting variables.

> **Note:** Delphi includes a DateTimePicker component, which provides a sophisticated way to input a date, selecting it from a

calendar.

Specific Windows Types

The predefined data types we have seen so far are part of the Pascal language. Delphi also includes other data types defined by Windows. These data types are not an integral part of the language, but they are part of the Windows libraries. Windows types include new default types (such as DWORD or UINT), many records (or structures), several pointer types, and so on.

Among Windows data types, the most important type is represented by handles, discussed in Chapter 9.

Typecasting and Type Conversions

As we have seen, you cannot assign a variable to another one of a different type. In case you need to do this, there are two choices. The first choice is typecasting, which uses a simple functional notation, with the name of the destination data type:

```
var
  N: Integer;
  C: Char;
  B: Boolean;
begin
  N := Integer ('X');
  C := Char (N);
  B := Boolean (0);
```

You can typecast between data types having the same size. It is usually safe to typecast between ordinal types, or between real types, but you can also typecast between pointer types (and also objects) as long as you know what you are doing.

Casting, however, is generally a dangerous programming practice, because it allows you to access a value as if it represented something else. Since the internal representations of data types generally do not match, you risk hard-to-track errors. For this reason, you should generally avoid typecasting.

The second choice is to use a type-conversion routine. The routines for the various types of conversions are summarized in Table 3.4. Some of these routines work on the data types that we'll discuss in the following sections. Notice that the table doesn't include routines for special types (such as TDateTime or variant) or routines specifically intended for formatting, like the powerful Format and FormatFloat routines.

Table 3.4: System Routines for Type Conversion

Routine	Description
Chr	Converts an ordinal number into an ANSI character.
Ord	Converts an ordinal-type value into the number indicating its order.
Round	Converts a real-type value into an Integer-type value, rounding its value.
Trunc	Converts a real-type value into an Integer-type value, truncating its value.
Int	Returns the Integer part of the floating-point value argument.
IntToStr	Converts a number into a string.
IntToHex	Converts a number into a string with its hexadecimal representation.

StrToInt	Converts a string into a number, raising an exception if the string does not represent a valid integer.
StrToIntDef	Converts a string into a number, using a default value if the string is not correct.
Val	Converts a string into a number (traditional Turbo Pascal routine, available for compatibility).
Str	Converts a number into a string, using formatting parameters (traditional Turbo Pascal routine, available for compatibility).
StrPas	Converts a null-terminated string into a Pascal-style string. This conversion is automatically done for AnsiStrings in 32-bit Delphi. (See the section on strings later in this chapter.)
StrPCopy	Copies a Pascal-style string into a null-terminated string. This conversion is done with a simple PChar cast in 32-bit Delphi. (See the section on strings later in this chapter.)
StrPLCopy	Copies a portion of a Pascal-style string into a null-terminated string.
FloatToDecimal	Converts a floating-point value to record including its decimal representation (exponent, digits, sign).
FloatToStr	Converts the floating-point value to its string representation using default formatting.
FloatToStrF	Converts the floating-point value to its string representation using the specified formatting.
FloatToText	Copies the floating-point value to a string buffer, using the specified formatting.
FloatToTextFmt	As the previous routine, copies the floating-point value to a string buffer, using the specified formatting.
StrToFloat	Converts the given Pascal string to a floating-point value.
TextToFloat	Converts the given null-terminated string to a floating-point value.

NEW Note: In recent versions of Delphi's Pascal compiler, the Round function is based on the FPU processor of the CPU. This processor adopts the so-called "Banker's Rounding", which rounds middle values (as 5.5 or 6.5) up and down depending whether they follow an odd or an even number.

Conclusion

In this chapter we've explored the basic notion of type in Pascal. But the language has another very important feature: It allows programmers to define new custom data types, called user-defined data types. This is the topic of the next chapter.

Next Chapter: User-Defined Data Types

Marco Cantù's Essential Pascal

Chapter 4 User-Defined Data Types

Along with the notion of type, one of the great ideas introduced by the Pascal language is the ability to define new data types in a program. Programmers can define their own data types by means of type constructors, such as subrange types, array types, record types, enumerated types, pointer types, and set types. The most important user-defined data type is the class, which is part of the object-oriented extensions of Object Pascal, not covered in this book.

If you think that type constructors are common in many programming languages, you are right, but Pascal was the first language to introduce the idea in a formal and very precise way. There are still few languages with so many mechanisms to define new types.

Named and Unnamed Types

These types can be given a name for later use or applied to a variable directly. When you give a name to a type, you must provide a specific section in the code, such as the following:

```
type
  // subrange definition
  Uppercase = 'A'..'Z';

  // array definition
  Temperatures = array [1..24] of Integer;

  // record definition
  Date = record
    Month: Byte;
    Day: Byte;
    Year: Integer;
  end;

  // enumerated type definition
  Colors = (Red, Yellow, Green, Cyan, Blue, Violet);

  // set definition
  Letters = set of Char;
```

Similar type-definition constructs can be used directly to define a variable without an explicit type name, as in the following code:

```
var
  DecemberTemperature: array [1..31] of Byte;
  ColorCode: array [Red..Violet] of Word;
  Palette: set of Colors;
```

Note: In general, you should avoid using unnamed types as in the code above, because you cannot pass them as parameters to routines or declare other variables of the same type. The type compatibility rules of Pascal, in fact, are based on type names, not on the actual definition of the types. Two variables of two identical types are still not compatible, unless their types have exactly the same name, and unnamed types are given internal names by the compiler. Get used to defining a data type each time you need a variable with a complicated structure, and you won't regret the time you've spent in it.

But what do these type definitions mean? I'll provide some descriptions for those who are not familiar with Pascal type constructs. I'll also try to underline the differences from the same constructs in other programming languages, so you might be interested in reading the following sections even if you are familiar with kind of type definitions exemplified above. Finally, I'll show some Delphi examples and introduce some tools that will allow you to access type information dynamically.

Subrange Types

A subrange type defines a range of values within the range of another type (hence the name subrange). You can define a subrange of the Integer type, from 1 to 10 or from 100 to 1000, or you can define a subrange of the Char type, as in:

```
type
  Ten = 1..10;
  OverHundred = 100..1000;
  Uppercase = 'A'..'Z';
```

In the definition of a subrange, you don't need to specify the name of the base type. You just need to supply two constants of that type. The original type must be an ordinal type, and the resulting type will be another ordinal type.

When you have defined a subrange, you can legally assign it a value within that range. This code is valid:

```
var
  UppLetter: UpperCase;
begin
  UppLetter := 'F';
```

But this one is not:

```
var
  UppLetter: UpperCase;
begin
  UppLetter := 'e'; // compile-time error
```

Writing the code above results in a compile-time error, "Constant expression violates subrange bounds." If you write the following code instead:

```
var
  UppLetter: Uppercase;
  Letter: Char;
begin
  Letter :='e';
  UppLetter := Letter;
```

Delphi will compile it. At run-time, if you have enabled the Range Checking compiler option (in the Compiler page of the Project Options dialog box), you'll get a Range check error message.

Note: I suggest that you turn on this compiler option while you are developing a program, so it'll be more robust and easier to debug, as in case of errors you'll get an explicit message and not an undetermined behavior. You can eventually disable the option for the final build of the program, to make it a little faster. However, the difference is really small, and for this reason I suggest you to leave all these run-time checks turned on, even in a shipping program. The same holds true for other run-time checking options, such as overflow and stack checking.

Enumerated Types

Enumerated types constitute another user-defined ordinal type. Instead of indicating a range of an existing type, in an enumeration you list all of the possible values for the type. In other words, an enumeration is a list of values. Here are some examples:

```
type
  Colors = (Red, Yellow, Green, Cyan, Blue, Violet);
  Suit = (Club, Diamond, Heart, Spade);
```

Each value in the list has an associated ordinality, starting with zero. When you apply the Ord function to a value of an enumerated type, you get this zero-based value. For example, Ord (Diamond) returns 1.

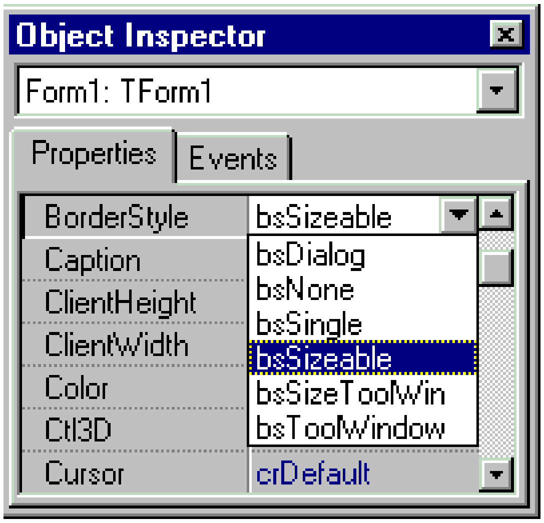
Note: Enumerated types can have different internal representations. By default, Delphi uses an 8-bit representation, unless there are more than 256 different values, in which case it uses the 16-bit representation. There is also a 32-bit representation, which might be useful for compatibility with C or C++ libraries. You can actually change the default behavior, asking for a larger representation, by using the $Z compiler directive.

The Delphi VCL (Visual Component Library) uses enumerated types in many places. For example, the style of the border of a form is defined as follows:

```
type
  TFormBorderStyle = (bsNone, bsSingle, bsSizeable,
    bsDialog, bsSizeToolWin, bsToolWindow);
```

When the value of a property is an enumeration, you usually can choose from the list of values displayed in the Object Inspector, as shown in Figure 4.1.

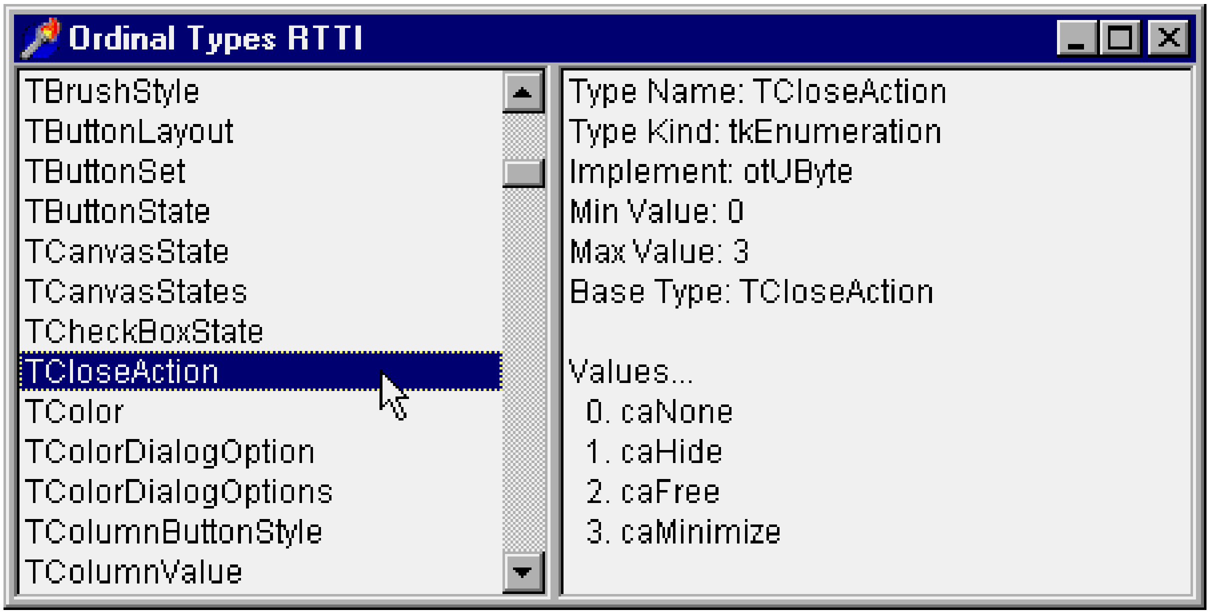
Figure 4.1: An enumerated type property in the Object Inspector



BorderStyle	bsSizeable
Caption	
ClientHeight	
ClientWidth	
Color	
Ctl3D	
Cursor	crDefault

The Delphi Help file generally lists the possible values of an enumeration. As an alternative you can use the OrdType program, available on www.marcocantu.com, to see the list of the values of each Delphi enumeration, set, subrange, and any other ordinal type. You can see an example of the output of this program in Figure 4.2.

Figure 4.2: Detailed information about an enumerated type, as displayed by the OrdType program (available on my web site).



```
Type Name: TCloseAction
Type Kind: tkEnumeration
Implement: otUByte
Min Value: 0
Max Value: 3
Base Type: TCloseAction

Values...
  0. caNone
  1. caHide
  2. caFree
  3. caMinimize
```

Set Types

Set types indicate a group of values, where the list of available values is indicated by the ordinal type the set is based onto. These ordinal types are usually limited, and quite often represented by an enumeration or a subrange. If we take the subrange 1..3, the possible values of the set based on it include only 1, only 2, only 3, both 1 and 2, both 1 and 3, both 2 and 3, all the three values, or none of them.

A variable usually holds one of the possible values of the range of its type. A set-type variable, instead, can contain none, one, two, three, or more values of the range. It can even include all of the values. Here is an example of a set:

```
type
```

```
  Letters = set of Uppercase;
```

Now I can define a variable of this type and assign to it some values of the original type. To indicate some values in a set, you write a comma-separated list, enclosed within square brackets. The following code shows the assignment to a variable of several values, a single value, and an empty value:

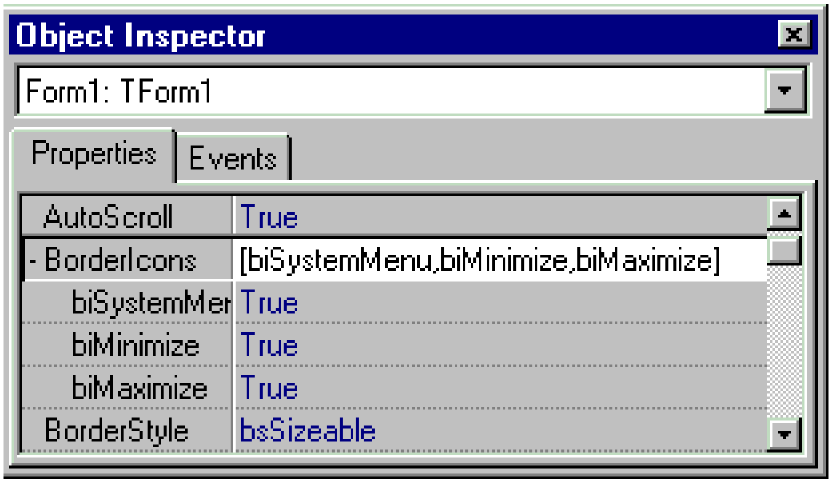
```
var
  Letters1, Letters2, Letters3: Letters;
begin
  Letters1 := ['A', 'B', 'C'];
  Letters2 := ['K'];
  Letters3 := [];
```

In Delphi, a set is generally used to indicate nonexclusive flags. For example, the following two lines of code (which are part of the Delphi library) declare an enumeration of possible icons for the border of a window and the corresponding set type:

```
type
  TBorderIcon = (biSystemMenu, biMinimize, biMaximize, biHelp);
  TBorderIcons = set of TBorderIcon;
```

In fact, a given window might have none of these icons, one of them, or more than one. When working with the Object Inspector (see Figure 4.3), you can provide the values of a set by expanding the selection (double-click on the property name or click on the plus sign on its left) and toggling on and off the presence of each value.

Figure 4.3: A set-type property in the Object Inspector



AutoScroll	True
- BorderIcons	[biSystemMenu,biMinimize,biMaximize]
biSystemMer	True
biMinimize	True
biMaximize	True
BorderStyle	bsSizeable

Another property based on a set type is the style of a font. Possible values indicate a bold, italic, underline, and strikethrough font. Of course the same font can be both italic and bold, have no attributes, or have them all. For this reason it is declared as a set. You can assign values to this set in the code of a program as follows:

```
Font.Style := []; // no style
Font.Style := [fsBold]; // bold style only
Font.Style := [fsBold, fsItalic]; // two styles
```

You can also operate on a set in many different ways, including adding two variables of the same set type (or, to be more precise, computing the union of the two set variables):

```
Font.Style := OldStyle + [fsUnderline]; // two sets
```

Again, you can use the OrdType examples included in the TOOLS directory of the book source code to see the list of possible values of many sets defined by the Delphi component library.

Array Types

Array types define lists of a fixed number of elements of a specific type. You generally use an index within square brackets to access to one of the elements of the array. The square brackets are used also to specify the possible values of the index when the array is defined. For example, you can define a group of 24 integers with this code:

```
type
  DayTemperatures = array [1..24] of Integer;
```

In the array definition, you need to pass a subrange type within square brackets, or define a new specific subrange type using two constants of an ordinal type. This subrange specifies the valid indexes of the array. Since you specify both the upper and the lower index of the array, the indexes don't need to be zero-based, as is necessary in C, C++, Java, and other programming languages.

Since the array indexes are based on subranges, Delphi can check for their range as we've already seen. An invalid constant subrange results in a compile-time error; and an out-of-range index used at run-time results in a run-time error if the corresponding compiler option is enabled.

Using the array definition above, you can set the value of a DayTemp1 variable of the DayTemperatures type as follows:

```
type
  DayTemperatures = array [1..24] of Integer;

var
  DayTemp1: DayTemperatures;

procedure AssignTemp;
begin
  DayTemp1 [1] := 54;
  DayTemp1 [2] := 52;
  ...
  DayTemp1 [24] := 66;
  DayTemp1 [25] := 67; // compile-time error
```

An array can have more than one dimension, as in the following examples:

```
type
  MonthTemps = array [1..24, 1..31] of Integer;
  YearTemps = array [1..24, 1..31, Jan..Dec] of Integer;
```

These two array types are built on the same core types. So you can declare them using the preceding data types, as in the following code:

```
type
  MonthTemps = array [1..31] of DayTemperatures;
  YearTemps = array [Jan..Dec] of MonthTemps;
```

This declaration inverts the order of the indexes as presented above, but it also allows assignment of whole blocks between variables. For example, the following statement copies January's temperatures to February:

```
var
  ThisYear: YearTemps;
begin
  ...
  ThisYear[Feb] := ThisYear[Jan];
```

You can also define a zero-based array, an array type with the lower bound set to zero. Generally, the use of more logical bounds is an advantage, since you don’t need to use the index 2 to access the third item, and so on. Windows, however, uses invariably zero-based arrays (because it is based on the C language), and the Delphi component library tends to do the same.

If you need to work on an array, you can always test its bounds by using the standard Low and High functions, which return the lower and upper bounds. Using Low and High when operating on an array is highly recommended, especially in loops, since it makes the code independent of the range of the array. Later, you can change the declared range of the array indices, and the code that uses Low and High will still work. If you write a loop hard-coding the range of an array you’ll have to update the code of the loop when the array size changes. Low and High make your code easier to maintain and more reliable.

Note: Incidentally, there is no run-time overhead for using Low and High with arrays. They are resolved at compile-time into constant expressions, not actual function calls. This compile-time resolution of expressions and function calls happens also for many other simple system functions.

Delphi uses arrays mainly in the form of array properties. We have already seen an example of such a property in the TimeNow example, to access the Items property of a ListBox component. I’ll show you some more examples of array properties in the next chapter, when discussing Delphi loops.

Note: Delphi 4 introduced dynamic arrays into Object Pascal , that is arrays that can be resized at runtime allocating the proper amount of memory. Using dynamic arrays is easy, but in this discussion of Pascal I felt they were not an proper topic to cover. You can find a description of Delphi's dynamic arrays in Chapter 8.

Record Types

Record types define fixed collections of items of different types. Each element, or field, has its own type. The definition of a record type lists all these fields, giving each a name you’ll use later to access it.

Here is a small listing with the definition of a record type, the declaration of a variable of that type, and few statements using this variable:

```
type
  Date = record
    Year: Integer;
    Month: Byte;
    Day: Byte;
  end;

var
  BirthDay: Date;

begin
  BirthDay.Year := 1997;
  BirthDay.Month := 2;
  BirthDay.Day := 14;
```

Classes and objects can be considered an extension of the record type. Delphi libraries tend to use class types instead of record types, but there are many record types defined by the Windows API.

Record types can also have a variant part; that is, multiple fields can be mapped to the same memory area, even if they have a different data type. (This corresponds to a union in the C language.) Alternatively, you can use these variant fields or groups of fields to access the same memory location within a record, but considering those values from different perspectives. The main uses of this type were to store similar but different data and to obtain an effect similar to that of typecasting (something less useful now that typecasting has been introduced also in Pascal). The use of variant record types has been largely replaced by object-oriented and other modern techniques, although Delphi uses them in some peculiar cases.

The use of a variant record type is not type-safe and is not a recommended programming practice, particularly for beginners. Expert programmers can indeed use variant record types, and the core of the Delphi libraries makes use of them. You won't need to tackle them until you are really a Delphi expert, anyway.

Pointers

A pointer type defines a variable that holds the memory address of another variable of a given data type (or an undefined type). So a pointer variable indirectly refers to a value. The definition of a pointer type is not based on a specific keyword, but uses a special character instead. This special symbol is the caret (^):

```
type
  PointerToInt = ^Integer;
```

Once you have defined a pointer variable, you can assign to it the address of another variable of the same type, using the @ operator:

```
var
  P: ^Integer;
  X: Integer;
begin
  P := @X;
  // change the value in two different ways
  X := 10;
  P^ := 20;
```

When you have a pointer P, with the expression P you refer to the address of the memory location the pointer is referring to, and with the expression P^ you refer to the actual content of that memory location. For this reason in the code fragment above ^P corresponds to X.

Instead of referring to an existing memory location, a pointer can refer to a new memory block dynamically allocated (on the heap memory area) with the New procedure. In this case, when you don't need the pointer any more, you'll also have to to get rid of the memory you've dynamically allocated, by calling the Dispose procedure.

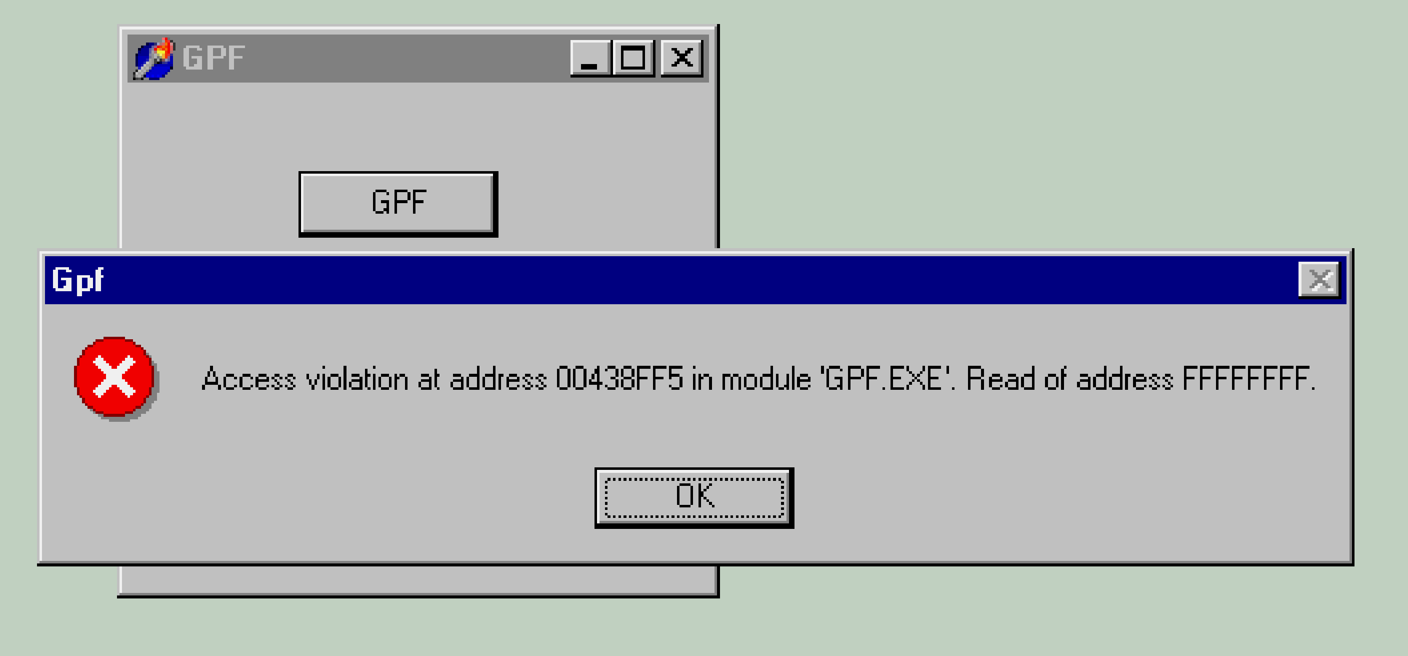
```
var
  P: ^Integer;
begin
  // initialization
  New (P);
  // operations
  P^ := 20;
  ShowMessage (IntToStr (P^));
  // termination
  Dispose (P);
end;
```

If a pointer has no value, you can assign the nil value to it. Then you can test whether a pointer is nil to see if it currently refers to a value. This is often used, because dereferencing an invalid pointer causes an access violation (also known as a general protection fault, GPF):

```
procedure TFormGPF.BtnGpfClick(Sender: TObject);
var
  P: ^Integer;
begin
  P := nil;
  ShowMessage (IntToStr (P^));
end;
```

You can see an example of the effect of this code by running the GPF example (or looking at the corresponding Figure 4.4). The example contains also the code fragments shown above.

Figure 4.4: The system error resulting from the access to a nil pointer, from the GPF example.



Access violation at address 00438FF5 in module 'GPF.EXE'. Read of address FFFFFFFF.

In the same program you can find an example of safe data access. In this second case the pointer is assigned to an existing local variable, and can be safely used, but I've added a safe-check anyway:

```
procedure TFormGPF.BtnSafeClick(Sender: TObject);
var
  P: ^Integer;
  X: Integer;
begin
  P := @X;
  X := 100;
  if P <> nil then
    ShowMessage (IntToStr (P^));
end;
```

Delphi also defines a Pointer data type, which indicates untyped pointers (such as void* in the C language). If you use an untyped pointer you should use GetMem instead of New. The GetMem procedure is required each time the size of the memory variable to allocate is not defined.

The fact that pointers are seldom necessary in Delphi is an interesting advantage of this environment. Nonetheless, understanding pointers is important for advanced programming and for a full understanding of the Delphi object model, which uses pointers "behind the scenes."

> Note: Although you don't use pointers often in Delphi, you do frequently use a very similar construct—namely, references. Every object instance is really an implicit pointer or reference to its actual data. However, this is completely transparent to the programmer, who uses object variables just like any other data type.

File Types

Another Pascal-specific type constructor is the file type. File types represent physical disk files, certainly a peculiarity of the Pascal language. You can define a new file data type as follows:

```
type
  IntFile = file of Integer;
```

Then you can open a physical file associated with this structure and write integer values to it or read the current values from the file.

> **Author's Note**: Files-based examples were part of older editions of Mastering Delphi and I plan adding them here as well)

The use of files in Pascal is quite straightforward, but in Delphi there are also some components that are capable of storing or loading their contents to or from a file. There is some serialization support, in the form of streams, and there is also database support.

Conclusion

This chapter discussing user-defined data types complete our coverage of Pascal type system. Now we are ready to look into the statements the language provides to operate on the variables we've defined.

Next Chapter: Statements

Marco Cantù's Essential Pascal

Chapter 5 Statements

If the data types are one of the foundations of Pascal programming the other are statements. Statements of the programming language are based on keywords and other elements which allow you to indicate to a program a sequence of operations to perform. Statements are often enclosed in procedures or functions, as we'll see in the next chapter. Now we'll just focus on the basic types of commands you can use to create a program.

Simple and Compound Statements

A Pascal statement is simple when it doesn't contain any other statements. Examples of simple statements are assignment statements and procedure calls. Simple statements are separated by a semicolon:

```
X := Y + Z;  // assignment
Randomize;   // procedure call
```

Usually, statements are part of a compound statement, marked by begin and end brackets. A compound statement can appear in place of a generic Pascal statement. Here is an example:

```
begin
  A := B;
  C := A * 2;
end;
```

The semicolon after the last statement before the end isn't required, as in the following:

```
begin
  A := B;
  C := A * 2
end;
```

Both versions are correct. The first version has a useless (but harmless) semicolon. This semicolon is, in fact, a null statement; that is, a statement with no code. Notice that, at times, null statements can be used inside loops or in other particular cases.

Note: Although these final semicolons serve no purpose, I tend to use them and suggest you do the same. Sometimes after you've written a couple of lines you might want to add one more statement. If the last semicolon is missing you should remember to add it, so it might be better to add it in the first place.

Assignment Statements

Assignments in Pascal use the colon-equal operator, an odd notation for programmers who are used to other languages. The = operator, which is used for assignments in some other languages, in Pascal is used to test for equality.

Note: By using different symbols for an assignment and an equality test, the Pascal compiler (like the C compiler) can translate source code faster, because it doesn't need to examine the context in which the operator is used to determine its meaning. The use of different operators also makes the code easier for people to read.

Conditional Statements

A conditional statement is used to execute either one of the statements it contains or none of them, depending on some test. There are two basic flavors of conditional statements: if statements and case statements.

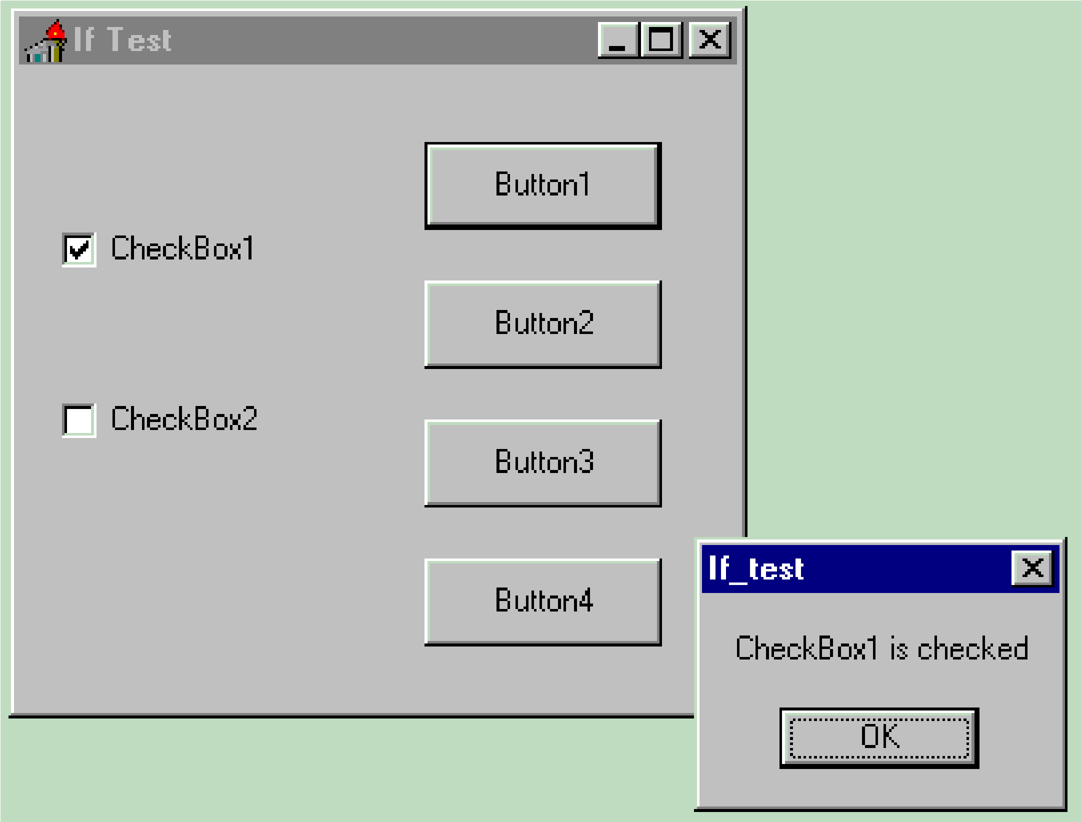
If Statements

The if statement can be used to execute a statement only if a certain condition is met (if-then), or to choose between two different alternatives (if-then-else). The condition is described with a Boolean expression. A simple Delphi example will demonstrate how to write conditional statements. First create a new application, and put two check boxes and four buttons in the form. Do not change the names of buttons or check boxes, but double-click on each button to add a handler for its OnClick event. Here is a simple if statement for the first button:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  // simple if statement
  if CheckBox1.Checked then
    ShowMessage ('CheckBox1 is checked')
end;
```

When you click on the button, if the first check box has a check mark in it, the program will show a simple message (see Figure 5.1). I've used the ShowMessage function because it is the simplest Delphi function you can use to display a short message to the user.

Figure 5.1: The message displayed by the IfTest example when you press the first button and the first check box is checked.



If you click the button and nothing happens, it means the check box was not checked. In a case like this, it would probably be better to make this more explicit, as with the code for the second button, which uses an if-then-else statement:

```
procedure TForm1.Button2Click(Sender: TObject);
begin
  // if-then-else statement
  if CheckBox2.Checked then
    ShowMessage ('CheckBox2 is checked')
  else
    ShowMessage ('CheckBox2 is NOT checked');
end;
```

Notice that you cannot have a semicolon after the first statement and before the else keyword, or the compiler will issue a syntax error. The if-then-else statement, in fact, is a single statement, so you cannot place a semicolon in the middle of it.

An if statement can be quite complex. The condition can be turned into a series of conditions (using the and, or and not Boolean operators), or the if statement can nest a second if statement. The last two buttons of the IfTest example demonstrate these cases:

```
procedure TForm1.Button3Click(Sender: TObject);
begin
  // statement with a double condition
  if CheckBox1.Checked and CheckBox2.Checked then
    ShowMessage ('Both check boxes are checked')
end;

procedure TForm1.Button4Click(Sender: TObject);
begin
  // compound if statement
  if CheckBox1.Checked then
    if CheckBox2.Checked then
      ShowMessage ('CheckBox1 and 2 are checked')
    else
      ShowMessage ('Only CheckBox1 is checked')
  else
    ShowMessage (
      'Checkbox1 is not checked, who cares for Checkbox2?')
end;
```

Look at the code carefully and run the program to see if you understand everything. When you have doubts about a programming construct, writing a very simple program such as this can help you learn a lot. You can add more check boxes and increase the complexity of this small example, making any test you like.

Case Statements

If your if statements become very complex, at times you can replace them with case statements. A case statement consists in an expression used to select a value, a list of possible values, or a range of values. These values are constants, and they must be unique and of an ordinal type. Eventually, there can be an else statement that is executed if none of the labels correspond to the value of the selector. Here are two simple examples:

```
case Number of
  1: Text := 'One';
  2: Text := 'Two';
  3: Text := 'Three';
end;

case MyChar of
  '+' : Text := 'Plus sign';
  '-' : Text := 'Minus sign';
  '*', '/': Text := 'Multiplication or division';
  '0'..'9': Text := 'Number';
  'a'..'z': Text := 'Lowercase character';
  'A'..'Z': Text := 'Uppercase character';
else
  Text := 'Unknown character';
end;
```

Loops in Pascal

The Pascal language has the typical repetitive statements of most programming languages, including for, while, and repeat statements. Most of what these loops do will be familiar if you've used other programming languages, so I'll cover them only briefly.

The For Loop

The for loop in Pascal is strictly based on a counter, which can be either increased or decreased each time the loop is executed. Here is a simple example of a for loop used to add the first ten numbers.

```
var
  K, I: Integer;
begin
  K := 0;
  for I := 1 to 10 do
    K := K + I;
```

This same for statement could have been written using a reverse counter:

```
var
  K, I: Integer;
begin
  K := 0;
  for I := 10 downto 1 do
    K := K + I;
```

The for loop in Pascal is less flexible than in other languages (it is not possible to specify an increment different than one), but it is simple and easy to understand. If you want to test for a more complex condition, or to provide a customized counter, you need to use a while or repeat statement, instead of a for loop.

Note: The counter of a for loop doesn't need to be a number. It can be a value of any ordinal type, such as a character or an enumerated type.

While and Repeat Statements

The difference between the while-do loop and the repeat-until loop is that the code of the repeat statement is always executed at least once. You can easily understand why by looking at a simple example:

```
while (I <= 100) and (J <= 100) do
begin
  // use I and J to compute something...
  I := I + 1;
  J := J + 1;
end;

repeat
  // use I and J to compute something...
  I := I + 1;
  J := J + 1;
until (I > 100) or (J > 100);
```

If the initial value of I or J is greater than 100, the statements inside the repeat-until loop are executed once anyway.

The other key difference between these two loops is that the repeat-until loop has a reversed condition. The loop is executed as long as the condition is not met. When the condition is met, the loop terminates. This is the opposite from a while-do loop, which is executed while the condition is true. For this reason I had to reverse the condition in the code above to obtain a similar statement.

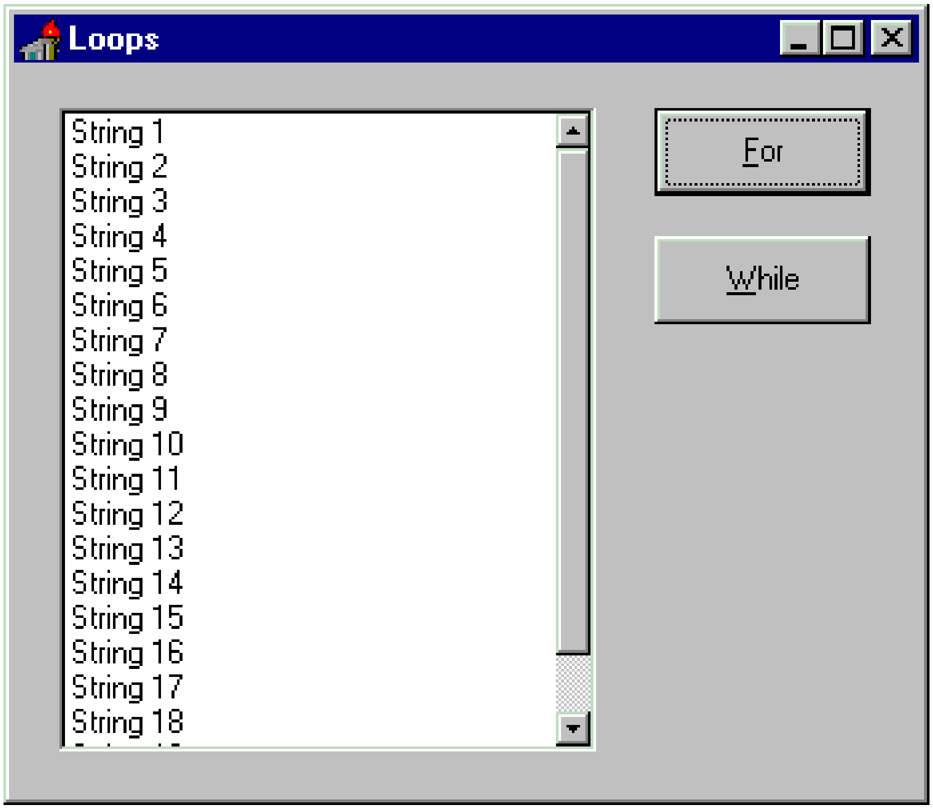
An Example of Loops

To explore the details of loops, let's look at a small Delphi example. The Loops program highlights the difference between a loop with a fixed counter and a loop with an almost random counter. Start with a new blank project, place a list box and two buttons on the main form, and give the buttons a proper name (BtnFor and BtnWhile) by setting their Name property in the Object Inspector. You can also remove the word Btn from the Caption property (and eventually even add the & character to it to activate the following letter as a shortcut key). Here is a summary of the textual description of this form:

```
object Form1: TForm1
  Caption = 'Loops'
  object ListBox1: TListBox ...
  object BtnFor: TButton
```

```
    Caption = '&For'
    OnClick = BtnForClick
  end
  object BtnWhile: TButton
    Caption = '&While'
    OnClick = BtnWhileClick
  end
end
```

Figure 5.2: Each time you press the For button of the Loops example, the list box is filled with consecutive numbers.



```
String 1
String 2
String 3
String 4
String 5
String 6
String 7
String 8
String 9
String 10
String 11
String 12
String 13
String 14
String 15
String 16
String 17
String 18
```

Now we can add some code to the OnClick events of the two buttons. The first button has a simple for loop to display a list of numbers, as you can see in Figure 5.2. Before executing this loop, which adds a number of strings to the Items property of the list box, you need to clear the contents of the list box itself:

```
procedure TForm1.BtnForClick(Sender: TObject);
var
  I: Integer;
begin
  ListBox1.Items.Clear;
  for I := 1 to 20 do
    Listbox1.Items.Add ('String ' + IntToStr (I));
end;
```

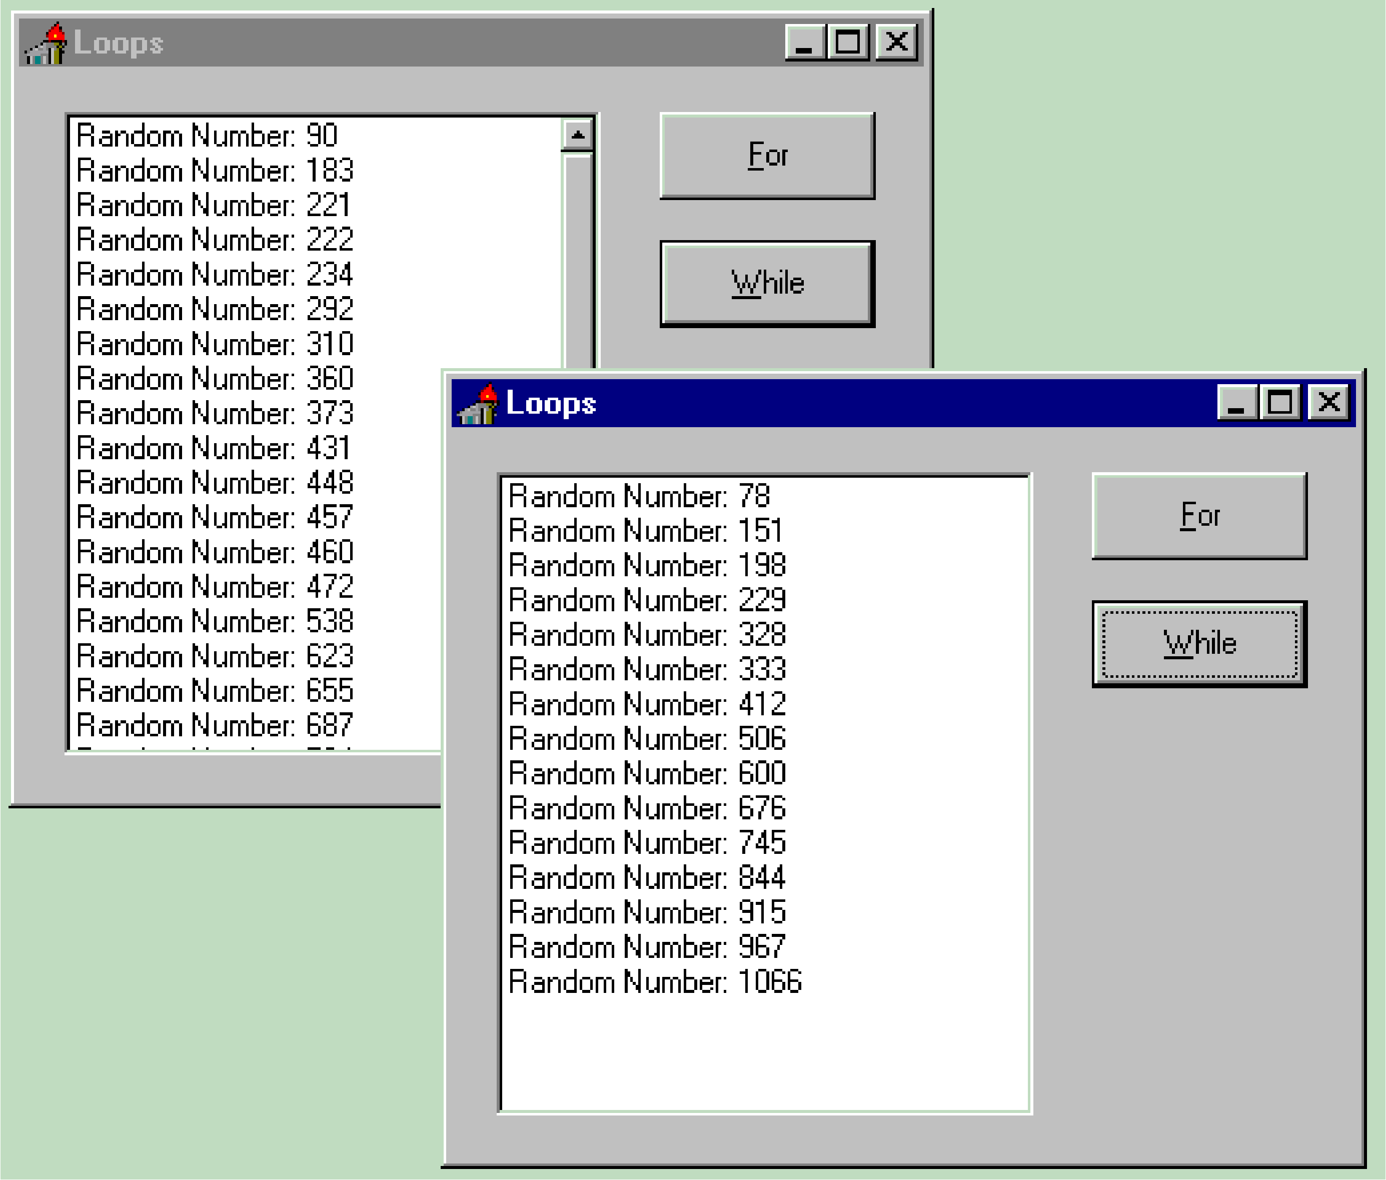
The code associated with the second button is slightly more complex. In this case, there is a while loop based on a counter, which is increased randomly. To accomplish this, I've called the Randomize procedure, which resets the random number generator, and the Random function with a range value of 100. The result of this function is a number between 0 and 99, chosen randomly. The series of random numbers control how many times the while loop is executed.

```
procedure TForm1.BtnWhileClick(Sender: TObject);
var
```

```
  I: Integer;
begin
  ListBox1.Items.Clear;
  Randomize;
  I := 0;
  while I < 1000 do
  begin
    I := I + Random (100);
    Listbox1.Items.Add ('Random Number: ' + IntToStr (I));
  end;
end;
```

Each time you click the While button, the numbers are different, because they depend on the random-number generator. Figure 5.3 shows the results from two separate button-clicks. Notice that not only are the generated numbers different each time, but so is the number of items. That is, this while loop is executed a random numbers of times. If you press the While button several times in a row, you'll see that the list box has a different number of lines.

Figure 5.3: The contents of the list box of the Loops example change each time you press the While button. Because the loop counter is incremented by a random value, every time you press the button the loop may execute a different number of times.



```
Random Number: 90
Random Number: 183
Random Number: 221
Random Number: 222
Random Number: 234
Random Number: 292
Random Number: 310
Random Number: 360
Random Number: 373
Random Number: 431
Random Number: 448
Random Number: 457
Random Number: 460
Random Number: 472
Random Number: 538
Random Number: 623
Random Number: 655
Random Number: 687
```

```
Random Number: 78
Random Number: 151
Random Number: 198
Random Number: 229
Random Number: 328
Random Number: 333
Random Number: 412
Random Number: 506
Random Number: 600
Random Number: 676
Random Number: 745
Random Number: 844
Random Number: 915
Random Number: 967
Random Number: 1066
```

Note: You can alter the standard flow of a loop's execution using the Break and Continue system procedures. The first interrupts the loop; the second is used to jump directly to the loop test or counter increment, continuing with the next iteration of the loop (unless the condition is zero or the counter has reached its highest value). Two more system procedures, Exit and Halt, let you immediately return from the current function or procedure or terminate the program.

The With Statement

The last kind of Pascal statement I'll focus on is the with statement, which used to be peculiar to this programming language (although it has been recentrly introduced also in JavaScript and Visual Basic) and can be very useful in Delphi programming.

The with statement is nothing but shorthand. When you need to refer to a record type variable (or an object), instead of repeating its name every time, you can use a with statement. For example, while presenting the record type, I wrote this code:

```
type
  Date = record
    Year: Integer;
    Month: Byte;
    Day: Byte;
  end;

var
  BirthDay: Date;

begin
  BirthDay.Year := 1997;
  BirthDay.Month := 2;
  BirthDay.Day := 14;
```

Using a with statement, I can improve the final part of this code, as follows:

```
begin
  with BirthDay do
  begin
    Year := 1995;
    Month := 2;
    Day := 14;
  end;
```

This approach can be used in Delphi programs to refer to components and other class types. For example, we can rewrite the final part of the last example, Loops, using a with statement to access the items of the list box:

```
procedure TForm1.WhileButtonClick(Sender: TObject);
var
  I: Integer;
begin
  with ListBox1.Items do
  begin
    Clear; // shortcut
    Randomize;
    I := 0;
    while I < 1000 do
    begin
      I := I + Random (100);
      // shortcut:
```

```
      Add ('Random Number: ' + IntToStr (I));
    end;
  end;
end;
```

When you work with components or classes in general, the with statement allows you to skip writing some code, particularly for nested fields. For example, suppose that you need to change the Width and the Color of the drawing pen for a form. You can write the following code:

```
Form1.Canvas.Pen.Width := 2;
Form1.Canvas.Pen.Color := clRed;
```

But it is certainly easier to write this code:

```
with Form1.Canvas.Pen do
begin
  Width := 2;
  Color := clRed;
end;
```

When you are writing complex code, the with statement can be effective and spares you the declaration of some temporary variables, but it has a drawback. It can make the code less readable, particularly when you are working with different objects that have similar or corresponding properties.

A further drawback is that using the with statement can allow subtle logical errors in the code that the compiler will not detect. For example:

```
with Button1 do
begin
  Width := 200;
  Caption := 'New Caption';
  Color := clRed;
end;
```

This code changes the Caption and the Width of the button, but it affects the Color property of the form, not that of the button! The reason is that the TButton components don't have the Color property, and since the code is executed for a form object (we are writing a method of the form) this object is accessed by default. If we had instead written:

```
Button1.Width := 200;
Button1.Caption := 'New Caption';
Button1.Color := clRed; // error!
```

the compiler would have issued an error. In general, we can say that since the with statement introduces new identifiers in the current scope, we might hide existing identifiers, or wrongfully access another identifier in the same scope (as in the first version of this code fragment). Even considering this kind of drawback, I suggest you get used to with statements, because they can be really very handy, and at times even make the code more readable.

You should, however, avoid using multiple with statements, such as:

```
with ListBox1, Button1 do...
```

The code following this would probably be highly unreadable, because for each property defined in this block you would need to think about which component it refers to, depending on the respective properties and the order of the components in the with statement.

Note: Speaking of readability, Pascal has no endif or endcase statement. If an if statement has a begin-end block, then the end of the block marks the end of the statement. The case statement, instead, is always terminated by an end. All these end statements, often found one after the other, can make the code difficult to follow. Only by tracing the indentations can you see which statement a particular end refers to. A common way to solve this problem and make the code more readable is to add a comment after the end statement indicating its role, as in:

```
if ... then
 ...
end; // if
```

Conclusion

This chapter has described how to code conditional statements and loops. Instead of writing long lists of such statements, programs are usually split in routines, procedures or functions. This is the topic of the next chapter, which introduces also some advanced elements of Pascal.

Next Chapter: Procedures

Marco Cantù's Essential Pascal

Chapter 6 Procedures and Functions

Another important idea emphasized by Pascal is the concept of the routine, basically a series of statements with a unique name, which can be activated many times by using their name. This way you avoid repeating the same statements over and over, and having a single version of the code you can easily modify it all over the program. From this point of view, you can think of routines as the basic code encapsulation mechanism. I'll get back to this topic with an example after I introduce the Pascal routines syntax.

Pascal Procedures and Functions

In Pascal, a routine can assume two forms: a procedure and a function. In theory, a procedure is an operation you ask the computer to perform, a function is a computation returning a value. This difference is emphasized by the fact that a function has a result, a return value, while a procedure doesn't. Both types of routines can have multiple parameters, of given data types.

In practice, however, the difference between functions and procedures is very limited: you can call a function to perform some work and then skip the result (which might be an optional error code or something like that) or you can call a procedure which passes a result within its parameters (more on reference parameters later in this chapter).

Here are the definitions of a procedure and two versions of the same function, using a slightly different syntax:

```
procedure Hello;
begin
  ShowMessage ('Hello world!');
end;

function Double (Value: Integer) : Integer;
begin
  Double := Value * 2;
end;

// or, as an alternative
function Double2 (Value: Integer) : Integer;
begin
  Result := Value * 2;
end;
```

The use of Result instead of the function name to assign the return value of a function is becoming quite popular, and tends to make the code more readable, in my opinion.

Once these routines have been defined, you can call them one or more times. You call the procedure to make it perform its task, and call a function to compute the value:

```
procedure TForm1.Button1Click (Sender: TObject);
begin
```

```
  Hello;
end;

procedure TForm1.Button2Click (Sender: TObject);
var
  X, Y: Integer;
begin
  X := Double (StrToInt (Edit1.Text));
  Y := Double (X);
  ShowMessage (IntToStr (Y));
end;
```

Note: For the moment don't care about the syntax of the two procedures above, which are actually methods. Simply place two buttons on a Delphi form, click on them at design time, and the Delphi IDE will generate the proper support code: Now you simply have to fill in the lines between begin and end. To compile the code above you need to add also an Edit control to the form.

Now we can get back to the encapsulation code concept I've introduced before. When you call the Double function, you don't need to know the algorithm used to implement it. If you later find out a better way to double numbers, you can easily change the code of the function, but the calling code will remain unchanged (although executing it will be faster!). The same principle can be applied to the Hello procedure: We can modify the program output by changing the code of this procedure, and the Button2Click method will automatically change its effect. Here is how we can change the code:

```
procedure Hello;
begin
  MessageDlg ('Hello world!', mtInformation, [mbOK]);
end;
```

Tip: When you call an existing Delphi function or procedure, or any VCL method, you should remember the number and type of the parameters. Delphi editor helps you by suggesting the parameters list of a function or procedure with a fly-by hint as soon as you type its name and the open parenthesis. This feature is called Code Parameters and is part of the Code Insight technology.

Reference Parameters

Pascal routines allow parameter passing by value and by reference. Passing parameters by value is the default: the value is copied on the stack and the routine uses and manipulates the copy, not the original value.

Passing a parameter by reference means that its value is not copied onto the stack in the formal parameter of the routine (avoiding a copy often means that the program executes faster). Instead, the program refers to the original value, also in the code of the routine. This allows the procedure or function to change the value of the parameter. Parameter passing by reference is expressed by the var keyword.

This technique is available in most programming languages. It isn't present in C, but has been introduced in C++, where you use the & (pass by reference) symbol. In Visual Basic every parameter not specified as ByVal is passed by reference.

Here is an example of passing a parameter by reference using the var keyword:

```
procedure DoubleTheValue (var Value: Integer);
begin
  Value := Value * 2;
end;
```

In this case, the parameter is used both to pass a value to the procedure and to return a new value to the calling code. When you write:

```
var
  X: Integer;
begin
  X := 10;
  DoubleTheValue (X);
```

the value of the X variable becomes 20, because the function uses a reference to the original memory location of X, affecting its initial value.

Passing parameters by reference makes sense for ordinal types, for old-fashioned strings, and for large records. Delphi objects, in fact, are invariably passed by value, because they are references themselves. For this reason passing an object by reference makes little sense (apart from very special cases), because it corresponds to passing a "reference to a reference."

Delphi long strings have a slightly different behavior: they behave as references, but if you change one of the string variables referring to the same string in memory, this is copied before updating it. A long string passed as a value parameter behaves as a reference only in terms of memory usage and speed of the operation. But if you modify the value of the string, the original value is not affected. On the contrary, if you pass the long string by reference, you can alter the original value.

Delphi 3 introduced a new kind of parameter, out. An out parameter has no initial value and is used only to return a value. These parameters should be used only for COM procedures and functions; in general, it is better to stick with the more efficient var parameters. Except for not having an initial value, out parameters behave like var parameters.

Constant Parameters

As an alternative to reference parameters, you can use a const parameter. Since you cannot assign a new value to a constant parameter inside the routine, the compiler can optimize parameter passing. The compiler can choose an approach similar to reference parameters (or a const reference in C++ terms), but the behavior will remain similar to value parameters, because the original value won't be affected by the routine.

In fact, if you try to compile the following (silly) code, Delphi will issue an error:

```
function DoubleTheValue (const Value: Integer): Integer;
begin
  Value := Value * 2;      // compiler error
  Result := Value;
end;
```

Open Array Parameters

Unlike C, a Pascal function or procedure always has a fixed number of parameters. However, there is a way to pass a varying number of parameters to a routine using an open array.

The basic definition of an open array parameter is that of a typed open array. This means you indicate the type of the parameter but do not know how many elements of that type the array is going to have. Here is an example of such a definition:

```
function Sum (const A: array of Integer): Integer;
var
  I: Integer;
begin
  Result := 0;
  for I := Low(A) to High(A) do
    Result := Result + A[I];
end;
```

Using High(A) we can get the size of the array. Notice also the use of the return value of the function, Result, to store temporary values. You can call this function by passing to it an array of Integer expressions:

```
X := Sum ([10, Y, 27*I]);
```

Given an array of Integers, of any size, you can pass it directly to a routine requiring an open array parameter or, instead, you can call the Slice function to pass only a portion of the array (as indicated by its second parameter). Here is an example, where the complete array is passed as parameter:

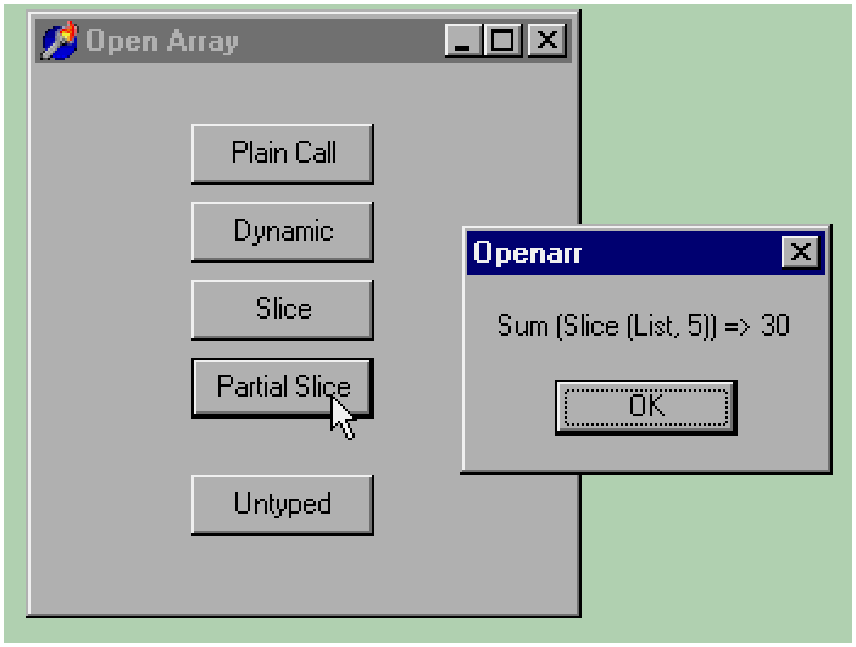
```
var
  List: array [1..10] of Integer;
  X, I: Integer;
begin
  // initialize the array
  for I := Low (List) to High (List) do
    List [I] := I * 2;
  // call
  X := Sum (List);
```

If you want to pass only a portion of the array to the Slice function, simply call it this way:

```
X := Sum (Slice (List, 5));
```

You can find all the code fragments presented in this section in the OpenArr example (see Figure 6.1, later on, for the form).

Figure 6.1: The OpenArr example when the Partial Slice button is pressed



Sum (Slice (List, 5)) => 30

> Typed open arrays in Delphi 4 are fully compatible with dynamic arrays (introduced in Delphi 4 and covered in Chapter 8). Dynamic arrays use the same syntax as open arrays, with the difference that you can use a notation such as array of Integer to declare a variable, not just to pass a parameter.

Type-Variant Open Array Parameters

Besides these typed open arrays, Delphi allows you to define type-variant or untyped open arrays. This special kind of array has an undefined number of values, which can be handy for passing parameters.

Technically, the construct array of const allows you to pass an array with an undefined number of elements of different types to a routine at once. For example, here is the definition of the Format function (we'll see how to use this function in **Chapter 7**, covering strings):

```
function Format (const Format: string;
  const Args: array of const): string;
```

The second parameter is an open array, which gets an undefined number of values. In fact, you can call this function in the following ways:

```
N := 20;
S := 'Total:';
Label1.Caption := Format ('Total: %d', [N]);
Label2.Caption := Format ('Int: %d, Float: %f', [N, 12.4]);
Label3.Caption := Format ('%s %d', [S, N * 2]);
```

Notice that you can pass a parameter as either a constant value, the value of a variable, or an expression. Declaring a function of this kind is simple, but how do you code it? How do you know the types of the parameters? The values of a type-variant open array parameter are compatible with the TVarRec type elements.

Note: Do not confuse the TVarRec record with the TVarData record used by the Variant type itself. These two structures have a different aim and are not compatible. Even the list of possible types is different, because TVarRec can hold Delphi data types, while TVarData can hold OLE data types.

The TVarRec record has the following structure:

```
type
  TVarRec = record
    case Byte of
      vtInteger:    (VInteger: Integer; VType: Byte);
      vtBoolean:    (VBoolean: Boolean);
      vtChar:       (VChar: Char);
      vtExtended:   (VExtended: PExtended);
      vtString:     (VString: PShortString);
      vtPointer:    (VPointer: Pointer);
      vtPChar:      (VPChar: PChar);
      vtObject:     (VObject: TObject);
      vtClass:      (VClass: TClass);
      vtWideChar:   (VWideChar: WideChar);
      vtPWideChar:  (VPWideChar: PWideChar);
      vtAnsiString: (VAnsiString: Pointer);
      vtCurrency:   (VCurrency: PCurrency);
      vtVariant:    (VVariant: PVariant);
      vtInterface:  (VInterface: Pointer);
  end;
```

Each possible record has the VType field, although this is not easy to see at first because it is declared only once, along with the actual Integer-size data (generally a reference or a pointer).

Using this information we can actually write a function capable of operating on different data types. In the SumAll function example, I want to be able to sum values of different types, transforming strings to integers, characters to the corresponding order value, and adding 1 for True Boolean values. The code is based on a case statement, and is quite simple, although we have to dereference pointers quite often:

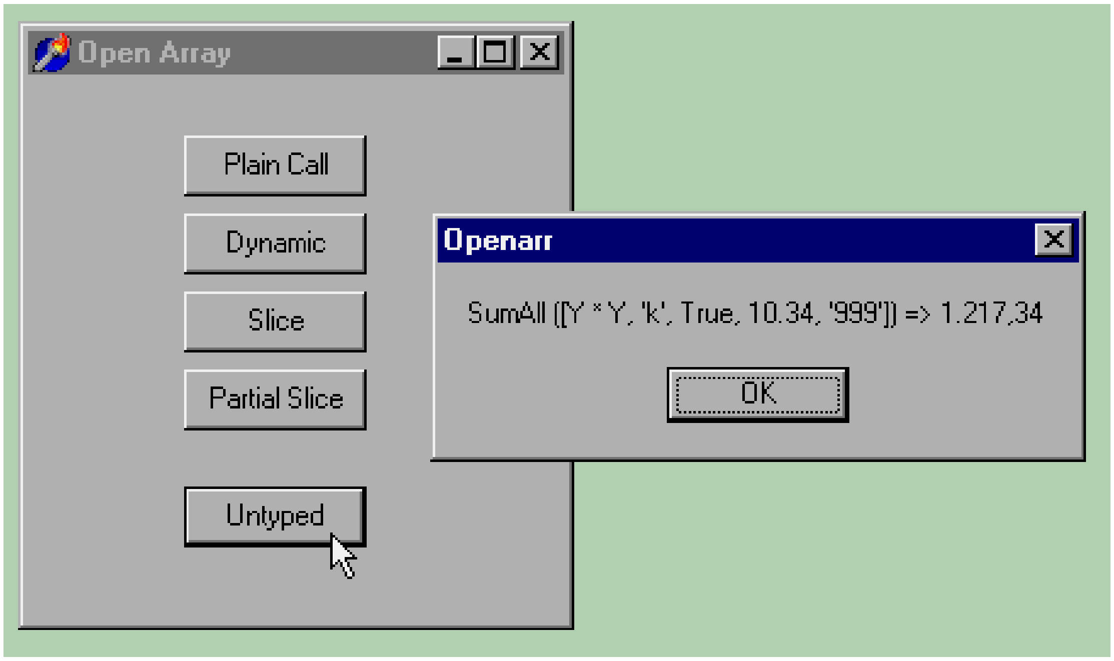
```
function SumAll (const Args: array of const): Extended;
var
  I: Integer;
begin
  Result := 0;
  for I := Low(Args) to High (Args) do
    case Args [I].VType of
      vtInteger: Result :=
        Result + Args [I].VInteger;
      vtBoolean:
        if Args [I].VBoolean then
          Result := Result + 1;
      vtChar:
        Result := Result + Ord (Args [I].VChar);
      vtExtended:
        Result := Result + Args [I].VExtended^;
      vtString, vtAnsiString:
        Result := Result + StrToIntDef ((Args [I].VString^), 0);
      vtWideChar:
        Result := Result + Ord (Args [I].VWideChar);
      vtCurrency:
        Result := Result + Args [I].VCurrency^;
    end; // case
end;
```

I've added this code to the OpenArr example, which calls the SumAll function when a given button is pressed:

```
procedure TForm1.Button4Click(Sender: TObject);
var
  X: Extended;
  Y: Integer;
begin
  Y := 10;
  X := SumAll ([Y * Y, 'k', True, 10.34, '99999']);
  ShowMessage (Format (
    'SumAll ([Y*Y, ''k'', True, 10.34, ''99999'']) => %n', [X]));
end;
```

You can see the output of this call, and the form of the OpenArr example, in Figure 6.2.

Figure 6.2: The form of the OpenArr example, with the message box displayed when the Untyped button is pressed.



SumAll ([Y * Y, 'k', True, 10.34, '999']) => 1.217,34

Delphi Calling Conventions

The 32-bit version of Delphi has introduced a new approach to passing parameters, known as fastcall: Whenever possible, up to three parameters can be passed in CPU registers, making the function call much faster. The fast calling convention (used by default in Delphi 3) is indicated by the register keyword.

The problem is that this is the default convention, and functions using it are not compatible with Windows: the functions of the Win32 API must be declared using the stdcall calling convention, a mixture of the original Pascal calling convention of the Win16 API and the cdecl calling convention of the C language.

There is generally no reason not to use the new fast calling convention, unless you are making external Windows calls or defining Windows callback functions. We'll see an example using the stdcall convention before the end of this chapter. You can find a summary of Delphi calling conventions in the Calling conventions topic under Delphi help.

What Is a Method?

If you have already worked with Delphi or read the manuals, you have probably heard about the term "method". A method is a special kind of function or procedure that is related to a data type, a class. In Delphi, every time we handle an event, we need to define a method, generally a procedure. In general, however, the term method is used to indicate both functions and procedures related to a class.

We have already seen a number of methods in the examples in this and the previous chapters. Here is an empty method automatically added by Delphi to the source code of a form:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  {here goes your code}
end;
```

Forward Declarations

When you need to use an identifier (of any kind), the compiler must have already seen some sort of declaration to know what the identifier refers to. For this reason, you usually provide a full declaration before using any routine. However, there are cases in which this is not possible. If procedure A calls procedure B, and procedure B calls procedure A, when you start writing the code, you will need to call a routine for which the compiler still hasn't seen a declaration.

If you want to declare the existence of a procedure or function with a certain name and given parameters, without providing its actual code, you can write the procedure or function followed by the forward keyword:

```
procedure Hello; forward;
```

Later on, the code should provide a full definition of the procedure, but this can be called even before it is fully defined. Here is a silly example, just to give you the idea:

```
procedure DoubleHello; forward;

procedure Hello;
begin
  if MessageDlg ('Do you want a double message?',
      mtConfirmation, [mbYes, mbNo], 0) = mrYes then
    DoubleHello
  else
    ShowMessage ('Hello');
end;

procedure DoubleHello;
begin
  Hello;
  Hello;
end;
```

This approach allows you to write mutual recursion: DoubleHello calls Hello, but Hello might call DoubleHello, too. Of course there must be a condition to terminate the recursion, to avoid a stack overflow. You can find this code, with some slight changes, in the DoubleH example.

Although a forward procedure declaration is not very common in Delphi, there is a similar case that is much more frequent. When you declare a procedure or function in the interface portion of a unit (more on units in the next chapter), it is considered a forward declaration, even if the forward keyword is not present. Actually you cannot write the body of a routine in the interface portion of a unit. At the same time, you must provide in the same unit the actual implementation of each routine you have declared.

The same holds for the declaration of a method inside a class type that was automatically generated by Delphi (as you added an event to a form or its components). The event handlers declared inside a TForm class are forward declarations: the code will be provided in the implementation portion of the unit. Here is an excerpt of the source code of an earlier example, with the declaration of the Button1Click method:

```
type
  TForm1 = class(TForm)
    ListBox1: TListBox;
    Button1: TButton;
    procedure Button1Click(Sender: TObject);
  end;
```

Procedural Types

Another unique feature of Object Pascal is the presence of procedural types. These are really an advanced language topic, which only a few Delphi programmers will use regularly. However, since we will discuss related topics in later chapters (specifically, method pointers, a technique heavily used by Delphi), it's worth a quick look at them here. If you are a novice programmer, you can skip this section for now, and come back to it when you feel ready.

In Pascal, there is the concept of procedural type (which is similar to the C language concept of function pointer). The declaration of a procedural type indicates the list of parameters and, in the case of a function, the return type. For example, you can declare a new procedural type, with an Integer parameter passed by reference, with this code:

```
type
  IntProc = procedure (var Num: Integer);
```

This procedural type is compatible with any routine having exactly the same parameters (or the same function signature, to use C jargon). Here is an example of a compatible routine:

```
procedure DoubleTheValue (var Value: Integer);
begin
  Value := Value * 2;
end;
```

Note: In the 16-bit version of Delphi, routines must be declared using the far directive in order to be used as actual values of a procedural type.

Procedural types can be used for two different purposes: you can declare variables of a procedural type or pass a procedural type (that is, a function pointer) as parameter to another routine. Given the preceding type and procedure declarations, you can write this code:

```
var
  IP: IntProc;
  X: Integer;
begin
  IP := DoubleTheValue;
  X := 5;
  IP (X);
end;
```

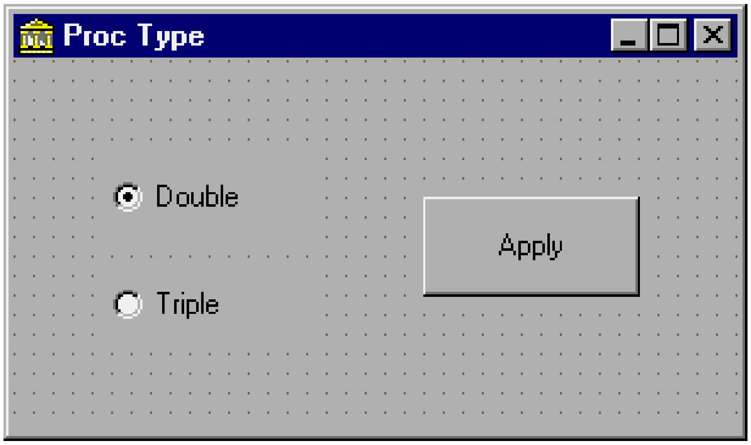
This code has the same effect as the following shorter version:

```
var
  X: Integer;
begin
  X := 5;
  DoubleTheValue (X);
end;
```

The first version is clearly more complex, so why should we use it? In some cases, being able to decide which function to call and actually calling it later on can be useful. It is possible to build a complex example showing this approach. However, I prefer to let you explore a fairly simple one, named ProcType. This example is more complex than those we have seen so far, to make the situation a little more realistic.

Simply create a blank project and place two radio buttons and a push button, as shown in Figure 6.3. This example is based on two procedures. One procedure is used to double the value of the parameter. This procedure is similar to the version I've already shown in this section. A second procedure is used to triple the value of the parameter, and therefore is named TripleTheValue:

Figure 6.3: The form of the ProcType example.



```
procedure TripleTheValue (var Value: Integer);
begin
  Value := Value * 3;
  ShowMessage ('Value tripled: ' + IntToStr (Value));
end;
```

Both procedures display what is going on, to let us know that they have been called. This is a simple debugging feature you can use to test whether or when a certain portion of code is executed, instead of adding a breakpoint in it.

Each time a user presses the Apply button, one of the two procedures is executed, depending on the status of the radio buttons. In fact, when you have two radio buttons in a form, only one of them can be selected at a time. This code could have been implemented by testing the value of the radio buttons inside the code for the OnClick event of the Apply button. To demonstrate the use of procedural types, I've instead used a longer but interesting approach. Each time a user clicks on one of the two radio buttons, one of the procedures is stored in a variable:

```
procedure TForm1.DoubleRadioButtonClick(Sender: TObject);
begin
  IP := DoubleTheValue;
end;
```

When the user clicks on the push button, the procedure we have stored is executed:

```
procedure TForm1.ApplyButtonClick(Sender: TObject);
begin
  IP (X);
end;
```

To allow three different functions to access the IP and X variables, we need to make them visible to the whole form; they cannot be declared locally (inside one of the methods). A solution to this problem is to place these variables inside the form declaration:

```
type
  TForm1 = class(TForm)
    ...
  private
    { Private declarations }
    IP: IntProc;
    X: Integer;
  end;
```

We will see exactly what this means in the next chapter, but for the moment, you need to modify the code generated by Delphi for the class type as indicated above, and add the definition of the procedural type I've shown before. To initialize these two variables with suitable values, we can handle the OnCreate event of the form (select this event in the Object Inspector after you have activated the form, or simply double-click on the form). I suggest you refer to the listing to study the details of the source code of this example.

You can see a practical example of the use of procedural types in Chapter 9, in the section A Windows Callback Function.

Function Overloading

The idea of overloading is simple: The compiler allows you to define two functions or procedures using the same name, provided that the parameters are different. By checking the parameters, in fact, the compiler can determine which of the versions of the routine you want to call.

Consider this series of functions extracted from the Math unit of the VCL:

```
function Min (A,B: Integer): Integer; overload;
function Min (A,B: Int64): Int64; overload;
function Min (A,B: Single): Single; overload;
function Min (A,B: Double): Double; overload;
function Min (A,B: Extended): Extended; overload;
```

When you call Min (10, 20), the compiler easily determines that you're calling the first function of the group, so the return value will be an Integer.

The basic rules are two:

- Each version of the routine must be followed by the overload keyword.
- The differences must be in the number or type of the parameters, or both. The return type, instead, cannot be used to distinguish among two routines.

Here are three overloaded versions of a ShowMsg procedure I've added to the OverDef example (an application demonstrating overloading and default parameters):

```
procedure ShowMsg (str: string); overload;
begin
  MessageDlg (str, mtInformation, [mbOK], 0);
end;

procedure ShowMsg (FormatStr: string;
  Params: array of const); overload;
begin
  MessageDlg (Format (FormatStr, Params),
    mtInformation, [mbOK], 0);
end;

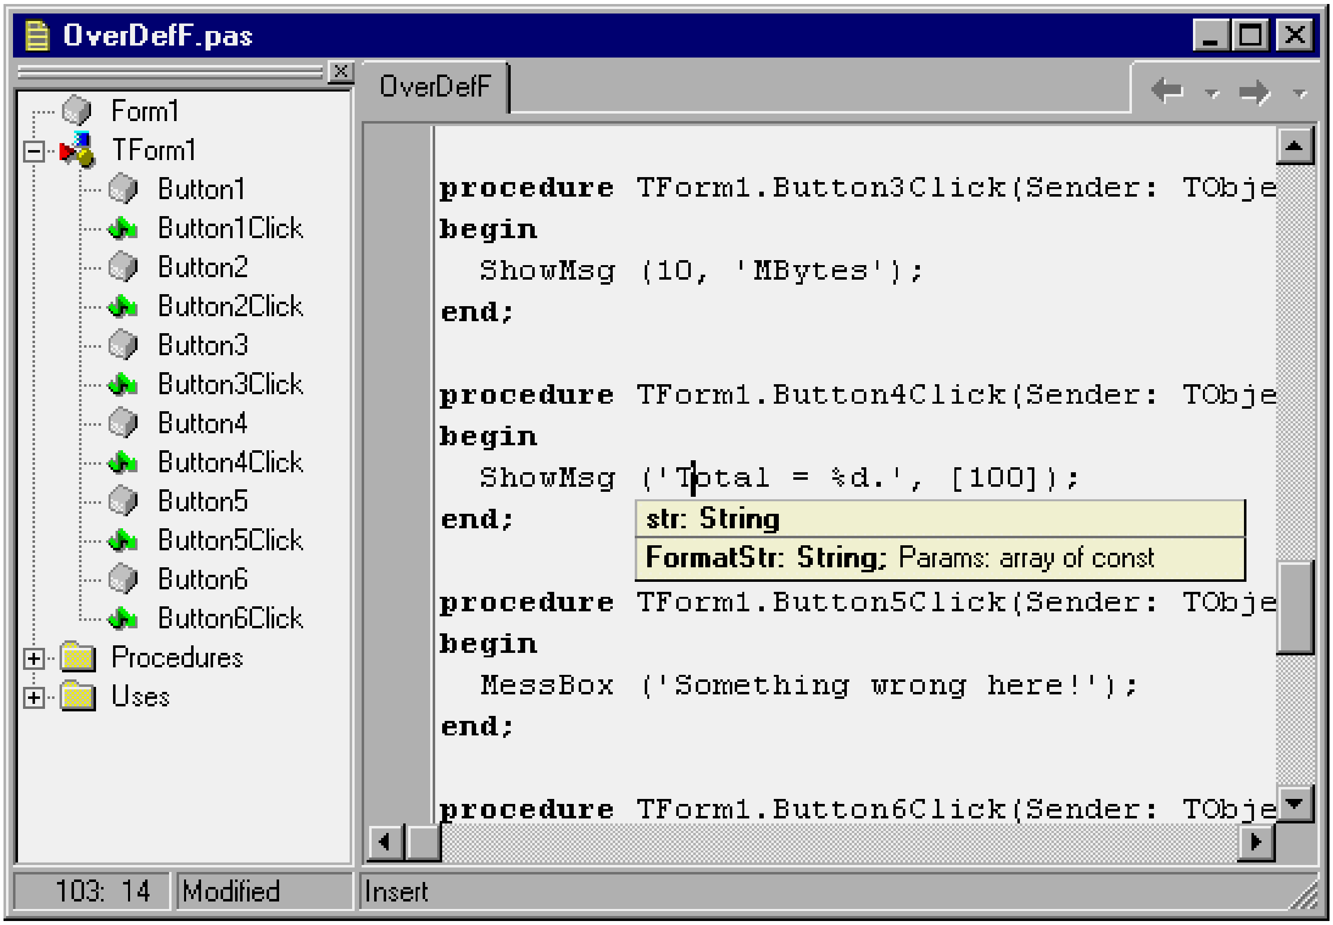
procedure ShowMsg (I: Integer; Str: string); overload;
begin
  ShowMsg (IntToStr (I) + ' ' + Str);
end;
```

The three functions show a message box with a string, after optionally formatting the string in different ways. Here are the three calls of the program:

```
ShowMsg ('Hello');
ShowMsg ('Total = %d.', [100]);
ShowMsg (10, 'MBytes');
```

What surprised me in a positive way is that Delphi's Code Parameters technology works very nicely with overloaded procedures and functions. As you type the open parenthesis after the routine name, all the available alternatives are listed. As you enter the parameters, Delphi uses their type to determine which of the alternatives are still available. In Figure 6.4 you can see that after starting to type a constant string Delphi shows only the compatible versions (omitting the version of the ShowMsg procedure that has an integer as first parameter).

Figure 6.4: The multiple alternatives offered by Code Parameters for overloaded routines are filtered according to the parameters already available.



```
procedure TForm1.Button3Click(Sender: TObje
begin
  ShowMsg (10, 'MBytes');
end;

procedure TForm1.Button4Click(Sender: TObje
begin
  ShowMsg ('Total = %d.', [100]);
end;       str: String
           FormatStr: String; Params: array of const

procedure TForm1.Button5Click(Sender: TObje
begin
  MessBox ('Something wrong here!');
end;

procedure TForm1.Button6Click(Sender: TObje
```

The fact that each version of an overloaded routine must be properly marked implies that you cannot overload an existing routine of the same unit that is not marked with the overload keyword. (The error message you get when you try is: "Previous declaration of '<name>' was not marked with the 'overload' directive.") However, you can overload a routine that was originally declared in a different unit. This is for compatibility with previous versions of Delphi, which allowed different units to reuse the same routine name. Notice, anyway, that this special case is not an extra feature of overloading, but an indication of the problems you can face.

For example, you can add to a unit the following code:

```
procedure MessageDlg (str: string); overload;
begin
  Dialogs.MessageDlg (str, mtInformation, [mbOK], 0);
end;
```

This code doesn't really overload the original MessageDlg routine. In fact if you write:

```
MessageDlg ('Hello');
```

you'll get a nice error message indicating that some of the parameters are missing. The only way to call the local version instead of the one of the VCL is to refer explicitly to the local unit, something that defeats the idea of overloading:

```
OverDefF.MessageDlg ('Hello');
```

Default Parameters

A related new feature of Delphi 4 is that you can give a default value for the parameter of a function, and you can call the function with or without the parameter. Let me show an example. We can define the following encapsulation of the MessageBox method of the Application global object, which uses PChar instead of strings, providing two default parameters:

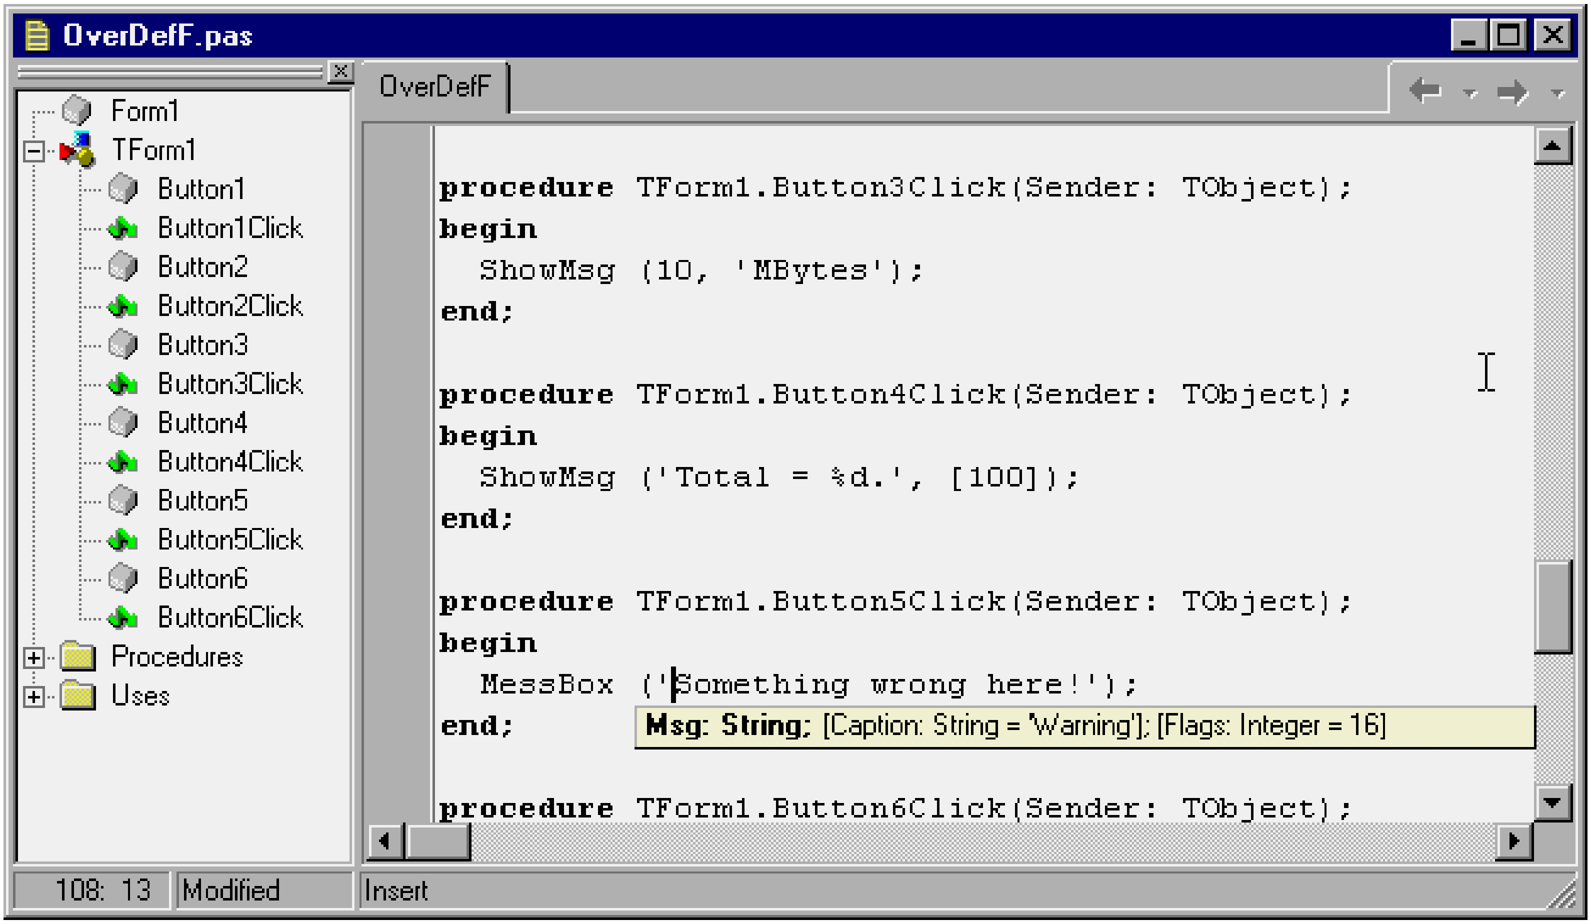
```
procedure MessBox (Msg: string;
  Caption: string = 'Warning';
  Flags: LongInt = mb_OK or mb_IconHand);
begin
  Application.MessageBox (PChar (Msg),
    PChar (Caption), Flags);
end;
```

With this definition, we can call the procedure in each of the following ways:

```
MessBox ('Something wrong here!');
MessBox ('Something wrong here!', 'Attention');
MessBox ('Hello', 'Message', mb_OK);
```

In Figure 6.5 you can see that Delphi's Code Parameters properly use a different style to indicate the parameters that have a default value, so you can easily determine which parameters can be omitted.

Figure 6.5: Delphi's Code Parameters mark out with square brackets the parameters that have default values; you can omit these in the call.



```
procedure TForm1.Button3Click(Sender: TObject);
begin
  ShowMsg (10, 'MBytes');
end;

procedure TForm1.Button4Click(Sender: TObject);
begin
  ShowMsg ('Total = %d.', [100]);
end;

procedure TForm1.Button5Click(Sender: TObject);
begin
  MessBox ('Something wrong here!');
end;

procedure TForm1.Button6Click(Sender: TObject);
```

Msg: String; [Caption: String = 'Warning']; [Flags: Integer = 16]

Notice that Delphi doesn't generate any special code to support default parameters; nor does it create multiple copies of the routines. The missing parameters are simply added by the compiler to the calling code.

There is one important restriction affecting the use of default parameters: You cannot "skip" parameters. For example, you can't pass the third parameter to the function after omitting the second one:

```
MessBox ('Hello', mb_OK); // error
```

This is the main rule for default parameters: In a call, you can only omit parameters starting from the last one. In other words, if you omit a parameter you must omit also the following ones.

There are a few other rules for default parameters as well:

- Parameters with default values must be at the end of the parameters list.
- Default values must be constants. Obviously, this limits the types you can use with default parameters. For example, a dynamic array or an interface type cannot have a default parameter other than nil; records cannot be used at all.
- Default parameters must be passed by value or as const. A reference (var) parameter cannot have a default value.

Using default parameters and overloading at the same time can cause quite a few problems, as the two features might conflict. For example, if I add to the previous example the following new version of the ShowMsg procedure:

```
procedure ShowMsg (Str: string; I: Integer = 0); overload;
begin
  MessageDlg (Str + ': ' + IntToStr (I),
    mtInformation, [mbOK], 0);
end;
```

then the compiler won't complain-this is a legal definition. However, the call:

```
ShowMsg ('Hello');
```

is flagged by the compiler as Ambiguous overloaded call to 'ShowMsg'. Notice that this error shows up in a line of code that compiled correctly before the new overloaded definition. In practice, we have no way to call the ShowMsg procedure with one string parameter, as the compiler doesn't know whether we want to call the version with only the string parameter or the one with the string parameter and the integer parameter with a default value. When it has a similar doubt, the compiler stops and asks the programmer to state his or her intentions more clearly.

Conclusion

Writing procedure and functions is a key element of programming, although in Delphi you'll tend to write methods -- procedures and functions connected with classes and objects.

Instead of moving on to object-oriented features, however, the next few chapters give you some details on other Pascal programming elements, starting with strings.

Marco Cantù's Essential Pascal

Chapter 7 Handling Strings

String handling in Delphi is quite simple, but behind the scenes the situation is quite complex. Pascal has a traditional way of handling strings, Windows has its own way, borrowed from the C language, and 32-bit versions of Delphi include a powerful long string data type, which is the default string type in Delphi.

Types of Strings

In Borland's Turbo Pascal and in 16-bit Delphi, the typical string type is a sequence of characters with a length byte at the beginning, indicating the current size of the string. Because the length is expressed by a single byte, it cannot exceed 255 characters, a very low value that creates many problems for string manipulation. Each string is defined with a fixed size (which by default is the maximum, 255), although you can declare shorter strings to save memory space.

A string type is similar to an array type. In fact, a string is almost an array of characters. This is demonstrated by the fact that you can access a specific string character using the [] notation.

To overcome the limits of traditional Pascal strings, the 32-bit versions of Delphi support long strings. There are actually three string types:

- The ShortString type corresponds to the typical Pascal strings, as described before. These strings have a limit of 255 characters and correspond to the strings in the 16-bit version of Delphi. Each element of a short string is of type ANSIChar (the standard character type).
- The ANSIString type corresponds to the new variable-length long strings. These strings are allocated dynamically, are reference counted, and use a copy-on-write technique. The size of these strings is almost unlimited (they can store up to two billion characters!). They are also based on the ANSIChar type.
- The WideString type is similar to the ANSIString type but is based on the WideChar type-it stores Unicode characters.

Using Long Strings

If you simply use the string data type, you get either short strings or ANSI strings, depending on the value of the $H compiler directive. $H+ (the default) stands for long strings (the ANSIString type), which is what is used by the components of the Delphi library.

Delphi long strings are based on a reference-counting mechanism, which keeps track of how many string variables are referring to the same string in memory. This reference-counting is used also to free the memory when a string isn't used anymore-that is, when the reference count reaches zero.

If you want to increase the size of a string in memory but there is something else in the adjacent memory, then the string cannot grow in the same memory location, and a full copy of the string must therefore be made in another location. When this situation occurs, Delphi's run-time support reallocates the string for you in a completely transparent way. You simply set the maximum size of the string with the SetLength procedure, effectively allocating the required amount of memory:

```
SetLength (String1, 200);
```

The SetLength procedure performs a memory request, not an actual memory allocation. It reserves the required memory space for future use, without actually using the memory. This technique is based on a feature of the Windows operating systems and is used by Delphi for all dynamic memory allocations. For example, when you request a very large array, its memory is reserved but not allocated.

Setting the length of a string is seldom necessary. The only case in which you must allocate memory for the long string using SetLength is when you have to pass the string as a parameter to an API function (after the proper typecast), as I'll show you shortly.

Looking at Strings in Memory

To help you better understand the details of memory management for strings, I've written the simple StrRef example. In this program I declare two global strings: Str1 and Str2. When the first of the two buttons is pressed, the program assigns a constant string to the first of the two variables and then assigns the second variable to the first:

```
Str1 := 'Hello';
Str2 := Str1;
```

Besides working on the strings, the program shows their internal status in a list box, using the following StringStatus function:

```
function StringStatus (const Str: string): string;
begin
  Result := 'Address: ' + IntToStr (Integer (Str)) +
    ', Length: ' + IntToStr (Length (Str)) +
    ', References: ' + IntToStr (PInteger (Integer (Str) - 8)^) +
    ', Value: ' + Str;
end;
```

It is vital in the StringStatus function to pass the string parameter as a const parameter. Passing this parameter by copying will cause the side effect of having one extra reference to the string while the function is being executed. By contrast, passing the parameter via a reference (var) or constant (const) parameter doesn't imply a further reference to the string. In this case I've used a const parameter, as the function is not supposed to modify the string.

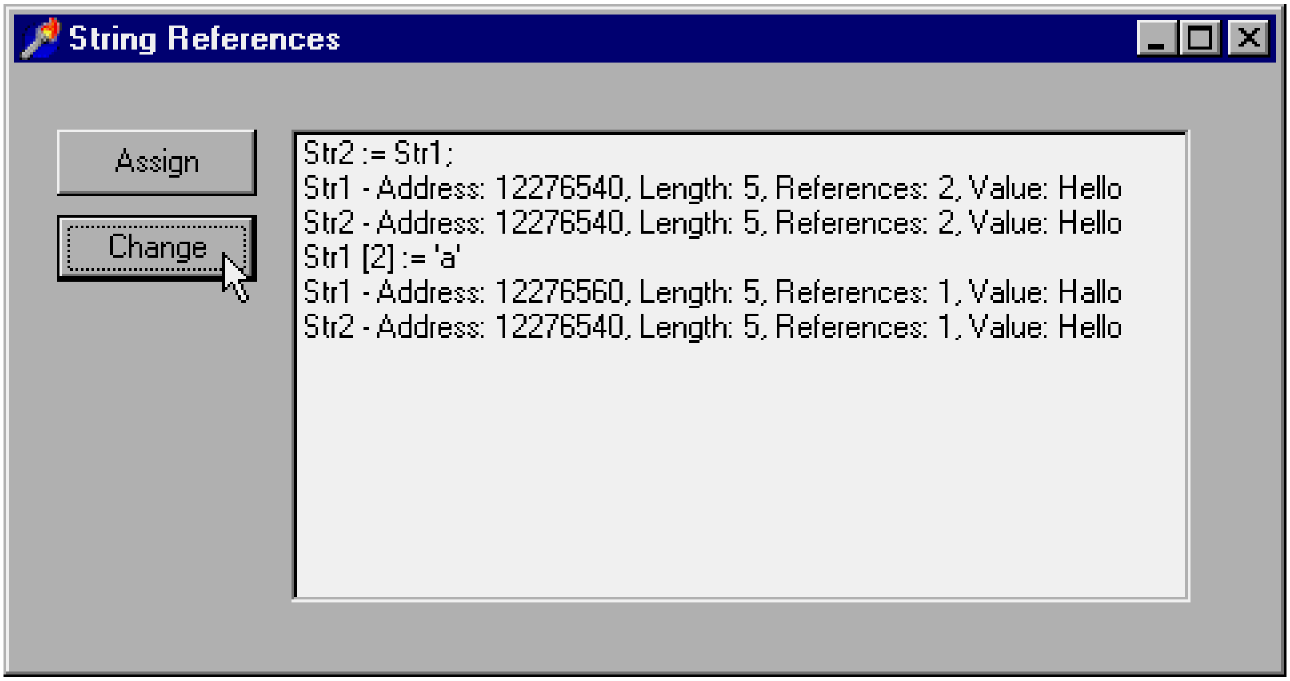
To obtain the memory address of the string (useful to determine its actual identity and to see when two different strings refer to the same memory area), I've simply made a hard-coded typecast from the string type to the Integer type. Strings are references-in practice, they're pointers: Their value holds the actual memory location of the string.

To extract the reference count, I've based the code on the little-known fact that the length and reference count are actually stored in the string, before the actual text and before the position the string variable points to. The (negative) offset is -4 for the length of the string (a value you can extract more easily using the Length function) and -8 for the reference count.

Keep in mind that this internal information about offsets might change in future versions of Delphi; there is also no guarantee that similar undocumented features will be maintained in the future.

By running this example, you should get two strings with the same content, the same memory location, and a reference count of 2, as shown in the upper part of the list box of Figure 2.1. Now if you change the value of one of the two strings (it doesn't matter which one), the memory location of the updated string will change. This is the effect of the copy-on-write technique.

Figure 7.1: The StrRef example shows the internal status of two strings, including the current reference count.



```
Str2 := Str1;
Str1 - Address: 12276540, Length: 5, References: 2, Value: Hello
Str2 - Address: 12276540, Length: 5, References: 2, Value: Hello
Str1 [2] := 'a'
Str1 - Address: 12276560, Length: 5, References: 1, Value: Hallo
Str2 - Address: 12276540, Length: 5, References: 1, Value: Hello
```

We can actually produce this effect, shown in the second part of the list box of Figure 7.1, by writing the following code for the OnClick event handler of the second button:

```
procedure TFormStrRef.BtnChangeClick(Sender: TObject);
begin
  Str1 [2] := 'a';
  ListBox1.Items.Add ('Str1 [2] := ''a''');
  ListBox1.Items.Add ('Str1 - ' + StringStatus (Str1));
  ListBox1.Items.Add ('Str2 - ' + StringStatus (Str2));
end;
```

Notice that the code of the BtnChangeClick method can be executed only after the BtnAssignClick method. To enforce this, the program starts with the second button disabled (its Enabled property is set to False); it enables the button at the end of the first method. You can freely extend this example and use the StringStatus function to explore the behavior of long strings in many other circumstances.

Delphi Strings and Windows PChars

Another important point in favor of using long strings is that they are null-terminated. This means that they are fully compatible with the C language null-terminated strings used by Windows. A null-terminated string is a sequence of characters followed by a byte that is set to zero (or null). This can be expressed in Delphi using a zero-based array of characters, the data type typically used to implement strings in the C language. This is the reason null-terminated character arrays are so common in the Windows API functions (which are based on the C language). Since Pascal's long strings are fully compatible with C null-terminated strings, you can simply use long strings and cast them to PChar when you need to pass a string to a Windows API function.

For example, to copy the caption of a form into a PChar string (using the API function GetWindowText) and then copy it into the Caption of the button, you can write the following code:

```
procedure TForm1.Button1Click (Sender: TObject);
var
  S1: String;
begin
  SetLength (S1, 100);
  GetWindowText (Handle, PChar (S1), Length (S1));
  Button1.Caption := S1;
end;
```

You can find this code in the LongStr example. Note that if you write this code but fail to allocate the memory for the string with SetLength, the program will probably crash. If you are using a PChar to pass a value (and not to receive one as in the code above), the code is even simpler, because there is no need to define a temporary string and initialize it. The following line of code passes the Caption property of a label as a parameter to an API function, simply by typecasting it to PChar:

```
SetWindowText (Handle, PChar (Label1.Caption));
```

When you need to cast a WideString to a Windows-compatible type, you have to use PWideChar instead of PChar for the conversion. Wide strings are often used for OLE and COM programs.

Having presented the nice picture, now I want to focus on the pitfalls. There are some problems that might arise when you convert a long string into a PChar. Essentially, the underlying problem is that after this conversion, you become responsible for the string and its contents, and Delphi won't help you anymore. Consider the following limited change to the first program code fragment above, Button1Click:

```
procedure TForm1.Button2Click(Sender: TObject);
var
  S1: String;
begin
  SetLength (S1, 100);
  GetWindowText (Handle, PChar (S1), Length (S1));
  S1 := S1 + ' is the title'; // this won't work
  Button1.Caption := S1;
end;
```

This program compiles, but when you run it, you are in for a surprise: The Caption of the button will have the original text of the window title, without the text of the constant string you have added to it. The problem is that when Windows writes to the string (within the GetWindowText API call), it doesn't set the length of the long Pascal string properly. Delphi still can use this string for output and can figure out when it ends by looking for the null terminator, but if you append further characters after the null terminator, they will be skipped altogether.

How can we fix this problem? The solution is to tell the system to convert the string returned by the GetWindowText API call back to a Pascal string. However, if you write the following code:

```
S1 := String (S1);
```

the system will ignore it, because converting a data type back into itself is a useless operation. To obtain the proper long Pascal string, you need to recast the string to a PChar and let Delphi convert it back again properly to a string:

```
S1 := String (PChar (S1));
```

Actually, you can skip the string conversion, because PChar-to-string conversions are automatic in Delphi. Here is the final code:

```
procedure TForm1.Button3Click(Sender: TObject);
```

```
var
  S1: String;
begin
  SetLength (S1, 100);
  GetWindowText (Handle, PChar (S1), Length (S1));
  S1 := String (PChar (S1));
  S1 := S1 + ' is the title';
  Button3.Caption := S1;
end;
```

An alternative is to reset the length of the Delphi string, using the length of the PChar string, by writing:

```
SetLength (S1, StrLen (PChar (S1)));
```

You can find three versions of this code in the LongStr example, which has three buttons to execute them. However, if you just need to access the title of a form, you can simply use the Caption property of the form object itself. There is no need to write all this confusing code, which was intended only to demonstrate the string conversion problems. There are practical cases when you need to call Windows API functions, and then you have to consider this complex situation.

Formatting Strings

Using the plus (+) operator and some of the conversion functions (such as IntToStr) you can indeed build complex strings out of existing values. However, there is a different approach to formatting numbers, currency values, and other strings into a final string. You can use the powerful Format function or one of its companion functions.

The Format function requires as parameters a string with the basic text and some placeholders (usually marked by the % symbol) and an array of values, one for each placeholder. For example, to format two numbers into a string you can write:

```
Format ('First %d, Second %d', [n1, n2]);
```

where n1 and n2 are two Integer values. The first placeholder is replaced by the first value, the second matches the second, and so on. If the output type of the placeholder (indicated by the letter after the % symbol) doesn't match the type of the corresponding parameter, a runtime error occurs. Having no compile-time type checking is actually the biggest drawback of using the Format function.

The Format function uses an open-array parameter (a parameter that can have an arbitrary number of values), something I'll discuss toward the end of this chapter. For the moment, though, notice only the array-like syntax of the list of values passed as the second parameter.

Besides using %d, you can use one of many other placeholders defined by this function and briefly listed in Table 7.1. These placeholders provide a default output for the given data type. However, you can use further format specifiers to alter the default output. A width specifier, for example, determines a fixed number of characters in the output, while a precision specifier indicates the number of decimal digits. For example,

```
Format ('%8d', [n1]);
```

converts the number n1 into an eight-character string, right-aligning the text (use the minus (-) symbol to specify left-justification) filling it with white spaces.

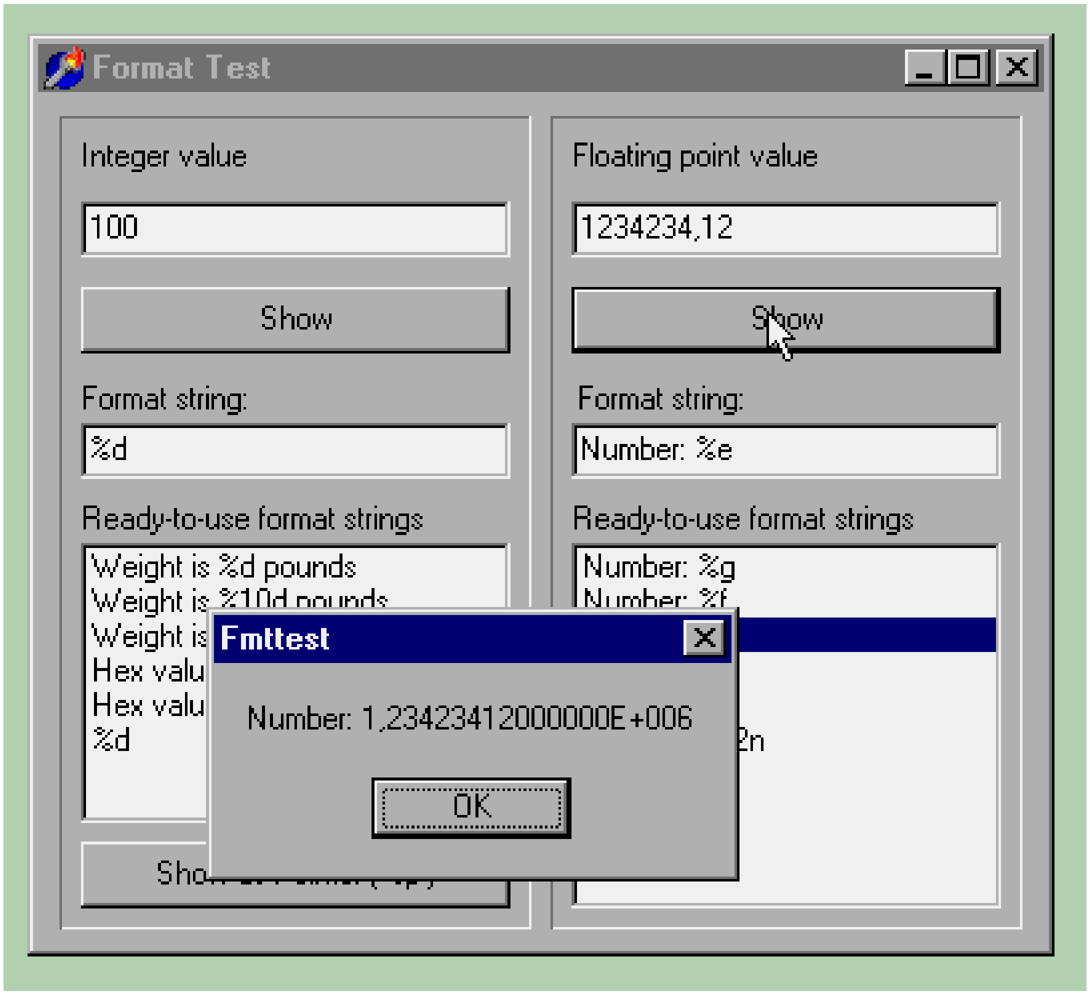
Table 7.1: Type Specifiers for the Format Function

TYPE SPECIFIER	DESCRIPTION
d (decimal)	The corresponding integer value is converted to a string of decimal digits.
x (hexadecimal)	The corresponding integer value is converted to a string of hexadecimal digits.
p (pointer)	The corresponding pointer value is converted to a string expressed with hexadecimal digits.
s (string)	The corresponding string, character, or PChar value is copied to the output string.
e (exponential)	The corresponding floating-point value is converted to a string based on exponential notation.
f (floating point)	The corresponding floating-point value is converted to a string based on floating point notation.
g (general)	The corresponding floating-point value is converted to the shortest possible decimal string using either floating-point or exponential notation.
n (number)	The corresponding floating-point value is converted to a floating-point string but also uses thousands separators.
m (money)	The corresponding floating-point value is converted to a string representing a currency amount. The conversion is based on regional settings-see the Delphi Help file under Currency and date/time formatting variables.

The best way to see examples of these conversions is to experiment with format strings yourself. To make this easier I've written the FmtTest program, which allows a user to provide formatting strings for integer and floating-point numbers. As you can see in Figure 7.2, this program displays a form divided into two parts. The left part is for Integer numbers, the right part for floating-point numbers.

Each part has a first edit box with the numeric value you want to format to a string. Below the first edit box there is a button to perform the formatting operation and show the result in a message box. Then comes another edit box, where you can type a format string. As an alternative you can simply click on one of the lines of the ListBox component, below, to select a predefined formatting string. Every time you type a new formatting string, it is added to the corresponding list box (note that by closing the program you lose these new items).

Figure 7.2: The output of a floating-point value from the FmtTest program



100

%d

Weight is %d pounds
Weight is %10d pounds
Weight is
Hex valu
Hex valu
%d

1234234,12

Number: %e

Number: %g
Number: %f
2n

Number: 1,23423412000000E+006

The code of this example simply uses the text of the various controls to produce its output. This is one of the three methods connected with the Show buttons:

```
procedure TFormFmtTest.BtnIntClick(Sender: TObject);
begin
  ShowMessage (Format (EditFmtInt.Text,
    [StrToInt (EditInt.Text)]));
  // if the item is not there, add it
  if ListBoxInt.Items.IndexOf (EditFmtInt.Text) < 0 then
    ListBoxInt.Items.Add (EditFmtInt.Text);
end;
```

The code basically does the formatting operation using the text of the EditFmtInt edit box and the value of the EditInt control. If the format string is not already in the list box, it is then added to it. If the user instead clicks on an item in the list box, the code moves that value to the edit box:

```
procedure TFormFmtTest.ListBoxIntClick(Sender: TObject);
begin
  EditFmtInt.Text := ListBoxInt.Items [
    ListBoxInt.ItemIndex];
end;
```

Conclusion

Strings a certainly a very common data type. Although you can safely use them in most cases without understanding how they work, this chapter should have made clear the exact behavior of strings, making it possible for you to use all the power of this data type.

Strings are handled in memory in a special dynamic way, as happens with dynamic arrays. This is the topic of the next chapter.

Chapter 8 Memory

Author's Note: This chapter will cover memory handling, discuss the various memory areas, and introduce dynamic arrays. Temporarily only this last part is available.

Delphi 4 Dynamic Arrays

Traditionally, the Pascal language has always had fixed-size arrays. When you declare a data type using the array construct, you have to specify the number of elements of the array. As expert programmers probably know, there were a few techniques you could use to implement dynamic arrays, typically using pointers and manually allocating and freeing the required memory.

Delphi 4 introduces a very simple implementation of dynamic arrays, modeling them after the dynamic long string type I've just covered. As long strings, dynamic arrays are dynamically allocated and reference counted, but they do not offer a copy-on-write technique. That's not a big problem, as you can deallocate an array by setting its variable to nil.

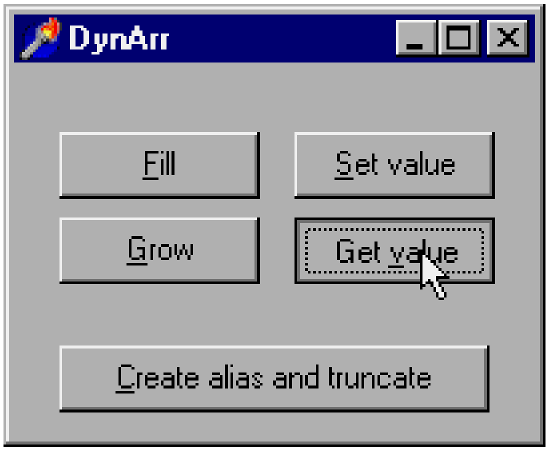
You can now simply declare an array without specifying the number of elements and then allocate it with a given size using the SetLength procedure. The same procedure can also be used to resize an array without losing its content. There are also other string-oriented procedures, such as the Copy function, that you can use on arrays.

Here is a small code excerpt, underscoring the fact that you must both declare and allocate memory for the array before you can start using it:

```
procedure TForm1.Button1Click(Sender: TObject);
var
  Array1: array of Integer;
begin
  Array1 [1] := 100; // error
  SetLength (Array1, 100);
  Array1 [99] := 100; // OK
  ...
end;
```

As you indicate only the number of elements of the array, the index invariably starts from 0. Generic arrays in Pascal account for a non-zero low bound and for non-integer indexes, two features that dynamic arrays don't support. To learn the status of a dynamic array, you can use the Length, High, and Low functions, as with any other array. For dynamic arrays, however, Low always returns 0, and High always returns the length minus one. This implies that for an empty array High returns -1 (which, when you think about it, is a strange value, as it is lower than that returned by Low).

Figure 8.1: The form of the DynArr example



After this short introduction I can show you a simple example, called DynArr and shown in Figure 8.1. It is indeed simple because there is nothing very complex about dynamic arrays. I'll also use it to show a few possible errors programmers might make. The program declares two global arrays and initializes the first in the OnCreate handler:

```
var
  Array1, Array2: array of Integer;

procedure TForm1.FormCreate(Sender: TObject);
begin
  // allocate
  SetLength (Array1, 100);
end;
```

This sets all the values to zero. This initialization code makes it possible to start reading and writing values of the array right away, without any fear of memory errors. (Assuming, of course, that you don't try to access items beyond the upper bound of the array.) For an even better initialization, the program has a button that writes into each cell of the array:

```
procedure TForm1.btnFillClick(Sender: TObject);
var
  I: Integer;
begin
  for I := Low (Array1) to High (Array1) do
    Array1 [I] := I;
end;
```

The Grow button allows you to modify the size of the array without losing its contents. You can test this by using the Get value button after pressing the Grow button:

```
procedure TForm1.btnGrowClick(Sender: TObject);
begin
  // grow keeping existing values
  SetLength (Array1, 200);
end;

procedure TForm1.btnGetClick(Sender: TObject);
begin
  // extract
  Caption := IntToStr (Array1 [99]);
end;
```

The only slightly complex code is in the OnClick event of the Alias button. The program copies one array to the other one with the := operator, effectively creating an alias (a new variable referring to the same array in memory). At this point, however, if you modify one of the arrays, the other is affected as well, as they both refer to the same memory area:

```
procedure TForm1.btnAliasClick(Sender: TObject);
begin
  // alias
  Array2 := Array1;
  // change one (both change)
  Array2 [99] := 1000;
  // show the other
  Caption := IntToStr (Array1 [99]);
```

The btnAliasClick method does two more operations. The first is an equality test on the arrays. This tests not the actual elements of the structures but rather the memory areas the arrays refer to, checking whether the variables are two aliases of the same array in memory:

```
procedure TForm1.btnAliasClick(Sender: TObject);
begin
  ...
  if Array1 = Array2 then
    Beep;
  // truncate first array
  Array1 := Copy (Array2, 0, 10);
end;
```

The second is a call to the Copy function, which not only moves data from one array to the other, but also replaces the first array with a new one created by the function. The effect is that the Array1 variable now refers to an array of 11 elements, so that pressing the Get value or Set value buttons produces a memory error and raises an exception (unless you have range-checking turned off, in which case the error remains but the exception is not displayed). The code of the Fill button continues to work fine even after this change, as the items of the array to modify are determined using its current bounds.

Conclusion

This chapter temporarily covers only dynamic arrays, certainly an important element for memory management, but only a portion of the entire picture. More material will follow.

The memory structure described in this chapter is typical of Windows programming, a topic I'll introduce in the next chapter (without going to the full extent of using the VCL, though).

Chapter 9: Windows Programming

Delphi provides a complete encapsulation of the low-level Windows API using Object Pascal and the Visual Component Library (VCL), so it is rarely necessary to build Windows applications using plain Pascal and calling Windows API functions directly. Nonetheless, programmers who want to use some special techniques not supported by the VCL still have that option in Delphi. You would only want to take this approach for very special cases, such as the development of new Delphi components based on unusual API calls, and I don't want to cover the details. Instead, we'll look at a few elements of Delphi's interaction with the operating system and a couple of techniques that Delphi programmers can benefit from.

Windows Handles

Among the data types introduced by Windows in Delphi, handles represent the most important group. The name of this data type is *THandle*, and the type is defined in the Windows unit as:

```
type
  THandle = LongWord;
```

Handle data types are implemented as numbers, but they are not used as such. In Windows, a handle is a reference to an internal data structure of the system. For example, when you work with a window (or a Delphi form), the system gives you a handle to the window. The system informs you that the window you are working with is window number 142, for example. From that point on, your application can ask the system to operate on window number 142—moving it, resizing it, reducing it to an icon, and so on. Many Windows API functions, in fact, have a handle as the first parameter. This doesn't apply only to functions operating on windows; other Windows API functions have as their first parameter a GDI handle, a menu handle, an instance handle, a bitmap handle, or one of the many other handle types.

In other words, a handle is an internal code you can use to refer to a specific element handled by the system, including a window, a bitmap, an icon, a memory block, a cursor, a font, a menu, and so on. In Delphi, you seldom need to use handles directly, since they are hidden inside forms, bitmaps, and other Delphi objects. They become useful when you want to call a Windows API function that is not supported by Delphi.

To complete this description, here is a simple example demonstrating Windows handles. The WHandle program has a simple form, containing just a button. In the code, I respond to the OnCreate event of the form and the OnClick event of the button, as indicated by the following textual definition of the main form:

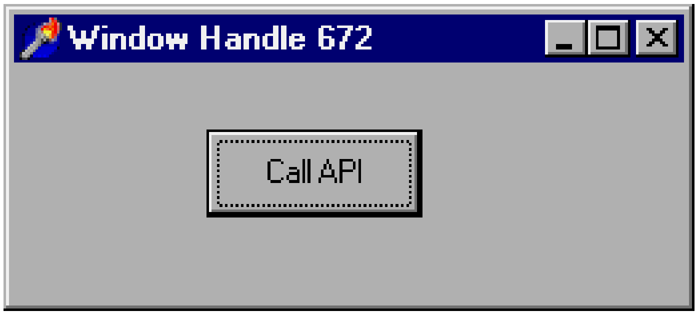
```
object FormWHandle: TFormWHandle
  Caption = 'Window Handle'
  OnCreate = FormCreate
  object BtnCallAPI: TButton
    Caption = 'Call API'
    OnClick = BtnCallAPIClick
  end
end
```

As soon as the form is created, the program retrieves the handle of the window corresponding to the form, by accessing the Handle property of the form itself. We call IntToStr to convert the numeric value of the handle into a string, and we append that to the caption of the form, as you can see in Figure 9.1:

```
procedure TFormWHandle.FormCreate(Sender: TObject);
begin
  Caption := Caption + ' ' + IntToStr (Handle);
end;
```

Because FormCreate is a method of the form's class, it can access other properties and methods of the same class directly. Therefore, in this procedure we can simply refer to the Caption of the form and its Handle property directly.

Figure 9.1: The WHandle example shows the handle of the form window. Every time you run this program you'll get a different value.



If you run this program several times you'll generally get different values for the handle. This value, in fact, is determined by Windows and is sent back to the application. (Handles are never determined by the program, and they have no predefined values; they are determined by the system, which generates new values each time you run a program.)

When the user presses the button, the program simply calls a Windows API function, SetWindowText, which changes the text or caption of the window passed as the first parameter. To be more precise, the first parameter of this API function is the handle of the window we want to modify:

```
procedure TFormWHandle.BtnCallAPIClick(Sender: TObject);
begin
  SetWindowText (Handle, 'Hi');
end;
```

This code has the same effect as the previous event handler, which changed the text of the window by giving a new value to the Caption property of the form. In this case calling an API function makes no sense, because there is a simpler Delphi technique. Some API functions, however, have no correspondence in Delphi, as we'll see in more advanced examples later in the book.

External Declarations

Another important element for Windows programming is represented by external declarations. Originally used to link the Pascal code to external functions that were written in assembly language, the external declaration is used in Windows programming to call a function from a DLL (a dynamic link library). In Delphi, there are a number of such declarations in the Windows unit:

```
// forward declaration
function LineTo (DC: HDC; X, Y: Integer): BOOL; stdcall;

// external declaration (instead of actual code)
function LineTo; external 'gdi32.dll' name 'LineTo';
```

This declaration means that the code of the function LineTo is stored in the GDI32.DLL dynamic library (one of the most important Windows system libraries) with the same name we are using in our code. Inside an external declaration, in fact, we can specify that our function refer to a function of a DLL that originally had a different name.

You seldom need to write declarations like the one just illustrated, since they are already listed in the Windows unit and many other Delphi system units. The only reason you might need to write this external declaration code is to call functions from a custom DLL, or to call undocumented Windows functions.

Note: In the 16-bit version of Delphi, the external declaration used the name of the library without the extension, and was followed by the name directive (as in the code above) or by an alternative index directive, followed by the ordinal number of the function inside the DLL. The change reflects a system change in the way libraries are accessed: Although Win32 still allows access to DLL functions by number, Microsoft has stated this won't be supported in the future. Notice also that the Windows unit replaces the WinProcs and WinTypes units of the 16-bit version of Delphi.

A Windows Callback Function

We've seen in Chapter 6 that Objet Pascal supports procedural types. A common use of procedural types is to provide callback functions to a Windows API function.

First of all, what is a callback function? The idea is that some API function performs a given action over a number of internal elements of the system, such as all of the windows of a certain kind. Such a function, also called an enumerated function, requires as a parameter the action to be performed on each of the elements, which is passed as a function or procedure compatible with a given procedural type. Windows uses callback functions in other circumstances, but we'll limit our study to this simple case.

Now consider the EnumWindows API function, which has the following prototype (copied from the Win32 Help file):

```
BOOL EnumWindows(
  WNDENUMPROC lpEnumFunc,  // address of callback function
  LPARAM lParam // application-defined value
  );
```

Of course, this is the C language definition. We can look inside the Windows unit to retrieve the corresponding Pascal language definition:

```
function EnumWindows (
  lpEnumFunc: TFNWndEnumProc;
  lParam: LPARAM): BOOL; stdcall;
```

Consulting the help file, we find that the function passed as a parameter should be of the following type (again in C):

```
BOOL CALLBACK EnumWindowsProc (
  HWND hwnd, // handle of parent window
  LPARAM lParam // application-defined value
  );
```

This corresponds to the following Delphi procedural type definition:

```
type
  EnumWindowsProc = function (Hwnd: THandle;
    Param: Pointer): Boolean; stdcall;
```

The first parameter is the handle of each main window in turn, while the second is the value we've passed when calling the EnumWindows function. Actually in Pascal the TFNWndEnumProc type is not properly defined; it is simply a pointer. This means we need to provide a function with the proper parameters and then use it as a pointer, taking the address of the function instead of calling it. Unfortunately, this also means that the compiler will provide no help in case of an error in the type of one of the parameters.

Windows requires programmers to follow the stdcall calling convention every time we call a Windows API function or pass a callback function to the system. Delphi, by default, uses a different and more efficient calling convention, indicated by the register keyword.

Here is the definition of a proper compatible function, which reads the title of the window into a string, then adds it to a ListBox of a given form:

```
function GetTitle (Hwnd: THandle; Param: Pointer): Boolean; stdcall;
var
  Text: string;
begin
  SetLength (Text, 100);
  GetWindowText (Hwnd, PChar (Text), 100);
  FormCallBack.ListBox1.Items.Add (
    IntToStr (Hwnd) + ': ' + Text);
  Result := True;
end;
```

The form has a ListBox covering almost its whole area, along with a small panel on the top hosting a button. When the button is pressed, the EnumWindows API function is called, and the GetTitle function is passed as its parameter:

```
procedure TFormCallback.BtnTitlesClick(Sender: TObject);
var
  EWProc: EnumWindowsProc;
begin
  ListBox1.Items.Clear;
  EWProc := GetTitle;
  EnumWindows (@EWProc, 0);
end;
```

I could have called the function without storing the value in a temporary procedural type variable first, but I wanted to make clear what is going on in this example. The effect of this program is actually quite interesting, as you can see in Figure 9.2. The Callback example shows a list of all the existing main windows running in the system. Most of them are hidden windows you usually never see (and many actually have no caption).

Figure 9.2: The output of the Callback example, listing the current main windows (visible and hidden).

A Minimal Windows Program

To complete the coverage of Windows programming and the Pascal language, I want to show you a very simple but complete application built without using the VCL. The program simply takes the command-line parameter (stored by the system in the cmdLine global variable) and then extracts information from it with the ParamCount and ParamStr Pascal functions. The first of these functions returns the number of parameters; the second returns the parameter in a given position.

Although users seldom specify command-line parameters in a graphical user interface environment, the Windows command-line parameters are important to the system. For example, once you have defined an association between a file extension and an application, you can simply run a program by selecting an associated file. In practice, when you double-click on a file, Windows starts the associated program and passes the selected file as a command-line parameter.

Here is the complete source code of the project (a DPR file, not a PAS file):

```
program Strparam;

uses
  Windows;

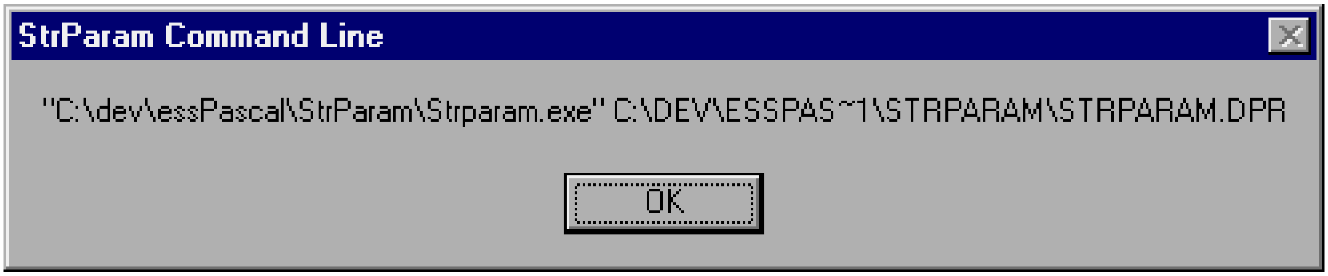
begin
  // show the full string
  MessageBox (0, cmdLine,
    'StrParam Command Line', MB_OK);

  // show the first parameter
  if ParamCount > 0 then
    MessageBox (0, PChar (ParamStr (1)),
      '1st StrParam Parameter', MB_OK)
  else
    MessageBox (0, PChar ('No parameters'),
      '1st StrParam Parameter', MB_OK);
end.
```

The output code uses the MessageBox API function, simply to avoid getting the entire VCL into the project. A pure Windows program as the one above, in fact, has the advantage of a very small memory footprint: The executable file of the program is about 16 Kbytes.

To provide a command-line parameter to this program, you can use Delphi's Run > Parameters menu command. Another technique is to open the Windows Explorer, locate the directory that contains the executable file of the program, and drag the file you want to run onto the executable file. The Windows Explorer will start the program using the name of the dropped file as a command-line parameter. Figure 9.3 shows both the Explorer and the corresponding output.

Figure 9.3: You can provide a command-line parameter to the StrParam example by dropping a file over the executable file in the Windows Explorer.



StrParam Command Line

"C:\dev\essPascal\StrParam\Strparam.exe" C:\DEV\ESSPAS~1\STRPARAM\STRPARAM.DPR

Conclusion

In this chapter we've seen a low-level introduction to Windows programming, discussing handles and a very simple Windows program. For normal Windows programming tasks, you'll generally use the visual development support provided by Delphi and based on the VCL. But this is beyond the scope of this book, which is the Pascal language.

Next chapter covers variants, a very strange addition to Pascal type system, introduced to provide full OLE support.

Next Chapter: Variants

Marco Cantù's Essential Pascal

Chapter 10 Variants

To provide full OLE support, the 32-bit version of Delphi includes the Variant data type. Here I want to discuss this data type from a general perspective. The Variant type, in fact, has a pervasive effect on the whole language, and the Delphi components library also uses them in ways not related to OLE programming.

Variants Have No Type

In general, you can use variants to store any data type and perform numerous operations and type conversions. Notice that this goes against the general approach of the Pascal language and against good programming practices. A variant is type-checked and computed at run time. The compiler won't warn you of possible errors in the code, which can be caught only with extensive testing. On the whole, you can consider the code portions that use variants to be interpreted code, because, as with interpreted code, many operations cannot be resolved until run time. This affects in particular the speed of the code.

Now that I've warned you against the use of the Variant type, it is time to look at what it can do. Basically, once you've declared a variant variable such as the following:

```
var
  V: Variant;
```

you can assign to it values of several different types:

```
V := 10;
V := 'Hello, World';
V := 45.55;
```

Once you have the variant value, you can copy it to any compatible-or incompatible-data type. If you assign a value to an incompatible data type, Delphi performs a conversion, if it can. Otherwise it issues a run-time error. In fact, a variant stores type information along with the data, allowing a number of run-time operations; these operations can be handy but are both slow and unsafe.

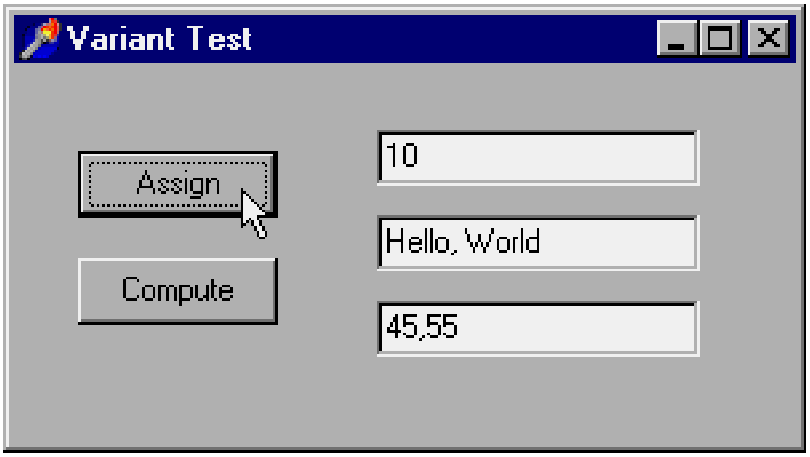
Consider the following example (called VariTest), which is an extension of the code above. I placed three edit boxes on a new form, added a couple of buttons, and then wrote the following code for the OnClick event of the first button:

```
procedure TForm1.Button1Click(Sender: TObject);
var
```

```
  V: Variant;
begin
  V := 10;
  Edit1.Text := V;
  V := 'Hello, World';
  Edit2.Text := V;
  V := 45.55;
  Edit3.Text := V;
end;
```

Funny, isn't it? Besides assigning a variant holding a string to the Text property of an edit component, you can assign to the Text a variant holding an integer or a floating-point number. As you can see in Figure 10.1, everything works.

Figure 10.1: The output of the VariTest example after the Assign button has been pressed.



Even worse, you can use the variants to compute values, as you can see in the code related to the second button:

```
procedure TForm1.Button2Click(Sender: TObject);
var
  V: Variant;
  N: Integer;
begin
  V := Edit1.Text;
  N := Integer(V) * 2;
  V := N;
  Edit1.Text := V;
end;
```

Writing this kind of code is risky, to say the least. If the first edit box contains a number, everything works. If not, an exception is raised. Again, you can write similar code, but without a compelling reason to do so, you shouldn't use the Variant type; stick with the traditional Pascal data types and type-checking approach. In Delphi and in the VCL (Visual Component Library), variants are basically used for OLE support and for accessing database fields.

Variants in Depth

Delphi includes a variant record type, TVarData, which has the same memory layout as the Variant type. You can use this to access the actual type of a variant. The TVarData structure includes the type of the Variant, indicated as VType, some reserved fields, and the actual value.

The possible values of the VType field correspond to the data types you can use in OLE automation, which are often called OLE types or variant types. Here is a complete alphabetical list of the available variant types:

- varArray
- varBoolean
- varByRef
- varCurrency
- varDate
- varDispatch
- varDouble
- varEmpty
- varError
- varInteger
- varNull
- varOleStr
- varSingle
- varSmallint
- varString
- varTypeMask
- varUnknown
- varVariant

You can find descriptions of these types in the Values in variants topic in the Delphi Help system.

There are also many functions for operating on variants that you can use to make specific type conversions or to ask for information about the type of a variant (see, for example, the VarType function). Most of these type conversion and assignment functions are actually called automatically when you write expressions using variants. Other variant support routines (look for the topic Variant support routines in the Help file) actually operate on variant arrays.

Variants Are Slow!

Code that uses the Variant type is slow, not only when you convert data types, but also when you add two variant values holding an integer each. They are almost as slow as the interpreted code of Visual Basic! To compare the speed of an algorithm based on variants with that of the same code based on integers, you can look at the VSpeed example.

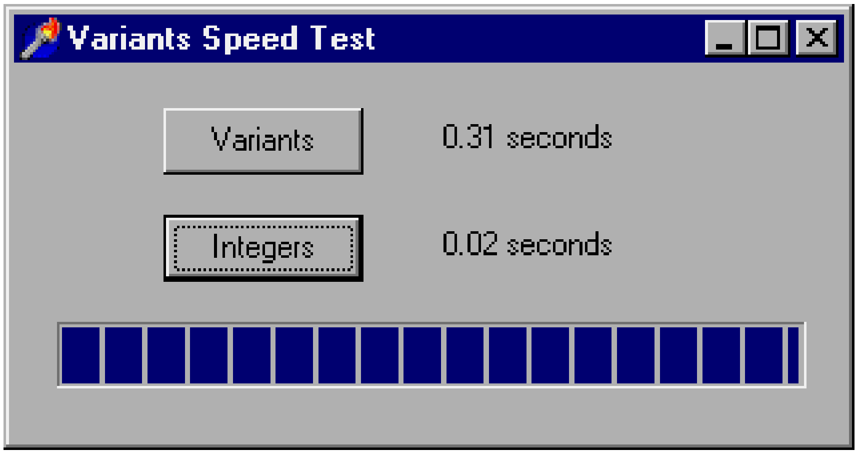
This program runs a loop, timing its speed and showing the status in a progress bar. Here is the first of the two very similar loops, based on integers and variants:

```
procedure TForm1.Button1Click(Sender: TObject);
var
  time1, time2: TDateTime;
  n1, n2: Variant;
begin
  time1 := Now;
  n1 := 0;
  n2 := 0;
  ProgressBar1.Position := 0;
  while n1 < 5000000 do
  begin
    n2 := n2 + n1;
    Inc (n1);
    if (n1 mod 50000) = 0 then
    begin
      ProgressBar1.Position := n1 div 50000;
      Application.ProcessMessages;
    end;
  end;
  // we must use the result
  Total := n2;
  time2 := Now;
  Label1.Caption := FormatDateTime (
    'n:ss', Time2-Time1) + ' seconds';
end;
```

The timing code is worth looking at, because it's something you can easily adapt to any kind of performance test. As you can see, the program uses the Now function to get the current time and the FormatDateTime function to output the time difference, asking only for the minutes ("n") and the seconds ("ss") in the format string. As an alternative, you can use the Windows API's GetTickCount function, which returns a very precise indication of the milliseconds elapsed since the operating system was started.

In this example the speed difference is actually so great that you'll notice it even without a precise timing. Anyway, you can see the results for my own computer in Figure 10.2. The actual values depend on the computer you use to run this program, but the proportion won't change much.

Figure 10.2: The different speeds of the same algorithm, based on integers and variants (the actual timing varies depending on the computer), as shown by the VSpeed example.



Conclusion

Variants are so different from traditional Pascal data types that I've decided to cover them in this short separate chapter. Although their role is in OLE programming, they can be handy to write quick and dirty programs without having even to think about data types. As we have seen, this affects performance by far.

Now that we have covered most of the language features, let me discuss the overall structure of a program and the modularization offered by units.

Next Chapter: Program and Units

Marco Cantù's Essential Pascal

Chapter 11 Program and Units

Delphi applications make intensive use of units, or program modules. Units, in fact, were the basis of the modularity in the language before classes were introduced. In a Delphi application, every form has a corresponding unit behind it. When you add a new form to a project (with the corresponding toolbar button or the File > New Form menu command), Delphi actually adds a new unit, which defines the class for the new form.

Units

Although every form is defined in a unit, the reverse is not true. Units do not need to define forms; they can simply define and make available a collection of routines. By selecting the File > New menu command and then the Unit icon in the New page of the Object Repository, you add a new blank unit to the current project. This blank unit contains the following code, delimiting the sections a unit is divided into:

```
unit Unit1;

interface

implementation

end.
```

The concept of a unit is simple. A unit has a unique name corresponding to its filename, an interface section declaring what is visible to other units, and an implementation section with the real code and other hidden declarations. Finally, the unit can have an optional initialization section with some startup code, to be executed when the program is loaded into memory; it can also have an optional finalization section, to be executed on program termination.

The general structure of a unit, with all its possible sections, is the following:

```
unit unitName;

interface

// other units we need to refer to
uses
  A, B, C;

// exported type definition
type
```

```
  newType = TypeDefinition;

// exported constants
const
  Zero = 0;

// global variables
var
  Total: Integer;

// list of exported functions and procedures
procedure MyProc;

implementation

uses
  D, E;

// hidden global variable
var
  PartialTotal: Integer;

// all the exported functions must be coded
procedure MyProc;
begin
  // ... code of procedure MyProc
end;

initialization
  // optional initialization part

finalization
  // optional clean-up code

end.
```

The uses clause at the beginning of the interface section indicates which other units we need to access in the interface portion of the unit. This includes the units that define the data types we refer to in the definition of other data types, such as the components used within a form we are defining.

The second uses clause, at the beginning of the implementation section, indicates more units we need to access only in the implementation code. When you need to refer to other units from the code of the routines and methods, you should add elements in this second uses clause instead of the first one. All the units you refer to must be present in the project directory or in a directory of the search path (you can set the search path for a project in the Directories/Conditionals page of the project's Options dialog box).

C++ programmers should be aware that the uses statement does not correspond to an include directive. The effect of a uses statement is to import just the precompiled interface portion of the units listed. The implementation portion of the unit is considered only when that unit is compiled. The units you refer to can be both in source code format (PAS) or compiled format (DCU), but the compilation must have taken place with the same version of the Delphi.

The interface of a unit can declare a number of different elements, including procedures, functions, global variables, and data types. In Delphi applications, the data types are probably used the most often. Delphi automatically places a new class data type in a unit each time you create a form. However, containing form definitions is certainly not the only use for units in Delphi. You can continue to have traditional units, with functions and procedures, and you can have units with classes that do not refer to forms or other visual elements.

Units and Scope

In Pascal, units are the key to encapsulation and visibility, and they are probably even more important than the private and public keywords of a class. (In fact, as we'll see in the next chapter, the effect of the private keyword is related to the scope of the unit containing the class.) The scope of an identifier (such as a variable, procedure, function, or a data type) is the portion of the code in which the identifier is accessible. The basic rule is that an identifier is meaningful only within its scope—that is, only within the block in which it is declared. You cannot use an identifier outside its scope. Here are some examples.

- Local variables: If you declare a variable within the block defining a routine or a method, you cannot use this variable outside that procedure. The scope of the identifier spans the whole procedure, including nested routines (unless an identifier with the same name in the nested routine hides the outer definition). The memory for this variable is allocated on the stack when the program executes the routine defining it. As soon as the routine terminates, the memory on the stack is automatically released.
- Global hidden variables: If you declare an identifier in the implementation portion of a unit, you cannot use it outside the unit, but you can use it in any block and procedure defined within the unit. The memory for this variable is allocated as soon as the program starts and exists until it terminates. You can use the initialization section of the unit to provide a specific initial value.
- Global variables: If you declare an identifier in the interface portion of the unit, its scope extends to any other unit that uses the one declaring it. This variable uses memory and has the same lifetime as the previous group; the only difference is in its visibility.

Any declarations in the interface portion of a unit are accessible from any part of the program that includes the unit in its uses clause. Variables of form classes are declared in the same way, so that you can refer to a form (and its public fields, methods, properties, and components) from the code of any other form. Of course, it's poor programming practice to declare everything as global. Besides the obvious memory consumption problems, using global variables makes a program less easy to maintain and update. In short, you should use the smallest possible number of global variables.

Units as Namespaces

The uses statement is the standard technique to access the scope of another unit. At that point you can access the definitions of the unit. But it might happen that two units you refer to declare the same identifier; that is, you might have two classes or two routines with the same name.

In this case you can simply use the unit name to prefix the name of the type or routine defined in the unit. For example, you can refer to the ComputeTotal procedure defined in the given Totals unit as Totals.ComputeTotal. This should not be required very often, as you are strongly advised against using the same name for two different things in a program.

However, if you look into the VCL library and the Windows files, you'll find that some Delphi functions have the same name as (but generally different parameters than) some Windows API functions available in Delphi itself. An example is the simple Beep procedure.

If you create a new Delphi program, add a button, and write the following code:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Beep;
end;
```

then as soon as you press the button you'll hear a short sound. Now, move to the uses statement of the unit and change the code from this:

```
uses
  Windows, Messages, SysUtils, Classes, ...
```

to this very similar version (simply moving the SysUtils unit before the Windows unit):

```
uses
  SysUtils, Windows, Messages, Classes, ...
```

If you now try to recompile this code, you'll get a compiler error: "Not enough actual parameters." The problem is that the Windows unit defines another Beep function with two parameters. Stated more generally, what happens in the definitions of the first units you include in the uses statement might be hidden by corresponding definitions of later units. The safe solution is actually quite simple:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  SysUtils.Beep;
end;
```

This code will compile regardless of the order of the units in the uses statements. There are few other name clashes in Delphi, simply because Delphi code is generally hosted by methods of classes. Having two methods with the same name in two different classes doesn't create any problem. The problems arise only with global routines.

Units and Programs

A Delphi application consists of two kinds of source code files: one or more units and one program file. The units can be considered secondary files, which are referred to by the main part of the application, the program. In theory, this is true. In practice, the program file is usually an automatically generated file with a limited role. It simply needs to start up the program, running the main form. The code of the program file, or Delphi project file (DPR), can be edited either manually or by using the Project Manager and some of the Project Options related to the application object and the forms.

The structure of the program file is usually much simpler than the structure of the units. Here is the source code of a sample program file:

```
program Project1;

uses
  Forms,
  Unit1 in ‘Unit1.PAS’ {Form1DateForm};

begin
  Application.Initialize;
  Application.CreateForm (TForm1, Form1);
  Application.Run;
end.
```

As you can see, there is simply a uses section and the main code of the application, enclosed by the begin and end keywords. The program's uses statement is particularly important, because it is used to manage the compilation and linking of the application.

Conclusion

At least for the moment, this chapter on the structure of a Pascal application written in Delphi or with one of the latest versions of Turbo Pascal, is the last of the book. Feel free to email me your comment and requests.

If after this introduction on the Pascal language you want to delve into the object-oriented elements of Object Pascal in Delphi, you can refer to my published book **Mastering Delphi 5** (Sybex, 1999). For more information on this and more advanced books of mine (and of other authors as well) you can refer to my web site, **www.marcocantu.com**. The same site hosts updated versions of this book, and its examples.

Marco Cantù's Essential Pascal

Appendix A Glossary

This is a short glossary of technical terms used throughout the book. They might also be defined elsewhere in the text, but I've decided to collect them here anyway, to make it easier to find them.

Heap (Memory)

The term Heap indicates a portion of the memory available to a program, also called dynamic memory area. The heap is the area in which the allocation and deallocation of memory happens in random order. This means that if you allocate three blocks of memory in sequence, they can be destroyed later on in any order. The heap manager takes care of all the details for you, so you simply ask for new memory with GetMem or by calling a constructor to create an object, and Delphi will return you a new memory block (optionally reusing memory blocks already discarded).

The heap is one of the three memory areas available to an application. The other two are the global area (this is where global variables live) and the stack. Contrary to the heap, global variables are allocated when the program starts and remain there until it terminates. For the stack see the specific entry in this glossary.

Delphi uses the heap for allocating the memory of each and every object, the text of the strings, for dynamic arrays, and for specific requests of dynamic memory (GetMem).

Windows allows an application to have up to 2 GigaBytes of address space, most of which can be used by the heap.

Stack (Memory)

The term Stack indicates a portion of the memory available to a program, which is dynamic but is allocated and deallocated following specific order. The stack allocation is LIFO, Last In First Out. This means that the last memory object you've allocated will be the first to be deleted. Stack memory is typically used by routines (procedure, function, and method calls). When you call a routine, its parameters and return type are placed on the stack (unless you optimize the call, as Delphi does by default). Also the variables you declare within a routine (using a var block before the begin statement) are stored on the stack, so that when the routine terminates they'll be automatically removed (before getting back to the calling routine, in LIFO order).

The stack is one of the three memory areas available to an application. The other two are called global memory and heap. See the heap entry in this glossary..

Delphi uses the stack for routine parameters and return values (unless you use the default register calling convention), for local routine variables, for Windows API function calls, and so on.

Windows applications can reserve a large amount of memory for the stack. In Delphi you set this in the linker page of the project options, however, the default generally does it. If you receive a stack full error message this is probably because you have a function recursively calling itself forever, not because the stack space is too limited.

MARCO CANTÙ'S ESSENTIAL DELPHI

A Friendly Introductory Guide to Borland Delphi

http://www.marcocantu.com/edelphi

Revision 1.03 - April 13, 2002

INTRODUCTION

After the successful publishing of the e-book Essential Pascal (available on my web site at the address `http://www.marcocantu.com/epascal`), I decided to follow up with an introduction to Delphi. Again most of the material you'll find here was in the first editions of my "printed" book Mastering Delphi, the best selling Delphi book I have written. Due to space constraints and because many Delphi programmers look for more advanced information, in the latest edition this material was completely omitted. To overcome the absence of this information, I have started putting together this second on-line book, titled ***Essential Delphi***.

Copyright

The text and the source code of this book are copyrighted by Marco Cantù. Of course, you can use the programs and adapt them to your own needs with no limitation, only you are not allowed to use them in books, training material, and other copyrighted formats without my permission (or in case you are using limited portions, referring to the original). Feel free to link your site with this one, but please do not duplicate the material (on your web site, on a CD) as it is subject to frequent changes and updates. Passing a copy to a friend, occasionally, is certainly something you can do if you do not modify it in any way.

You can print out this book both for personal use and for non-profit training (user-groups, schools, and universities are free to distribute a printed versions as long as they don't charge more than the printing costs and make it clear that this material is freely available, referring readers to the Essential Delphi web site (`http://www.marcocantu.com/edelphi`) for updates.

Book Structure

The book structure is still under development, as the book evolves. This is the current structure:

Chapter 1: A Form is a Window:
Chapter 2: Highlights of the Delphi Environment:

Chapter 3: The Object Repository and the Delphi Wizards:

Chapter 4: A Tour of the Basic Components

Chapter 5: Creating and Handling Menus [some figures still missing]

Chapter 6: Multimedia Fun [all figures missing]

Planned chapters:

Chapter 7: Exploring Forms

Chapter 8: Delphi Database 101

Chapter 9: Reporting Basics

Source Code

The source code of all the examples mentioned in the book is available on the book web site. The code has the same Copyright as the book: Feel free to use it at will but don't publish it on other documents or site. Links back to this site are welcome.

Feedback

Please let me know of any errors you find (indicating revision number and page number), but also of topics not clear enough for a beginner. I'll be able to devote time to the project depending also on the feedback I receive. Let me know also which other topics (not covered in Mastering Delphi) you'd like to see here.

For reporting errors please use the books section of my newsgroup, as described on www.marcocantu.com or use my mailbox (which gets far too jammed) at marco@marcocantu.com.

Acknowledgments

I have first started thinking about on-line publishing after Bruce Eckel's experience with *Thinking in Java*. I'm a friend of Bruce and think he really did a great job with that book and few others. After the overwhelming response of the "Essential Pascal" book, I started this new one and plan releasing the two as a printed book introducing Delphi (the only problem being to find a publisher).

About the Author

Marco Cantù lives in Piacenza, Italy. After writing C++ and Object Windows Library books and articles, he delved into Delphi programming. He is the author of the *Mastering Delphi* book series, published by Sybex, as well as the advanced *Delphi Developers Handbook*. He writes articles for many magazines, including *The Delphi Magazine*, speaks at Delphi and Borland conferences around the world, and teaches Delphi classes at basic and advanced levels. More recently, he's specializing in XML technologies, still making most of his programming in Delphi. Of course, you can learn more details about Marco and his work by visiting his web site, www.marcocantu.com.

Donations

I'll probably set up an account on one of those donation/contribution systems, to let people who have enjoyed the book and learned from it, particularly if programming is their job (and not a hobby) and they do it for profit, contribute to its development. No extra material is offered to those donating to the book fund, only because I want to let anyone (particularly students and people leaving in poor countries) benefit from the availability of this material. Information will be available on the book web site.

Table of Contents

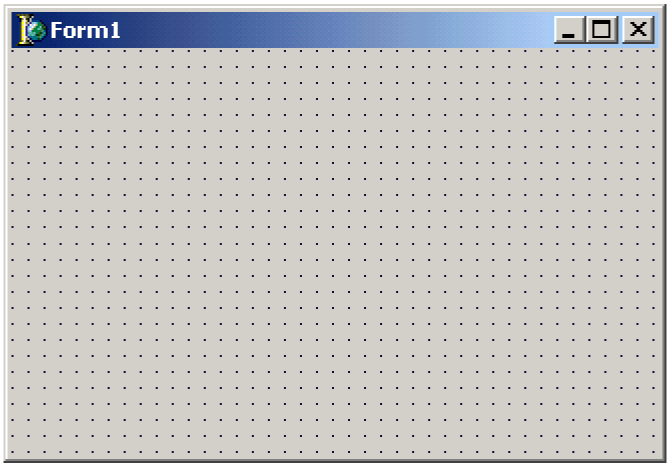
Chapter 1: A Form Is a Window

Windows applications are usually based on windows. So, how are we going to create our first window? We'll do it by using a form. As the first part of the title suggests, a form really is a window in disguise. There is no real difference between the two concepts, at least from a general point of view.

> If you look closely, a form is always a window, but the reverse isn't always true. Some Delphi components are windows, too. A push button is a window. A list box is a window. To avoid confusion, I'll use the term *form* to indicate the main window of an application or a similar window and the term *window* in the broader sense.

Creating Your First Form

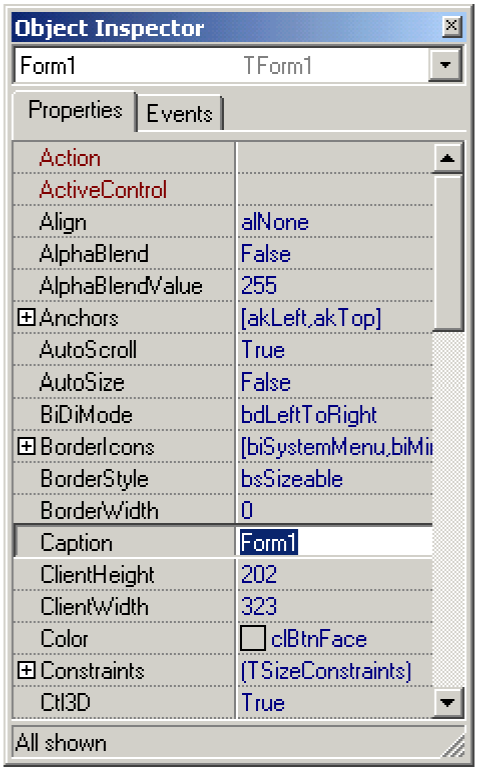
Even though you have probably already created at least some simple applications in Delphi, I'm going to show you the process again, to highlight some interesting points. Creating a form is one of the easiest operations in the system: you only need to open Delphi, and it will automatically create a new, empty form for you, as you can see in the figure below. That's all there is to it.



If you already have another project open, choose File | New | Application to close the old project (you may be prompted to save some of the files) and open a new blank project. Believe it or not, you already have a working application. You can run it, using the Run button on the toolbar or the Run | Run menu command, and it will result in a standard Windows program. Of course, this application won't be very useful, since it has a single empty window with no capabilities, but the default behavior of any Windows window.

Adding a Title

Before we run the application, let's make a quick change. The title of the form is *Form1*. For a user, the title of the main window stands for the name of the application. Let's change *Form1* to something more meaningful. When you first open Delphi, the Object Inspector window should appear on the left side of the form (if it doesn't, open it by choosing View | Object Inspector or pressing the F11 key):



Action	
ActiveControl	
Align	alNone
AlphaBlend	False
AlphaBlendValue	255
⊞Anchors	[akLeft,akTop]
AutoScroll	True
AutoSize	False
BiDiMode	bdLeftToRight
⊞BorderIcons	[biSystemMenu,biMi
BorderStyle	bsSizeable
BorderWidth	0
Caption	Form1
ClientHeight	202
ClientWidth	323
Color	□ clBtnFace
⊞Constraints	(TSizeConstraints)
Ctl3D	True

The Object Inspector shows the properties of the selected component. The window contains a tab control with two pages. The first page is labeled Properties. The other page is labeled Events and shows a list of events that can take place in the form or in the selected component.

The properties are listed in alphabetical order, so it's quite easy to find the ones you want to change (it is also possible to group them by category, as we'll see in the next chapter, but this feature is seldom used by Delphi developers). We can change the title of the form simply by changing the `Caption` property, which is selected by default. While you type a new caption, you can see the title of the form change. If you type *Hello*, the title of the form changes immediately. As an alternative, you can modify the internal name of the form by changing its `Name` property. If you have not entered a new caption, the new value of the `Name` property will be used for the `Caption` property, too.

Only a few of the properties of a component change while you type the new value. Most are applied when you finish the editing operation and press the Enter key (or move the input focus to a new property).

Although we haven't done much work, we have built a full-blown application, with a system menu and the default Minimize, Maximize, and Close buttons. You can resize the form by dragging its borders, move it by dragging its caption, maximize it to full-screen size, or minimize it. It works, but again, it's not very useful. If you look at the icon in the Taskbar, you'll see that something isn't right. Instead of showing the caption of the form as the icon caption, it shows the name of the project, something like *Project1*. We can fix this by giving a name to the project, which we'll do by saving it to disk with a new name.

Saving the Form

Select the Save Project or Save Project As command from the File menu, and Delphi will ask you to give a name to the source code file associated with the form, and then to name the project file. Since the name of the project should match the caption of the form (*Hello*), I've named the form source file `HELLOF.PAS`, which stands for *Hello Form*. I've given the project file the name `HELLO.DPR`.

Unfortunately, we cannot use the same name for the project and the unit that defines the form; for each application, these items must have unique names. You can add the letter *F*, add *Form*, call every form unit *MainForm*, or choose any other naming convention you like. I tend to use a name similar to the project name, as simply calling it `Mainform` means you'll end up with a number of forms (in different projects) that all have the same name.

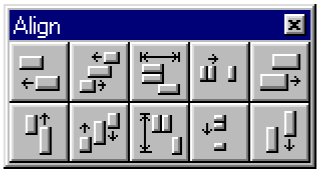
The name you give to the project file is used by default at run-time as the title of the application, displayed by Windows in the taskbar while the program is running. For this reason, if the name of the project matches the caption of the main form, it will also correspond to the name on the taskbar. You can also change the title of the application by using the Application page of the Project Options dialog box (choose Project | Options), or by writing a line of code to change the `Title` property of the Application global object.

Using Components

Now it's time to start placing something useful in our Hello form. Forms can be thought of as component containers. Each form can host a number of components or controls. You can choose a component from the Components Palette above the form, in the Delphi window. There are four simple ways to place a component on a form. If you choose the Button component from the Standard page of the Components Palette, for example, you can do any of the following:

- Click on the component, move the mouse cursor to the form, press the left mouse button to set the upper-left corner of the button, and drag the mouse to set the button's size.
- Select the component as above, and then simply click on the form to place a button of the default height and width.
- Double-click on the icon in the Components Palette, and a component of that type will be added in the center of the form.
- Shift-click on the component icon, and place several components of the same kind in the form using one of the above procedures.

Our form will have only one button, so we'll center it in the form. You can do this by hand, with a little help from Delphi. When you choose View | Alignment Palette, a toolbox with alignment icons appears:



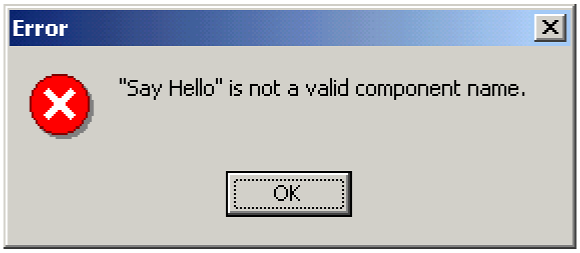
This toolbox makes a number of operations easy. It includes buttons to align controls or to center them in the form. Using the two buttons in the third column, you can place a component in the center of the form. Although we've placed the button in the center, as soon as you run the program, you can resize the form so that the button won't be in the center anymore. So the button is only in the center of the form at startup. Later on, we'll see how to make the button remain in the center after the form is resized, by adding some code. For now, our first priority is to change the button's label.

Changing Properties

Like the form, the button has a `Caption` property that we can use to change its label (the text displayed inside it). As a better alternative, we can change the name of the button. The name is a kind of internal property, used only in the code of the program. However, as I mentioned earlier, if you change the name of a button before changing its caption, the `Caption` property will have the same text as the `Name` property. Changing the `Name` property is usually a good choice, and you should generally do this early in the development cycle, before you write much code.

> It is quite common to define a naming convention for each type of component (usually the full name or a shorter version, such as "btn" for Button). If you use a different prefix for each type of component (as in "*ButtonHello*" or "*BtnHello*"), the combo box above the Object Inspector will list the components of the same kind in a group, because they are alphabetically sorted. If you instead use a suffix, naming the components "*HelloButton*" or "*HelloBtn*," components of the same kind will be in different positions on the list. In this second case, however, finding a particular component using the keyboard might be faster. In fact, when the Object Inspector is selected you can type a letter to jump to the first component whose name starts with that letter.

Besides setting a proper name for a component, you often need to change its `Caption` property. There are at least two reasons to have a caption different from the name. The first is that the name often follows a naming convention (as described in the note above) that you won't want to use in a caption. The second reason is that captions should be descriptive, and therefore they often use two or more words, as in my *Say hello* button. If you try to use this text as the `Name` property, however, Delphi will show an error message:



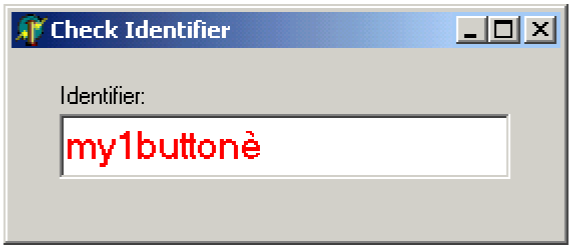
Error

"Say Hello" is not a valid component name.

The name is an internal property, and it is used as the name of a variable referring to the component. Therefore, for the `Name` property, you must follow the rules for naming an identifier in the Pascal language:

- An identifier is a sequence of letters, digits, or underscore characters of any length (although only the first 63 characters are significant).
- The first character of an identifier cannot be a number; it must be a letter or the underscore character.
- No spaces are allowed in an identifier.
- Identifiers are not case-sensitive, but usually each word in an identifier begins with a capital letter, as in BtnHello. But btnhello, btnHello, and BTNHello refer to this same identifier.

You can use the `IsValidIdent` system function to check whether a given string is a valid identifier. The CheckId example calls this function while you type an identifier in its edit box, and changes the text color to indicate whether the string is valid (green) or not (red). The code of the example is quite simple, and you can look at it yourself on the disk. Try running this program to check any doubts about allowed component names.



Check Identifier

Identifier:

my1buttonè

Here is a summary of the changes we have made to the properties of the button and form. At times, I'll show you the structure of the form of the examples as it appears once it has been converted in a readable format (I'll describe how to convert a form into text later in this chapter). I won't show you the entire textual description of a form (which is often quite long), but rather only its key elements. I won't include the lines describing the position of the components, their sizes, or some less important default values. Here is the code:

```
object Form1: TForm1
  Caption = 'Hello'
  OnClick = FormClick
  object BtnHello: TButton
    Caption = 'Say hello'
    OnClick = BtnHelloClick
  end
```

```
end
```

This description shows some attributes of the components and the events they respond to. We will see the code for these events in the following sections. If you run this program now, you will see that the button works properly. In fact, if you click on it, it will be pushed, and when you release the mouse button, the on-screen button will be released. The only problem is that when you press the button, you might expect something to happen; but nothing does, because we haven't assigned any action to the mouse-click yet.

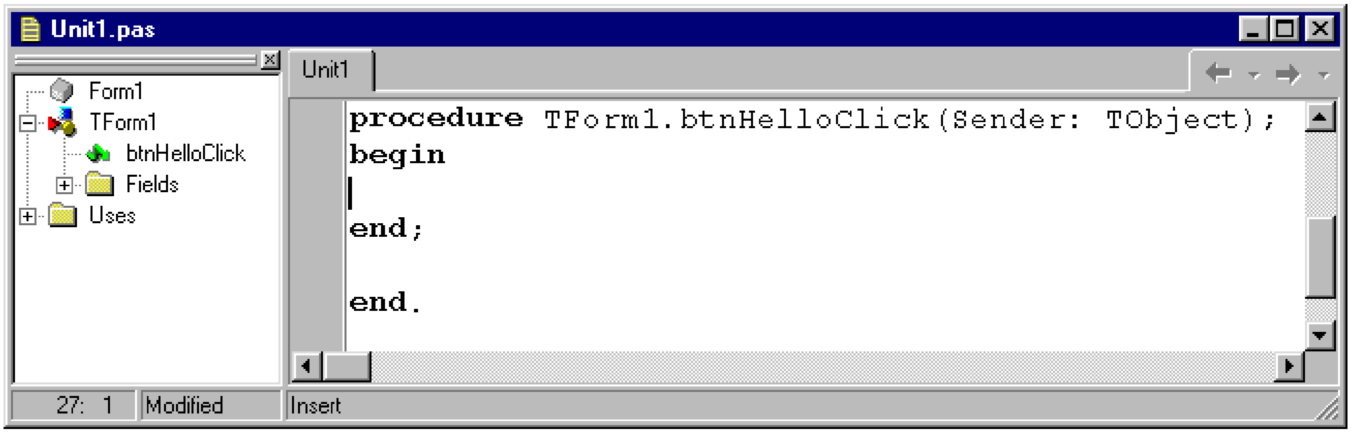
Responding to Events

When you press the mouse button on a form or a component, Windows informs your application of the event by sending it a message. Delphi responds by receiving an event notification and calling the appropriate event-handler method. As a programmer, you can provide several of these methods, both for the form itself and for the components you have placed in it. Delphi defines a number of events for each kind of component. The list of events for a form is different from the list for a button, as you can easily see by clicking on these two components while the Events page is selected in the Object Inspector. Some events are common to both components.

There are several techniques you can use to define a handler for the `OnClick` event of the button:

- Select the button, either in the form or by using the Object Inspector's combo box (called the Object Selector), select the Events page, and double-click in the white area on the right side of the OnClick event. A new method name will appear, *BtnHelloClick*.
- Select the button, select the Events page, and enter the name of a new method in the white area on the right side of the `OnClick` event. Then press the Enter key to accept it.
- Double-click on the button, and Delphi will perform the default action for this component, which is to add a handler for the `OnClick` event. Other components have completely different default actions.

With any of these approaches, Delphi creates a procedure named `BtnHelloClick` (or the name you've provided) in the code of the form and opens the source code file in that position:



```
procedure TForm1.btnHelloClick(Sender: TObject);
begin

end;

end.
```

The default action for a button is to add a procedure to respond to the click event. Even if you are not sure of the effect of the default action of a component, you can still double-click on it. If you end up adding a new procedure you don't need, just leave it empty. Empty method bodies generated by Delphi will be removed as soon as you save the file. In other words, if you don't put any code in them, they simply go away.

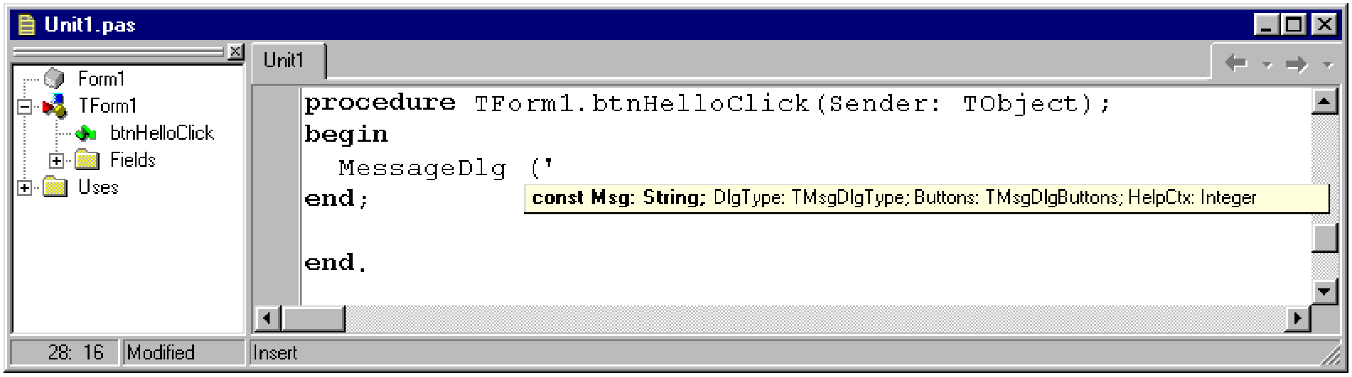
> When you want to remove an event-response method you have written from the source code of a Delphi application, you could delete all of the references to it. However, a better way is to delete all of the code from the corresponding procedure, leaving only the declaration and the `begin` and `end` keywords. The text should be the same as what Delphi automatically generated when you first decided to handle the event. When you save or compile a project, Delphi removes any empty methods from the source code and from the form description (including the reference to them in the Events page of the Object Inspector). Conversely, to keep an event-handler that is still empty, consider adding a comment to it, so that it will not be removed.

Now we can start typing some instructions between the `begin` and `end` keywords that delimit the code of the procedure. Writing code is usually so simple that you don't need to be an expert in the language to start working with Delphi. (If you need to brush up your knowledge of Pascal you can refer to my online Essential Pascal book, while if you need derailede coverage of Object Pascal you can refer to my Mastering Delphi series.)

You should type only the line in the middle, but I've included the whole source code of the procedure to let you know where you need to add the new code in the editor:

```
procedure TForm1.BtnHelloClick(Sender: TObject);
begin
  MessageDlg ('Hello, guys', mtInformation, [mbOK], 0);
end;
```

The code is simple. There is only a call to a function, `MessageDlg`, to display a small message dialog box. The function has four parameters. Notice that as you type the open parenthesis, the Delphi editor will show you the list of parameters in a hint window, making it simpler to remember them.



```
procedure TForm1.btnHelloClick(Sender: TObject);
begin
  MessageDlg ('
end;

end.
```

const Msg: String; DlgType: TMsgDlgType; Buttons: TMsgDlgButtons; HelpCtx: Integer

If you need more information about the parameters of this function and their meanings, you can click on its name in the edit window and press F1. This brings up the Help information. Since this is the first code we are writing, here is a summary of that description (the rest of this book, however, generally does *not* duplicate the reference information available in Delphi's Help system, concentrating instead on examples that demonstrate the features of the language and environment):

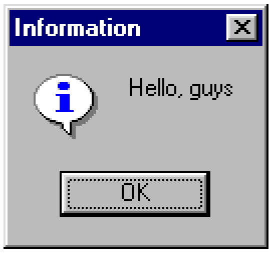
- The first parameter of the MessageDlg function is the string you want to display: the message.

- The second parameter is the type of message box. You can choose mtWarning, mtError, mtInformation, or mtConfirmation. For each type of message, the corresponding caption is used and a proper icon is displayed at the side of the text.
- The third parameter is a set of values indicating the buttons you want to use. You can choose mbYes, mbNo, mbOK, mbCancel, or mbHelp. Since this is a set of values, you can have more than one of these values. Always use the proper set notation with square brackets ([and]) to denote the set, even if you have only one value, as in the line of the code above. (Essential Pascal discusses Pascal sets.)
- The fourth parameter is the help context, a number indicating which page of the Help system should be invoked if the user presses F1. Simply write `0` if the application has no help file, as in this case.

The function also has a return value, which I've just ignored, using it as if it were a procedure. In any case, it's important to know that the function returns an identifier of the button that the user clicked to close the message box. This is useful only if the message box has more than one button.

> Programmers unfamiliar with the Pascal language, particularly those who use C/C++, might be confused by the distinction between a function and a procedure. In Pascal, there are two different keywords to define procedures and functions. The only difference between the two is that functions have a return value.

After you have written this line of code, you should be able to run the program. When you click on the button, you'll see the message box shown below.



Hello, guys

Every time the user clicks on the push button in the form, a message is displayed. What if the mouse is pressed outside that area? Nothing happens. Of course, we can add some new code to handle this event. We only need to add an `OnClick` event to the form itself. To do this, move to the Events page of the Object Inspector and select the form. Then double-click at the right side of the `OnClick` event, and you'll end up in the proper position in the edit window. Now add a new call to the `MessageDlg` function, as in the following code:

```
procedure TForm1.FormClick(Sender: TObject);
begin
  MessageDlg ('You have clicked outside of the button',
    mtWarning, [mbOK], 0);
end;
```

With this new version of the program, if the user clicks on the button, the hello message is displayed, but if the user misses the button, a warning message appears. Notice that I've written the code on two lines, instead of one. The Pascal compiler completely ignores new lines, white spaces, tab spaces, and similar formatting characters. Program statements are separated by semicolons (`;`), not by new lines.

> There is one case in which Delphi doesn't completely ignore line breaks: Strings cannot extend across multiple lines. In some cases, you can split a very long string into two different strings, written on two lines, and merge them by writing one after the other.

Compiling and Running a Program

Before we make any further changes to our Hello program, let's stop for a moment to consider what happens when you run the application. When you click on the toolbar Run button or select Run | Run, Delphi does the following:

1: Compiles the Pascal source code file describing the form.

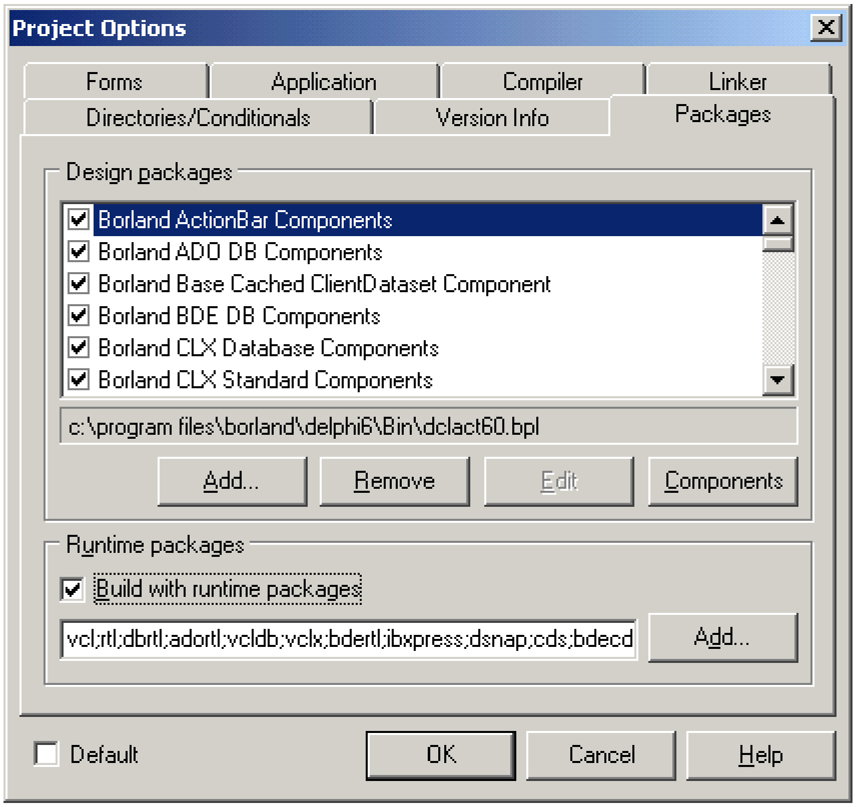
2: Compiles the project file.

3: Builds the executable (`EXE`) file, linking the proper libraries.

4: Runs the executable file, usually in debug mode.

> In early versions of Delphi, the executable file you obtained was invariably a stand-alone program. Starting with version 3, Delphi allows you to link all the required libraries into the executable file, but you can also specify the use of separate run-time packages, making the executable file much smaller.

The key point is that when you ask Delphi to run your application, it compiles it into an executable file. You can easily run this file from the Windows Explorer or using the Run command on the Start button. Compiling this program as usual, linking all the required library code, produces an executable of about a couple of hundred Kb. By using run-time packages, this can shrink the executable to about 20 Kb. Simply select the Project | Options menu command, move to the Packages page, and select the check box *Build with runtime packages*:



☑ Borland ActionBar Components
☑ Borland ADO DB Components
☑ Borland Base Cached ClientDataset Component
☑ Borland BDE DB Components
☑ Borland CLX Database Components
☑ Borland CLX Standard Components

c:\program files\borland\delphi6\Bin\dclact60.bpl

☑ Build with runtime packages

vcl;rtl;dbrtl;adortl;vcldb;vclx;bdertl;ibxpress;dsnap;cds;bdecd

□ Default

Packages are dynamic link libraries containing Delphi components (the Visual Components Library). By using packages you can make an executable file much smaller. However, the program won't run unless the proper dynamic link libraries (such as `vcl60.bpl`) are available on the computer where you want to run the program. The `BPL` extensions stands for Borland Package Libraries; it is the extension used by Delphi (and C++Builder) packages, which are technically DLL files. Using this extension makes it easier to recognize them (and find them on a hard disk).

If you add the size of this dynamic library to that of the small executable file, the total amount of disk space required by the program built with run-time packages is much bigger than the space required by the bigger stand-alone executable file. For this reason the use of packages is not always recommended. The great advantage of Delphi over competing development tools is that you can easily choose whether to use the stand-alone executable or the small executable with run-time packages.

> In both cases, Delphi executables are extremely fast to compile, and the speed of the resulting application is comparable with that of a C or C++ program. Delphi compiled code runs much faster (at least 10 times faster) than the equivalent code in interpreted or *semi-compiled* tools.

Some users cannot believe that Delphi generates real executable code, because when you run a small program, its main window appears almost immediately, as happens in some interpreted environments. To see for yourself, try this: Open the Environment Options dialog box (using Tools | Options), move to the Preferences page, and turn on the Show Compile Progress option. Now select Project | Build All. You'll see a dialog box with the compilation status. You'll find that this takes just a few seconds, or even less on a fast machine.

In the tradition of Borland's Turbo Pascal compilers, the Object Pascal compiler embedded in Delphi works very quickly. For a number of technical reasons, it is much faster than any C++ compiler. If you try using the new Borland C++ Builder development environment (which is very similar to Delphi) the compilation requires more time, particularly the first time you build an application. One reason for the higher speed of the Delphi compiler is that the language definition is simpler. Another is that the Pascal compilers and linkers have less work to do to include libraries or other compiled source files in a program, because of the structure of units.

Changing Properties at Run-Time

Let's return to the Hello application. We now want to try to change some properties at run-time. For example, we might change the text of `HelloButton` from *Say hello* to *Say hello again* after the first time a user clicks on it. You may also need to widen the button, as the caption becomes longer. This is really simple. You only need to change the code of the `HelloButtonClick` procedure as follows:

```
procedure TForm1.HelloButtonClick(Sender: TObject);
begin
  MessageDlg ('Hello, guys', mtInformation, [mbOK], 0);
  btnHello.Caption := 'Say Hello Again';
end;
```

> The Pascal language uses the `:=` operator to express an assignment and the `=` operator to test for equality. At the beginning, this can be confusing for programmers coming from other languages. For example in C and C++, the assignment operator is `=`, and the equality test is `==`. After a while, you'll get used to it. In the meantime, if you happen to use `=` instead of `:=`, you'll get an error message from the compiler.

A property such as `Caption` can be changed at run-time very easily, by using an assignment statement. Most properties can be changed at run-time, and some can be changed *only* at run-time. You can easily spot this last group: They are not listed in the Object Inspector, but they appear in the Help file for the component. Some of these run-time properties are defined as read-only, which means that you can access their value but cannot change it.

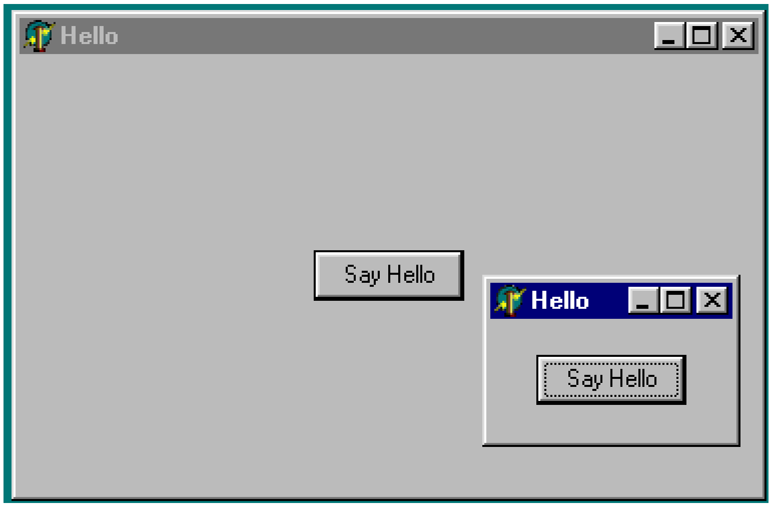
Adding Code to the Program

Our program is almost finished, but we still have a problem to solve, which will require some real coding. The button starts in the center of the form, but will not remain there when you resize the form. This problem can be solved in two radically different ways.

One solution is to change the border of the form to a thin frame, so that the form cannot be resized at run-time. Just move to the `BorderStyle` property of the form, and choose `bsSingle` instead of `bsSizeable` from the combo box. The other approach is to write some code to move the button to the center of the form each time the form is resized, and that's what we'll do next. Although it might seem that most of your work in programming with Delphi is just a matter of selecting options and visual elements, there comes a time when you need to write code. As you become more expert, the percentage of the time spent writing code will generally increase.

When you want to add some code to a program, the first question you need to ask yourself is Where? In an event-driven environment, the code is always executed in response to an event. When a form is resized, an event takes place: `OnResize`. Select the form in the Object Inspector and double-click next to `OnResize` in the Events page. A new procedure is added to the source file of the form. Now you need to type some code in the editor, as follows:

```
procedure TForm1.FormResize(Sender: TObject);
begin
  BtnHello.Top := Form1.ClientHeight div 2 -
    BtnHello.Height div 2;
  BtnHello.Left := Form1.ClientWidth div 2 -
    BtnHello.Width div 2;
end;
```



To set the `Top` and `Left` properties of the button — that is, the position of its upper-left corner — the program computes the center of the frame, dividing the height and the width of the internal area or client area of the frame by 2, and then subtracts half the height or width of the button. Note also that if you use the `Height` and `Width` properties of the form, instead of the `ClientWidth` and `ClientHeight` properties, you will refer to the center of the whole window, including the caption at the top border. This final version of the example works quite well as you can see below.

This figure includes two versions of the form, with different sizes. By the way, this figure is a real snapshot of the screen. Once you have created a Windows application, you can run several copies of it at the same time by using the Explorer. By contrast, the Delphi environment can run only one copy of a program. When you run a program within Delphi, you start the integrated debugger, and it cannot debug two programs at the same time — not even two copies of the same program — unless you are using Windows NT/2000/XP.

A Two-Way Tool

In the Hello example, we have written three small portions of code, to respond to three different events. Each portion of code was part of a different procedure (actually a method, as you'll learn reading Chapter 5). But where does the code we write end up? The source code of a form is written in a single Pascal language source file, the one we've named HELLOF.PAS. This file evolves and grows not only when you code the response of some events, but also as you add components to the form. The properties of these components are stored together with the properties of the form in a second file, named HELLOF.DFM.

Delphi can be defined as a two-way tool, since everything you do in the visual environment ends up in some code. Nothing is hidden away and inaccessible. You have the complete code, and although some of it might be fairly complex, you can edit everything. Of course, it is easier to use only the visual tools, at least until you are an expert Delphi programmer.

The term *two-way tool* also means that you are free to change the code that has been produced, and then go back to the visual tools. This is true as long as you follow some simple rules.

Looking at the Source Code

Let's take a look at what Delphi has generated from our operations so far. Every action has an effect — in the Pascal code, in the code of the form, or in both. When you start a new, blank project, the empty form has some code associated with it, as in the following listing.

```
unit Unit1;

interface

uses
  SysUtils, Windows, Messages, Classes, Graphics,
  Controls, Forms, Dialogs;

type
  TForm1 = class(TForm)
  private
    { Private declarations }
  public
    { Public declarations }
  end;

var
  Form1: TForm1;

implementation

{$R *.DFM}

end.
```

The file, named Unit1, uses a number of units and defines a new data type (a class) and a new variable (an object of that class). The class is named TForm1, and it is derived from TForm. The object is Form1, of the new type TForm1.

> *Units* are the modules into which a Pascal program is divided. When you start a new project, Delphi generates a program module and a unit that defines the main form. Each time you add a form to a Delphi program, you add a new unit. Units are then compiled separately and linked into the main program. By default, unit files have a .PAS extension and program files have a .DPR extension.

If you rename the files as suggested in the example, the code changes slightly, since the name of the unit must reflect the name of the file. If you name the file Hellof.pas, the code begins with

```
unit Hellof;
```

As soon as you start adding new components, the form class declaration in the source code changes. For example, when you add a button to the form, the portion of the source code defining the new data type becomes the following:

```
type
  TForm1 = class(TForm)
    Button1: TButton;
    ...
```

Now if you change the button's Name property (using the Object Inspector) to BtnHello, the code changes slightly again:

```
type
  TForm1 = class(TForm)
    BtnHello: TButton;
    ...
```

Setting properties other than the name has no effect in the source code. The properties of the form and its components are stored in a separate form description file (with a DFM extension).

Adding new event handlers has the biggest impact on the code. Each time you define a new handler for an event, a line is added to the data type definition of the form, an empty method body is added in the implementation part, and some information is stored in the form description file, too.

```
unit HelloForm;

interface

uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
  StdCtrls;

type
  TForm1 = class(TForm)
    btnHello: TButton;
    procedure btnHelloClick(Sender: TObject);
    procedure FormCreate(Sender: TObject);
    procedure FormResize(Sender: TObject);
  private
    { Private declarations }
  public
    { Public declarations }
  end;

var
  Form1: TForm1;
```

```
implementation

{$R *.DFM}

procedure TForm1.btnHelloClick(Sender: TObject);
begin
  MessageDlg ('Hello, guys', mtInformation, [mbOK], 0);
  btnHello.Caption := 'Say Hello Again';
end;

procedure TForm1.FormCreate(Sender: TObject);
begin
  MessageDlg ('You have clicked outside of the button',
    mtWarning, [mbOK], 0);
end;

procedure TForm1.FormResize(Sender: TObject);
begin
  BtnHello.Top := Form1.ClientHeight div 2 -
    BtnHello.Height div 2;
  BtnHello.Left := Form1.ClientWidth div 2 -
    BtnHello.Width div 2;
end;

end.
```

It is worth noting that there is a single file for the whole code of the form, not just small fragments. Of course, the code is only a partial description of the form. The source code determines how the form and its components react to events. The form description (the `DFM` file) stores the values of the properties of the form and of its components. In general, source code defines the actions of the system, and form files define the initial state of the system.

The Textual Description of the Form

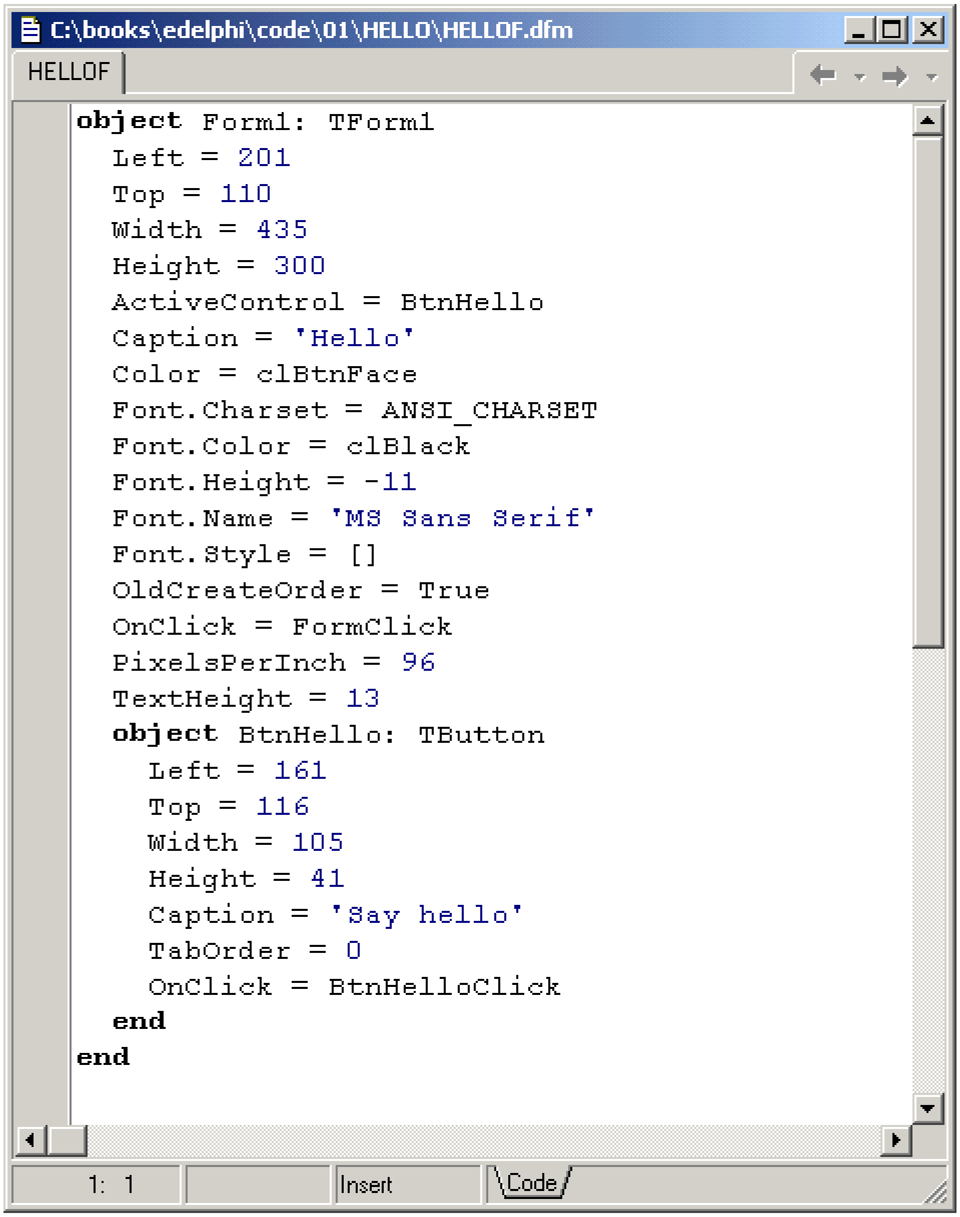
As I've just mentioned, along with the `PAS` file containing the source code, there is another file describing the form, its properties, its components, and the properties of the components. This is the `DFM` file, a binary or text file (this latter option has been introduced with Delphi 5). Whatever the format, if you load this file in the Delphi code editor, it will be converted into a textual description. This might give the false impression that the `DFM` file is indeed a text file, but this can be only if you've selected the corresponding option (available since Delphi 5).

> You can open the textual description of a form simply by selecting the shortcut menu of the form designer (that is, right-clicking on the surface of the form at design-time) and selecting the View as Text command. This closes the form, saving it if necessary, and opens the `DFM` file in the editor. You can later go back to the form using the View as Form command of the local menu of the editor window. The alternative is to open the `DFM` file directly in the Delphi editor.

To understand what is stored in the `DFM` file, you can look at the next listing, which shows the textual description of the form of the first version of the Hello example. This is exactly the code you'll see if you give the View as Text command in the local menu of the form:

```
object Form1: TForm1
  Left = 235
  Top = 108
  Width = 430
  Height = 308
  Caption = 'Hello'
  Color = clBtnFace
  Font.Charset = DEFAULT_CHARSET
  Font.Color = clWindowText
  Font.Height = -11
  Font.Name = 'MS Sans Serif'
  Font.Style = []
  OldCreateOrder = False
  OnCreate = FormCreate
  OnResize = FormResize
  PixelsPerInch = 96
  TextHeight = 13
  object btnHello: TButton
    Left = 165
    Top = 111
    Width = 75
    Height = 25
    Caption = 'Say Hello'
    TabOrder = 0
    OnClick = btnHelloClick
  end
end
```

You can compare this code with what I used before to indicate the key features and properties of the form and its components. As you can see in this listing, the textual description of a form contains a number of objects (in this case, two) at different levels. The `Form1` object contains the `BtnHello` object, as you can immediately see from the indentation of the text. Each object has a number of properties, and some methods connected to events (in this case, `OnClick`).



```
object Form1: TForm1
  Left = 201
  Top = 110
  Width = 435
  Height = 300
  ActiveControl = BtnHello
  Caption = 'Hello'
  Color = clBtnFace
  Font.Charset = ANSI_CHARSET
  Font.Color = clBlack
  Font.Height = -11
  Font.Name = 'MS Sans Serif'
  Font.Style = []
  OldCreateOrder = True
  OnClick = FormClick
  PixelsPerInch = 96
  TextHeight = 13
  object BtnHello: TButton
    Left = 161
    Top = 116
    Width = 105
    Height = 41
    Caption = 'Say hello'
    TabOrder = 0
    OnClick = BtnHelloClick
  end
end
```

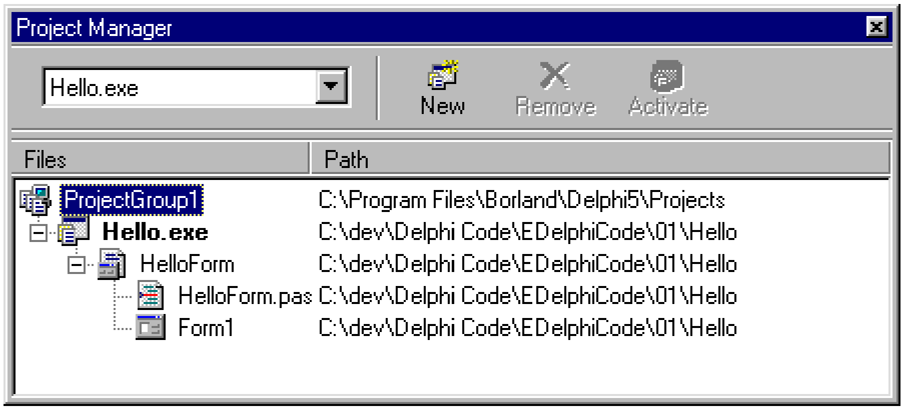
Once you've opened this file in Delphi, you can *edit* the textual description of the form, although this should be done with extreme care. As soon as you save the file, it will be turned back into a binary file. If you've made incorrect changes, this compilation will stop with an error message, and you'll need to correct the contents of your `DFM` file before you can reopen the form in the editor. For this reason, you shouldn't try to change the textual description of a form manually until you have a good knowledge of Delphi programming.

An expert programmer might choose to work on the text of a form for a number of reasons. For big projects, the textual description of the form is a powerful documenting tool, an important form of backup (in case someone plays with the form, you can understand what has gone wrong by comparing the two textual versions), and a good target for a version-control tool. For these reasons, Delphi also provides a DOS command-line tool, `CONVERT.EXE`, which can translate forms from the compiled version to the textual description and vice versa.

As we will see in the next chapter, the conversion is also applied when you cut or copy components from a form to the Clipboard.

The Project File

In addition to the two files describing the form (PAS and DFM), a third file is vital for rebuilding the application. This is the Delphi project file (DPR). This file is built automatically, and you seldom need to change it, particularly for small programs. If you do need to change the behavior of a project, there are basically two ways to do so: You can use the Delphi Project Manager and set some project options, or you can manually edit the project file directly.



Files	Path
ProjectGroup1	C:\Program Files\Borland\Delphi5\Projects
Hello.exe	C:\dev\Delphi Code\EDelphiCode\01\Hello
HelloForm	C:\dev\Delphi Code\EDelphiCode\01\Hello
HelloForm.pas	C:\dev\Delphi Code\EDelphiCode\01\Hello
Form1	C:\dev\Delphi Code\EDelphiCode\01\Hello

This project file is really a Pascal language source file, describing the overall structure of the program and its startup code:

```
program Hello;

uses
  Forms,
  Hellof in 'HelloForm.PAS' {Form1};

{$R *.RES}

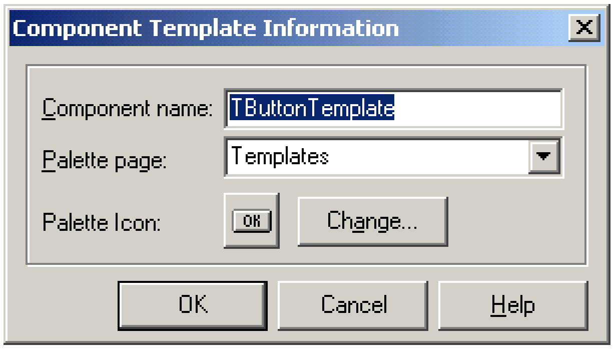
begin
  Application.Initialize;
  Application.CreateForm(TForm1, Form1);
  Application.Run;
end.
```

You can see this file with the View | Project Source menu command. As an alternative, you can click on the Select unit button of the toolbar or issue the equivalent menu command, View | Units. When you use one of these commands, Delphi shows a dialog box with the list of the source files of the project. You can choose the project file (named Hello in the example), or any other file you are interested in seeing.

Using Component Templates

Suppose you want to create a brand new application, with a similar button and a similar event handler to the Hello program. It is possible to copy a component to the Clipboard, and then paste it into another form to create a perfect clone. However, doing so you copy only the properties of the component, and not the events associated with it.

Delphi allows you to copy one or more components, and install them as a new component template. This way, you also copy the code of the methods connected with the events of the component. Simply open the Hello example, or any other one, select the component you want to move to the template (or a group of components), and then select the Component | Create Component Template menu command. This opens the Component Template Information dialog box, shown below. Here you enter the name of the template, the page of the Component Palette where it should appear, and an icon.



Component name: TButtonTemplate

Palette page: Templates

What's Next

In this chapter, we created a simple program, added a button to it, and handled some basic events, such as a click with the mouse or a resize operation. We also saw how to name files, projects, forms, and components, and how this affects the source code of the program. We looked at the source code of the simple programs we've built, although some of you might not be fluent enough in Object Pascal to understand the details.

Before we can look into more complex examples, we need to explore the Delphi development environment. This is the topics of the next chapter. The examples in this chapter should have shown you that Delphi is really easy to use. Now we'll start to look at the complex mechanisms behind the scenes that make this all possible. You'll see that Delphi is a very powerful tool, even though you can use it to write programs easily and quickly.

Chapter 2: Highlights of the Delphi Environment

In a visual programming tool such as Delphi, the role of the environment is certainly important, at times even more important than the programming language used by its compiler or interpreter. This is a good reason to spend some time reading this chapter.

This chapter won't discuss all of the features of Delphi or list all of its menu commands. Instead, it will give you the overall picture and help you to explore some of the environment traits that are not obvious, while suggesting some tips that may help you. You'll find more information about specific commands and operations throughout the book.

Different Versions of Delphi

Before delving into the details of the Delphi programming environment, let's take a side step to underline two key ideas. First, there isn't a single version of Delphi; there are three of them:

- The basic version (the "Standard" edition) is aimed at Delphi newcomers and casual programmers. It has all the features required to write programs in Delphi for Windows but (starting with Delphi 5) it has no support for any type of database programming.
- The second level (the "Professional" edition) is aimed at professional developers. It includes database support (with BDE and ODBC connectivity), limited Web support, and many more components.
- The full-blown Delphi (the "Enterprise" edition starting with Delphi 5, or the "Client/Server Suite" edition in previous versions) is aimed at developers building client/server applications. It includes also drivers for native Client/Server connection, full ADO support, MIDAS and Internet Express support, and (in Delphi) all of the new Snap technologies: BizSnap, WebSnap, and DataSnap.

Besides the different editions available, there are a number of ways to customize the Delphi environment. You can change the buttons of the toolbar, attach new commands to the Tools menu, hide some of the windows or elements, and resize and move all of them. In the screen illustrations throughout the book, I'll try to use a standard user interface (as it comes out of the box); however, I have my preferences, and I generally install many add-ons (written by third parties or by me), which might be reflected in some of the screen shots.

Asking for Help

Now we can really start our tour. The first element of the environment we'll explore is the Help system. There are basically two ways to invoke the Help system: select the proper command in the Help pull-down menu, or choose an element of the Delphi interface or a token in the source code and press F1.

> When you press F1, Delphi doesn't search for an exact match in the Help Search list. Instead, it tries to understand what you are asking. For example, if you press F1 when the text cursor is on the name of the Button1 component in the source code, the Delphi Help system automatically opens the description of the TButton class, since this is what you are probably looking for. This technique also works when you give the component a new name. Try naming the button Foo, then move the cursor to this word, press F1, and you'll still get the help for the TButton class. This means Delphi looks at the contextual meaning of the word for which you are asking help.

Note that there isn't just a single help file in Delphi. Most of the time, you'll invoke Delphi Help, but this file is complemented by an Object Pascal Help file, the Windows API Help, the Component Writer's Help, and many others (depending on your version of Delphi). These and other Help files have a common outline and a common search engine you can activate by pressing the Help Topics button while in the Help system. The Windows help engine dialog box that appears allows you to browse the contents of all of the help files in the group, search for a keyword in the index, or start the Find engine. The three capabilities are available in separate pages of the Help Topics dialog box.

You can find almost everything in the Help system, but you need to know what to search for. Usually this is obvious, but at times it is not. Spending some time just playing with the Help system will probably help you understand the structure of these files and learn how to find the information you need.

The Help files provide a lot of information, both for beginner and expert programmers, and they are especially valuable as a reference tool. They list all of the methods and properties for each component, the parameters of each method or function, and similar details, which are particularly important while you are writing code. Borland also distributes reference materials in the form of Adobe Acrobat files. These are electronic versions of the printed manuals that come in the Delphi box, so you can search them for a word, and you can also print the portions you are interested in (or even the whole file if you've got some spare paper).

> The first version of Delphi included some Interactive Tutors in addition to the Help system. If you've never used Delphi (and if you have Delphi 1 installed), you might consider running these Tutors. They will guide you through Delphi's basic features and help you understand some of the terminology of the environment. Unluckily they were soon discontinued by Borland.

Besides the Delphi Help files, there are many sources of collections of tips and suggestions for Delphi programmers. Borland web sites provides some FAQs (Frequently Asked Questions) and a collection of Technical Information short papers (TI). You can find updates of both at the Borland Community Web site (http://community.borland.com). Besides these official Borland documents, you'll find many more tips in Borland newsgroups (and also on mine). Obviously the Web is a great source of information about Delphi itself and third party products. You can find a collection of my favorite Delphi Web pages in the Links portion of my web site (http://www.marcocantu.com/links).

Delphi Menus and Commands

There are basically three ways to issue a command in the Delphi environment:

- Use the menu.

- Use the toolbar.
- Use one of the local menus activated by pressing the right mouse button.

The Delphi menus offer many commands. I won’t bore you with a detailed description of the menu structure. For this type of information, you can refer to the printed documentation or the Help file. In the following sections, I’ll present some suggestions on the use of some of the menu commands. Other suggestions will follow in the rest of the chapter.

The File Menu

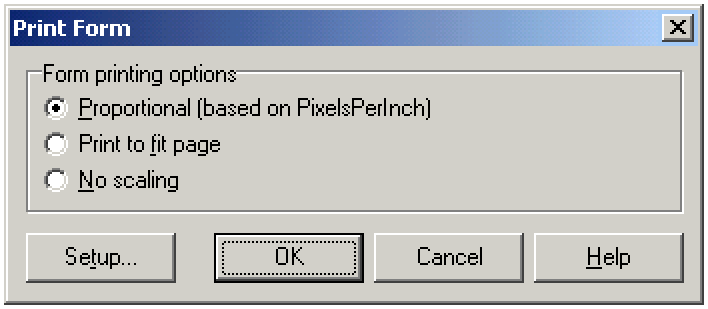
Our starting point is the File pull-down menu. The structure of this menu has kept changing from version to version of Delphi, with menu items for handling projects moving away, and specific commands to create new designer (for example data modules) coming and going. Still, this menu contains commands that operate on projects and commands that operate on source code files.

*[*** The File menu structure has changed in Delphi 6, with the File | New submenu, and the text here has not been updated accordingly]* Some commands can even be used to operate both on projects and on source code files. The commands related to projects are New, New Application, Open, Save Project As, Save All, Close All, Add to Project, and Remove from Project. Besides these, there is also a specific Project pull-down menu. The commands related to source code files are New, New Form, New Data Module, Open, Reopen, Save, Save As, Close, and Print. Most of these commands are very intuitive, but some require a little explanation.

> Use the Reopen menu command to open projects or source code files you have worked on recently.

The New command actually opens the New Items dialog box, also called the Object Repository. This dialog box can be used to invoke Delphi Wizards and to create items such as new applications, forms that inherit from existing forms, threads, DLLs, Delphi components, and ActiveX controls. I’ll cover the Object Repository’s rich set of features in the next chapter.

Another peculiar command is Print. If you are editing source code and select this command, the printer will output the text with syntax highlighting as an option. If you are working on a form and select Print from the File menu, the printer will produce the graphical representation of the form. This is certainly nice, but it can be confusing, particularly if you are working on other Delphi windows. Fortunately, two different print options dialog boxes are displayed, so that you can check that the operation is correct.



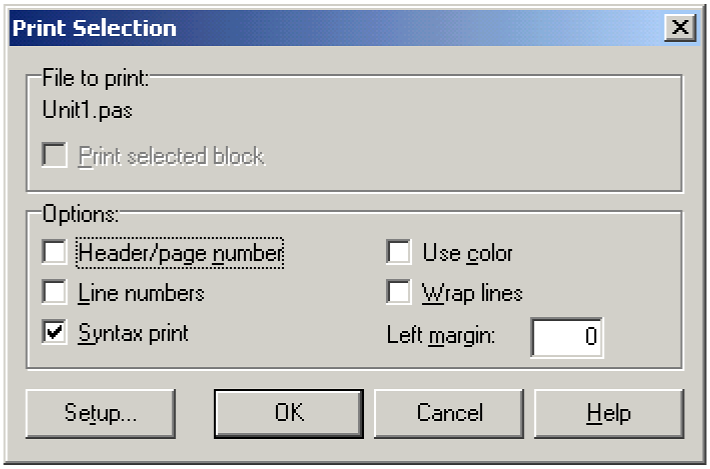
Print Form

Form printing options

● Proportional (based on PixelsPerInch)

○ Print to fit page

○ No scaling



File to print:
Unit1.pas
☐ Print selected block

Options:
☐ Header/page number ☐ Use color
☐ Line numbers ☐ Wrap lines
☑ Syntax print Left margin: 0

The Edit Menu

The Edit menu has some typical operations, such as Undo and Redo, and the Cut, Copy, and Paste commands, plus some specific commands for form or editor windows. The important thing to notice is that the standard features of the Edit menu (and the standard Ctrl+Z, Ctrl+X, Ctrl+C, and Ctrl+V keyboard shortcuts) work both with text and with form components. There are also some differences worth noting. For example, when you work with the editor, the first command of this pull-down menu is Undo; when you work with the form, it becomes Undelete. Unfortunately, the Form Designer has very limited Undo capabilities.

Of course, you can copy and paste some text in the editor, and you can also copy and paste components in one form, or from one form to another. You can even paste components to a different parent window of the same form, such as a panel or group box.

Besides using cut and paste commands, the Delphi editor allows you to move source code by selecting and dragging words, expressions, or lines. If you drag text while pressing the Ctrl key, it will be copied instead of moved.

Copying and Pasting Components

What you might not have noticed is that you can also copy components from the form to the editor and vice versa. Delphi places components in the Clipboard along with their textual description. You can even edit the text version of a component, copy the text to the Clipboard, and then paste it back into the form as a new component.

For example, if you place a button on a form, copy it, and then paste it into an editor (which can be Delphi’s own source code editor or any word processor), you’ll get the following description:

```
object Button1: TButton
  Left = 56
  Top = 48
  Width = 161
  Height = 57
  TabOrder = 0
  Caption = 'Button1'
end
```

Now, if you change the name of the object, caption, or position, or add a new property, these changes can be copied and pasted back to a form. Here are some sample changes:

```
object MyButton: TButton
  Left = 200
  Top = 200
  Width = 180
  Height = 60
  TabOrder = 0
  Caption = 'My Button'
  Font.Name = 'Arial'
end
```

Copying the above description and pasting it into the form will create a button in the specified position with the caption *My Button* in an Arial font. To make use of this technique, you need to know how to edit the textual representation of a component, what properties are valid for that particular component, and how to write the values for string properties, set properties, and other special properties. When Delphi interprets the textual description of a component or form, it might also change the values of other properties related to those you've changed, and change the position of the component so that it doesn't overlap a previous copy. You can see how Delphi modifies the properties of the component by copying it back to the editor. For example, this is what you get if you paste the text above in the form, and then copy it again into the editor:

```
object MyButton: TButton
  Left = 112
  Top = 128
  Width = 180
  Height = 60
  Caption = 'My Button'
  Font.Charset = DEFAULT_CHARSET
  Font.Color = clWindowText
  Font.Height = -11
  Font.Name = 'Arial'
  Font.Style = []
  ParentFont = False
  TabOrder = 0
end
```

As you can see, some lines have been added automatically, to specify other properties of the font. Of course, if you write something completely wrong, such as this code:

```
object Button3: TButton
  Left = 100
  eight = 60
end
```

which has a spelling error (a missing 'H'), and try to paste it into a form, Delphi will show an error indicating what has gone wrong. You can also select several components and copy them all at once, either to another form or to a text editor. This might be useful when you need to work on a series of similar components. You can copy one to the editor, replicate it a number of times, make the proper changes, and then paste the whole group into the form again.

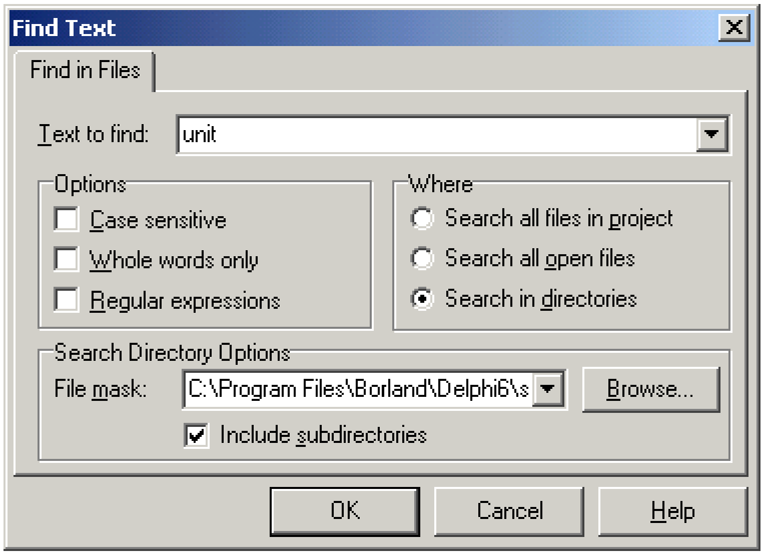
More Edit Commands

Along with the typical commands found on most Edit menus in Windows applications, Delphi includes a number of commands that are mostly related to forms. The specific operations for forms can also be accessed through the form shortcut menu (the local menu you can invoke with the right mouse button) and will be covered later in the chapter.

> One command not replicated in a form’s local menu is Lock Controls, which is very useful for avoiding an accidental change to the position of a component in a form. For example, you might try to double-click on a component and actually end up moving it. Since there is no Undo operation on forms, protecting from similar errors by locking the controls after the form has been designed can be really useful.

The Search Menu

The Search menu has some standard commands, too, such as Search and Replace, and the Find in Files command (you can see its dialog box here):



Find Text

Find in Files

Text to find: unit

Options

□ Case sensitive

□ Whole words only

□ Regular expressions

Where

○ Search all files in project

○ Search all open files

● Search in directories

Search Directory Options

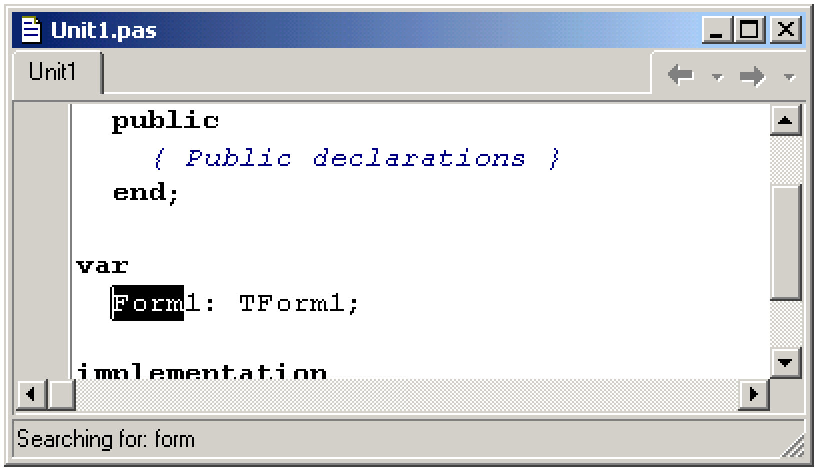
File mask: C:\Program Files\Borland\Delphi6\s

☑ Include subdirectories

The Find in Files command allows you to search for a string in all of the source code files of a project, all the open files, or all the files in a directory (optionally including its subdirectories), depending on the radio button you check. The result of the search will be displayed in the message area at the bottom of the editor window. You can select an entry to open the corresponding file and jump to the line containing the text.

> You can use the Find in Files command to search for component, class, and type definitions in the VCL source code (if your version of Delphi includes it). This is an easy way to get detailed information on a component, although using Help is generally faster and simpler.

Other commands are not so simple to understand. The Incremental Search command is one of them. When you select this command, instead of showing a dialog box where you enter the text you want to find, Delphi moves to the editor. There, you can type the text you want to search for directly in the editor message area, as you can see here:



```
  public
    { Public declarations }
  end;

var
  Form1: TForm1;

implementation
```

Searching for: form

When you type the first letter, the editor will move to the first word starting with that letter. (But if your search text isn't found, the letters you typed won't even be displayed in the editor message area.) If that is not the word you are looking for, just keep typing; the cursor will continue to jump as you add letters. Although this command might look strange at first, it is very effective and extremely fast, particularly if you are typing and invoke it with a shortcut key (Ctrl+E if you are using the standard editor shortcuts).

The Go to Line Number command is quite intuitive. The Find Error command might seem strange at first. It is used to find a particular run-time error, not to search for a compiler error. When you are running a stand-alone program and you hit a very bad error, Delphi displays an internal address number (that is, the *logical* address of the compiled code). You can enter this value in the Find Error dialog box to have Delphi recompile the program, looking for the specific address. When it finds the address, Delphi shows the corresponding source code line. Often, however, the error is not in one of the lines of your code, but in a line of library or system code; in this (quite frequent) case the Find Error command cannot locate the offending line.

The last command on the Search menu, Browse Symbol, invokes the Object Browser, a tool you can use to explore all the symbols defined in a compiled program. To understand the output of the Object Browser, you need a good understanding of the Object Pascal language and of the Visual Component Library (VCL).

The View Menu

The View pull-down menu combines the features you usually find in View and Window menus. There is no Window menu, because the Delphi environment is not an MDI application. Most of the View commands can be used to display one of the windows of the Delphi environment, such as Project Manager, the Breakpoints list, or the Components command. Some of these windows are used during debugging; others when you are writing code. Most of these windows will be described later in this chapter.

> It is possible to add a new item to the View menu, CPU Window, which can be used during debugging to view the Assembler code generated by the Delphi compiler, execute it step by step, and view the status of the CPU registers.

The commands on the second part of the View menu are important, which is why they are also available on the default toolbar. The Toggle Form/Unit (or F12) command is used to move between the form you are working on and its source code. If you use a source code window big enough to hold a reasonable amount of text, you'll use this command often. As an alternative, you can place the two windows (the editor and the form) so that a portion of the one below is always visible. With this arrangement, you can click on it with the mouse to move it to the front.

The New Edit Window command opens a second edit window. It is the only way to view two files side by side in Delphi, since the editor uses tabs to show the multiple files you can load. Once you have duplicated the edit window, you can make each one hold a different set of files, or view two portions of the same file.

The last two commands on the View menu can be used to hide the toolbar or the Components palette, although this is a good way to make Delphi look silly and uncomfortable. Working on forms without the Components palette is certainly not easy. If you remove both the toolbar and the Components palette, the Delphi main window is reduced to a bare menu.

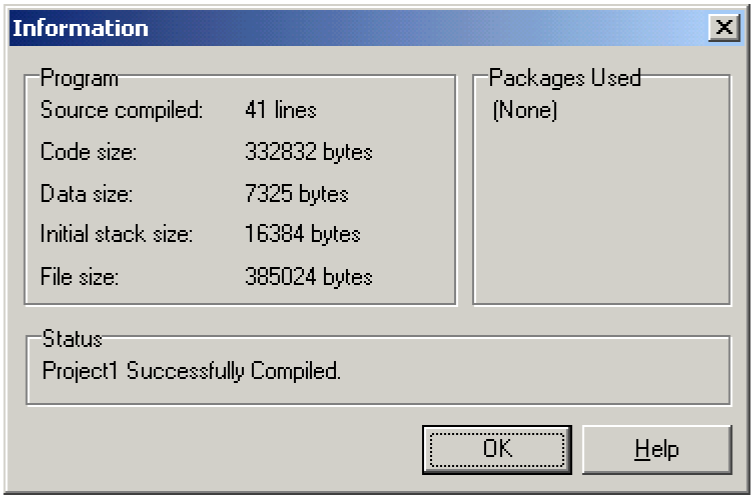
The Project Menu

The next pull-down menu, Project, has commands to manage a project and compile it. Add to Project and Remove from Project are used to add forms or Pascal source code files to a program and to remove them from a project.

> The Enterprise version of Delphi includes two more commands, Web Deploy Options and Web Deploy, which are not available in the other editions. These features are related with ActiveX and ActiveForms, some (now obsolete) Microsoft web technologies.

The Compile command builds or updates the application executable file, checking which source files have changed and recompiling them when needed. With Build All, you can ask Delphi to compile every source file of the project, even if it has not been changed since the last compilation. If you just want to know whether the syntax of the code you've written is correct, but you do not want to build the program, you can use the Syntax Check command.

The next Project command, Information, displays some details about the last compilation you've made. The following figure shows the information related to the compilation of the a short program:



Source compiled: 41 lines
Code size: 332832 bytes
Data size: 7325 bytes
Initial stack size: 16384 bytes
File size: 385024 bytes

(None)

Project1 Successfully Compiled.

> The Compile command can be used only when you have loaded a project in the editor. If no project is active and you load a Pascal source file, you cannot compile it. However, if you load the source file *as if it were a project*, that will do the trick and you'll be able to compile the file. To do this, simply select the Open Project toolbar button and load a PAS file. Now you can check its syntax or compile it, building a DCU (Delphi Compiled Unit).

At the end of the Project menu comes the Options menu, used to set compiler and linker options, application object options, and so on. When you change the project options, you can check the Default box to indicate that the same set of options should be used for new projects. We will discuss project options again in this chapter and then throughout the book in the context of related topics.

The Run Menu

The Run menu could have been named Debug as well. Most of its commands are related to debugging, including the Run command itself. When you run a program within the Delphi environment, you execute it under the integrated debugger (unless you disable the corresponding Environment option). The Run command and the corresponding toolbar icon are among the most commonly used commands, since Delphi automatically recompiles a program before running it — at least if the source code has changed. Simply hit F9 as a shortcut to compile and run a program.

The next command, Parameters, can be used to specify parameters to be passed on the command line to the program you are going to run, and to provide the name of an executable file when you want to debug a DLL (DLL debugging is another new Delphi 3 feature). The remaining commands are all used during debugging, to execute the program step by step, set breakpoints, inspect the values of variables and objects, and so on. Some of these debugging commands are also available directly in the editor local menu.

Delphi 3 has a couple of new commands related to ActiveX development (and not found in the “Standard” edition). The Register ActiveX Server and Unregister ActiveX Server menu commands basically add or remove the Windows Registry information about the ActiveX control defined by the current project.

The Component Menu

The commands of the Component menu can be used to write components, add them to a package, or to install packages in Delphi. The New Component command invokes the simple Component Wizard. The three installation commands, Install Component, Import ActiveX Library, and Install Packages, can be used to add to the environment new Delphi components, packages, or ActiveX controls. Executing any of these commands adds the new components to the specified package and to the Components palette.

Component Templates

We briefly used the Create Component Template menu item in the last chapter. When you issue this command after selecting one or more components in a form, it opens a dialog box where you specify the name of the new component template, a page on the Palette, and an icon. By default, the template name is the name of the first component you’ve selected followed by the word *template*. The default template icon is the icon of the first component you’ve selected, but you can replace it with an icon file. The name you give to the component template will be used to describe it in the Components palette (when Delphi displays the fly-by hint).

All the information about component templates is stored in a single file, DELPHI32.DCT, but there is apparently no way to retrieve this information and edit a template. What you can do, however, is place the component template in a brand new form, edit it, and install it again as a component template *using the same name*. This way you can override the previous definition.

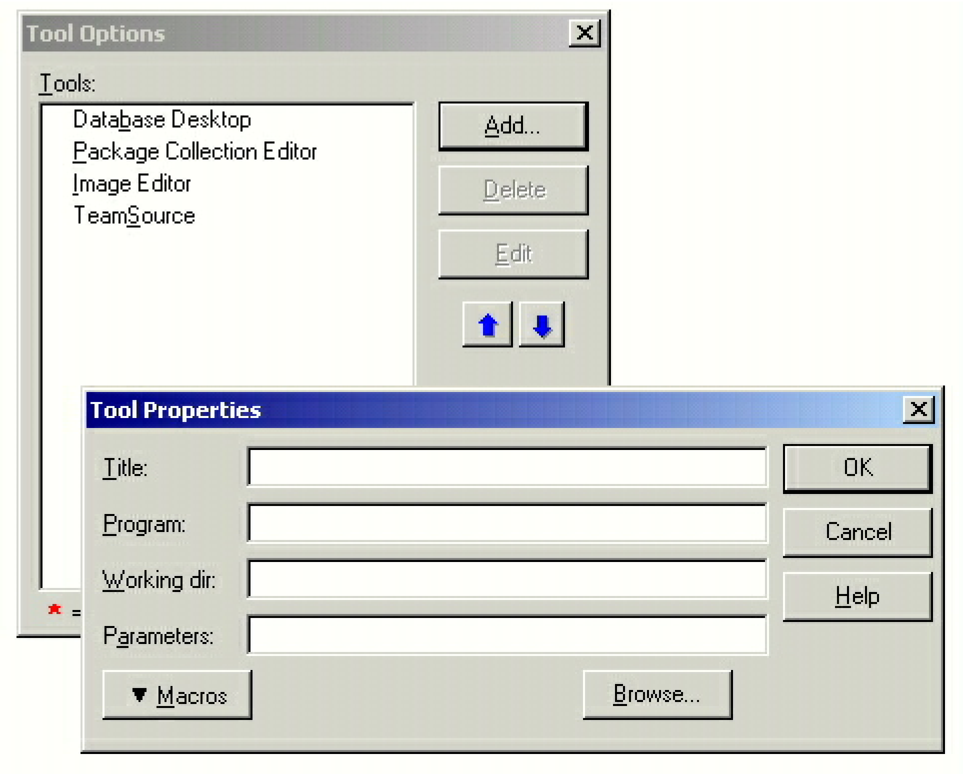
The Database Menu

The Database menu collects the Delphi database-related tools, such as the Database Form Wizard and the Database Explorer. The Enterprise edition has the SQL Explorer instead of the Database Explorer (although the menu items is invariably called Database | Explore) and a menu item to start the SQL Monitor.

The Tools Menu

The Tools menu simply lists a number of external programs and tools, just to make it easier to run them. You can use the Tools command to configure and add new external tools to the pull-down. Besides simply running a program, you can pass some parameters to it. Simple parameter lists can be passed directly on the command line, while complex ones can be built by clicking the Macros button in the lower part of the Tool Properties dialog box.

The Tools menu also includes a command to configure the Repository (discussed in the next chapter) and the Options command to configure the whole Delphi development environment. The Environment Options dialog box has many pages related to generic environment settings (the Preferences page), packages and library settings, many editor options (in the pages Editor, Display, and Colors), a page to configure the Components Palette, one for the object Browser, and one of the new Code Insight technology. I'll discuss many of these options when covering related features. You can see the dialog used to customize the Tools menu below.



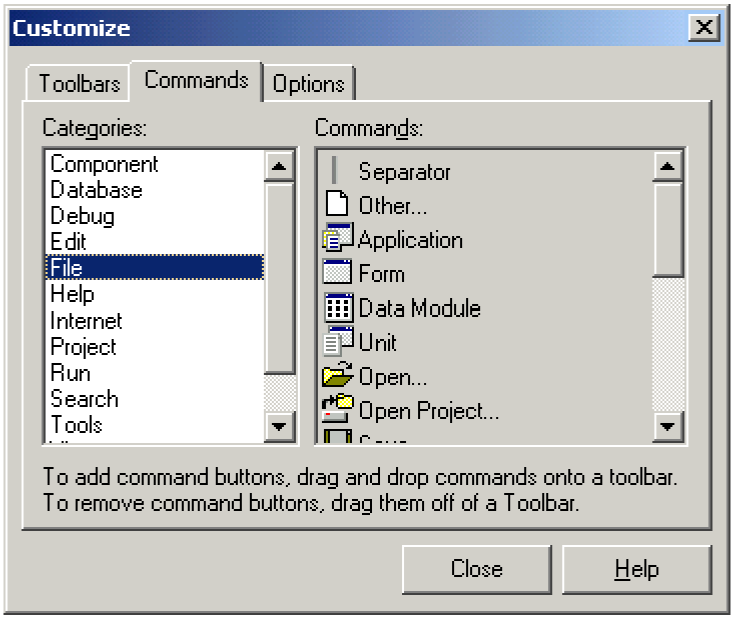
The Help Menu

The Help menu can be used to get information about Delphi (Help | Help Topics) and also to display the Delphi About box. In this window, you can hold down the Alt key and type the letters VERSION to see the Delphi version and build number. Using other key combinations (as mentioned in the acknowledgments at the beginning of the book) you can see a list of the people involved in building Delphi. The Help menu was often populated by third-party Delphi Wizards (before the new ToolsApi made it harder to place wizards in what was their default location).

The Delphi Toolbar

After you have used Delphi for a while, you'll realize that you use only a small subset of the available commands frequently. Some of these commands are probably already on the toolbar (Borland's name for a toolbar); some are not. If the commands you use a lot are not there, it's time to customize the toolbar so that it really helps you to use Delphi more efficiently.

> An alternative to using the toolbar is to use shortcut keys. Although you must remember some key combinations to use them, shortcut keys let you invoke commands very quickly, particularly when you are writing code and your fingers are already on the keyboard.



To add command buttons, drag and drop commands onto a toolbar.
To remove command buttons, drag them off of a Toolbar.

You can easily resize the toolbar by dragging the thick line between it and the Components Palette. But the most important operations you can do with the toolbar are adding, removing, or replacing the icons using the Configure command of the toolbar local menu (simply press the right mouse button over it). This operation invokes the toolbar Editor (see above), one of the Delphi tools with the best user interface, at least in my opinion.

To add an icon to the toolbar, you simply need to find it under the proper category (corresponding to a pull-down menu), and drag it to the bar. In the same way, you can drag an icon away from the toolbar or simply move it to another location. During these operations, you can easily leave some space between groups of icons, to make them easier to remember and select.

The Local Menus

Although Delphi has a good number of menu items, not all of the commands are available though the pull-down menus. At times, you need to use local menus for specific window areas. To activate a local menu, right-click over a window, or press Alt+F10. Even if you have other alternatives, using a local menu is usually faster because you don't need to move the mouse up to the menu bar and select two levels of menus. It's also often easier, since all the local menu commands are related to the current window. Almost every window in Delphi (with the exclusion of dialog boxes) has its own local menu with related commands. I really suggest you get used to right-clicking on windows, because this is not only important in Delphi, but also has become a standard for most applications in Windows. Get used to it, and add local menu to the applications you build with Delphi, too.

Working with the Form Designer

Designing forms is the core of visual development in the Delphi environment. Every component you place on a form and every property you set is stored in a file describing the form (a DFM file) and has some effect on the source code associated with the form (the PAS file).

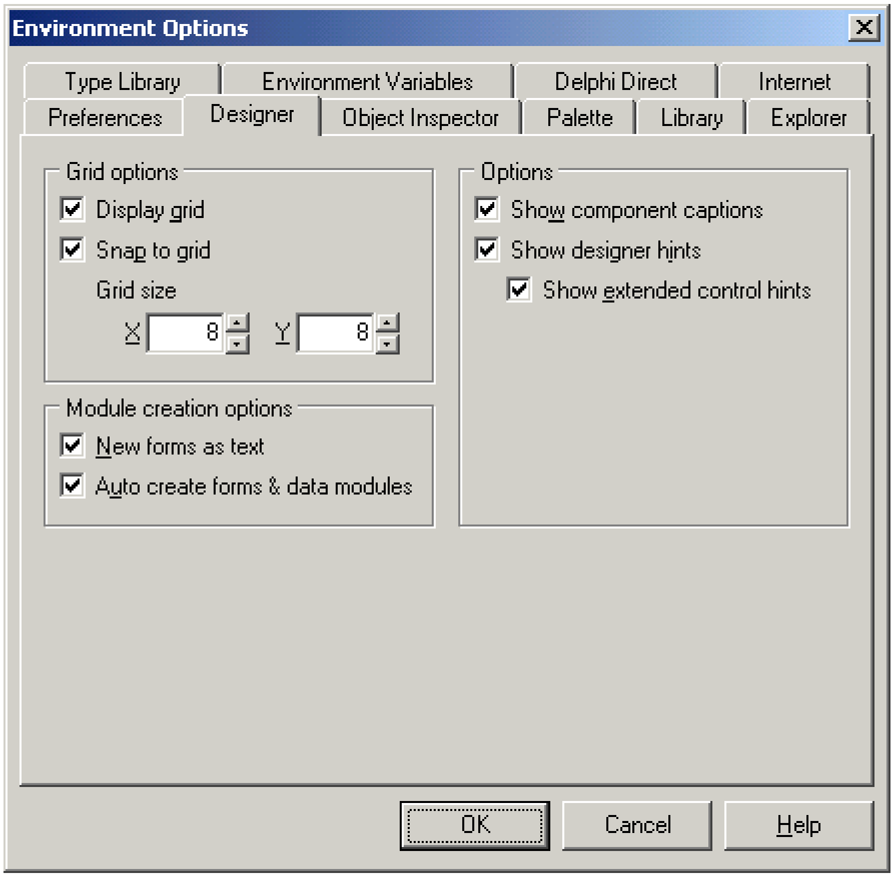
When you start a new, blank project, Delphi creates an empty form, and you can start working with it. You can also start with an existing form (using the various templates available), or add new forms to a project. A project (an application) can have any number of forms. Every time you work with a form at design-time, you are actually using Delphi's Form Designer. When you are working with a form, you can operate on its properties, on the properties of one of its components, or on those of several components at a time. To select the form or a component, you can simply click on it or use the Object Selector (the combo box in the Object Inspector), where you can always see the name and type of the selected item. You can select more than one component by Shift-clicking on the components, or by dragging a selection rectangle around the components on the form.

> Even when a component covers the whole surface of the form, you can still select the form with the mouse. Just press and hold Shift while you click on the selected component. This will deselect the component and select the form by default. Using the keyboard, you can press Esc to select the parent of the current component.

While you are working on a form, the local menu has a number of useful features (some of which are also available in the Edit menu). You can use the Bring to Front and Send to Back commands to change the relative position of components of the same kind (you can never bring a graphical component in front of a component based on a window). In an inherited form, you can use the command Revert to Inherited to restore the properties of the selected component to the values of the parent form.

When you have selected more than one component, you can align or size them. Most of the options in the Alignment dialog box are also available in the Alignment palette (accessible through the View | Alignment Palette menu command). You can also open the Tab Order and Creation Order dialog boxes to set the tab order of the visual controls and the creation order of the non-visual controls. You can use the Add to Repository command to add the form you are working on to a list of forms available for use in other projects. Finally, you can use the View as Text command to close the form and open its textual description in the editor. A corresponding command in the editor local menu (View as Form) will reverse the situation.

Along with specific local menu commands, you can set some form options by using the Tools | Options command and choosing the Preferences page (up to Delphi 5) or the Designer page (from Delphi 6). This latter page is shown here:



Grid options

☑ Display grid

☑ Snap to grid

Grid size

X 8 Y 8

Module creation options

☑ New forms as text

☑ Auto create forms & data modules

Options

☑ Show component captions

☑ Show designer hints

☑ Show extended control hints

The options related to forms refer to grid activation and size. The grid makes it easier to place components exactly where you want them on the form by "snapping" them to fixed positions and sizes. Without a grid, it is difficult to align two components manually (using the mouse).

There are two alternatives to using the mouse to set the position of a component: you can either set values for the Left and Top properties, or you can use the arrow keys while holding down Ctrl. Using arrow keys is particularly useful for fine-tuning an element's position. (The Snap to Grid option works only for mouse operations.) Similarly, by pressing the arrow keys while you hold down Shift, you can fine-tune the size of a component. If you press Shift+Ctrl+an arrow key, instead, the component will be moved only at grid intervals.

Along with the commands described so far, a form's local menu offers other commands when particular components are selected. In some cases, these menu commands correspond to component properties; others contain particularly useful commands. Table 2.1 lists the commands added to the local menu of a form when some of the components are selected (the TeeChart, Quick Report and Decision Cube components add too many commands to list here). Notice that in some cases these actions are also the default action of the component, the one automatically activated when you double-click on it in the Form Designer.

Table 2.1: Local menu commands added when specific components are selected: [*** not updated for recent versions of Delphi]

Menu Command	**Components**
Menu Designer	MainMenu, PopupMenu

Query Builder	Query (if the Visual Query Builder is available)
Fields Editor	Table, Query, StoredProc, ClientDataSet
Explore	Table, Query, StoredProc, Database
Define Parameters	Query, StoredProc
Database Editor	Database
Assign Local Data	ClientDataSet
UpdateSQL Editor	UpdateSQL
Execute	BatchMove
Columns Editor	DBGrid
Edit Report	Report
ImageList Editor	ImageList
New Page	Page Control
Next/Previous Page	Page Control, NoteBook, TabbedNotebbok
Next/Previous Frame	Animate
Insert Object	OleContainer
New Button	ToolBar
New Separator	
Properties, About	All the ActiveX controls
Action Editor	WebDispatcher
ResponseEditor	QueryTableProducer, DataSetTableProducer

The Component Palette

When you want to add a new component to the form you are working on, you can click on a component in one of the pages of the Component palette, and then click on the form to place the new component. On the form, you can press the left mouse button and drag the mouse to set the position and size of the component at once, or just click to let Delphi use a default size.

Each page of the palette has a number of components; each component has an icon and a name, which appears as a “fly-by” hint (just move the mouse on the icon and wait for a second). The hints show the official names of components, which I’ll use in this book. They are drawn from the names of the classes defining the component, without the initial *T* (for example, if the class is TButton, the name is *Button*).

> If you need to place a number of components of the same kind into a form, shift-click on that component in the palette. Then, every time you click on the form, Delphi adds a new component of that kind. To stop this operation, simply click on the standard selector (the arrow icon) on the left side of the Component palette.

If you are temporarily using a mouse-less computer, you can add a component by using the View | Components List command. Select a component in the resulting list or type its name in the edit window, and then click on the Add to Form button.

Of course, you can completely rearrange the components in the various pages of the palette, adding new elements or just moving them from page to page: select Tools | Options and move to the Palette page. In this page of the dialog box, you can simply drag a component from the Components list box to the Pages list box to move that component to a different page. It’s not a good idea to move components on the palette too often. If you do, you’ll probably waste time trying to locate them afterward.

> When you have too many pages in the Component palette, you'll need to scroll them to reach a component. There is a simple trick you can use in this case: rename the pages with shorter names, so that all the pages will fit on the screen. Obvious...once you've thought about it.

The Object Inspector

When you are designing a form, you use the Object Inspector to set values of component or form properties. Its window lists the properties (or events) of the selected element and their values in two resizable columns. An Object Selector at the top of the Object Inspector indicates the current component and its data type; and you can use it to change the current selection. The Object Inspector doesn't list all of the properties of a component. It includes only the properties that can be set at design-time. As mentioned in Chapter 1, other properties are accessible only at run-time. To know about all the different properties of a component, refer to the Help files.

The right column of the Object Inspector allows only the editing appropriate for the data type of the property. Depending on the property, you will be able to insert a string or a number, choose from a list of options (indicated by an arrow), or invoke a specific editor (indicated by an ellipsis button). When a property allows only two values, such as True and False, you can toggle the value by double-clicking on it. If there are many values available, a double-click will select the next one in the list. If you double-click a number of times, all the values of the list will appear, but it is easier to select a multiple-choice value using the small combo box. For some properties, such as Color, you can enter a value, select an element from the list, or invoke a specific editor! Other properties, such as Font, can be customized either by expanding their sub-properties (indicated by a plus or minus sign next to the name) or by invoking an editor. In other cases, such as with string lists, the special editors are the only way to change a property.

The sub-property mechanism is available with sets and with classes. When you expand sub-properties, each of them has its own behavior in the Object Inspector, again depending on its data type.

You will use the Object Inspector often. It should always be visible when you are editing a form, but it can also be useful to look at the names of components and properties while you are writing code. For this reason, the Object Inspector's local menu has a Stay on Top command, which keeps the Object Inspector window in front of the Form Designer and the editor.

> In Delphi 5 and 6 the features of the Object Inspector have been largely extended, with grouping and hiding or little-used properties, interface references, showing of read-only properties, and many other features too complex to discuss here.

The Alignment Palette

The last tool related to form design is the Alignment palette. You can open this palette with the View menu's Alignment Palette command. As an alternative, you can choose the components you want to align, and then issue the Align command from the local menu of the form.

The Alignment palette features a number of commands to position the various controls, center them, space them equally, and so on. To see the effect of each button, simply move the mouse over the window and look at the fly-by hints. When I'm designing complex forms, I position the Alignment palette on the far side of the screen and make sure it always stays in sight by using the Stay on Top command of its local menu.

Writing Code in the Editor

Once you have designed a form in Delphi, you usually need to write some code to respond to some of its events, as we did in Chapter 1. Every time you work on an event, Delphi opens the editor with the source file related to the form. You can easily jump back and forth between the Form Designer and the source code editor by clicking the Toggle Form Unit button on the toolbar, by clicking on the corresponding window, or by pressing the F12 function key.

The Delphi editor allows you to work on several source code files at once, using a "notebook with tabs" metaphor. Each page of the notebook corresponds to a different file. You can work on units related to forms, independent units of Pascal code, and project files; open the form description files in textual format; and even work on plain text files. You can jump from a page of the editor to the next by pressing the Ctrl+Tab keys (or Shift+Ctrl+Tab to move in the opposite direction).

When you work with the editor, you should probably expand its window so that you can see as many full lines of code as possible. A good approach is to size the editor so that it and the Object Inspector are the only windows that appear on the screen when you are writing code. By having the Object Inspector visible you can immediately see the names of the design-time properties of the components.

There are a number of environment options that affect the editor, mostly located in the Editor Options, Editor Display, and Editor Colors pages of the Environment Options dialog box. In the Preferences page, you can set the editor's Autosave feature. Saving the source code files each time you run the program can save the day when your program happens to crash the whole system (something not so rare as you might think). The other three pages of editor options can be used to set the default editor settings like keystroke mappings, syntax highlighting features, and font. Most of these options are fairly simple to understand.

The local menu of the edit window has some commands for debugging and others related to the editor itself, such as those to close the current page, open the file or unit under the cursor, view or hide the message pane below the window, and invoke the editor options discussed before.

Using Editor Bookmarks

The Delphi editor also lets you set line bookmarks. When you are on a line of the editor, you can press Ctrl+Shift plus a number key from 0 to 9 to set a new bookmark, which then appears in the small gutter margin of the editor. Then you can use the Ctrl key plus the number key to jump back at that line of the editor. Pressing the Ctrl+Shift+*number* toggles the status of the bookmark, so you can use this combination again to remove it.

Bookmarks are quite useful when you have a long file and you are editing multiple methods at the same time, or to jump from the class definition to the definition of a method of the class.

Bookmarks have limitation that make them hardly usable. If you set again a given bookmark, the editor moves it. This might seem reasonable, but is actually a problem: If you create a new bookmark and happen to use the number of an existing one, by error, the older bookmark will be removed. Another odd behavior is that you can add multiple bookmarks on the same line, but you'll only see the glyph of one of them. The real problem, however, is that bookmarks are not saved along with the file, nor restored when you reopen it. So they can be used only for a single editing session.

Code Insight

Delphi editor has several features collectively known as Code Insight. The basic idea of this technology is to make it easier for both newcomers and experienced programmers to write code. There are four capabilities that Borland calls Code Insight:

- The Code Completion Wizard allows you to choose the property or method of an object simply by looking it up on a list, or by typing its initial letters. It also allows you to look for a proper value in an assignment statement.
- The Code Templates Wizard allows you to insert one of the predefined code templates, such as a complex statement with an inner begin-end block. You can also easily define new templates.
- The Code Parameter Wizard displays, in a hint or ToolTip window, the data type of a function's or method's parameters while you are typing them.
- The ToolTip Expression Evaluation is a debug-time feature. It shows you the value of the identifier, property, or expression under the mouse cursor.

I'll cover the ToolTip Expression Evaluation later in this chapter, while introducing debugging features; in the next three sections I'll give you some more details on the other three Code Insight capabilities. You can enable and disable (or configure) each of these wizards in the Code Insight page of the Environment Options dialog box.

Code Completion

There are two ways to activate this Wizard. You can simply type the name of an object, such as Button1, then add the dot, and wait:

```
Button1.
```

Delphi will display a list of valid properties and methods you can apply to the object. The time you have to wait before the list is displayed depends on the Code Completion Delay option, which you can configure in the Code Insight page.

As an alternative you can type the initial portion of the property or method name, as in Button1.Ca, and then press Ctrl+SpaceBar to get the list immediately, but this time, the Wizard will try to guess which property or method you were looking for by looking at the characters you typed. You can also use this key combination in an assignment statement. If you type:

```
x :=
```

and then press Ctrl+SpaceBar, Delphi will show you a list of possible objects, variables, or constants you can use at this point in the program (that is, in the current scope).

Notice that Delphi determines the elements to show in this list dynamically, by constantly parsing the code you write in the background. So if you add a new variable to a unit, it will show up in the list.

Code Templates

Unlike the Code Completion Wizard, the Code Templates Wizard must be activated manually. You can do this by typing Ctrl+J to show a list of all of the templates.

More often, you'll first type a keyword, such as if or array, and then press Ctrl+J, to activate only the templates starting with those letters. For some keywords Borland has defined multiple templates, all starting with the keyword name (such as *ifA* and *ifB*). So if you press the keyword and then Ctrl+J, you'll get all the templates related to the keyword.

You can also use Code Templates Wizard simply to give a name to a common expression. For example, if you use the MessageDlg function often, you might want to enter a new Code Template called *mess*, type a description, and add then the following text:

```
MessageDlg ('|',
  mtInformation, [mbOK], 0);
```

Now every time you need to create a message dialog box, you simply type *mess* and then Ctrl+J, and you get the full text. The vertical line (or pipe) character indicates the position in the source code where Delphi will move the cursor after pasting the text. You should choose the position where you want to start typing to edit the code generated by the template.

As this example demonstrates, Code Templates have no direct correspondence to language keywords, but are a more general mechanism. Code Templates are saved in the DELPHI32.DCI file, so it should be possible to copy this file to make your templates available on different machines. There seems to be no easy way to merge two Code Templates files, and there are no third-party tools yet to add more templates to a machine. Those enhancements will need to wait until Borland documents the internal structure of the .DCI file.

Code Parameter

The third Code Insight technology I'll discuss here is Code Parameters, the one I was really hoping for and probably like best. Previously when I had to call an unfamiliar function I used to type the name, and then press F1 to jump to the Help system and see its parameters. Now I can simply type the function name, type the open (left) parenthesis, and the parameter names and types appear immediately on a fly-by hint window.

Notice in this figure that the first parameter appear in boldface type. After you type the first parameter and a comma, the second parameter will be set in bold, the same with the third, and so on. This is very useful for functions with many parameters, like some functions of the Window API. Try typing *CreateWindow(* and you'll understand what I mean.

Again, the Code Parameters Wizard works by parsing your code in the background. So if you write the following procedure at the beginning of the implementation section of a unit:

```
implementation

procedure ShowInt (X: Integer);
begin
  MessageDlg (IntToStr (X),
    mtInformation, [mbOK], 0);
end;
```

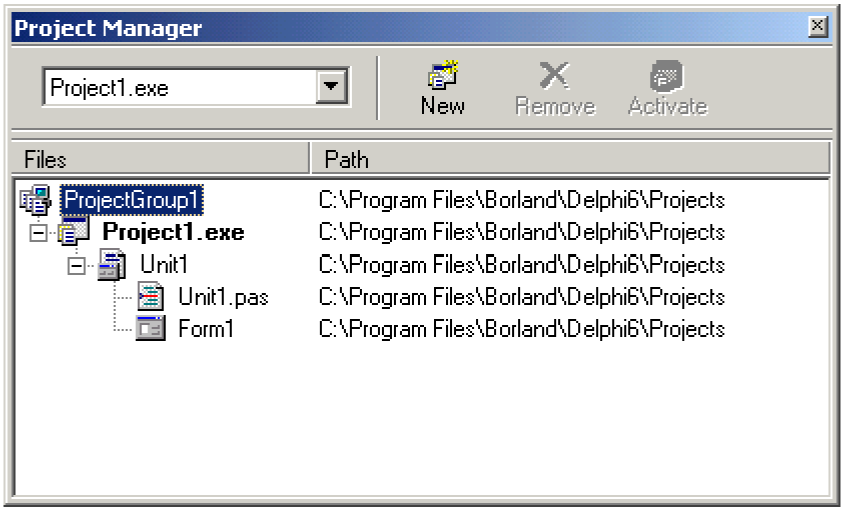
you'll have full information about its parameters when you type *ShowInt(* later.

Managing Projects

In Delphi you also need to know how to manage project files. In Chapter 1, we saw that you can open a project file in the editor and edit the file. However, there are simpler ways to change some of the features of a project. For example, you can use the Project Manager window and Project Options.

The Project Manager

When a project is loaded, you can choose the View | Project Manager command to open a project window. The window lists all of the forms and units that make up the current project. The Project Manager's local menu allows you to perform a number of operations on the project, such as adding new or existing files, removing files, viewing a source code file or a form, and adding the project to the repository. Most of these commands are also available in the toolbar of this window.



Files	Path
ProjectGroup1	C:\Program Files\Borland\Delphi6\Projects
Project1.exe	C:\Program Files\Borland\Delphi6\Projects
Unit1	C:\Program Files\Borland\Delphi6\Projects
Unit1.pas	C:\Program Files\Borland\Delphi6\Projects
Form1	C:\Program Files\Borland\Delphi6\Projects

Setting Project Options

From the Project Manager (or from the Project menu), you can invoke the Project Options dialog. The first page of Project Options, named Forms, lists the forms that should be created automatically at program startup (the default behavior) and the forms that are created manually by the program. You can easily move a form from one list to the other. The next page, Application, is used to set the name of the application and the name of its Help file, and to choose its icon. Other Project Options choices relate to the Delphi compiler and linker, version information, and the use of run-time packages.

> There are two ways to set compiler options. One is to use the Compiler page of the Project Options, the other is to set or remove individual options in the source code with the {$X+} or {$X-} commands, where X is the option you want to set. This second approach is more flexible, since it allows you to change an option only for a specific source code file, or even for just a few lines of code.

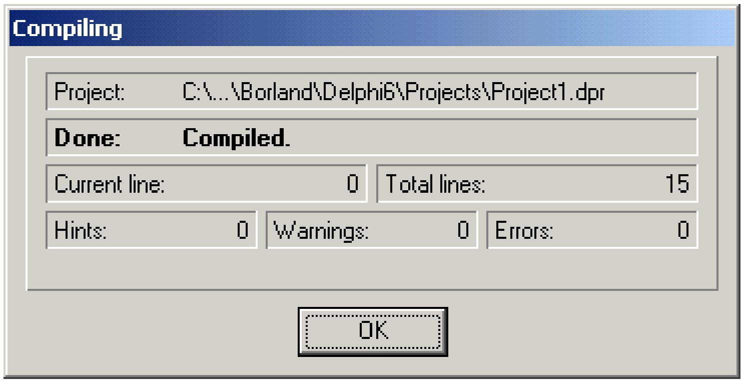
All of the Project Options are saved automatically with the project, but in a separate file with a DOF extension. This is a text file you can easily edit. You should not delete this file if you have changed any of the default options.

Compiling a Project

There are several ways to compile a project. If you run it (by pressing F9 or clicking on the toolbar icon), Delphi will compile it first. When Delphi compiles a project, it compiles only the files that have changed. If you select Compile | Build All, instead, every file is compiled, even if it has not changed. This second command is seldom used, since Delphi can usually determine which files have changed and compile them as required. The only exception is when you change some project options. In this case you have to use the Build All command to put the new options into effect.

The project lists the source code files that are part of it, and any related forms. This list is visible both in the project source and in the Project Manager, and is used to compile or rebuild a project. First, each source code file is turned into a Delphi compiled unit, a file with the same name as the Pascal source file and the DCU extension. For example, Unit1.pas is compiled into Unit1.dcu.

When the source code of the project itself is compiled, the compiled units that constitute the project are merged (or linked) into the executable file, together with code from the VCL library. You can better understand the compilation steps and follow what happens during this operation if you enable the Show Compiler Progress option. You'll find this option on the Preferences page of the Environment Options dialog box, under the Compiling heading. Although this slows down the compilation a little, the Compile window lets you see which source files are compiled each time (unless your computer is too fast; Delphi might compile several files per second on a fast PC).



Project: C:\...\Borland\Delphi6\Projects\Project1.dpr

Done: Compiled.

Current line: 0
Total lines: 15

Hints: 0
Warnings: 0
Errors: 0

Exploring a Compiled Program

Delphi provides a number of tools you can use to explore a compiled program, including the debugger and the Object Browser.

The Integrated Debugger

Delphi has an integrated debugger with a huge number of features. However, Borland also sells a more powerful stand-alone debugger, called Turbo Debugger. For nearly all of your debugging tasks, the integrated debugger works well enough, particularly if you activate the CPU view window. The stand-alone Turbo Debugger might be useful in a few special cases.

You don’t need to do much to use the integrated debugger. In fact, each time you run a program from Delphi, it is executed by default in the debugger. This means that you can set a breakpoint to stop the program when it reaches a specific line of code. For example, open the Hello2 example we created in Chapter 1 and double-click on the button in the form to jump to the related code. Now set a breakpoint by clicking in the editor gutter margin, by choosing the Toggle Breakpoint command of the editor local menu, or by pressing F5.

The editor will highlight the line where you’ve placed the breakpoint, showing it in a different color. Now you can run the program as usual, but each time you press the button, the debugger will halt the program, showing you the corresponding line of code. You can execute this and the following lines one at a time (that is, step-by-step), look at the code of the functions called by the code, or continue running the program.

When a program is stopped, you can inspect its status in detail. Although there are many ways to inspect a value, the simplest approach is the ToolTip Expressions Evaluation. Simply move the mouse over the name of any variable, and you’ll see its current value in a small hint window.

At times the ToolTip Expressions Evaluation seems not to work. This may happen if the optimizing compiler has removed some sections of generated code and placed variables in CPU registers. If you disable the compiler optimizations, you’ll get more ToolTips.

The Object Browser

Once you have compiled a program, you can run the Object Browser (available with the View | Browser menu command) to explore it, even if you are not running or debugging it. This tool allows you to see all of the classes defined by the program (or by the units used directly and indirectly by the program), all the global names and variables, and so on. For every class, the Object Browser shows the list of properties, methods, and variables — both local and inherited, private and public. The information displayed in the Object Browser may not mean much if you’re still not familiar with the Object Pascal language used by Delphi.

Additional Delphi Tools

Delphi provides many other programming tools. For example, the Menu Designer is a visual tool used to create the structure of a menu. There are also the various Wizards, used to generate the structure of an application or a new form. Other tools are stand-alone applications related to the development of a Windows application, such as the Image Editor and WinSight, a “spy” program that lets you see the Windows message flow.

There are several external database tools, such as the Database Desktop and the Database Explorer (some of which are not available in the lower-level editions of Delphi). A programmer can use other third-party tools to cover weak areas of Delphi. For example, you can use a full-blown resource editor (such as Borland’s Resource Workshop), or a tool to generate Help files more easily.

You can also install and use many additional Delphi add-on tools from third-party vendors. You’ll find demo versions of some of these tools on the companion CD, but there are many others available. Some of the add-on tools really complement Delphi nicely, and make you more productive.

The Files Produced by the System

As you have seen, Delphi produces a number of files for each project, and you should know what they are and how they are named. There are basically two elements that have an impact on how files are named: the names you give to a project and its forms, and the predefined file extensions used by Delphi for the files you write and those generated by the system.

The great advantage of Delphi over other visual programming environments is that most of the source code files are plain ASCII text files. We explored Pascal source code, project code, and form description files at the end of Chapter 1. Now let’s take a minute to look at the structure of options and desktop files. Both types of files use a structure similar to Windows INI files, in which each section is indicated by a name enclosed in square brackets. For example, this is a fragment of the HELLO.DOF file of the Hello2 example:

```
[Compiler]
A=1
B=0
...
[Linker]
MapFile=0
MinStackSize=16384
MaxStackSize=1048576
...
[Directories]
OutputDir=
SearchPath=
```

> In Delphi the option files use the DOF extension, in Kylix the KOF extension (in Delphi 1 they used the OPT extension. These files have different contents and are not fully compatible.

The initial part of this file, which I've omitted, is a long list of compiler options. The same structure is used by the desktop files, which are usually much longer. It is worth looking at what is stored in these files to understand their role. In short, a desktop file (.DSK) lists Delphi windows, indicating their position and status. For example, this is the description of the main window:

```
[MainWindow]
Create=1
Visible=1
State=0
Left=2
Top=0
Width=800
Height=97
```

These are some of the sections related to other windows:

```
[ProjectManager]
[AlignmentPalette]
[PropertyInspector]
[Modules]
[formxxx]
[EditWindowxxx]
[Viewxxx]
```

Besides environment options and window positions, the desktop file contains a number of history lists (lists of files of a certain kind), and an indication of the current breakpoints, watches, active modules, closed modules, and forms.

What's Next

This chapter presented an overview of the Delphi programming environment, including a number of tips and suggestions. Getting used to a new programming environment takes some time, particularly if it is a complex one. I could have devoted this entire book to detailing the Delphi programming environment, but I hope you'll agree that describing how to actually write programs is more useful and interesting.

A good way to learn about the Delphi environment is to use the Help system, where you can look up information about the environment elements, windows, and commands. Spend some time just browsing through the Help files. Of course, the best way to learn how the Delphi environment works is to use it to write programs. That's what Delphi is about. Now we can move on to an important feature of the Delphi environment we have only mentioned: the Object Repository and the Wizards.

CHAPTER THREE: THE OBJECT REPOSITORY AND THE DELPHI WIZARDS

- Delphi's Object Repository
- Reusing existing applications and forms
- The Database Form Wizard
- Other Delphi Wizards
- Configuring the Object Repository

When you start working on a new application (or simply a new form), you have two choices. You can start from scratch with a blank application or form, or you can choose a predefined model from the Object Repository. If you decide to pick an existing model from the Object Repository, you have even more alternatives. You can make a copy of an existing item (called a template in Delphi 1), you can inherit from an existing item, or you can use one of the available Wizards.

A *Wizard* is a code generator. (Borland used to call them *Experts*, but in Delphi 3 the official name has been changed to Wizards, following Microsoft tradition.) Wizards ask you a number of questions, and use your answers to create some basic code, following predefined rules. You then start working on a project or a form that already has some code and components. Usually, the code generated by these tools can be compiled immediately, and it makes up the basic structure on which you build your program or form.

The purpose of this short chapter is simply to introduce you to the Object Repository and the Delphi Wizards, and to show you how easy they are to use. We won't study the code they generate, since that will be the topic of many examples in the book. From a programming standpoint, the Wizards are really useful. The pitfall is that you might be tempted to use them without trying to understand what they do. For this reason, in some examples I'll build the code manually instead of using the corresponding Wizard.

The Object Repository

Delphi has several menu commands you can use to create a new form, a new application, a new data module, a new component, and so on. These commands are located in the File menu, and also in other pull-down menus. What happens if you simply select File | New | Other (from Delphi 6, or File | New in earlier versions)? Delphi opens the Object Repository (also called the New dialog box). The Object Repository is used to create new elements of any kind: forms, applications, data modules, libraries, thread objects, components, automation objects, and more. The Object Repository dialog box has a number of pages:

- The *New* and *ActiveX* pages allow you to create many different types of new items. At times when you create a new item, Delphi asks you the name of a new class and few other things, in a sort of *mini-Wizard*.
- The "current project" page (actually you'll see the name of the project) allows you to inherit from a form or data module included in your current project. In this page you can create new

forms or data modules that inherit from those of the current project. The content of this page depends exclusively on the units included in the current project. Simply create a couple of forms and then return to this page, and you'll see that its contents have already changed.

- The *Forms*, *Dialogs*, and *Data Modules* pages allow you to create a new element of these kinds starting from an existing one or using a Wizard.
- The *Projects* page allows you to copy the files from an existing project stored in the Repository, or use the Application Wizard.
- The *Multitier, Business, WebSnap,* and *WebServices* pages provide a starting point for using some of the advanced features found only in the Enterprise edition (and mostly only starting with Delphi 6)

Use the radio buttons at the bottom of the Object Repository dialog box to indicate that you want to copy an existing item, inherit from it, or use it directly without making a copy.

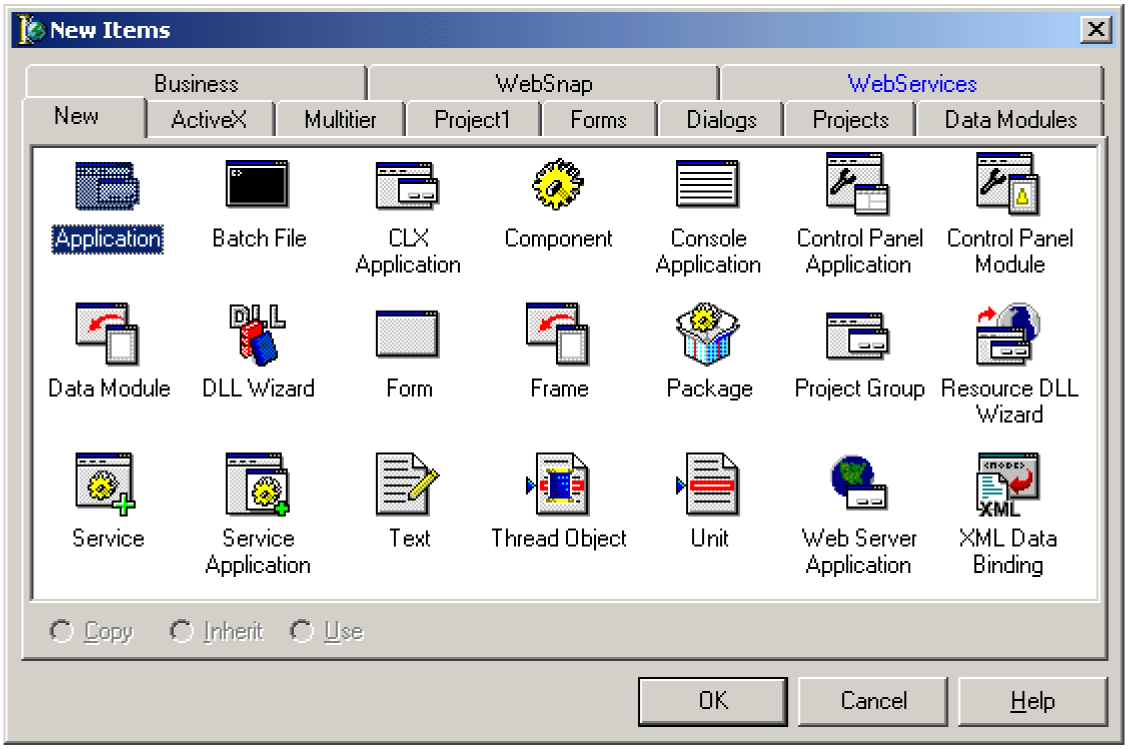
> The concept of inheritance in object-oriented programming is discussed in Mastering Delphi. In short, it is a way to add new capabilities to an existing form (or class in general) without making a full copy. This way, if you make a change in the original form (or class), the inherited form (or class) will be affected, too.

When you select a Wizard instead of a template, the only available radio button is *Copy*, meaning you'll end up with a new copy, the generated code. Keep in mind that I am discussing the pages of the Object Repository as they appear in Delphi 6 Enterprise, but different editions and versions of Delphi have fewer or different pages and items; and you can further customize the Repository, as we will see later on in this chapter.

> The Object Repository has a local menu that allows you to sort items in different ways (by name, by author, by date, or by description) and to show different views (large icons, small icons, lists, details). This last view is the only one that gives you the description, the author, and the date of the tool. This information is particularly important when looking at Wizards, projects, or forms you've added to the Repository.

The New Page

The New page of the Object Repository (shown below) allows you to create several new items of the more commonly used kinds and is often an alternative to a direct menu command. Here is a list of the elements you can create from this page:



- *Application* creates a new blank project (the same as the command File | New | Application).
- *Batch File* opens a batch file you can include in a project group for automatic processing (to fully automate a complex build and deploy process).
- *CLX Application* creates a new blank project based on the CLX library (and on Qt), so that it will be fully portable to Kylix on the Linux platform (the same as the command File | New | CLX Application).
- *Component* creates a new Delphi component after you've completed the information requested by the simple Component Wizard. The same wizard can be activated with the Component | New Component menu command.
- *Console Application*
- *Control Panel Application*
- *Control Panel Module*
- *Data Module* creates a new blank data module (the same as the command File | New Data Module).
- *DLL Wizard* creates a simple DLL skeleton.
- *Form* creates a new blank form (the same as the command File | New Form).
- *Frame*
- *Package* creates a new Delphi component package. (You can also create a new package when creating a component.)

- *Project Group*
- *Resource DLL Wizard*
- *Service*
- *Service Application*
- *Text* opens a new ASCII text file in the Delphi editor.
- *Thread Object* creates a new thread object after asking you to fill in the New Thread Object dialog box. Multithreading in Windows is introduced in Chapter 25.
- *Unit* creates a new blank unit, a Pascal source file not connected with a form.
- *Web Server Application* allows you to create an ISAPI/NSAPI add-in DLL, a CGI stand-alone executable, a Win-CGI stand-alone executable, an Apache module, or a server application based on Delphi's Web Debugger. In each case Delphi creates a simple project based on a Web module (a special type of data module) instead of a form.
- *XML Data Binding*

*[***Many of the descriptions for newer entries are still missing]*

As some of the features made available by the Object Repository are quite advanced, it doesn't make

The Forms Page

This page lists predefined forms. Here is a short list of the predefined forms available in Delphi:

- *About box* is a simple About box.
- *Dual list box* is a form with two different list boxes, allowing a user to select a number of elements from one list and move them to the other list by pressing a button. Along with the components, this form contains a good amount of nontrivial Pascal code.
- *QuickReport Labels* creates a report form based on the QuickReport component.
- *QuickReport List* creates another form based on QuickReport, with a different layout.
- *QuickReport Master/Detail* is a third predefined report form with a more complex structure.
- *Tabbed pages* is a form based on the Windows PageControl.

Wizards can only be executed. The other forms, by contrast, can be used in multiple ways. You can add them into a project, inherit from them (in this case the original form will be automatically added to your project), or use them directly. When you use a form or inherit from one, take care not to make any change on the original forms in the Repository.

The Dialogs Page

This page is similar to the previous one, but includes forms that are typically used as dialog boxes. Here is the list of its items:

- *Dialog with help* is available in two versions. One has the buttons on the right side of the form (*Vertical*), and the other has them in the lower portion (*Horizontal*), as you can see from the corresponding icons.
- *Dialog Wizard* is a simple Wizard capable of generating different kinds of dialog boxes with one or more pages, as we will see later in this chapter.
- *Password dialog* is a dialog box with a simple edit box for entering a password.
- *Reconcile Error Dialog* is used in MIDAS or DataSnap applications.
- *QuickReport Wizard* creates a Print Options dialog box for a report.
- *Standard dialog* is also available in two versions, again *Horizontal* and *Vertical*, with buttons in different positions.

The Data Modules Page

You already know what a project and a form are, but what is a data module? It is a sort of form that never appears on screen at run-time and can be used to hold nonvisual components. It is mostly used to implement code related to database access. This page has only a data module at start-up, *Customer Data*. If you have several forms or applications accessing the same data tables and database queries, you can easily define new data modules and add them to the repository.

The Projects Page

The last page we will look at in this introduction contains project schemes you can use as the starting point for your own application. These projects often include one or more forms. Here is the list of them:

- *Application Wizard* is another simple Wizard that allows you some limited choices for the file structure and other elements of an application.
- *MDI Application* defines the main elements of a Multiple Document Interface (MDI) program. It defines a main form for the MDI frame window, with a menu, a status bar, and a toolbar. It also defines a second form that can be used at run-time to create a number of child windows.
- *SDI Application* defines a main form with the standard attributes of a modern user interface, including a toolbar and a status bar, and also a typical About box.
- *Win2000 Logo Application* defines a sample application with most of the elements required by Microsoft for an application to get the Windows 2000 compatibility logo. This command basically creates an SDI application with a RichEdit component in it, and adds the code needed to make the application mail-enabled.

- *Win95 Logo Application* defines a sample application with most of the elements required by Microsoft for an application to get the Windows 95/98 compatibility logo. The application is similar to the one above.

When you select one of these projects, Delphi asks you to enter the name of an existing or a new directory. If you indicate a new directory, Delphi will automatically create it.

For example, we can create an SDI project based on the corresponding template. Then we can customize it, giving it a proper title, removing or adding new components, and writing some code. Some interesting components are already there, however, and there is even some ready-to-use code to make those components work properly. The menu and toolbar of the application, can be used to open some dialog boxes. File Open and File Save dialog boxes are wrapped up in components that are added to the form by the template; the About box is defined by the template as a second form.

In the simple SdiTemp example, I've decided to make just a few limited changes: I've entered a new title for the main form and some text for the labels for the About box (the property to use is Caption in both cases). The result is the application shown in *[***missing figure]* and available in the source code.

Delphi Wizards

Besides copying or using existing code, Delphi allows you to create a new form, application, or other code files, using a Wizard. Wizards (or Experts) allow you to enter a number of options and produce the code corresponding to your choices.

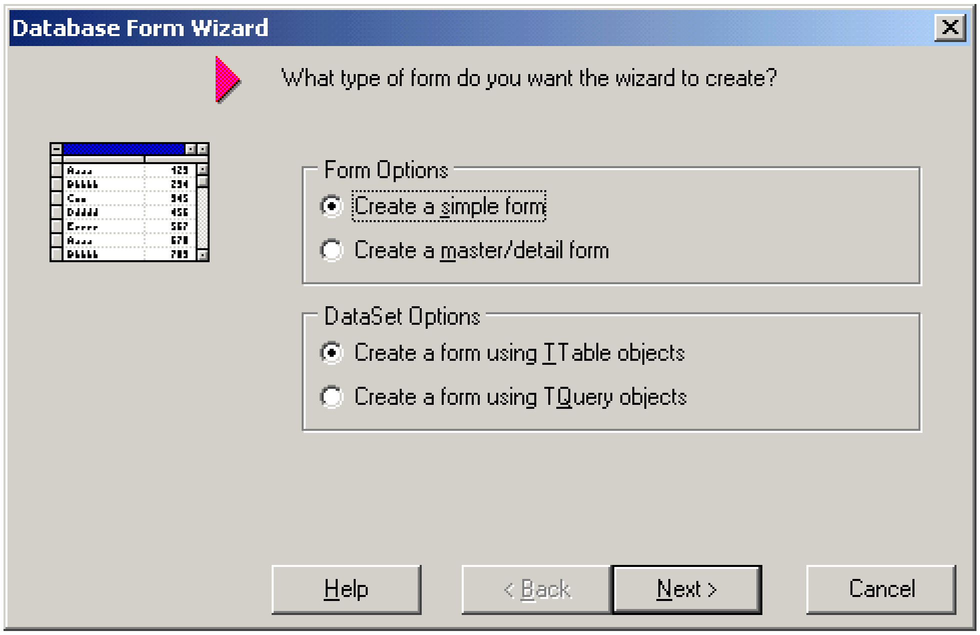
One of the most important predefined wizards is the Database Form Wizard, which you can activate using the Database | Form Wizard menu item or the icon in the Forms page of the Object Repository. There are also some other simple Wizards in Delphi, such as the Application Wizard and the Dialog Wizard. I've listed various other Wizards in the description of the pages of the Object Repository, in the last section.

You can also buy add-on Wizards from third-party tool providers, download one from my web site, or even write your own Wizard. Add-on Wizards often show up in the Help menu, but it is possible to add new menu items in other Delphi pull-down menus or install Wizards in various pages of the Object Repository.

The Database Form Wizard

In this section, I'll show you a quick example of the use of the Database Form Wizard, but I won't describe the application we build in detail. In this example, we'll build a database program using some of the data already available in Delphi. Note that you have to create a project first, and then start the Database Form Wizard. So you usually end up with two forms, unless you remove the original form from the project. Fortunately, one of the Wizard's options, displayed at the end, lets you select the new form generated by the Wizard as the main form.

1. As soon as you start the Database Form Wizard, you will be presented with a number of choices, which depend on the options you choose at each step. The first page lets you choose between a simple or a master detail form, and between the use of tables or queries. Leave the selections as they are by default, and move on by clicking on the Next button.



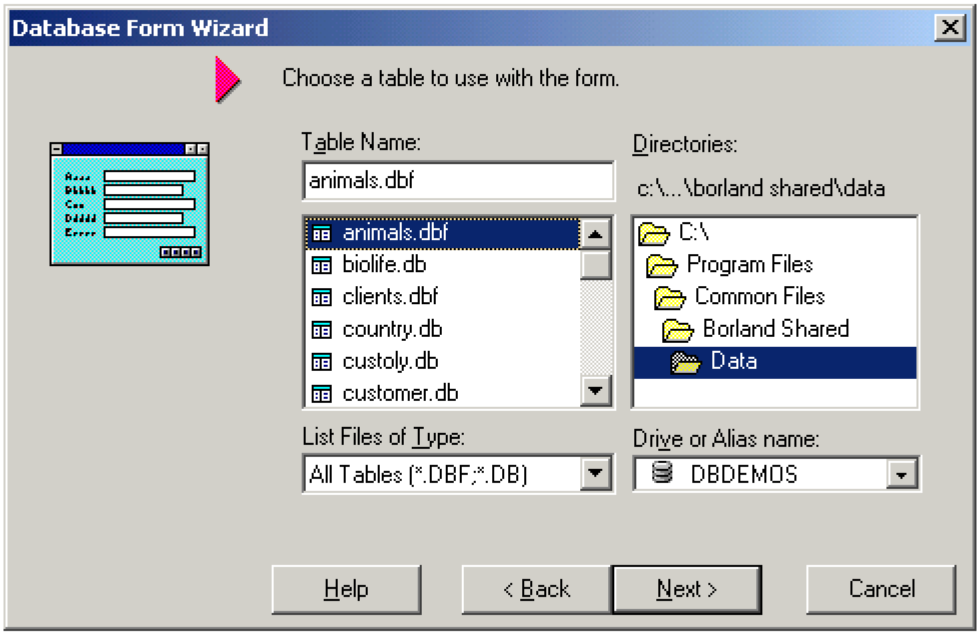
Database Form Wizard

What type of form do you want the wizard to create?

Form Options
● Create a simple form
○ Create a master/detail form

DataSet Options
● Create a form using TTable objects
○ Create a form using TQuery objects

- **2.** In the next page you can choose an existing database table to work on. In the Drive or Alias Name combo box, there should be a DBDEMOS alias. After you select this option, a number of Delphi demo database tables appear in the list. Choose the first, `animals.dbf`.



Database Form Wizard

Choose a table to use with the form.

Table Name: animals.dbf

animals.dbf
biolife.db
clients.dbf
country.db
custoly.db
customer.db

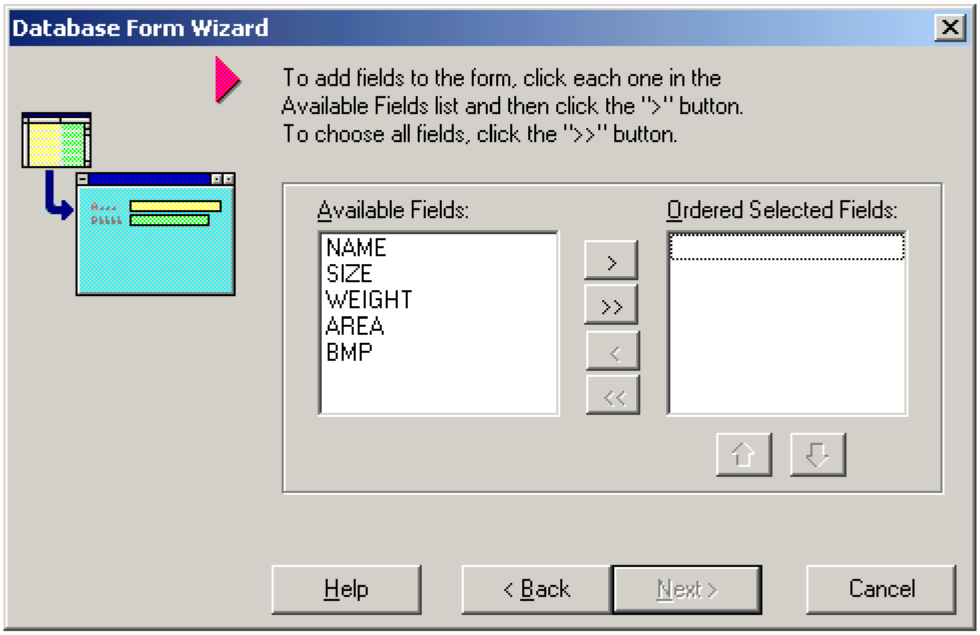
Directories: c:\...\borland shared\data

C:\
Program Files
Common Files
Borland Shared
Data

List Files of Type: All Tables (*.DBF;*.DB)

Drive or Alias name: DBDEMOS

- **3.** In the third page, you can choose the fields of the selected database table that you want to consider. To build this first example, choose all of the fields by clicking on the >> button.



Database Form Wizard

To add fields to the form, click each one in the Available Fields list and then click the ">" button. To choose all fields, click the ">>" button.

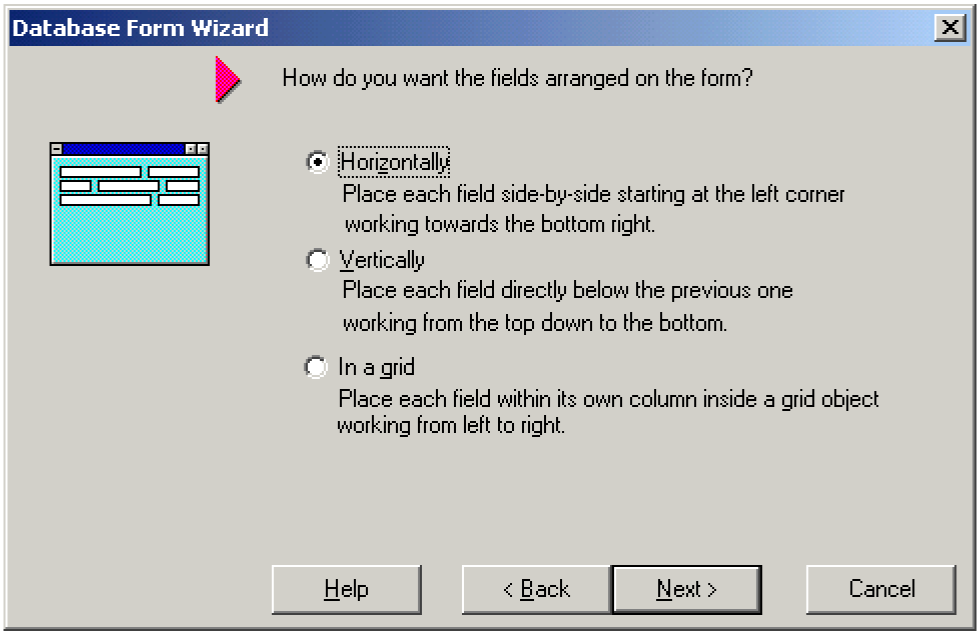
Available Fields:

- NAME
- SIZE
- WEIGHT
- AREA
- BMP

Ordered Selected Fields:

-

4. On the next page, you can choose from various layouts. If you choose Vertical, the next page will ask you the position of the labels. The default option, Horizontal, might do.



Database Form Wizard

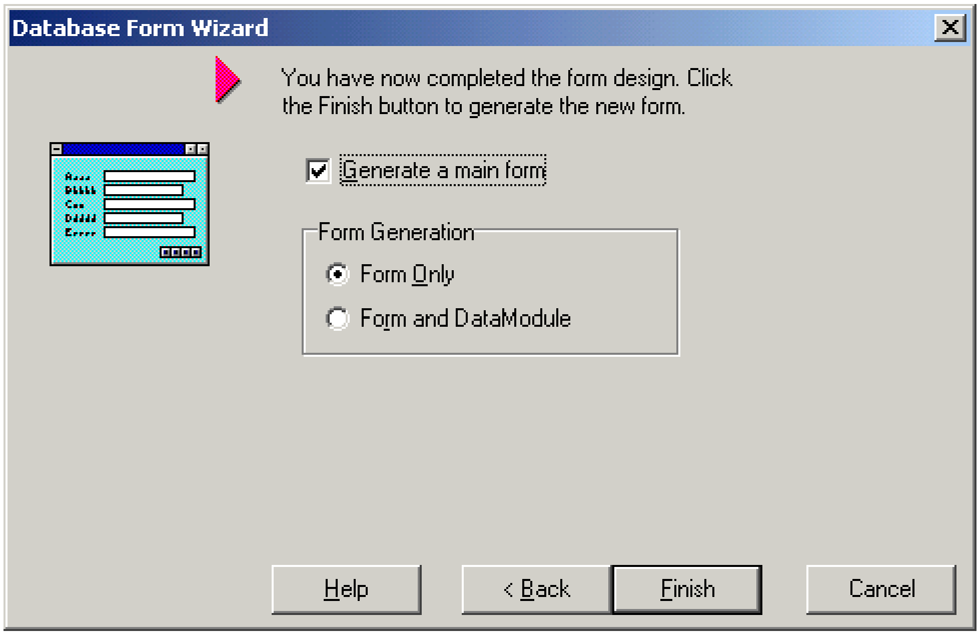
How do you want the fields arranged on the form?

● Horizontally
Place each field side-by-side starting at the left corner working towards the bottom right.

○ Vertically
Place each field directly below the previous one working from the top down to the bottom.

○ In a grid
Place each field within its own column inside a grid object working from left to right.

- **5.** The next page is the last. Leave the Generate a Main Form check box and the Form Only radio button selected, and click on the Finish button.



Database Form Wizard

You have now completed the form design. Click the Finish button to generate the new form.

☑ Generate a main form

Form Generation

● Form Only

○ Form and DataModule

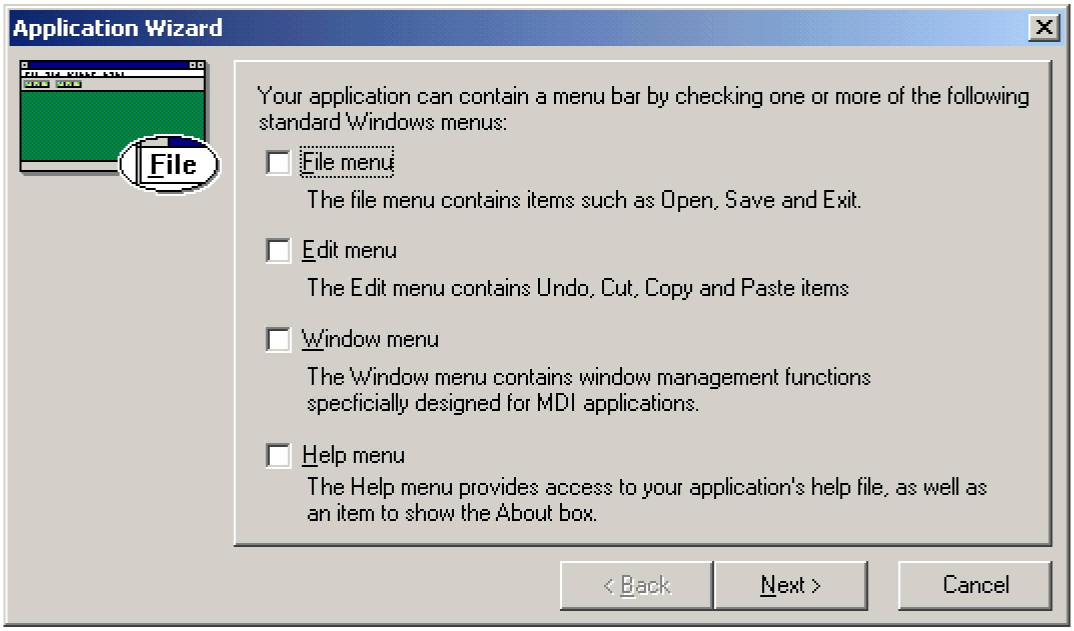
You can immediately compile and run the application. The result is a working database application, which allows you to navigate among many records using the buttons. This specific application (the DataExp example) even has a graphical field, displaying a bitmap with the current animal.

The output of the generated form is usually far from adequate. In this case, the image area is too small; at other times the positioning of the controls may not be satisfactory. Of course, you can easily move and resize the various components placed on the form at design-time.

To make this task easier, you can select the Table component (the one in the upper-left corner of the form) and toggle its Active property to True. Then the data of the table's first record will be displayed at design-time. This is helpful because it allows you to see an example of the length of the field's text and the size of the image. Note that the Database Form Wizard generates almost no Pascal code, besides a line used to open the table when the program starts. The capabilities of the resulting programs stem from the power of the database-related components available in Delphi.

The Application Wizard

Another interesting (although less powerful) tool is the Application Wizard. You can activate it from the Projects page of the Object Repository. The Application Wizard allows you to create the skeleton of a number of different kinds of applications, depending on the options you select.



Your application can contain a menu bar by checking one or more of the following standard Windows menus:

□ File menu

The file menu contains items such as Open, Save and Exit.

□ Edit menu

The Edit menu contains Undo, Cut, Copy and Paste items

□ Window menu

The Window menu contains window management functions specficially designed for MDI applications.

□ Help menu

The Help menu provides access to your application's help file, as well as an item to show the About box.

The first page of this Wizard allows you to add some standard pull-down menus to the program: File, Edit, Window, and Help. If you select the File menu, the second page will ask you to enter the file extensions the program should consider. You should enter both a description of the file, such as *Text file (*.txt)*, and the extension, *txt*. (You can input several extensions, each with its own description.) These values will be used by the default File Open and File Save dialog boxes that the Application Wizard will add to the program if you select the file support option.

Then, if you have selected any of the pull-down menus, the Application Wizard displays a nice visual tool you can use to build a toolbar. Unfortunately, this tool is not available as a separate editor inside Delphi. You simply select one of the pull-down menus, and a number of standard buttons corresponding to the typical menu items of this pull-down menu appear (but only if the menu has been selected on the first page of the Application Wizard).

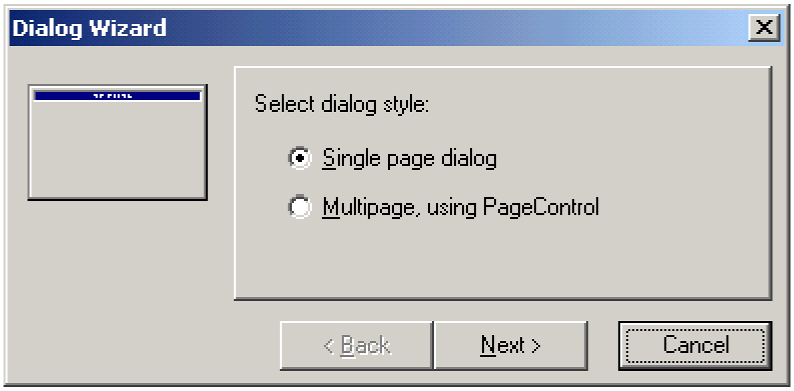
To add a new button, select one of them in the graphical list box on the right and press the Insert button. The new toolbar button will be added at the position of the small triangular cursor. You can move this cursor by clicking on one of the elements already added to the toolbar. This cursor is also used to indicate a button you want to remove from the toolbar.

When the toolbar is finished, you can move to the last page. Here you can set several other options, such as choosing MDI support, adding a status bar, and enabling hints. You can also give a name to the new application and specify a directory for the source files. The name of the application can be long, but it cannot contain white spaces (it should be a valid Pascal identifier), and the directory for the application should be an existing directory. To place the project files in a new directory, choose the Browse button, enter the new path, and the dialog box will prompt you to create the new directory.

Although it is somewhat bare and it has room for improvement, the Delphi Application Wizard is much more useful than the predefined application templates for building the first version of an application. One of its biggest advantages is that you can define your own toolbar. Another advantage is that the Application Wizard generates more code (and more comments) than the corresponding templates do. The disadvantage of this Wizard is that it generates an application with a single form. Its MDI support is limited, because no child form is defined, and the generated application has no About box.

The Dialog Wizard

Delphi's Dialog Wizard is a simple Wizard provided mostly as a demo, with its own source code. From the code of this Wizard, in theory you should be able to learn how to build other Wizards of your own. However, you can still use the Dialog Wizard as a tool to build two kinds of dialog boxes: simple dialog boxes and multiple-page dialog boxes based on the Windows PageControl component.



Select dialog style:

● Single page dialog

○ Multipage, using PageControl

If you choose the simple dialog box, the Wizard will jump to the third page, where you can choose the button layout. If you choose the multiple-page dialog box, an intermediate page will appear to let you input the text of the various tabs. This Wizard is an alternative to the corresponding form templates of the Object Repository. Its advantage is that it allows you to input the names of the PageControl tabs directly.

Customizing the Object Repository

Since writing a new wizard is far from simple, the typical way to customize the Object Repository is to add new projects, forms, and data modules as templates. You can also add new pages and arrange the items on some of them (not including the *New* and "current project" pages).

Adding New Application Templates

Adding a new template to Delphi's Object Repository is as simple as using an existing template to build an application. When you have a working application you want to use as a starting point for further development of two or more similar programs, you can save the current status to a template, ready to use later on.

> Although Borland calls everything you can put in the Object Repository an *object*, from an object-oriented perspective this is far from true. For this reason I call the schemes you can save to disk for later use *templates*. Application templates, in particular, do not relate to objects or classes in any way, but are copied to the directory of your new project. *Object Repository* sounds much better than *Browse Gallery* (the name used in Delphi 1), but besides the capability to activate form inheritance, there is not much object-oriented in this tool.

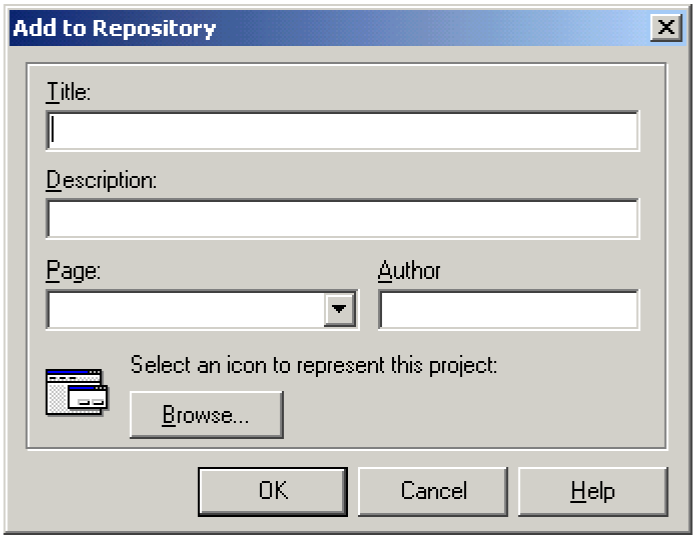
You can add a project to the Repository by using the Project | Add to Repository command, or by using the corresponding item of the local menu of the Project Manager window. As a very simple example, just to demonstrate the process, the following steps describe how you can save the slightly modified version of the default SDI template (shown earlier) as a template:

1. Open the modified SdiTemp example (or any other project you are working on).

2. Select the Project | Add to Repository menu command (or the Add Project to Repository command in the local menu of the Project Manager window).

3. In the Add to Repository dialog box, enter a title, a description for the new project template, and the name of the author. You can also choose an icon to indicate the new template or accept the default image. Finally, choose the page of the Repository where you wish to add the project.

4.: Click on OK, and the new template is added to the Delphi Object Repository.



Now, each time you open the Object Repository, it will include your custom template. If you later discover that the template is not useful any more, you can remove it. You can also use a project template to make a copy of an existing project so that you can continue to work on it after saving the original version.

However, there is a simpler way to accomplish this: copy the source files to a new directory and open the new project. If you do copy the source files, do *not* copy the DSK file, which indicates the position of the Windows on the screen. The DSK file holds a list of files open in the editor, using an absolute path. This means that as soon as you open the new project and start working on it, you may well end up editing the source code files of the original project and compiling the files of the new version (the project manager stores relative paths).

This will certainly surprise you when the changes you make in code or in forms seem to have no effect. Simply deleting the DSK file, or not copying it in the first place, avoids this problem.

The Empty Project Template

When you start a new project, it automatically opens a blank form, too. If you want to base a new project on one of the form objects or wizards, this is not what you want. To solve this problem, you can add an Empty Project template to the Gallery.

The steps required to accomplish this are simple:

1: Create a new project as usual.

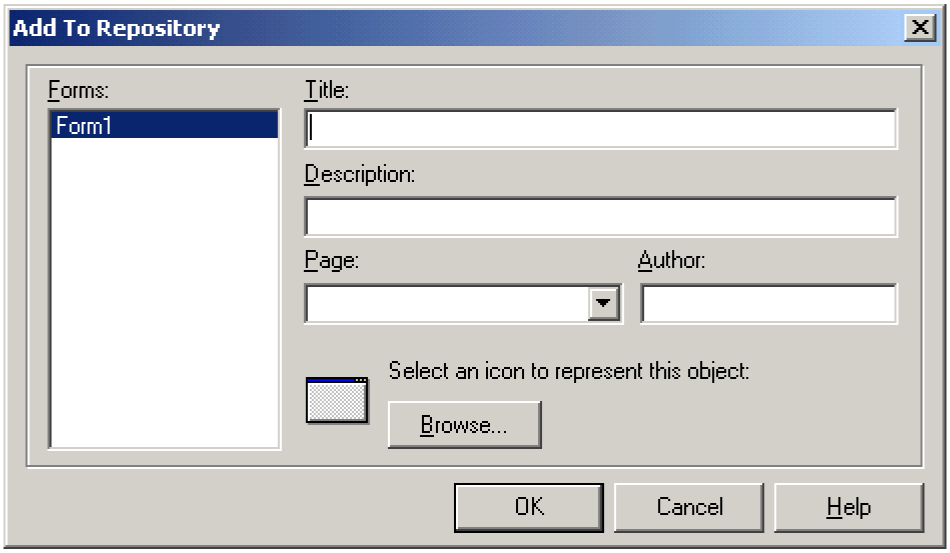
2: Remove its only form from the project.

3: Add this project to the templates, naming it *Empty Project*.

When you select this project from the Object Repository, you gain two advantages. You have your project without a form, and you can pick a directory where the project template's files will be copied. There is also a disadvantage—you need to use the File | Save Project As command to give a new name to the project, since saving the project automatically uses the default name in the template.

Adding New Form Templates to the Object Repository

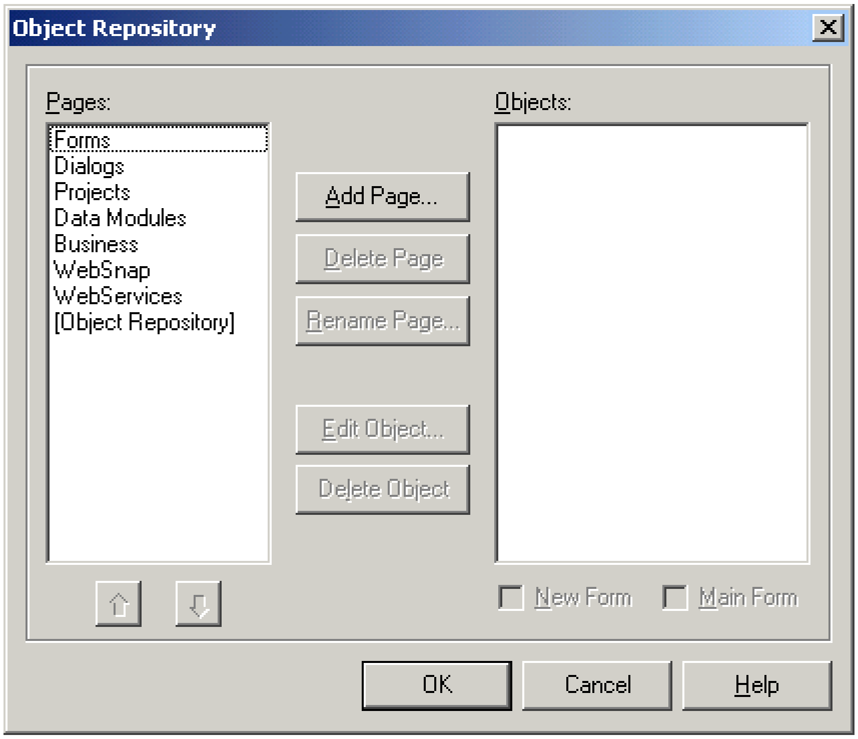
Just as you can add new project templates to the Object Repository, you can also add new form templates. Simply move to the form you want to add, right-click on it, and select Add to Repository from the local menu. In the dialog box that appears (see below), you can choose which form of the current project should be added to the Repository, and set the title, description, author, page, and icon, as usual. Once you have set these elements and clicked on OK, the form is added to the proper page of the Object Repository.



This approach is suggested if you have a complex form to make available to other applications and other programmers. They will be able to use your form as is, make a copy of it, and inherit from it. For this reason, adding forms to the Repository is far more flexible than adding projects, which can only be copied as the starting point of a new application.

The Object Repository Options

To further customize the Repository, you can use the Tools | Repository command to open the Object Repository dialog box. This dialog box is quite easy to use; on the left is the list of current Repository pages and on the right the list of items in each page, including both templates and Wizards. You can use this dialog to move repository items to different pages, to add new elements, or to delete existing ones.



You can use the three page-related buttons and the two buttons with arrows below the list of pages to arrange the structure of the Object Repository, adding new pages, renaming or deleting them, and changing their order. All these operations affect some of the tabs of the Object Repository itself (other tabs are fixed).

An important element of the Object Repository setup is the use of defaults:

- Use the *New Form* check box below the list of objects to designate the current form or Wizard as the default, to be used when a new form is created (File | New | Form). Only one object in the Object Repository can be used as a default; it is marked with a special symbol placed over its icon.

- The *Main Form* check box, instead, is used to indicate the form or Wizard used to create the main form of a new application (File | New | Application) when no special New Project is selected (see next bullet). The current Main form is indicated by a second special symbol.
- The New Project check box, available when you select a project object, can be used to mark the default project that Delphi uses when you issue the File | New | Application command. Also, the New Project is indicated by its own special symbol.

If no project is selected as New Project, Delphi creates a default project based on the form marked as Main Form. If no form is marked as the main form, Delphi creates a default project with an empty form.

When you work on the Object Repository, you work with forms and modules saved in the OBJREPOS subdirectory of the Delphi main directory. At the same time, if you directly use a form or any other object without copying it, then you end up having some files of your project in this directory. It is important to realize how the repository works, because if you want to modify a project or an object saved in the repository, the best approach is to operate on the original files, without copying data back and forth to the Repository.

Installing new DLL Wizards

Technically, new Wizards come in two different forms. Wizards may be part of components or packages, and in this case are installed the same way you install a component or a package. Other Wizards are distributed as stand-alone DLLs. In this case you should add the name of the DLL in the Windows Registry under the key:

Software\Borland\Delphi x.0\Experts.

Simply add a new string key under this, choose a name you like (it doesn't really matter) and use as text the path and filename of the Wizard DLL. You can look at the entries already present under the Experts key to see how the path should be entered.

What's Next

In this short chapter, we have seen how you can start the development of an application by using Delphi templates and Wizards. You can use one of the predefined application templates or form objects, start the Database Form Wizard, or use the other Wizards for a fast start with applications, forms, and other objects.

However, I'll rarely use these templates and Wizards in the rest of the book. With the exception of the Database Form Wizard, these tools let you build only very simple applications, which you can often put together yourself in seconds when you are an experienced Delphi programmer. For beginners, Wizards and templates provide a quick start in code development. But you are not going to *remain* a beginner, are you?

So with the next chapter we'll start focusing on the use of the actual components and controls available in Delphi, to build actual applications, even if simple ones. Differently form other books of mine, which focus more on the foundations, this text proceeds mainly though practical examples.

Notice that the only reason there is no introduction to the use of the language and the core structure of the VCL, is that because you can find these topics covered in Essential Pascal (for the core language) and Mastering Delphi (for the OOP features and the VCL architecture).

Chapter 4: A Tour of the Basic Components

- Clicking a button or another component
- Adding colored text to a form
- Dragging from one component to another
- Accepting input from the user
- Creating a simple editor
- Making a choice with radio buttons and list boxes
- Allowing multiple selections
- Choosing a value in a range

Now that you've been introduced to the Delphi environment and have seen an overview of the Object Pascal language and the Visual Component Library, we are ready to delve into the central part of the book: the use of components. This is really what Delphi is about. Visual programming using components is the key feature of this development environment.

The system comes with a number of ready-to-use components. I will not describe every component in detail, examining each of its properties and methods. If you need this information, you can find it easily in the Help system. The aim of Part II of this book is to show you how to use some of the features offered by the Delphi predefined components to build applications. In fact, this chapter and those following will be based heavily on sample programs. These examples tend to be quite simple — although I've tried to make them meaningful — in order to focus on only a couple of features at a time.

I'll start by focusing on a number of basic components, such as buttons, labels, list boxes, edit fields, and other related controls. Some of the components discussed in this chapter are present in the Standard page of the Delphi Components palette; others are in different pages. I'm not going to describe all the components of the Standard page, either. My approach will be to discuss, in each chapter, logically related components, ignoring the order suggested by the pages of the Components palette.

Windows Own Components

You might have asked yourself where the idea of using components for Windows programming came from. The answer is simple: Windows itself has some components, usually called controls. A *control* is technically a predefined window with a specific behavior, some properties, and some methods (although traditional C language code used to access the predefined components in Windows by sending and receiving messages). These controls were the first step in the direction of component development. The second step was probably Visual Basic controls, and the third step is Delphi components.

Actually Microsoft's third step is its ActiveX controls (an extension of the older OCX technology), the natural successor of VBX controls. In Delphi you can use both ActiveX and native components, but if you look at the technology, Delphi components are really ahead of the ActiveX controls. It is enough to say that Delphi components use OOP to its full extent, while ActiveX controls do not fully implement the concept of inheritance. With the recent introduction of the .NET framework, Microsoft has finally followed Borland and Sun (with Java) with the adoption of a technology that treats components as classes and vice verse.

Windows 3 had six kinds of predefined controls, generally used inside dialog boxes. They were buttons (push buttons, check boxes, and radio buttons), static labels, edit fields, list boxes, combo boxes, and scroll bars. Windows 95 added a number of new predefined components, such as the list view, the status bar, the spin button, the progress bar, the tab control, and many others. These controls were already used by programmers, who had to re-implement them each time. Windows 95 developers could for the first time use the standard common controls provided by the system, and starting with Delphi 3 developers had the advantage of having corresponding easy-to-use components.

The standard system controls are the basic components of each Windows application, regardless of the programming language used to write it, and are very well known by every Windows user. Delphi literally wraps these Windows predefined controls in some of its basic components — including those discussed in this chapter.

Notice that CLX provides components similar to Windows common controls that are portable to Kylix. This is important as Linux, of course, hasn't got Microsoft's common controls!

Clicking a Button

In the first chapter of this book, we built small applications based on a button. Clicking on that button caused a "*Hello*" message to appear on the screen. The only other operation that program performed was moving the button so that it always appeared in the middle of the form. Since then we've seen other examples that used buttons as a way to perform a given action (using their `OnClick` event).

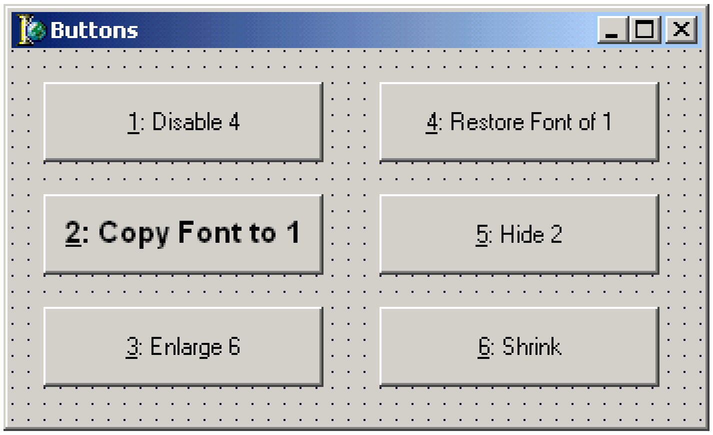
Now we are going to build another form with several buttons and change some of their properties at run-time; in this example, clicking a button will usually change a property of another button. To build the Buttons program, I suggest you follow the instructions closely at first and then make any changes you want. Of course, you can read the description in the book and then work on the source files, if you prefer.

The Buttons Example

First, open a new project and give it a name by saving it to disk. I've given the name `ButtonF.pas` to the unit describing the form and the name `Buttons.dpr` to the project. Now you can create a number of buttons, let's say six.

> Instead of selecting the component, dragging it to the form, and then selecting it again to repeat the operation, you can take a shortcut. Simply select the component by clicking on the Components palette while holding down Shift. The component will remain selected, as indicated by a little border around it. Now you can create a number of instances of that component.

Even if you use the grid behind the form, you might need to use the Edit | Align command to arrange the buttons properly. Remember that to select all six buttons at a time, you can either drag a rectangle around them or select them in turn, holding down the Shift key. In this case, it's probably better to select a column of three buttons at a time and arrange them.



Now that we have a form with six buttons, we can start to set their properties. First of all, we can give the form a name (`ButtonsForm`) and a caption (*Buttons*). The next step is to set the text, or `Caption` property, of each button. Usually, a button's `Caption` describes the action performed when a user clicks on it. We want to follow this rule, adding the number of the button at the beginning of each caption. So if the first button disables button number four (which is the one on the same row), we can name it *1: Disable 4*. Following the same rule, we can create captions for the other buttons.

For a summary of the properties of the components of this form, you can refer to its textual description:

```
object ButtonsForm: TButtonsForm
  Caption = 'Buttons'
  object Button1: TButton
    Caption = '&1: Disable 4'
    OnClick = Button1Click
  end
  object Button2: TButton
    Caption = '&2: Copy Font to 1'
    Font.Color = clBlack
    Font.Height = -15
    Font.Name = 'Arial'
    Font.Style = [fsBold]
    ParentFont = False
    OnClick = Button2Click
  end
  object Button3: TButton
    Caption = '&3: Enlarge 6'
    OnClick = Button3Click
  end
  object Button4: TButton
    Caption = '&4: Restore Font of 1'
    OnClick = Button4Click
  end
  object Button5: TButton
    Caption = '&5: Hide 2'
    OnClick = Button5Click
  end
  object Button6: TButton
    Caption = '&6: Shrink'
    OnClick = Button6Click
  end
end
```

Notice that every button has an underlined shortcut key, in this case the number of the button. Simply by placing an ampersand (&) character in front of each caption, as in *'&1: Disable 4'*, we can create buttons that can be used with the keyboard. Just press a number below 7, and one of the buttons will be selected, although you won't see it pressed and released.

The final step, of course, is to write the code to provide the desired behavior. We want to handle the OnClick event of each button. The easiest code is that of Button2 and Button4. When you press Button2, the program copies the font of this button (which is different from the standard font of the other buttons) to Button1, and then disables itself:

```
procedure TButtonsForm.Button2Click(Sender: TObject);
begin
  Button1.Font := Button2.Font;
  Button2.Enabled := False;
end;
```

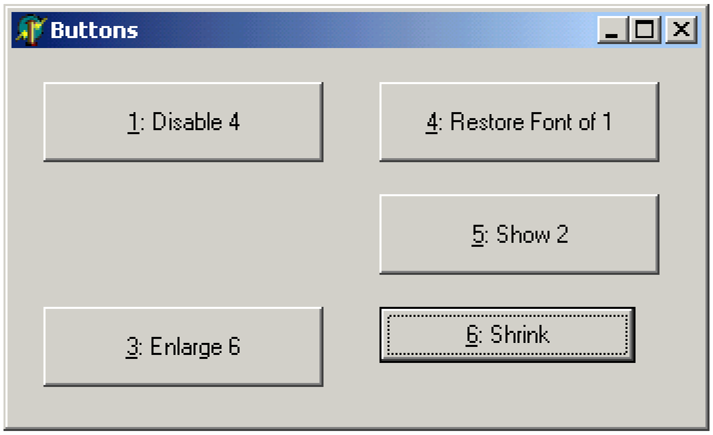
Pressing Button4 restores the original font of the button. Instead of copying the font directly, we can restore the font of the form, using the ParentFont property of the button. The event also enables Button2, so that it can be used again to change the font of Button1:

```
procedure TButtonsForm.Button4Click(Sender: TObject);
begin
  Button1.ParentFont := True;
  Button2.Enabled := True;
end;
```

To implement the Disable and Hide operations of Button1 and Button5, we might use a Boolean variable to store the current status. As an alternative, we can decide which operation to perform while checking the current status of the button — the status of the Enabled property. The two methods use two different approaches, as you can see in the following code:

```
procedure TButtonsForm.Button1Click(Sender: TObject);
begin
  if not Button4.Enabled then
  begin
    Button4.Enabled := True;
    Button1.Caption := '&1: Disable 4';
  end
  else
  begin
    Button4.Enabled := False;
    Button1.Caption := '&1: Enable 4';
  end;
end;

procedure TButtonsForm.Button5Click(Sender: TObject);
begin
  Button2.Visible := not Button2.Visible;
  if Button2.Visible then
    Button5.Caption := '&5: Hide 2'
  else
    Button5.Caption := '&5: Show 2';
end;
```



You can see the results of this code in the figure above. The last two buttons have *unconstrained* code. This means that you can shrink Button6 so much that it will eventually disappear completely:

```
procedure TButtonsForm.Button3Click(Sender: TObject);
begin
  Button6.Height := Button6.Height + 3;
  Button6.Width := Button6.Width + 3;
end;

procedure TButtonsForm.Button6Click(Sender: TObject);
begin
  Button6.Height := Button6.Height - 3;
  Button6.Width := Button6.Width - 3;
end;
```

It would have been quite easy, in any case, to check the current size of the button and prevent its reduction or enlargement by more than a certain value.

Clicking the Mouse Button

Up to now we have based the examples on the OnClick event of buttons. Almost every component has a similar click event. But what exactly is a click? And how is it related to other events, such as OnMouseDown and OnMouseUp?

First, consider the click. At first sight you might think that to generate a click, a user has to press and release the left mouse button on the control. This is certainly true, but the situation is more complex. When the user clicks the left mouse button on a button component, the component is graphically pressed, too. However, if the user moves the cursor (holding down the left mouse button) outside the button surface, this button will be released. If the user now releases the left mouse button outside the button area, no effect — no click — takes place. On the other hand, if the user places the cursor back on the button, it will be *pressed* again, and when the mouse button is released, the click will occur. If this is not clear, experiment with a button; any button in any Windows application will do.

Now to the second question. In Windows, the behavior just described is typical of buttons, although Delphi has extended it to most components, as well as to forms. In any case, the system generates more basic events — one each time a mouse button is pressed, and another each time a button is released. In Delphi, these events are called OnMouseDown and OnMouseUp. Since the mouse has more than one button, these same events are generated when the user presses any mouse button.

You might want different actions to occur, depending on the mouse button. For this reason, these event handlers include a parameter indicating which button was pressed. These methods also include another parameter, indicating whether some special key (such as Shift or Ctrl) has been pressed and, finally, two more values indicating the *x* and *y* positions where the action took place. This is the method corresponding to this event for a form:

```
procedure TForm1.FormMouseDown(
  Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
```

Most of the time, we do not need such a detailed view, and handling the mouse-click event is probably more appropriate.

Adding Colored Text to a Form

Now that you have played with buttons for a while, it's time to move to a new component, labels. Labels are just text, or comments, written in a form. Usually, the user doesn't interact with a label at all — or at least not directly. It doesn't make much sense to click on a label (although in Delphi this is technically possible). Keep in mind, however, that not all of the text you see in a form corresponds to a label. A form (and any other component) can simply output text on its surface, for example using the TextOut method.

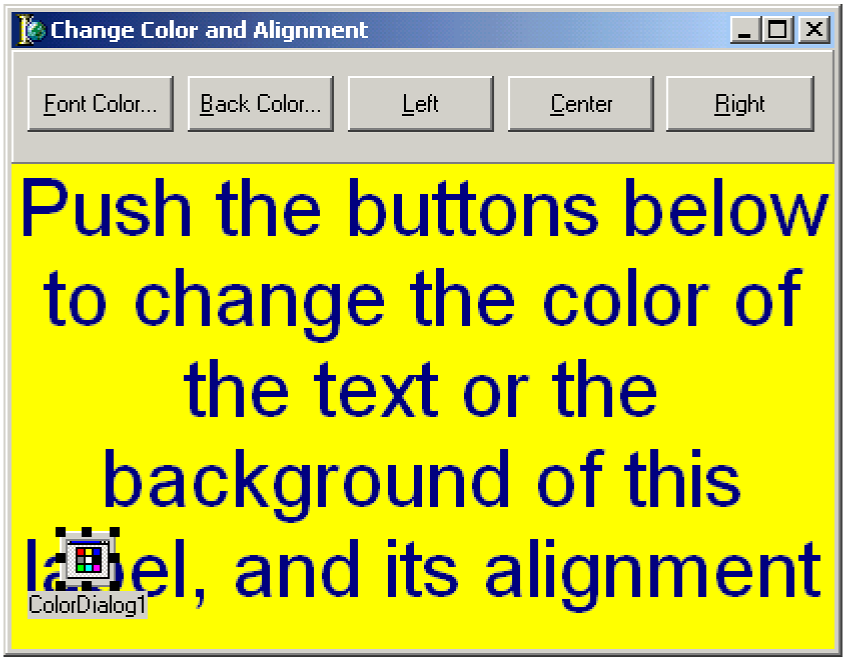
We use labels to provide descriptions of other components, particularly edit fields and list or combo boxes, because they have no title. If you open a dialog box in any Windows application, you'll probably see some text. These are *static controls* (in Windows terms) or *labels* (in Delphi terms).

Windows implements labels as windows of the static class. Delphi, instead, implements labels as non-windowed, graphical components. This is very important since it allows you to speed up form creation and save some Windows resources. However, Delphi also includes a new component that corresponds to the Windows label, the StaticText component. This component has similar properties and the same events, and Borland seems to have added it mainly for ActiveX support. We will use this component in the next example.

Besides using labels for descriptions, we can use instances of this component to improve and add some color to the user interface of our application. This is what we are going to do in the next example, LabelCo. The basic idea of this application is to test a couple of properties of the label component at run-time. Specifically, we want to alter the background color of the label, the color of its font, and the alignment of the text.

The LabelCo Example

The first thing to do is to place a big label in the form and enter some text. Write something long. I suggest you set the `WordWrap` property to `True`, to have several lines of text, and the `AutoSize` property to `False`, to allow the label to be resized freely. It might also be a good idea to select a large font, to choose a color for the font, and to select a color for the label itself.



Push the buttons below to change the color of the text or the background of this label, and its alignment

To change the font color, background color, and alignment properties of the label at run-time, we can use buttons. Instead of placing these buttons directly on the form, we can place a Panel component in the form, and then place the five buttons over (or actually inside) the panel. We need two to change the colors and three more to select the alignment — left, center, or right. Placing the buttons inside the panel, this last control will become the `Parent` component of the buttons: the coordinates of the buttons will be relative to the panel, so that moving the panel will move the buttons, hiding the Panel will hide the buttons, and so on.

> The difference between the `Parent` and the `Owner` properties of a component is very important. The first indicates visual containment (like a button being inside a panel) while the latter indicates construction and destruction ownership (like a button being owned and destroyed by a form).

Making the label and the panel child components of the form allows us to align them (something you cannot do with buttons). Simply set the `Align` property of the Panel to `alTop`, and the `Align` property of the Label to `alClient`, and the two components will take up the full client area of the form. What's interesting is that when we resize the form, the two components will adjust their size and position correspondingly. Notice, by the way, that the StaticText component has no `Align` property.

The last component we have to place on the form is a ColorDialog component (you can find it in the Dialogs page of the Components palette). This component invokes the standard Windows Color dialog box. The resulting form is detailed in the following listing:

```
object ColorTextForm: TColorTextForm
  Caption = 'Change Color and Alignment'
  object Label1: TLabel
    Align = alClient
    Alignment = taCenter
    Caption = 'Push the buttons...' // omitted
    Color = clYellow
    Font.Color = clNavy
    Font.Height = -40
    Font.Name = 'Arial'
    WordWrap = True
  end
  object Panel1: TPanel
    Align = alTop
    object BtnFontColor: TButton...
    object BtnBackColor: TButton...
    object BtnLeft: TButton...
    object BtnCenter: TButton...
    object BtnRight: TButton...
  end
  object ColorDialog1: TColorDialog...
end
```

> The two buttons used to change the color will display a dialog box, instead of performing an action directly. For this reason at the end of their `Caption` there is an ellipsis (...), which is the standard Windows convention for button and menu items to indicate the presence of a dialog box.

Now it's time to write some code. The click methods for the three alignment buttons are very simple. The program has to change the alignment of the label, as in:

```
procedure TColorTextForm.BtnLeftClick(Sender: TObject);
begin
  Label1.Alignment := taLeftJustify;
end;
```

The other two methods should use the values `taCenter` and `taRightJustify` instead of `taLeftJustify`. You can find the names of these three choices in the `Alignment` property of the label, in the Object Inspector.

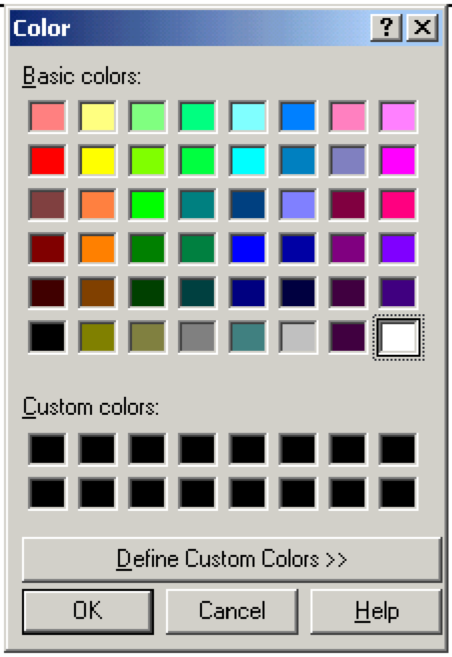
Writing code to change the color is a little more complex. In fact, we can provide a new value for the color, maybe choosing it from a list with a series of possible values. We might solve this problem, for example, by declaring an array of colors, entering a number of values, and then selecting a different element of the array each time. However, a more professional solution needs even less code: using the Windows standard dialog box to select a color.

The Standard Color Dialog Box

To use the standard Color dialog box, move to the Dialogs page of the Delphi Components palette, select the ColorDialog component, and place it anywhere on the form. The position has no effect, since at run-time this component is not visible inside the form. Now we can use the component, writing the following code:

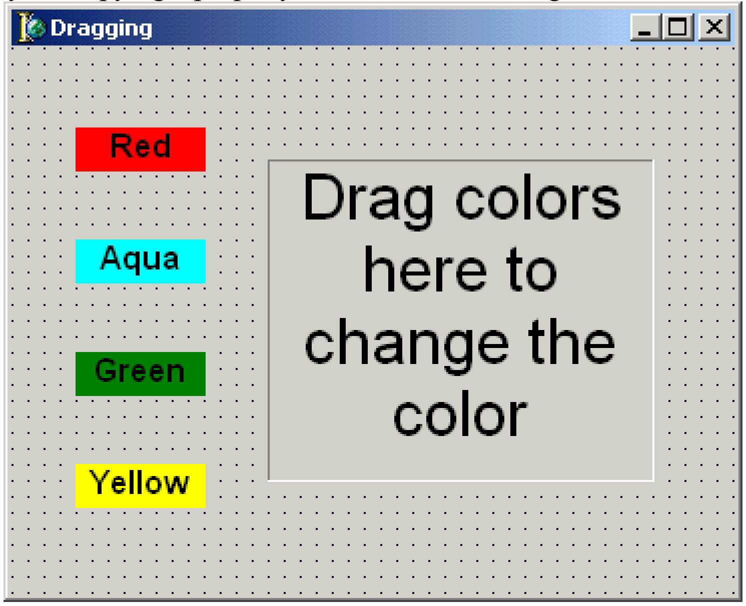
```
procedure TColorTextForm.BtnFontColorClick(Sender: TObject);
begin
  ColorDialog1.Color := Label1.Font.Color;
  if ColorDialog1.Execute then
    Label1.Font.Color := ColorDialog1.Color;
end;
```

The three lines in the body of the procedure have the following meanings: with the first, we select the background color of the label as the initial color displayed by the dialog box; with the second, we run the dialog box; with the third, the color selected by the user in the dialog box is copied back to the label. We do this last operation only if the user closes the dialog box by pressing the OK button (in which case the `Execute` method returns `True`). If the user presses the Cancel button (and `Execute` returns `False`), we skip this last statement. To change the color of the label's text, we write similar code, referring this time to the `Label1.Font.Color` property. (The complete source code for the form LabelCo example is on the CD in the file `LABELF.PAS`.) You can see the Color dialog box in action in the figure below. This dialog box can also be expanded by clicking on the Define Custom Colors button.



Dragging from One Component to Another

Before we try out other Delphi components, it's helpful to examine a particular technique: *dragging.* The dragging operation is quite simple and is increasingly common in Windows. In Windows you can drag files and programs from a folder to another, drop them on the desktop, or perform similar dragging operations on files and folders with the Windows Explorer. You usually perform this operation by pressing the mouse button on one component (or window) and releasing it on another component (or window). When this operation occurs, you can provide some code, usually for copying a property, a value, or something else to the destination component.



As an example, consider the form in the figure above. There are four color labels, with the name of each color as text, and a destination label, with some descriptive text. Actually the destination label is implemented with a StaticText component. This component has a special value for the `Border` property, `sbsSunken`, with a *lowered* effect. A similar capability is not available for plain labels. The aim of this example, named Dragging, is to be able to drag the color from one of the labels on the left to the static text, changing its color accordingly. The components have very simple properties, as the following textual description of the form summarizes:

```
object DraggingForm: TDraggingForm
  Caption = 'Dragging'
  Font.Color = clBlack
  Font.Height = -16
  Font.Name = 'Arial'
  Font.Style = [fsBold]
  object LabelRed: TLabel
    Alignment = taCenter
    AutoSize = False
    Caption = 'Red'
    Color = clRed
    DragMode = dmAutomatic
  end
  object LabelAqua: TLabel...
  object LabelGreen: TLabel...
  object LabelYellow: TLabel...
  object StaticTarget: TStaticText
    Alignment = taCenter
    AutoSize = False
    BorderStyle = sbsSunken
    Caption = 'Drag colors here to change the color'
    Font.Height = -32
    OnDragDrop = StaticTargetDragDrop
    OnDragOver = StaticTargetDragOver
  end
end
```

After preparing the labels by supplying the proper values for the names and caption, as well as a corresponding color, you have to enable dragging. You can do this by selecting the value `dmAutomatic` for the `DragMode` property of the four labels on the left and responding to a couple of events in the destination label.

> As an alternative to the automatic dragging mode, you might choose the manual dragging mode. This is based on the use of the `BeginDrag` and `EndDrag` methods. An alternative approach is to handle dragging manually, simply by providing a handler for events related to moving the mouse and pressing and releasing mouse buttons.

The Code for the Dragging Example

The first event I want to consider is `OnDragOver`, which is called each time you are dragging and move the cursor over a component. This event indicates that the component accepts dragging. Usually, the event takes place after a determination of whether the Source component (the one that originated the dragging operation) is of a specific type:

```
procedure TDraggingForm.StaticTargetDragOver(
  Sender, Source: TObject; X, Y: Integer;
  State: TDragState; var Accept: Boolean);
begin
  Accept := Source is TLabel;
end;
```

This code accepts the dragging operation, activating the corresponding cursor, only if the Source object is really a Label component. Notice the use of the is dynamic type checking operator. The second method we have to write corresponds to the OnDragDrop event:

```
procedure TDraggingForm.StaticTargetDragDrop(
  Sender, Source: TObject;  X, Y: Integer);
begin
  StaticTarget.Color := (Source as TLabel).Color;
end;
```

To read the value of the Color property from the Source object, we need to cast this object to the proper data type, in this case TLabel. We have to perform a type conversion — technically speaking, a type downcast (a typecast from a base class to a derived class, down through the hierarchy). A type downcast is not always safe. In fact, the idea behind this cast is that we receive the parameter Source of type TObject, which is really a label, and want to use it as a TLabel object, where TLabel is a class derived fromTObject. However, in general, we face the risk of down-casting to TLabel an object that wasn't originally a label but, say, a button. When we start using the button as a label, we might have run-time errors.

In any case, when we use the as typecast, a type check is performed. Had the type of the Source object not been TLabel, an exception would have been raised. In this particular case, however, we haven't much to worry about. In fact, the OnDragDrop event is received only when the Accept parameter of the OnDragOver method is set to True, and we make this only if the Source object really is a TLabel.

Accepting Input from the User

We have seen a number of ways a user can interact with the application we write using a mouse: mouse clicks, mouse dragging, and so on. What about the keyboard? We know that the user can use the keyboard instead of the mouse to select a button by pressing the key corresponding to the underlined letter of the caption (if any).

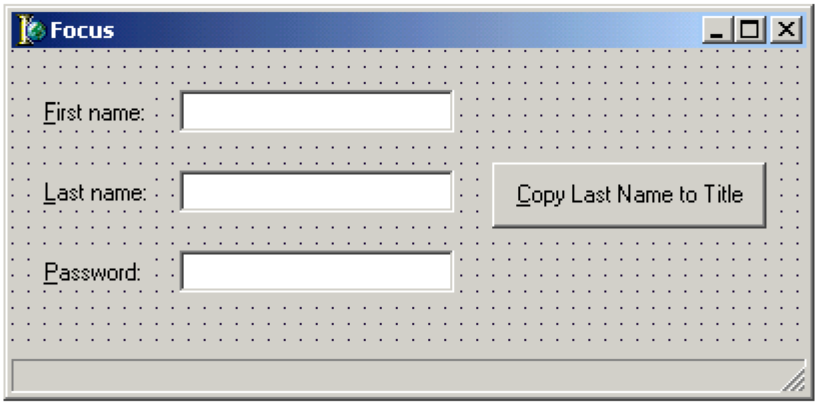
Aside from some particular cases, Windows can handle keyboard input directly. Defining handlers for keyboard-related events isn't a common operation, anyway. In fact, the system provides ready-to-use controls to build edit fields and a simple text editor. Delphi has several slightly different components in this area: Edit, MaskEdit, Memo, RichText, and the related data-aware controls. The two basic components are Edit and Memo.

An Edit component allows a single line of text and has some specific properties, such as one that allows only a limited number of characters or one that shows a special password character instead of the actual text. A Memo component, as we will see in a while, can host several lines of text.

Our first example of the Edit component, named Focus, will demonstrate a feature common to many controls, the *input focus*. In Windows, it's fairly simple to determine which is the active main window: it is in front of the other windows, and the title bar is a different color. It is not as easy to determine which window (or component) has the input focus. If the user presses a key, which component is going to receive the corresponding keyboard input message? It can be the active window, but it can also be one of its controls. Consider a form with several edit fields. Only one has the input focus at a given time. A user can move the input focus by using Tab or by clicking with the mouse on another component.

Handling the Input Focus

What's important for our example is that each time a component receives or loses the input focus, it receives a corresponding event indicating that the user either has reached (`OnEnter`) or has left (`OnExit`) the component. So we can add some methods to the form to take control over the input focus and display this information in a label or a status bar.



Besides three edit boxes, the form has also some labels indicating the meaning of the three edit fields (*First name*, *Last name*, and *Password*). For the output of the status information I've used a specific Windows common control, the StatusBar, but using a label or a panel would have had a similar effect. In fact, you can use the StatusBar component as a single-line output tool, by setting its `SimplePanel` property to `True`. Here is a summary of the properties for this example:

```
object FocusForm: TFocusForm
  Caption = 'Focus'
  object Label1: TLabel
    Caption = '&First name:'
    FocusControl = EditFirstName
  end
  object Label2: TLabel
    Caption = '&Last name:'
    FocusControl = EditLastName
  end
  object Label3: TLabel
    Caption = '&Password:'
    FocusControl = EditPassword
  end
  object EditFirstName: TEdit
    TabOrder = 0
    OnEnter = EditFirstNameEnter
  end
  object EditLastName: TEdit
    TabOrder = 1
    OnEnter = EditLastNameEnter
  end
  object EditPassword: TEdit
    PasswordChar = '*'
    TabOrder = 2
    OnEnter = EditPasswordEnter
  end
  object ButtonCopy: TButton
    Caption = '&Copy Last Name to Title'
    TabOrder = 3
    OnClick = ButtonCopyClick
    OnEnter = ButtonCopyEnter
  end
  object StatusBar1: TStatusBar
    SimplePanel = True
  end
end
```

As you can see, the form also contains a button we can use to copy the text of the `LastNameEdit` to the form's caption. This is just an example of how to work with text entered in an edit box. As you can see in the following code, before using the `Text` property of an edit box, it's a good idea to test whether the user has actually typed something or if the edit field is still empty:

```
procedure TFocusForm.ButtonCopyClick(Sender: TObject);
begin
  if EditLastName.Text <> '' then
    FocusForm.Caption := EditLastName.Text;
end;
```

Now we can move to the most interesting part of the program. We can write a comment in the status bar each time the focus is moved to a different control.

Displaying text in the status bar as the focus moves from control to control is a good way to guide the user through the steps of an application.

To accomplish this, we need four methods, one for each of the Edit components and one for the button, referring to the `OnEnter` event. Here is the code of one of the methods (the other three event handlers are very similar):

```
procedure TFocusForm.EditFirstNameEnter(Sender: TObject);
begin
  StatusBar1.SimpleText := 'Entering the first name...';
end;
```

You can test this program with the mouse or use the keyboard. If you press the Tab key, the input focus cycles among the Edit components and the button, without involving the labels. To have a proper sequence, you can change the `TabOrder` property of the windowed component. You can change this order either by entering a proper value for this property in the Object Inspector or (much better and easier) by using the Edit Tab Order dialog box, which can be called using the Tab Order command on the form's local menu. If you open this dialog box for the Focus example. Notice that the status bar is listed but you cannot actually move onto it using the Tab key.

A second way to select a component is to use a shortcut key. It is easy to place a shortcut key on the button, but how can you jump directly to an edit box? It isn't possible directly (the `Text` of the edit box changes as a user types), but there is an indirect way. You can add the shortcut key — the ampersand (`&`) — to a label, then set the `FocusControl` property of the label to the corresponding Edit component.

> Since Windows 95, the edit controls automatically have a local menu displayed when the user presses the right mouse button over them. Although you can easily customize such a menu in Delphi (as we will see in the next chapter), it is important to realize that this is standard behavior in the system.

A Generic OnEnter Event Handler

The problem with this code is that we have to write four different `OnEnter` event handlers, copying four strings to the text of the StatusBar component. To add more edit boxes to the example, you would need to add more event handlers, copying the code over and over. And if you wanted to provide a slightly different output (for example, by changing the output of the StatusBar allowing for multiple panels), you would need to change the code many times.

The alternative solution is to write a single event handler for the `OnEnter` event of each edit box (and the button, too). We simply need to store the message for the status bar in a property, then refer to this property for the `Sender` object. A good technique is to use the `Hint` property, which is actually designed for providing descriptions to the user.

Simply store the proper messages in the `Hint` property of the edit boxes and of the button, then remove the current `OnEnter` event handler, and install this method for each of them:

```
procedure TFocusForm.GlobalEnter(Sender: TObject);
begin
  StatusBar1.SimpleText := (Sender as TControl).Hint;
end;
```

Notice you cannot write `Sender as TEdit` because the control might be a button as well. The solution is to typecast to a common ancestor class of `TButton` and `TEdit`, which defines the `Hint` property, as you can see in the code above.

Entering Numbers

We saw in the previous example that it is very easy to use an Edit component to ask the user to input some text, although it must be limited to a single line. In general, it’s quite common to ask users for numeric input, too. To accomplish this, you can use the MaskEdit component (in the Additional page of the Components palette) or simply use an Edit component and then convert the input string into an integer, using the standard Pascal `Val` procedure or the Delphi `IntToStr` function.

This sounds good, but what if the user types a letter when a number is expected? Of course, these conversion functions return an error code, so we can use it to test whether the user has really entered a number. The second question is, when can we perform this test? Maybe when the value of the edit box changes, when the component loses focus, or when the user clicks on a particular button, such as the OK button in a dialog box. As you’ll see, not all of these techniques work well.

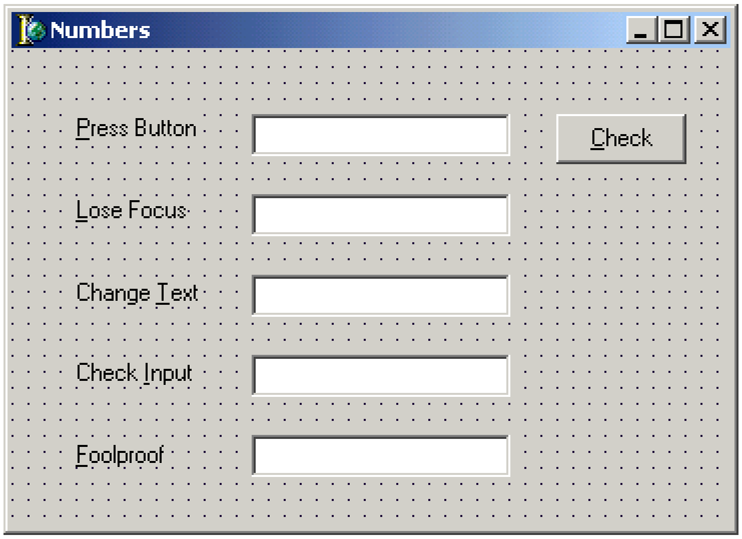
There is another, radically different, solution to the problem of allowing only numerical input in an edit box. You can look at the input stream to the edit box and stop any non-numerical input. This technique is not foolproof (a user can always paste some text into an edit box), but it works quite well and is easy to implement. Of course, you can improve it by combining it with one of the other techniques.

The next example, Numbers (see the form in the following figure), shows some of the techniques you can use to handle numerical input with an Edit component, so you can compare them easily. This example is meant as an exercise to discuss keyboard input and the input focus. To handle numerical input in an application you'll generally use specific components, as the SpinEdit or the UpDown controls available in Delphi. We will see an example of the use of another even more sophisticated control for keyboard input, the MaskEdit component.

In this example we're going to compare the effect of testing the input at different stages. First of all, build a form with five edit fields and five corresponding labels, describing in which occasion the corresponding Edit component checks the input. The form also has a button to check the contents of the first edit field. The contents of the first edit box are checked when the Check button is pressed. In the handler of the `OnClick` event of this button, the text is first converted into a number, using the `Val` procedure, which eventually returns an error code. Depending on the value of the code, a message is shown to the user:

```
procedure TNumbersForm.CheckButtonClick(Sender: TObject);
var
  Number, Code: Integer;
begin
  if Edit1.Text <> '' then
  begin
    Val (Edit1.Text, Number, Code);
    if Code <> 0 then
    begin
      Edit1.SetFocus;
      MessageDlg ('Not a number in the first edit',
        mtError, [mbOK], 0);
    end
    else
      MessageDlg ('OK, the number in the first edit box is' +
        IntToStr (Number), mtInformation, [mbOK], 0);
  end;
end;
```

If an error occurs, the application moves the focus back to the edit field before showing the error message to the user, thus inviting the user to correct the value. Of course, in this sample application a user can ignore this suggestion and move to another edit field.



The same kind of check is made on the second edit field when it loses the focus. In this case, the message is displayed automatically, but only if an error occurs. Why bother the user if everything is fine? The code here differs from that of the first edit field; it makes no reference to the `Edit2` component but always refers to the generic `Sender` control, making a safe typecast. To indicate the number of each button, I've used the `Tag` property, entering the number of the edit control.

> As you can see in the following listing, instead of casting the `Sender` parameter to the `TEdit` class several times in the same method, it is better to do this operation once, saving the value in a local variable of the `TEdit` type. The type checking involved with these casts, in fact, is quite slow.

This method is a little more complex to write, but we will be able to use it again for a different component. Here is its code:

```
procedure TNumbersForm.Edit2Exit(Sender: TObject);
var
  Number, Code: Integer;
  CurrEdit: TEdit;
begin
  CurrEdit := Sender as TEdit;
  if CurrEdit.Text <> '' then
  begin
    Val (CurrEdit.Text, Number, Code);
    if Code <> 0 then
    begin
      CurrEdit.SetFocus;
      MessageDlg ('The edit field number ' +
        IntToStr (CurrEdit.Tag) + ' does not have a valid number',
        mtError, [mbOK], 0);
    end;
  end;
end;
```

> Since Delphi 2, this code produces a warning message (a hint) when compiled, because the `Number` variable is not used after a value has been assigned to it. To avoid these hints, you can ask the compiler to disable its generation inside a specific method using the `$HINTS` compiler directive. Simply write `{$HINTS OFF}` before the method and `{$HINTS ON}` after it, as I've done in the source code of this example.

The third Edit component makes a similar test each time its content changes (using the `OnChange` event). Although we have checked the input on different occasions — using different events — the three functions are very similar to each other. The idea is to check the string once the user has entered it.

For the fourth Edit component, I want to show you a completely different technique. We are going to make a check *before* the Edit even knows that a key has been pressed. The Edit component has an event, `OnKeyPress`, that corresponds to the action of the user. We can provide a method for this event and test whether the character is a number or the Backspace key (which has a numerical value of 8, so we can refer to it as the character `#8`). If not, we change the value of the key to the null character (`#0`), so that it won't be processed by the edit control, and produce a little warning sound:

```
procedure TNumbersForm.Edit4KeyPress(
  Sender: TObject; var Key: Char);
begin
  // check if the key is a number or backspace
  if not (Key in ['0'..'9', #8]) then
  begin
    Key := #0;
    Beep;
  end;
end;
```

The fourth Edit component accepts only numbers for input, but it is not foolproof. A user can copy some text to the Clipboard and paste it into this Edit control with the Shift+Ins key combination (but not using Ctrl+V), avoiding any check. To solve this problem, we might think of adding a check for a change to the contents, as in the third edit field, or a check on the contents when the user leaves the edit field, as in the second component. This is the reason for the fifth, Foolproof edit field: it uses the `OnKeyPress` event of the fourth edit field, the `OnChange` method of the third, and the `OnExit` event of the second, thus requiring no new code.

To reuse an existing method for a new event, just select the Events page of the Object Inspector, move to the component, and instead of double-clicking to the left of the event name, select the button in the combo box at the right. A list of names of old methods compatible with the current event — having the same number of parameters — will be displayed.

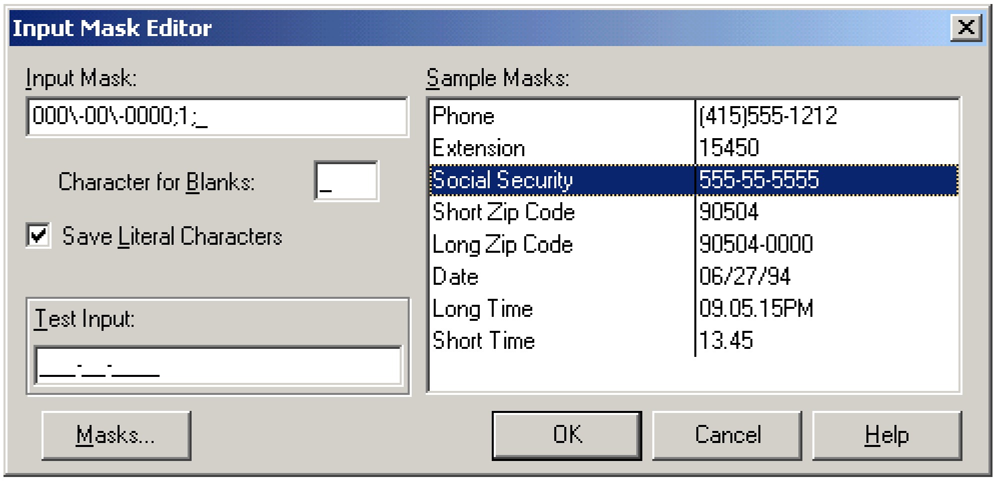
If you select the proper methods, the fifth component will combine the features of the third and the fourth. This is possible because in writing these methods, I took care to avoid any reference to the control to which they were related. The technique I used was to refer to the generic `Sender` parameter and cast it to the proper data type, which in this case was `TEdit`. As long as you connect a method of this kind to a component of the same kind, no problem should arise. Otherwise, you should make a number of type checks (using the `is` operator), which will probably make the code more complex to read. My suggestion is to share code only between controls of the same kind.

Notice also that to tell the user which edit box has incorrect text, I've added to each Edit component a value for the `Tag` property, as I mentioned before. Every edit box has a tag with its number, from 1 to 5.

Sophisticated Input Schemes

In the last example, we saw how an Edit component can be customized for special input purposes. The components could really accept only numbers, but handling complex input schemes with a similar approach is not straightforward. For this reason, Borland has supplied a ready-to-use *masked edit component*, an edit component with an input mask stored in a string.

For example, to handle numbers of no more than five digits, we can set the `EditMask` property to `99999.` (The character `9` stands for *non-compulsory digit*; refer to the Delphi documentation for the meaning of the various characters and symbols in the edit mask.) I suggest that you don't enter a string directly in this property, but instead always open the associated editor by clicking on the small ellipses button. The Input Mask editor has a test window and includes sample masks for commonly used input values.



Input Mask: 000\-00\-0000;1;_

Character for Blanks: _

☑ Save Literal Characters

Test Input: ___-__-____

Sample Masks:

Phone	(415)555-1212
Extension	15450
Social Security	555-55-5555
Short Zip Code	90504
Long Zip Code	90504-0000
Date	06/27/94
Long Time	09:05:15PM
Short Time	13:45

Notice that the Input Mask editor allows you to enter a mask, but it also asks you to indicate a character to be used as a placeholder for the input and to decide whether to save the *literals* present in the mask, together with the final string. For example, you can choose to have the parentheses around the area code of a phone number only as an input hint or to save them with the string holding the resulting number. These two entries in the Input Mask editor correspond to the last two fields of the mask (separated, by default, with semicolons).

To see more default input masks, you can press the Masks button, which allows you to open a mask file. The predefined files hold standard codes grouped by country. For example, if you open the Italian group, you can find the taxpayer number (or *fiscal code*, which is used like social security numbers in the U.S.). This code is a complex mix of letters and numbers (including the consonants representing name, birth date, area code, and more), as its mask demonstrates:

```
LLLLLL00L00L000L
```

In this kind of code, `L` stands for a letter and `0` for a number. While you can look these up in the Help file, there is a summary of these codes in the following Mask1 example.

The form of this example includes a MaskEdit and an Edit component. The Edit is used to change the `EditMask` property of the first one at run-time. To accomplish this, I've just written a couple of lines of code to copy the text of the property into the edit box at the beginning (the `OnCreate` event) and reverse the action each time the plain edit box changes (`Edit1Change`):

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  Edit1.Text := MaskEdit1.EditMask;
end;

procedure TForm1.Edit1Change(Sender: TObject);
begin
  MaskEdit1.EditMask := Edit1.Text;
end;
```

The form also has a list box with the description of the most important codes used to build the mask.

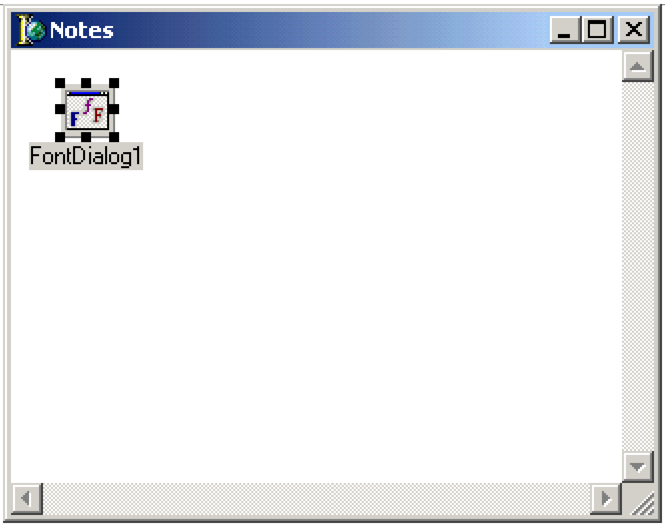
Creating a Simple Editor

Edit components can handle a limited amount of text, and only on a single line. If you need to accept longer text input, you should use the Memo component. A Memo component is like an Edit component, but it can span several lines, contain scroll bars to move through the text, and contain more text.

The easiest way to use a Memo is as a text editor, as you'll see in the next example, Notes. The idea is to implement an editor covering all of the window (or form) which contains it, to resemble Windows Notepad. The only other feature we will implement is to give the user the option of choosing the font for the editor.

Both parts are very easy to implement. Create a new project and place a Memo component on the form. Delete its text, remove the border, and set the `Alignment` property to `alClient`, so that it will always cover the whole client area — the internal surface — of the form. Also add both scroll bars, horizontal and vertical, selecting the value `ssBoth` for the memo's `ScrollBars` property. Here is the summary (and the design time image of the form):

```
object NotesForm: TNotesForm
  Caption = 'Notes'
  object Memo1: TMemo
    Align = alClient
    BorderStyle = bsNone
    Font.Height = -19
    Font.Name = 'Times New Roman'
    ScrollBars = ssBoth
    OnDblClick = Memo1DblClick
  end
  object FontDialog1: TFontDialog...
end
```



The Font Dialog Box

The second portion of the program involves the font. In the same way we used the standard Color dialog box in a previous example, we can use the standard Font selection dialog box provided by Windows. Just move to the Dialogs page of the Components palette and select the FontDialog component. Place it anywhere on the form, and add the following code when the user double-clicks inside the Memo:

```
procedure TNotesForm.Memo1DblClick(Sender: TObject);
begin
  FontDialog1.Font := Memo1.Font;
  if FontDialog1.Execute then
    Memo1.Font := FontDialog1.Font;
end;
```

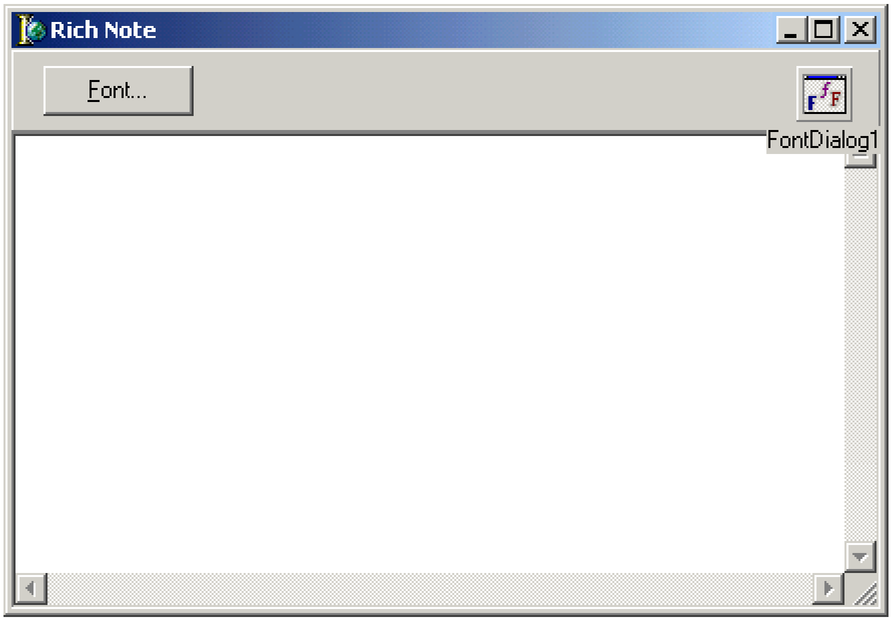
This code copies the current font to the corresponding property of the dialog component so it will be selected by default. Then it executes the dialog box. At the end, the `Font` property will contain the font the user selected. If the user presses the OK button, the third line of the above code copies the font back to the Memo.

This program is more powerful than it appears at first glance. For example, it allows copy and paste operations using the keyboard — this means you can copy text from your favorite word processor — and can handle the color of the font. Why not use it to place a big and colorful message on your screen?

Creating a Rich Editor

Although you can choose a font in the Notes program, all of the text you have written will have the same font. Windows has a control that can handle the Rich Text Format (RTF). A Delphi component, RichEdit, encapsulates the behavior of this standard control.

You can find an example of a complete editor based on the RichEdit component among the examples that ship with Delphi. (The example is named RichEdit, too). Here, we'll only change the previous program slightly by replacing the Memo component with a RichEdit, and allow a user to change the font of the selected portion of the text, not the whole text.



The RichNote example has a RichEdit component filling its client area. However, the component has no double-click event, so I added a button to select the font and placed it in a panel aligned to the top of the form, making a very simple toolbar. Here is the textual description of some of the properties of the three components:

```
object RichEdit1: TRichEdit
  Align = alClient
  HideScrollBars = False
  ScrollBars = ssBoth
end
object Panel1: TPanel
  Align = alTop
  object Button1: TButton
    Caption = '&Font...'
  end
end
```

Notice the caption of the button, which has an ampersand for the shortcut key, and an ellipsis at the end to indicate that pressing it will open a dialog box. When the user clicks on the button, if some text is selected, the program shows the standard Font dialog box using the default font of the RichEdit component as the initial value. At the end, the selected font is copied to the attributes of the current selection. The `DefAttributes` and `SelAttributes` properties of the RichEdit component are not of the `TFont` type, but they are compatible, so we can use the `Assign` method to copy the value:

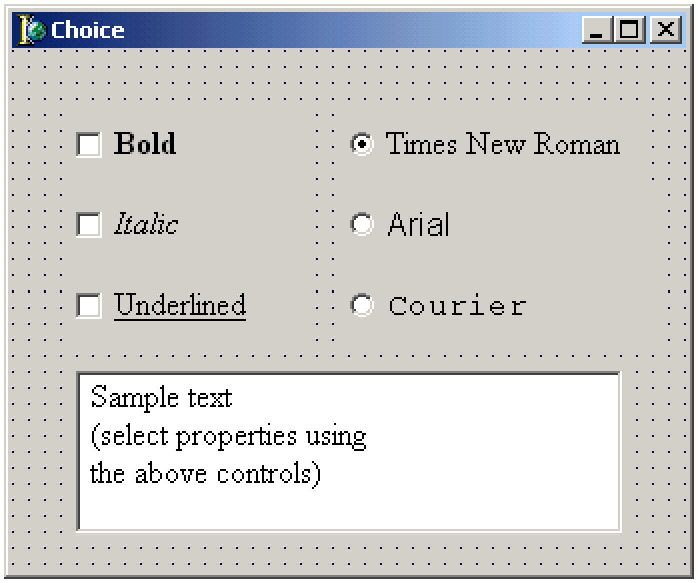
```
procedure TForm1.Button1Click(Sender: TObject);
begin
  if RichEdit1.SelLength > 0 then
  begin
    FontDialog1.Font.Assign(RichEdit1.DefAttributes);
    if FontDialog1.Execute then
      RichEdit1.SelAttributes.Assign(FontDialog1.Font);
  end
  else
    ShowMessage ('No text selected');
end;
```

The RichEdit component has other attributes related to fonts and paragraph formatting. We will use this component in further examples of the book; however, the simple code above is enough to let users produce much more complex output than the Memo component allows.

Making Choices

There are two standard Windows controls that allow the user to choose different options. The first is the *check box*, which corresponds to an option that can be selected freely (unless it has been disabled). The second control is the *radio button*, which corresponds to an exclusive selection. For example, if you see two radio buttons with the labels *A* and *B*, you can select *A* or select *B*, but not both of them at the same time. The other characteristic of a multiple choice is that you *must* check one of the radio buttons.

If the difference between check boxes and radio buttons is still not clear, an example might help you. The example has three check boxes to select the style *Bold*, *Italic*, or *Underlined*, and three radio buttons to choose a font (*Times New Roman*, *Arial*, or *Courier*). There is also a memo field with some text to show the effect of the user selections immediately.



Sample text
(select properties using
the above controls)

The difference between the use of the check boxes and the radio buttons should be obvious. The text might be bold and italic at the same time, but it cannot be Arial and Courier at once. A user must choose only one font (and cannot choose none) but can select each of the styles independently from the other two (including no style at all).

This program requires some simple code. Each time the user clicks on a check box or radio button, we have to create a corresponding action. For the text styles, we have to look at the `Check` property of the control and add or remove the corresponding element from the memo's Font property `Style` set:

```
procedure TForm1.CheckBoldClick(Sender: TObject);
begin
  if CheckBold.Checked then
    Memo1.Font.Style := Memo1.Font.Style + [fsBold]
  else
```

```
    Memo1.Font.Style := Memo1.Font.Style - [fsBold];
end;
```

The other two check boxes have similar code for their `OnClick` events. The basic code for the radio buttons is even simpler since you cannot deselect a radio button by clicking on it:

```
procedure TForm1.RadioTimesClick(Sender: TObject);
begin
  Memo1.Font.Name := 'Times New Roman';
end;
```

Grouping Radio Buttons

Radio buttons represent exclusive choices. However, a form might contain several groups of radio buttons. Windows cannot determine by itself how the various radio buttons relate to each other. The solution, both in Windows and in Delphi, is to place the related radio buttons inside a container component. The standard Windows user interface uses a group box control to hold the radio buttons together, both functionally and visually. In Delphi, this control is implemented in the GroupBox component. However, Delphi has a second, similar component that can be used specifically for radio buttons: the RadioGroup component. A RadioGroup is a group box with some radio button inside it.

Using the radio group is probably easier than using the group box, but I'll use the more traditional approach to show you the code you can write to work with controls that have been placed inside another control. The RadioGroup component can automatically align its own internal radio buttons, and you can easily add new choices at run-time. You can see the differences between the two approaches in the next example.

The rules for building a group box with radio buttons are very simple. Place the GroupBox component in the form, then place the radio buttons in the group box. The GroupBox component contains other controls and is one of the container components used most often, together with the Panel component. If you disable or hide the group box, all the controls inside it will be disabled or hidden.

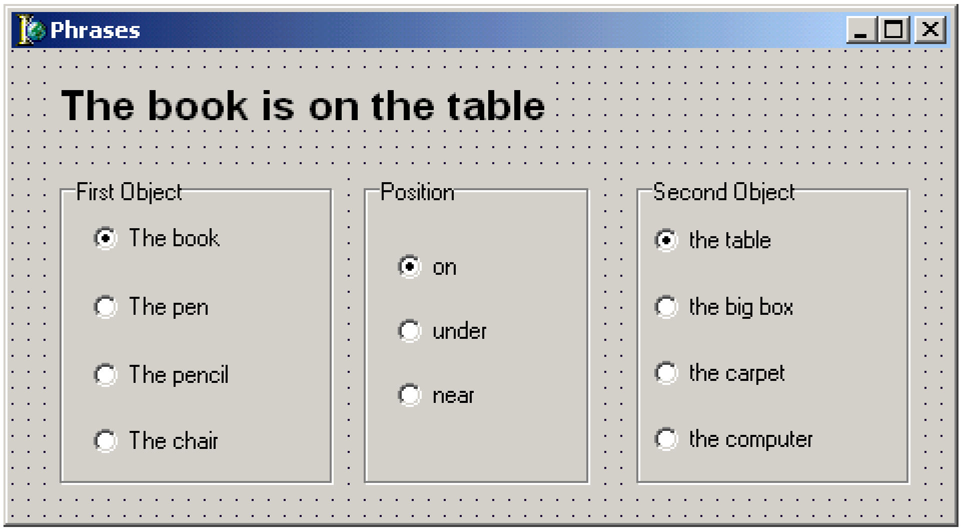
You can continue handling the individual radio buttons, but you might as well navigate through the array of controls owned by the group box. As discussed in the last chapter, the name of this property referring to this array of controls is `Controls`. Another property, `ControlCount`, holds the number of elements. These two properties can be accessed only at run-time.

The Phrases1 Example

If you've ever tried to learn a foreign language, you probably spent some time repeating the same silly and useless phrases over and over. Probably the most typical, when you learn English, is the infamous *"The book is on the table."* To demonstrate radio buttons, the Phrases1 example creates a tool to build such phrases by choosing among different available options.

This form is quite complex. If you rebuild it, remember that you must place the GroupBox components first and the radio buttons later. After doing this, you have to enter a proper caption for each element. The last selection is based on a radio group component, instead of a group box holding some radio buttons (as you can see in the textual description of the form below). In this case you create the options by entering a list of values in the Items property.

Remember that you also need to add a label, select a large font for it, and enter text corresponding to the radio buttons that are checked at design-time. This is an important point: When you place some radio buttons in a form or in a group box, remember to check one of the elements at design-time. One radio button in each group should always be checked, and the `ItemIndex` property of the radio group, indicating the current selection, should have a proper value.



Here is the textual description of the form with a summary of this information:

```
object Form1: TForm1
  Caption = 'Phrases'
  object Label1: TLabel
    Width = 243
    Caption = 'The book is on the table'
    Font.Height = -21
    Font.Name = 'Arial'
    Font.Style = [fsBold]
  end
  object GroupBox1: TGroupBox
    Caption = 'First Object'
    object RadioBook: TRadioButton
      Caption = 'The book'
      Checked = True
      OnClick = ChangeText
    end
    object RadioPen: TRadioButton
      Caption = 'The pen'
      OnClick = ChangeText
    end
    object RadioPencil: TRadioButton...
    object RadioChair: TRadioButton...
  end
  object GroupBox2: TGroupBox
    Caption = 'Position'
    object RadioOn: TRadioButton
      Caption = 'on'
      Checked = True
      OnClick = ChangeText
    end
```

```
      object RadioUnder: TRadioButton...
      object RadioNear: TRadioButton...
    end
    object RadioGroup1: TRadioGroup
      Caption = 'Second Object'
      Items.Strings = (
        'the table'
        'the big box'
        'the carpet'
        'the computer')
      OnClick = ChangeText
    end
  end
```

Now we have to write some code so that when the user clicks on the radio buttons, the phrase changes accordingly. There are different ways to do this. One is to follow the same approach as in the last example, providing a method for each button's `OnClick` event. Then we need to store the various portions of the phrase in some of the form's variables, change the portion corresponding to that button, and rebuild the whole phrase.

An alternative solution is to write a single method that looks at which buttons are currently checked and builds the corresponding phrase. This single method must be connected to the `OnClick` event of every radio button and of the RadioGroup component, a task we can easily accomplish. Select each of the radio buttons on the form (clicking on each one while you hold down the Shift key) and enter the name of the method in the Object Inspector. Since the method used to compute the new phrase doesn't refer to a specific control, you might name it yourself, simply entering a name in the second column of the Object Inspector next to the `OnClick` event. Here is the code of this single complex method:

```
procedure TForm1.ChangeText(Sender: TObject);
var
  Phrase: string;
  I: integer;
begin
  {look at which radio button is selected
  and add its text to the phrase}
  for I := 0 to GroupBox1.ControlCount - 1 do
    if (GroupBox1.Controls[I] as TRadioButton).Checked then
      Phrase := (GroupBox1.Controls[I] as TRadioButton).Caption;

  {add the verb and blank spaces}
  Phrase := Phrase + ' is ';

  {repeat the operation on the second group box}
  for I := 0 to GroupBox2.ControlCount - 1 do
    with GroupBox2.Controls[I] as TRadioButton do
      if Checked then
        Phrase := Phrase + Caption;

  {retrieve the radio group selection, and display
  the result in the label}
  Label1.Caption := Phrase + ' ' +
    RadioGroup1.Items [RadioGroup1.ItemIndex];
end;
```

The `ChangeText` method starts looking at which of the first group of radio buttons is selected, then moves on to adding a verb and the proper spaces between words. To determine which control in a group box is checked, the procedure scans these controls in a `for` loop. The `for` loop ranges from 0 to the number of controls minus 1, because the `Controls` array is zero-based, and tests whether the `Checked` property of the radio button is `True`. A cast is required to perform this operation — we cannot use the `Checked` property on a generic control. When the checked radio button has been found, the program simply copies its caption to the string. At this point, the `for` loop might terminate, but since only one radio button is checked at a time, it is safe to let it reach its natural end — testing all the elements. The same operation is repeated two times, but you can see that the second time a `with` statement is used to make the code shorter and more readable.

As you can see from the final portion of the method above, if you are using the RadioGroup component, the code is much simpler. This control, in fact, has an `ItemIndex` property indicating which radio button is selected and an `Items` property with a list of the text of the fake radio buttons. Overall, using a radio group is very similar to using a list box (as we will see in the next example), aside from the obvious difference in the user interface of the two components.

A List with Many Choices

If you want to add many selections, radio buttons are not appropriate, unless you create a really big form. The usual number of radio buttons is no more than 5 or 6. Another problem is that although you can disable a radio button, the elements of a group are usually fixed. Only when using a radio group can you have some flexibility. For both of these problems, the solution is to use a list box. A list box can host a large number of choices in a small space, because it can contain a scroll bar to show on screen only a limited portion of the whole list. Another advantage of a list box is that you can easily add new items to it or remove some of the current items. List boxes are extremely flexible and powerful.

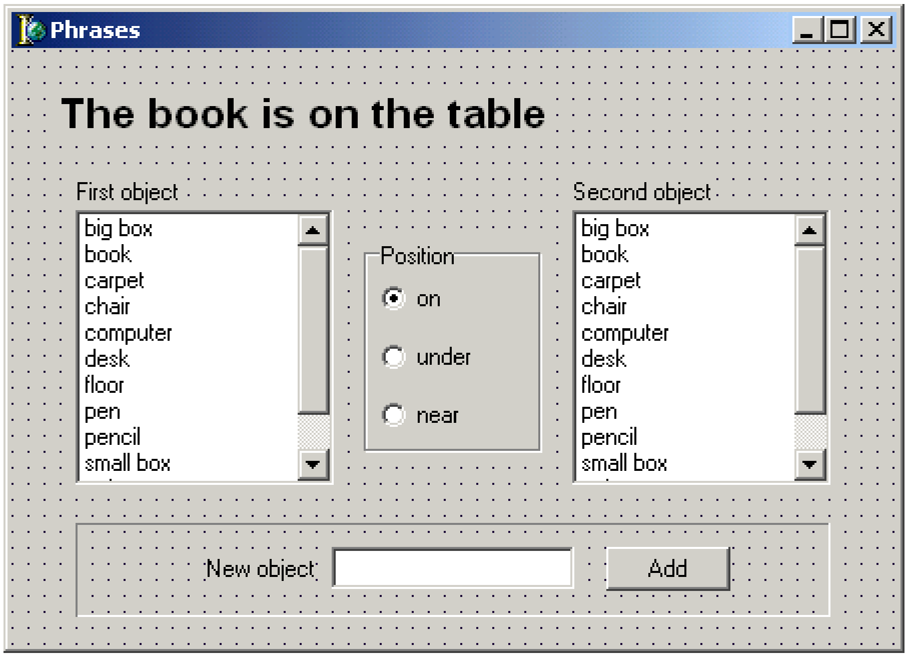
> Another important feature is that by using the ListBox component, you can choose between allowing only a single selection, a behavior similar to a group of radio buttons, and allowing multiple selections, which is similar to a group of check boxes. The next version of this example will have a multiple-selection list box.

For the moment, let's focus on a single-selection list box. We might use a couple of these components to change the Phrases1 example slightly. Instead of having a number of radio buttons to select the first and second objects of the phrase, we can use two list boxes. Besides allowing us to have a larger number of items, the advantage is that we can allow the user to insert new objects in the list and prevent selection of the same object twice, to avoid a phrase such as "The book is on the book." As you might imagine, this example is really much more complicated than the previous one and will require some fairly complex code.

The Form of the Phrases2 Example

As usual, the first step is to build a form. You can start with the form from the last example and remove the two group boxes on the sides and replace them with two list boxes. The radio buttons inside the group boxes will be deleted automatically. I've also replaced the central group box with a radio group. Actually, there's not much left hfrom the previous example!

Now, add some strings to the `Items` property of both list boxes. For the example to work properly, the two list boxes should have the same strings; you can copy and paste them from the editor of the `Items` property of one list box to the editor of the same property of the other component. To improve the usability of the program, you might sort the strings in the list boxes, setting their `Sorted` property to `True`. Remember also to add a couple of labels above the list boxes, to describe their contents.



In the lower part of the form, I've also added an edit field, with its label, and a button, and a bevel around them to group them visually (the bevel is just a graphical component, not a container). As we will see later, when a user presses the button, the text in the Edit control is added to both list boxes. This operation will take place only if the text of the edit box is not empty and the string is not already present in the list boxes.

Here is the textual description of the components of this updated form (which is really very different from the previous version):

```
object Form1: TForm1
  Caption = 'Phrases'
  OnCreate = FormCreate
  object Label1: TLabel... // as in Phrases1
  object Label2: TLabel
    Caption = 'First object'
  end
  object Label3: TLabel
    Caption = 'Second object'
  end
  object ListBox1: TListBox
    Items.Strings = (
      'big box'
      'book'
      'carpet'
      'chair'
      'computer'...)
    Sorted = True
    OnClick = ChangeText
  end
  object RadioGroup1: TRadioGroup
    Caption = 'Position'
    Items.Strings = (
      'on'
      'under'
      'near')
  end
  object ListBox2: TListBox... // identical to ListBox1
  object Bevel1: TBevel...
  object Label4: TLabel
    Caption = 'New object'
  end
  object EditNew: TEdit...
  object ButtonAdd: TButton
    Caption = 'Add'
    OnClick = ButtonAddClick
  end
end
```

Working with the List Boxes

Once you have built this or a similar form, you can start writing some code. The first thing to do is to provide a new `ChangeText` procedure, connected with the `OnClick` event of the radio group and of the two list boxes. This procedure is simpler than in the previous example. In fact, to retrieve the selected text from the list box, you only need to get the number of the item selected (stored in the run-time property `ItemIndex`) and then retrieve the string at the corresponding position of the Item array, as the Phrases1 program did.

Here is what the code for the procedure looks like initially (this is just a temporary version, different from the one in the source code):

```
procedure TForm1.ChangeText(Sender: TObject);
var
  Phrase: String;
begin
  Phrase := 'The ';
  Phrase := Phrase + ListBox1.Items [ListBox1.ItemIndex];
  Phrase := Phrase + ' is ';
  Phrase := Phrase + RadioGroup1.Items [RadioGroup1.ItemIndex];
  Phrase := Phrase + ' the ';
  Phrase := Phrase + ListBox2.Items [ListBox2.ItemIndex];
  Label1.Caption := Phrase;
end;
```

This program, however, won’t work properly because, at the beginning, no item is selected in either list box. To solve this problem, we can add some code to the form’s `OnCreate` event. In this code, we can look for the two default strings, book and table, and select them. You should do this operation in two steps. First, you need to look for the string’s index in the array of strings, with the `IndexOf` method. Then you can use that value as the index of the currently selected item:

```
procedure TForm1.FormCreate(Sender: TObject);
var
  N : Integer;
begin
```

```
  N := ListBox1.Items.IndexOf ('book');
  ListBox1.ItemIndex := N;
  N := ListBox2.Items.IndexOf ('table');
  ListBox2.ItemIndex := N;
end;
```

Removing a Selected String from the Other List Box

Once this part of the program works, we have two more problems to solve: We must remove the selected string from the other list box (to avoid using the same term twice in a phrase), and we must write the code for the click event on the button.

The first problem is more complex, but I'll address it immediately since the solution of the second problem will be based partially on the code we write for the first one. Our aim is to delete from a list box the item currently selected in the other list box. This is easy to code. The problem is that once the selection changes, we have to restore the previous items, or our list boxes will rapidly become empty. A good solution is to store the two currently selected strings for the two list boxes in two private fields of the form, `String1` and `String2`:

```
type
  TForm1 = class(TForm)
  ...
 private
    String1, String2: String;
  end;
```

Now we have to change the code executed at startup and the code executed each time a new selection is made. In the `FormCreate` method, we need to store the initial value of the two strings and remove them from the other list box; the first string should be removed from the second list box, and vice versa. Since the `Delete` method of the `TStrings` class requires the index, we have to use the `IndexOf` function again to determine it:

```
procedure TForm1.FormCreate(Sender: TObject);
var
  N : Integer;
begin
  String1 := 'book';
  String2 := 'table';

  {delete the selected string from the other list box
  to avoid a double selection}
  ListBox2.Items.Delete (ListBox2.Items.IndexOf (String1));
  ListBox1.Items.Delete (ListBox1.Items.IndexOf (String2));

  {select the two strings in their respective list boxes}
  N := ListBox1.Items.IndexOf (String1);
  ListBox1.ItemIndex := N;
  N := ListBox2.Items.IndexOf (String2);
  ListBox2.ItemIndexh := N;
end;
```

> The code to select the string should be executed after calling `Delete`, because removing an element before the one currently selected will alter the selection. The fact is that the selection is just a number referring to a string, not the reverse, as it should probably be. By the way, this doesn't depend on Delphi implementation but on the behavior of list boxes in Windows.

Things get complicated when a new item is selected in one of the list boxes. The `ChangeText` procedure has some new code at the beginning, executed only if the click took place on one of the list boxes (remember that the code is also associated with the group box). For each string, we have to check whether the selected item has changed and, in this case, add the previously selected string to the other list box and delete the new string. Here is the new version of the `ChangeText` method:

```
procedure TForm1.ChangeText(Sender: TObject);
var
  TmpStr: String;
begin
  // if a list box has changed
  if Sender is TListBox then
  begin
    // get the text of the first string
    TmpStr := ListBox1.Items [ListBox1.ItemIndex];
    // if the first one has changed
    if TmpStr <> String1 then
    begin
      // update the strings in ListBox2
      {1.} ListBox2.Items.Add (String1);
      {2.} ListBox2.Items.Delete (
             ListBox2.Items.IndexOf (TmpStr));
      {3.} ListBox2.ItemIndex :=
             ListBox2.Items.IndexOf (String2);
      {4.} String1 := TmpStr;
    end;

    // get the text of the second string
    TmpStr := ListBox2.Items [ListBox2.ItemIndex];
    // if the second one has changed
    if TmpStr <> String2 then
    begin
      // update the strings in ListBox1
      ListBox1.Items.Add (String2);
      ListBox1.Items.Delete (ListBox1.Items.IndexOf (TmpStr));
      ListBox1.ItemIndex := ListBox1.Items.IndexOf (String1);
      String2 := TmpStr;
    end;
  end;

  // build the phrase with the current strings
  Label1.Caption := 'The ' + String1 + ' is ' +
    RadioGroup1.Items [RadioGroup1.ItemIndex] +
    ' the ' + String2;
end;
```

What is the effect of the first part of this code? Here is a detailed description of the operations, referring to a new selection in the first list box. The procedure stores the selected element of the first list box in the temporary string TmpStr. If this is different from the older selection, String1, four operations take place (refer to the numbers in the listing above):

1. The previously selected string, String1, is added to the other list box, ListBox2.
2. The new selection, TmpStr, is removed from the other list box.
3. The selected string of the other list box, String2, is reselected in case its position has been changed by the two preceding operations.
4. Once the two lists contain the correct elements, we can store the new value in String1 and use it later on to build the phrase.

We perform the same steps for the other list box a few lines later. Notice that we don't need to access the list boxes again to build the phrase at the end of the OnChange method, since String1 and String2 already contain the values we need.

Implementing the OnClick event for the Add button is quite simple. The only precautions we have to take are to test whether there is actually some text in the edit box or if it is empty and to check whether the string is already present in one of the two list boxes. Checking only one of the list boxes will miss a correspondence between the text of the edit box and the item currently selected in the other list box.

To make this check, we can ask both ListBox components for the index of the new string; if it is not present in the list — if there is no match — the value –1 will be returned. Otherwise, the IndexOf function returns the correct index, starting with 0 for the first element. In technical terms, we can say that the function returns the zero-based index of the element, or the error code –1 if it is not found. Here is the code:

```
procedure TForm1.ButtonAddClick(Sender: TObject);
begin
  {if there is a string in the edit control and
  the string is not already present in one of the lists}
  if (EditNew.Text <> '') and
    (ListBox1.Items.IndexOf(EditNew.Text) < 0) and
    (ListBox2.Items.IndexOf(EditNew.Text) < 0) then
  begin
    {add the string to both list boxes}
    ListBox1.Items.Add (EditNew.Text);
    ListBox2.Items.Add (EditNew.Text);

    {reselects the current items properly}
    ListBox1.ItemIndex := ListBox1.Items.IndexOf (String1);
    ListBox2.ItemIndex := ListBox2.Items.IndexOf (String2);
  end
  else
    MessageDlg ('The edit control is empty or contains'
      + ' a string which is already present',
      mtError, [mbOK], 0);
end;
```

In the final part of this method's code, we need to reselect the current item of each list box since the position of the selected item might change. This happens if the new item is inserted before the one that is currently selected — that is, if it has a lower sort order.

Allowing Multiple Selections

A list box can allow the selection of either a single element or a number of elements. We make this choice in setting up a list box by specifying the value of its `Multiple` property. As the name implies, setting `Multiple` to `True` allows multiple selections. There are really two different kinds of multiple selections in Windows and in Delphi list boxes: *multiple selection* and *extended selection*. In the first case a user selects multiple items simply by clicking on them, while in the second case the user can use the Shift and Ctrl keys to select multiple consecutive or nonconsecutive items. This second choice is determined by the `ExtendedSelect` property.

While setting up a multiple-selection list box is very simple, the problems start to appear when you have to write the code. Accessing the selected item of a single-selection list box is simple. The `ItemIndex` property holds the index of the selected item, and the selected string can be retrieved with a simple expression:

```
ListBox2.Items[ListBox2.ItemIndex];
```

In a multiple-selection list box, on the other hand, we do not know how many items are selected, or even whether there is any item selected. In fact, a user can click on an item to select it, drag the cursor to select a number of consecutive items in the list, or click the mouse button on an item while holding down Ctrl key to toggle the selection of a single item without affecting the others. Using this last option, a user can even deselect all the items in a list box.

A program can retrieve information on the currently selected items by examining the `Selected` array. This array of `Boolean` values has the same number of entries as the list box. Each entry indicates whether the corresponding item is selected.

For example, to know how many items are selected in a list box, we need to scan the `Selected` array, usually with a `for` loop ranging from `0` to the number of items in the list minus one:

```
SelectCount := 0;
for ListItem := 0 to ListBox1.Items.Count - 1 do
  if ListBox1.Selected[ListItem] then
    Inc (SelectCount);
```

Actually, the ListBox component has an undocumented `SelCount` property, you can use to obtain exactly the information computed in the code above. We won't use this code in the next example, anyway, but a more complex version.

The Third Version of the Phrases Example

With this information, we can build a new version of the Phrases example, allowing a user to select several items in the first list box. The only real difference between the form of this new version and that of the last one is the value of the `MultiSelect` property in the first list box is not set to `True`.

In addition, the label at the top of the form has been enlarged, enabling the `WordWrap` property and disabling the `AutoSize` property, to accommodate longer phrases. Since the example's code is complex enough, I've removed the portion used to delete from a list box the item selected in the other list box. In the case of multiple selections, this would have been really complicated.

The main problem we face is building the different phrases correctly. The basic idea is to scan the `Selected` array each time and add each of the selected objects to the phrase. However, we need to place an *"and"* before the name of the last object, omitting the comma if there are only two. Moreover, we need to decide between singular and plural (*is* or *are*) and provide some default text if no element is selected. As you can see from the table below, building these phrases is not simple. In fact, if we store the phrase *"The book and the computer,"* when we need to add a third item, we must go back and change it.

Items Selected	SelectCount	Phrase
{none}	0	Nothing is
book	1	The book is
book, computer	2	The book and the computer are
book, computer, pen	3	The book, the computer, and the pen are
book, computer, pen, small box	4	The book, the computer, the pen, and the small box are

An alternative idea is to create two different phrases, one valid if no other elements will be added, the other prepared to host future objects (without the *and*). In the code, the `TmpStr1` string is the tentative final statement, while `TmpStr2` is the temporary string used to add a further element. At the end of the loop, `TmpStr1` holds the correct value. As you can see in the code below, in case only two items are selected we have to build the phrase in a slightly different way, removing the comma before the *and* conjunction.

Notice when scanning a sorted list box that the objects are always added to the resulting string in alphabetical order, not in the order in which they were selected. You can study how this idea has been implemented by looking at the new version of the `ChangeText` method, in the following code (and by studying the following table, which describes step-by-step how the strings are built):

```
procedure TForm1.ChangeText(Sender: TObject);
var
  Phrase, TmpStr1, TmpStr2: String;
  SelectCount, ListItem: Integer;
begin
  SelectCount := 0;

  {look at each item of the multiple selection list box}
  for ListItem := 0 to ListBox1.Items.Count - 1 do
    if ListBox1.Selected [ListItem] then
    begin
      {if the item is selected increase the count}
      Inc (SelectCount);
      if SelectCount = 1 then
      begin
        {store the string of the first selection}
        TmpStr1 := ListBox1.Items.Strings [ListItem];
        TmpStr2 := TmpStr1;
      end
      else if SelectCount = 2 then
      begin
        {add the string of the second selection}
        TmpStr1 := TmpStr1 + ' and the ' +
          ListBox1.Items.Strings [ListItem];
        TmpStr2 := TmpStr2 + ', the ' +
          ListBox1.Items.Strings [ListItem];
      end
      else // SelectCount > 2
      begin
```

```
        {add the string of the further selection}
        TmpStr1 := TmpStr2 + ', and the ' +
          ListBox1.Items.Strings [ListItem];
        TmpStr2 := TmpStr2 + ', the ' +
          ListBox1.Items.Strings [ListItem];
      end;
    end;

  {build the first part of the phrase}
  if SelectCount > 0 then
    Phrase := 'The ' + TmpStr1
  else
    Phrase := 'Nothing';

  if SelectCount <= 1 then
    Phrase := Phrase + ' is '
  else
    Phrase := Phrase + ' are ';

  {add the text of the radio button}
  Phrase := Phrase +
    RadioGroup1.Items [RadioGroup1.ItemIndex];

  {add the text of the second list box}
  Phrase := Phrase + ' the ' +
    ListBox2.Items [ListBox2.ItemIndex];
  Label1.Caption := Phrase;
end;
```

Items Selected	Steps	TmpStr1 (Tentative Final Statement)	TmpStr2 (Temporary Statement)
book	1	book	book
+ computer	2	book and the computer	book, the computer
+ pen	3	book, the computer, and the pen	book, the computer, the pen
+ small box	4	book, the computer, the pen, and the small box	book, the computer, the pen, the small box

The other procedures of the program change only slightly. The `FormCreate` method is simplified because we do not need to delete the selected item from the other list box. The `Add` method is simplified because both list boxes always have the same items and because the multiple-selection list box creates no problems with the selection if you add a new element.

An alternative solution to handle the status of multiple-selection list boxes is to look at the value of the `ItemIndex` property, which holds the number of the item of the list having the focus. If a user clicks on several items while holding down Ctrl, each time a click event takes place, you know which of the items have been selected or deselected — you can easily determine which of the two operations took place by looking at the value of the `Selected` array for that index. The problem is that if the user selects a number of elements by dragging the mouse, this method won't work. You need to intercept the dragging events, and this is considerably more complex than the technique described earlier.

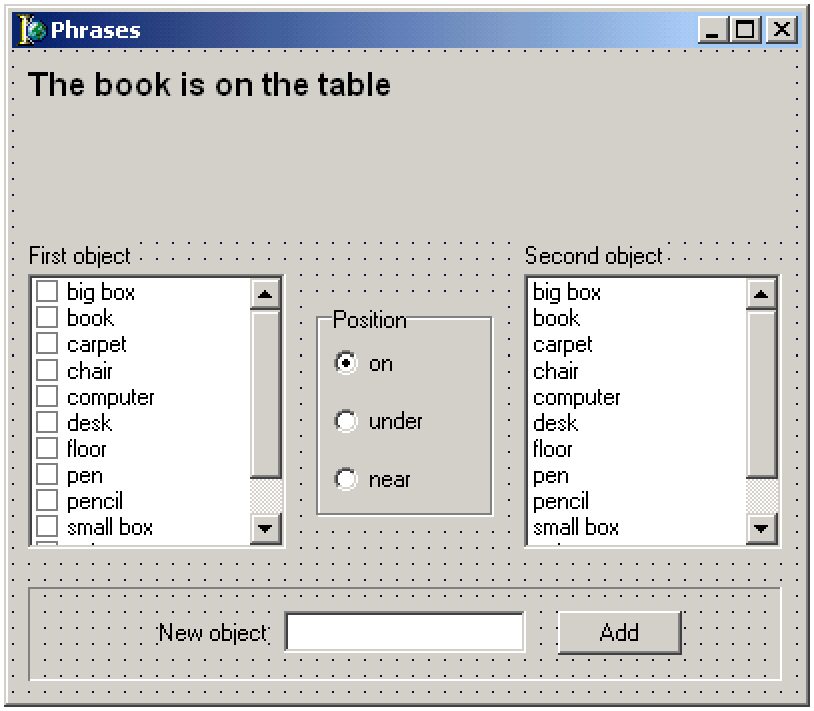
Using a CheckListBox Component

A further extension to the Phrases example is the use of the CheckListBox component, a component originally introduced by Borland in Delphi 3. This is basically a list box with a custom output (or an *owner-draw* list box, to use the proper technical term). Each item of the list is preceded by a check box. A user can select a single item of the list, but can also click on the check boxes to toggle their status.

If the component has the `AllowGrayed` property set to `True`, then each check box can be non-selected, grayed, or selected. Clicking on the check box alternates these three possible conditions. To check the current status of each item you can use the `Checked` and the `State` property. Both are array properties. The first, `Checked`, is a Boolean property you should use when `AllowGrayed` is set to `False`. The second, `State`, is a property of the `TCheckBoxState` data type:

```
type
  TCheckBoxState = (cbUnchecked, cbChecked, cbGrayed)
```

This property should be used when `AllowGrayed` is set to `True`, to distinguish among the three different states of each item. Apart from these properties, the specific user interface, and the new `OnClickCheck` event, this component behaves as a ListBox.



As I mentioned at the beginning of this section, to show you an example of the use of this component I've further updated the Phrases3 example, building the Phrases4 version. I've basically replaced the first multiple selection list box with the new CheckListBox component, set its `Sorted` property to `True`, and copied the `Items`. Then I've updated the code, replacing the `ListBox1` object with the `CheckListBox1` object, and replacing the `Selected` property of the first with the `Checked` property of the second in the `ChangeText` method. Here is an excerpt of the new version of this method:

```
  for ListItem := 0 to CheckListBox1.Items.Count - 1 do
```

```
if CheckListBox1.Checked [ListItem] then
begin
  {if the item is selected increase the count}
  Inc (SelectCount);
  if SelectCount = 1 then
  begin
    {store the string of the first selection}
    TmpStr1 := CheckListBox1.Items.Strings [ListItem];
    TmpStr2 := TmpStr1;
  end
  else if SelectCount = 2 then
    ...
```

The important point of this program is that this component makes it more obvious to the user that the list box allows multiple selections. The plain list box, in fact, gives no clue of this fact.

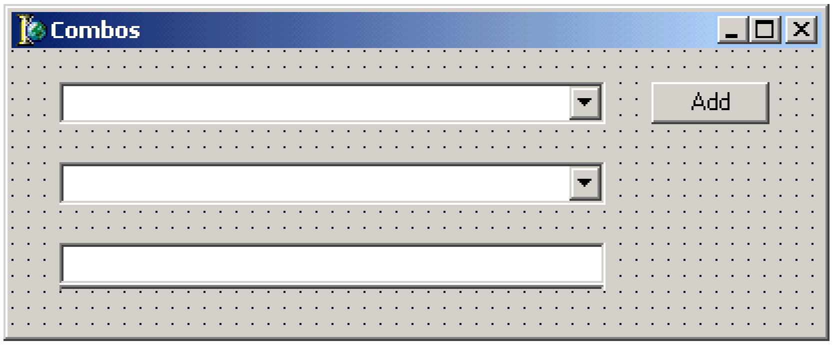
Many Lists, Little Space

List boxes take up a lot of screen space, and they offer a fixed selection. That is, a user can choose only among the items in the list box and cannot make any choice that the programmer did not specifically foresee.

You can solve both problems by using a ComboBox control. A combo box is similar to an edit box, and you can often enter some text in it. It is also similar to a list box, with a drop-down arrow that displays a list box. Even the name of the control suggests that it is a combination of two other controls, an Edit and a ListBox. However, the behavior of a ComboBox component might change a lot, depending on the value of its `Style` property. Here is a short description of the various styles:

- The `csDropDown` style defines a typical combo box, which allows direct editing and displays a list box on request.
- The `csDropDownList` style defines a combo box that does not allow editing. By pressing a key, the user selects the first word starting with that letter in the list.
- The `csSimple` style defines a combo box that always displays the list box below it. This version of the control allows direct editing.
- The `csOwnerDrawFixed` and `csOwnerDrawVariable` styles define combo boxes based on an owner-draw list — that is, a list containing graphics determined by the program rather than simple strings.

To see the difference between the first three types, you can run the Combos example, which I'll describe in a moment. As you can appreciate by testing the program, Combos displays three combo boxes having three different styles: drop-down, drop-down list, and simple.



This program is very simple. Each combo box has the same basic strings—the names of more than 20 different animals. The first combo box contains an *Add* button. If the user presses the button, any text entered in the combo box is added to its list, provided it is not already present. This is the code associated with the `OnClick` event of the button:

```
procedure TForm1.ButtonAddClick(Sender: TObject);
begin
with ComboBox1 do
  if (Text <> '') and (Items.IndexOf (Text) < 0) then
    Items.Add (Text);
end;
```

You can use the second combo box to experiment with the automatic lookup technique. If you press a key, the first of the names in the list starting with that letter will be selected. By pressing the up arrow key and the down arrow key, you can further navigate in the list without opening it. This navigation technique of using initial letters and arrows can be used with each of the combo boxes.

The third combo box is a variation of the first. Instead of adding the new element when the Add button is pressed, that action is performed when the user presses the Enter key. To test for this event, we can write a method for the combo box's `OnKeyPress` event and check whether the key is the Enter key , which has the numeric code 13. The remaining statements are similar to those of the button's `OnClick` event:

```
procedure TForm1.ComboBox3KeyPress(
  Sender: TObject; var Key: Char);
begin
  {if the user presses the Enter key}
  if Key = Chr (13) then
    with ComboBox3 do
      if (Text <> '') and (Items.IndexOf (Text) < 0) then
        Items.Add (Text);
end;
```

Delphi's `DateTimePicker` component has a user interface similar to that of a ComboBox.

Choosing a Value in a Range

The last basic component I want to explore in this chapter is the scroll bar. Scroll bars are usually associated with other components, such as list boxes and memo fields, or are associated directly with forms. Notice, however, that when a scroll bar is associated with another component, it is really a portion of that component — one of its properties — and there is little relationship to the ScrollBar component itself. Forms having a scroll bar have no ScrollBar component. A portion of their border is used to display that graphical element.

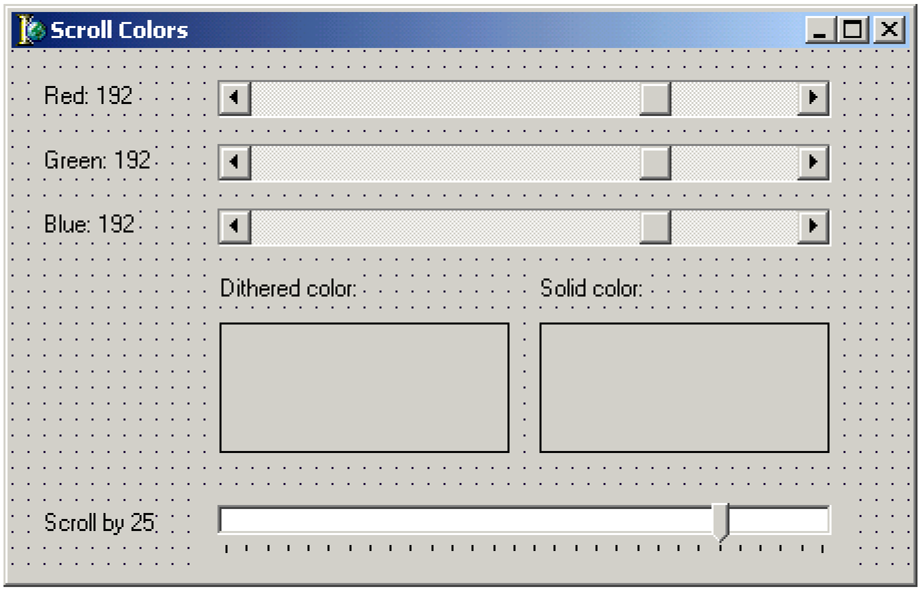
Direct usage of the ScrollBar component is quite rare, especially with the TrackBar Windows common control. However, there are cases in which it can play a role. The typical example is to allow a user to choose a numerical value in a large range (since a TrackBar is generally used for smaller ranges).

Most Windows programming books describe scroll bars using the example of selecting a color, and this book is no exception. But if you've seen a typical Windows example, you'll notice something very interesting: using Delphi, you can build this example in about one-fourth the time and writing a minimal amount of code.

The Scroll Color Example

The ScrollC example — the name stands for scroll color — has a simple form with three scroll bars and three corresponding labels, a track bar with its own label, and some shape components to show the current color. Each scroll bar refers to one of the three fundamental colors, which in Windows are red, green, and blue (RGB). Each label displays the name of the corresponding color and the current value.

Scroll bars have a number of peculiar properties. You can use `Min` and `Max` to determine the range of possible values; `Position` holds the current position; and the `LargeChange` and `SmallChange` properties indicate the increment caused by clicking on the bar or on the arrow at the end of the bar, respectively.



In the ScrollC example, the value of each bar ranges from 0 to 255. The range is determined by the fact that each color is a DWORD with the lower three bytes representing the Red, Green, and Blue values (which is how colors are represented in Windows and in the VCL). The initial value of 192 has been chosen for the position because with settings of 192 for red, 192 for green, and 192 for blue, you get the typical light gray, which is the default value for the color of the form and of the shapes. Here is the textual description of one of these three ScrollBar components:

```
object ScrollBarRed: TScrollBar
  LargeChange = 25
  Max = 255
  Position = 192
  OnScroll = ScrollBarRedScroll
end
```

The TrackBar components has similar properties (Min, Max, Position):

```
object TrackBar1: TTrackBar
  Max = 30
  Min = 1
  Orientation = trHorizontal
  Frequency = 1
  Position = 25
  TickMarks = tmBottomRight
  TickStyle = tsAuto
  OnChange = TrackBar1Change
end
```

This control is used, in this example, to set the LargeChange property of the three scrollbars, with the following code:

```
procedure TFormScroll.TrackBar1Change(Sender: TObject);
begin
  LabelScroll.Caption := 'Scroll by ' +
    IntToStr(TrackBar1.Position);
  ScrollBarGreen.LargeChange := TrackBar1.Position;
  ScrollBarRed.LargeChange := TrackBar1.Position;
  ScrollBarBlue.LargeChange := TrackBar1.Position;
end;
```

When one of the scroll bars changes (the OnScroll event), the program has to update the corresponding label and the color of the shapes. The first of these shapes is used to show the color as it is determined by the three RGB values of the scroll bars. Assigning the color to the Color property of the brush used to fill the surface of the shape, we obtain a dithered color, an approximation of the real tint made with the colors available on the video adapter. The same color is assigned to the Color property of the pen of the second shape, resulting in the closest approximation of the requested color. Pens, in fact, do not use dithering, but rather the closest *pure* color. You can see the difference by running this example, although the effect might change depending on your video adapter.

If you browse through the code of the program, notice also that there is a third shape component used to mimic the border of the second shape. The real border of this shape, in fact, is enlarged to fill its whole surface, using a very wide pen. This way we use the color of the pen — the wide border — to actually fill the shape. Here is the code corresponding to one of the scroll bars:

```
procedure TFormScroll.ScrollBarRedScroll(Sender: TObject;
  ScrollCode: TScrollCode; var ScrollPos: Integer);
begin
  LabelRed.Caption := 'Red: ' + IntToStr(ScrollPos);
  Shape1.Brush.Color := RGB (ScrollBarRed.Position,
    ScrollBarGreen.Position, ScrollBarBlue.Position);
  Shape2.Pen.Color := RGB (ScrollBarRed.Position,
    ScrollBarGreen.Position, ScrollBarBlue.Position);
end;
```

You need to copy this code once for each scroll bar and correct the name of the label and its output text. The second and third statements always remain the same. They are based on a Windows function, RGB, which takes three values in the range 0–255 and creates a 32-bit value with the code of the corresponding color.

It is interesting to note that the OnScroll event has three parameters: the sender, the kind of event (ScrollCode), and the final position of the thumb (ScrollPos). This type of event can be used for very precise control of the user's actions. The ScrollCode parameter indicates if the user is dragging the thumb (scTrack, scPosition, or scEndScroll), has clicked on one of the two final arrows (scLineUp or scLineDown), has clicked on the bar in one of the two directions (scPageUp or scPageDown), or is trying to scroll out of the range (scTop or scBottom).

What's Next

In this chapter, we have started to explore some of the basic components available in Delphi. These components correspond to the standard Windows controls and some of the Windows common controls, and are extremely common in applications (with the exception of the stand-alone scroll bars). Of course, when you start adding more advanced Delphi components to an application, you can easily build more complex and colorful user interfaces and more powerful programs.

The next chapter is devoted to a specific and important topics: the use of menus. After that, we'll see more about forms, have a light excursus on multimedia, and wrap up the book with some simple specific techniques.

Chapter 5: Creating and Handling Menus

- The structure of a menu
- Using menu templates
- Checking, disabling, and modifying menus at run-time
- Creating menu items at run-time
- A custom menu check mark
- Bitmap menu items and owner-draw menu items
- The system menu
- Pop-up menus

The sample programs we have built so far have lacked one of the most important user-interface elements of any Windows application: the menu bar. Although our forms have each had a system menu, its use has been very limited. In practical applications, however, the menu bar is a central element in the development of a program. While the user can click and sometimes drag the mouse to select options, most complex tasks usually involve menu commands. Consider the applications you use and the number of menu commands you issue in those programs (including those invoked by a shortcut key, such as Ctrl+C, which is equivalent to the Edit | Copy command in most applications).

Menus are so important that almost any real Windows application has at least one. In fact, an application can also have several menus that change at run-time (more on this later), various local menus (usually activated with a right mouse click), and even a customized system menu.

The Borland programmers who created Delphi considered menus so important that they have placed the corresponding components in the Standard page of the Components palette.

The Structure of the Main Menu

Before looking at the use of menus in Delphi, let me recap some general information about menus and their structure. Usually, a menu has two levels. A menu bar, appearing below the title of the window, contains the names of the pull-down menus, each of which in turn contains a number of items. However, the menu structure is very flexible. It is possible to place a menu item directly in the menu bar and to place a *second level* pull-down menu inside another pull-down menu.

You should avoid placing commands directly on the menu bar, because users tend to select the elements of the menu bar to explore the structure of the menu. They do not expect to issue a command this way. If, for some reason, you really need to place a command in the menu bar, at least place the standard exclamation mark after it. Using an exclamation mark is a standard hint, but most users have never seen this “convention,” so it’s best to avoid the whole situation altogether and simply have a pull-down menu with a single menu item. A typical example is a Help menu with a single About menu item.

Putting a pull-down menu inside another pull-down menu — a second-level pull-down — is far more common, and Windows in this case provides a default visual clue, a small triangular glyph at the right of the menu. Many applications use this technique, because the system makes heavy use of multilevel menus (consider the Programs menu of the Start button). However, keep in mind that selecting a menu item in a second-level pull-down takes more time and can become tedious.

Many times, instead of having a second-level pull-down, you can simply group a number of options in the original pull-down and place two separator bars, one before and one after the group. You can see an exaggerated multilevel menu in the Levels example in the source code. Since this is a demonstration of what you should try to *avoid*, I won't list the structure of the menu here.

Different Roles of Menu Items

Now let's turn our attention to menu items, regardless of their position in the menu structure. There are three fundamental kinds of menu items:

- *Commands* are menu items used to execute an action. They have no special visual clue.
- *State-setters* are menu items used to toggle an option on and off, to change the state of a particular element. These commands usually have a check mark on the left to indicate they are active. In this case, selecting the command produces the opposite action.
- *Dialog menu items* are menu items that cause a dialog box to appear. The real difference between these and the other menu items is that a user should be able to explore the possible effects of the corresponding dialog box and eventually abort it by choosing the Cancel button. These commands should have a visual clue, consisting of an ellipsis (three dots) after the text.

> Besides the traditional state-setters with a check mark, you can also have radio menu items with a bullet check mark. These menu items represent alternative selections, just as RadioButton components do, and simply checking one of them disables the other elements of the group. We'll explore radio menu items in an example later on.

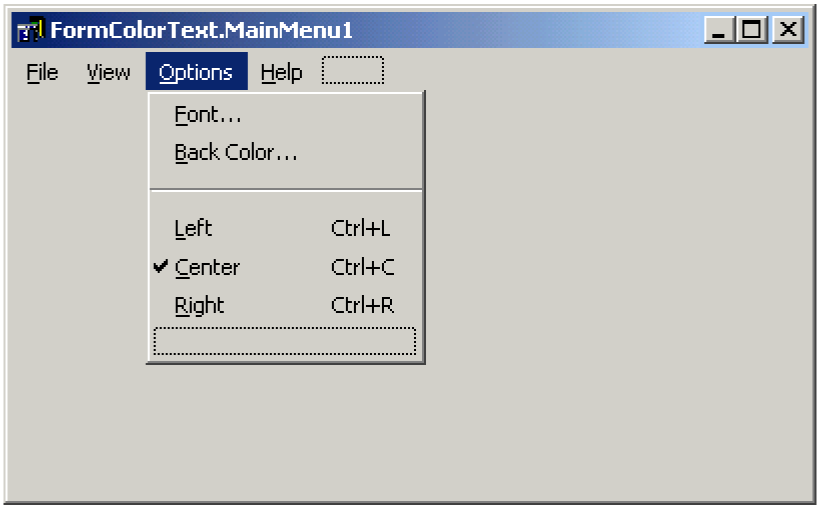
Building a Menu with the Menu Designer

Delphi includes a special editor for menus, the Menu Designer. To invoke this tool, place a MainMenu component on a form and double-click on it. Don't worry too much about the position of the menu component on the form, since it doesn't affect the result; the menu is always placed properly, below the form's caption.

> To be more precise, the form displays, below its caption, the menu indicated in its `Menu` property, which is set by default as soon as you create the first main menu component of the form. If the form has more than one main menu component, this property should be set manually and can be changed both at design-time and at run-time.

The Menu Designer is really powerful: It allows you to create a menu simply by writing the text of the commands, to move the items or pull-down menus by dragging them around, and to set the properties of the items easily. It is also very flexible, allowing you to place a command directly in the menu bar (this happens each time you do not write any element in the corresponding pull-down menu) or to create second-level pull-down menus.

To accomplish this, select the Create Submenu command on the Menu Designer's local menu (the local menu invoked with the right mouse button).



Another very important feature available through the Menu Designer is the ability to create a menu from a template. You can easily define new templates of your own. Simply create a menu, and use the Save As Template command on the local menu to add it to the list. This makes sense particularly if you need to have a similar menu in two applications or in two different forms of the same application.

The Standard Structure of a Menu

If you've used Windows applications for some time, you have certainly noticed that the structure of an application's menu is not an invention of its programmers. There are a number of standard Windows guidelines describing how to arrange the commands in a menu. You can infer most of these rules by looking at the menus of some of the best-selling applications.

An application's menu bar should start with a File pull-down, followed by Edit, View, and then some commands specific to the application. The final part of the sequence includes Options, Tools, and Window (in MDI, or Multiple Document Interface, applications) and always terminates with Help. Each of these pull-down menus has a standard layout, although the actual items depend on the application. The File menu, for example, usually has commands such as New, Open, Save, Save As, Print, Print Setup, and Exit.

Shortcut Keys and Hotkeys

A common feature of menu items is that they contain an underlined letter, generally called a *hotkey*. This letter, which is often the first letter of the text, can be used to select the menu using the keyboard. Pressing Alt plus the underlined key selects the corresponding pull-down menu. By pressing another underlined key on that menu, you issue a command.

Of course, each element of the menu bar must have a different underlined character. The same is true for the menu items on a specific pull-down menu. (Obviously, menu items on different pull-down menus can have the same underlined letter.) To indicate the underlined key, you simply place an ampersand (&) before it, as in Save &As... or &File. In these examples, the underlined keys would be A for Save As and F for File.

Menu items have another standard feature: shortcut keys. When you see the shorthand description of a key, or key combination, beside a menu item, it means you can press those keys to give that command. Although giving menu commands with the mouse is easier, it tends to be somewhat slow, particularly for keyboard-intensive applications, since you have to move one of your hands from the keyboard to the mouse. Pressing Alt and the underlined letter might be faster, but it still requires two operations. Using a shortcut key usually involves pressing a special key and another key at the same time (such as Ctrl+C). Windows doesn't even display the corresponding pull-down menu, so this results in a faster internal operation, too.

In Delphi, associating a shortcut key with a menu item (pull-down menus cannot have a shortcut key) is very easy. You simply select a value for the ShortCut property, choosing one of the standard combinations: Ctrl or Shift plus almost any key.

You might even add shortcut keys to a program without adding a real menu. For example, you can create a pop-up menu, connect it to a form (by setting the PopupMenu property of the form), set the Visible property of all of its items to False, and add the proper shortcut keys; a user will never see the menu, but the shortcuts (documented in your Help system, of course) will work. If this is not clear, you can look at the HShort example (the name stands for "Hidden Shortcut") in the book code.

Using the Predefined Menu Templates

To let you start developing an application's menu following the standard guidelines, Delphi contains some predefined menu templates. The templates include two different File pull-down menus, an Edit menu (including OLE commands), a Window menu, and two Help menus. There is also a complete MDI menu bar template, which has the same four menu categories.

Using these standard templates brings you some advantages. First of all, it is faster to reuse an existing menu than to build one from scratch. Second, the menu template follows the standard Windows guidelines for naming menu commands, for using the proper shortcuts, and so on. Of course, using these menus makes sense in a file-based application. But if the program you are writing doesn't handle files, has no editing capabilities, and is not MDI, you'll end up using only the template Help pull-down menu.

Responding to Menu Commands

To build the MenuOne example, the first example with a menu, we will extend the LabelCo example of the last chapter. The new version of the form has been extended with a MainMenu component. This menu bar has four pull-down menus: the File pull-down with only the Exit option, the View pull-down with only the Toolbar menu item, the Options menu with various options, and the Help menu with the About menu item.

To add the separator in the Options pull-down menu, simply insert a hyphen as the text of the command. Do not change the Break property. (Except for rare situations, the Break property will make a mess of your menu. You are better off forgetting that this property even exists.)

> Of course, the `Break` property has its uses, or it would not have been added to the component. You can better understand it if I use different names for its possible values, NewLine or NewColumn. If an item on the menu bar has the `mbMenuBarBreak` (or NewLine) value, this item will be displayed in a second or subsequent line. If a menu item has the `mbMenuBreak` (or NewColumn) value, this item will be added to a second or subsequent column of the pull-down. Neither of these features are used very often.

The Code Generated by the Menu Designer

Once you have built this menu, take a look at the list of components displayed by the Object Inspector, or open the `DFM` file with the textual description of the form, which will also contain a textual description of the menu structure. Here is the portion of the textual description of the form related to the menu and its items:

```
object MainMenu1: TMainMenu
  object File1: TMenuItem
    Caption = '&File'
    object Exit1: TMenuItem
      Caption = 'E&xit'
      OnClick = Exit1Click
    end
  end
  object View1: TMenuItem
    Caption = '&View'
    object Toolbar1: TMenuItem
      Caption = '&Toolbar'
      Checked = True
      OnClick = Toolbar1Click
    end
  end
  object Options1: TMenuItem
    Caption = '&Options'
    object Font1: TMenuItem
      Caption = '&Font...'
      OnClick = Font1Click
    end
    object BackColor1: TMenuItem
      Caption = '&Back Color...'
      OnClick = BackColor1Click
    end
    object N1: TMenuItem
      Caption = '-'
    end
    object Left1: TMenuItem
      Caption = '&Left'
      ShortCut = 16460 // stands for Ctrl+L
      OnClick = Left1Click
    end
    object Center1: TMenuItem
      Caption = '&Center'
      Checked = True
      ShortCut = 16451 // stands for Ctrl+C
```

```
        OnClick = Center1Click
      end
      object Right1: TMenuItem
        Caption = '&Right'
        ShortCut = 16466 // stands for Ctrl+R
        OnClick = Right1Click
      end
    end
    object Help1: TMenuItem
      Caption = '&Help'
      object About1: TMenuItem
        Caption = '&About Menu One...'
        OnClick = About1Click
      end
    end
  end
```

As you can see in the listing above, there is a specific component for each menu item, one for each pull-down menu, and, surprisingly, even one for each separator. Delphi builds the names of these components automatically when you insert the menu item's label. The rules are simple:

- Any blank or special character (including ampersands and hyphens) is removed.
- If there are no characters left, the letter `N` is added.
- A number is always added at the end of the name (1 if this is the first menu item with this name, a higher number if not).

All of these new components are listed in the Object Inspector, and you can select them directly or navigate among them by opening the Menu Designer and selecting menu items visually. Actually each of these items is also listed as a component in the class definition of the form:

```
type
  TFormColorText = class(TForm)
    MainMenu1: TMainMenu;
    Options1: TMenuItem;
    Font1: TMenuItem;
    BackColor1: TMenuItem;
    N1: TMenuItem;
    Left1: TMenuItem;
    Center1: TMenuItem;
    Right1: TMenuItem;
    Help1: TMenuItem;
    About1: TMenuItem;
    File1: TMenuItem;
    Exit1: TMenuItem;
    View1: TMenuItem;
    Toolbar1: TMenuItem;
    ...
```

> If there are menu items your code will not refer to (such as the separators), you can actually delete the fields declaring these objects (as `N1` above). They will be created anyway, since they are listed in the form definition file, but you won't be able to access them easily from within the source code of the form. Since the objects are created anyway, you won't save much memory, though (only the space for the reference inside the form class), but removing useless statements may improve code readability.

To respond to menu commands, you should define a method for the `OnClick` event of each menu item. The `OnClick` event of the pull-down menus is used only in special cases — for example, to check whether the menu items below should be disabled. The `OnClick` event of the separators is totally useless, because it will never be activated.

> Once you have defined the main menu of a form and it is displayed below the caption, you can add a new method for the `OnClick` event of a menu command simply by selecting it in the menu bar. If a handler is already present, Delphi will show you the corresponding portion of the source code; otherwise, a new method will be added to the form.

The Code of the MenuOne Example

The code of the MenuOne example is very simple, and is similar to that of the LabelCo example it extends. The `OnClick` event of the menu command for the background color and of the corresponding toolbar button are connected to the same method:

```
object BtnBackColor: TButton
  Caption = '&Back Color...'
  OnClick = BackColor1Click
end
```

This method has the same code as the earlier version. The menu command and button related to the font are both connected to the `Font1Click` method, which this time displays the font selection dialog box, not the color selection dialog box. Notice that the code is quite compact, because it uses a `with` statement:

```
procedure TFormColorText.Font1Click(Sender: TObject);
begin
  with FontDialog1 do
  begin
    Font := Label1.Font;
    if Execute then
      Label1.Font := Font;
  end;
end;
```

The other three menu items of the Options pull-down menu (and the last three buttons of the toolbar) have basically the same code as the LabelCo example: the code of their `OnClick` event handlers simply set the `Alignment` property of the label. This works fine, but the resulting application doesn't follow the standard user-interface guidelines. Each time you have a series of choices in a menu, the selected choice should have a check mark beside it.

To accomplish this, you need to create two different operations. First, you have to place a check mark near the default choice, Center, changing the value of the menu item's `Check` property in the Object Inspector. Second, you should correct the code so that each time the selection changes, the check mark is properly set:

```
procedure TFormColorText.Left1Click(Sender: TObject);
begin
  Label1.Alignment := taLeftJustify;
  Left1.Checked := True;
  Center1.Checked := False;
  Right1.Checked := False;
end;
```

The other two methods are similar. You can simply copy the source code of the last three statements, paste this text twice into the other two methods, and correct the values of the three `Checked` properties so that each time one of them is set to `True`. Removing the check marks from the other items of the group can be handled in more efficient ways, but the real solution is to use radio menu items, instead of check marks. We'll look at this technique later on.

The View | Toolbar menu item is a typical item with a check mark, set when the toolbar is visible. Here is its code:

```
procedure TFormColorText.Toolbar1Click(Sender: TObject);
begin
  Panel1.Visible := not Panel1.Visible;
  Toolbar1.Checked := Panel1.Visible;
end;
```

The program toggles the status of the `Visible` property of the panel, then sets the check mark — the `Checked` property — of the menu item accordingly. You should only remember to set the initial value of this property, to match the initial status of the panel. The Help | About and File | Exit commands simply show a message box or call the `Close` method of the form, respectively. They are so simple I won't show their source code here. (You can find it in the `MenuOneF.PAS` file among th source code.)

Modifying the Menu at Run-Time

You can perform a number of operations in Windows to change the structure of a menu at run-time. We'll start by examining in detail the operations you can do on a single menu item, then move to pull-down menus, build a flexible main menu, and change the default bitmap for the check mark.

Changing Menu Items at Run-Time

It is important to note that menu items can change at run-time. For example, when a menu command cannot or should not be selected, it is usually grayed. In this case, the user has no way to issue that command. You shouldn't generally hide a menu item when it is not available, but simply disable it. This standard technique lets users know that the command is currently not available. Otherwise, they might think the menu command was somewhere else in the menu structure, and keep looking for it.

Another visual change is the use of the check mark, which applications can toggle on and off easily, as we've seen in the last example. At times, to implement a state-setter menu item, you can change the text of the menu item altogether, which might result in an easier interface. For example, suppose an application has a Show Toolbar command. If you select it, a toolbar will appear and a check mark will be added to the item. This means that if you again select the Show Toolbar command, the toolbar will disappear: The command you issue has the opposite effect as its name. To avoid this problem, you might use two different captions for the two states of the menu item, such as *Show Toolbar* and *Hide Toolbar*.

When the user can select more than two choices, it is better to use multiple menu items with a check mark, or even better the new radio menu item user interface, which is becoming the standard approach.

Three properties are commonly used to modify a menu item:

- We used the `Checked` property in the example above to add or remove a check mark beside the menu item.
- The `Enabled` property can be used to gray a menu item so that it cannot be selected by a user (but it remains visible).
- The last property of this group is the `Caption`, the text of the menu item, which can be modified to reflect the actual effect of a command, as discussed above.

I'll demonstrate the use of these properties by extending the MenuOne example (the name of the new project is MenuOne2) with new menu items. I've added two new menu items to the View pull-down menu (Hide Label and Fixed Font) and two new menu items in the Options pull-down menu (Fixed View and Disable Help), plus a couple of new separators.

The Hide Label menu item demonstrates the use of different captions for an item depending on the status of the program. Here is its `OnClick` event handler:

```
procedure TFormColorText.HideLabel1Click(Sender: TObject);
begin
  Label1.Visible := not Label1.Visible;
  if Label1.Visible then
    HideLabel1.Caption := 'Hide &Label'
  else
    HideLabel1.Caption := 'Show &Label'
end;
```

Disabling Menu Items and Hiding Pull-Down Menus

The other three new menu items of the MenuOne2 example are used to disable or hide other menu items or pull-down menus. The View | Fixed Font command is used to disable the Options | Font menu item:

```
procedure TFormColorText.FixedFont1Click(Sender: TObject);
begin
  ToggleCheck (FixedFont1);
  Font1.Enabled := not Font1.Enabled;
end;
```

This method calls the custom `ToggleCheck` procedure I've written as a shortcut to the code for toggling the check mark (something all these three final menu commands do). Here is its simple code:

```
procedure ToggleCheck (Item: TMenuItem);
begin
  Item.Checked := not Item.Checked;
end;
```

I've already advised you against hiding menu items (by turning off their `Visible` property), because users will probably try to find them in a different pull-down menu. Menu items should generally be disabled when you want to prevent users from calling them. Hiding entire pull-down menus, however, is a common practice. In many applications the pull-down menus you see reflect the window you are working on. Technically, it is possible to disable a pull-down menu as well, but this is not very common. The last two menu items I've added to the program do these two operations, as you can see in their corresponding `OnClick` event handlers:

```
procedure TFormColorText.FixedView1Click(Sender: TObject);
begin
  ToggleCheck (FixedView1);
  View1.Visible := not View1.Visible;
end;

procedure TFormColorText.DisableHelp1Click(Sender: TObject);
begin
  ToggleCheck (DisableHelp1);
  Help1.Enabled := not Help1.Enabled;
end;
```

The View pull-down menu has been removed, and the Help pull-down menu is grayed.

Using Radio Menu Items

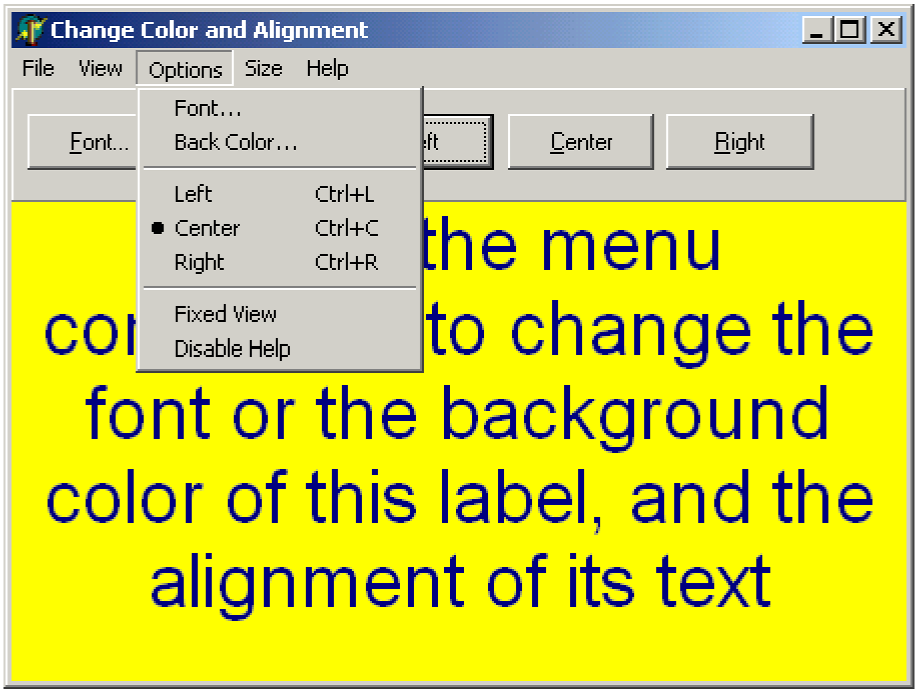
In addition to using check marks, in Windows you can use radio menu items. These provide not only a different user interface, but also different behavior (basically simpler code, since the system does some of the work for us). A notable example of this new user-interface feature is the View menu of the Windows Explorer.

In Delphi, simply set the `RadioItem` property of a MenuItem component to `True` and you get the new check mark for the item. If you set this property for several consecutive menu items and set their `GroupIndex` property to the same value, they'll use the new mark and behave as radio buttons. This means that only one of the menu items in the group will be selected at a time. Instead of having to deselect all other items manually, as you did in the first version of the MenuOne example, now you can simply select the proper menu item, and the rest is automatic.

Here is how you can implement this feature, in the third version of the MenuOne example (which also has another feature I'll discuss in the next section). The following listing shows the updated textual description of this group of menu items:

```
object Options1: TMenuItem
  Caption = '&Options'
  ...
  object Left1: TMenuItem
    Caption = '&Left'
    GroupIndex = 1
    RadioItem = True
    OnClick = Left1Click
  end
  object Center1: TMenuItem
    Caption = '&Center'
    Checked = True
    GroupIndex = 1
    RadioItem = True
    OnClick = Center1Click
  end
```

```
object Right1: TMenuItem
  Caption = '&Right'
  GroupIndex = 1
  RadioItem = True
  OnClick = Right1Click
end
```



This code will work as is, but we can actually simplify it. Here is the new version of the `Right1Click` method:

```
procedure TFormColorText.Right1Click(Sender: TObject);
begin
  Label1.Alignment := taRightJustify;
  // Left1.Checked := False; // now useless
  // Center1.Checked := False; // now useless
  Right1.Checked := True;
end;
```

I've simply commented out the two useless statements, instead of deleting them, to let you see the differences from the older version.

Creating Menu Items Dynamically

The run-time changes on menu items and pull-down menus we've seen so far were all based on the direct manipulation of some properties. These components, however, also have some interesting methods, such as `Insert` and `Remove`, that you can use to make further changes.

The basic idea is that each object of the `TMenuItem` class — which Delphi uses for both menu items and pull-down menus — contains a list of menu items. Each of these items has the same structure, in a kind of recursive way. A pull-down menu has a list of submenus, and each submenu has a list of submenus, each with its own list of submenus, and so on.

The properties you can use to explore the structure of an existing menu are `Items`, which contains the actual list of menu items, and `Count`, which contains the number of subitems. Adding new menu items (or entire pull-down menus) to a menu is fairly easy. Slightly more complex is the handling of the commands related to the new menu items. Basically, you need to write a specific message-response method in your code (without any help from the Delphi environment), and then assign it to the new menu item by setting its `OnClick` property. As an alternative, you can have a single method used for several `OnClick` events and use its `Sender` parameter to determine which menu command the user issued.

All these features are demonstrated by the MenuOne3 example. As soon as you start this program, it creates a new pull-down with menu items used to change the size of the font of the big label hosted by the form. Instead of creating a bunch of menu items with captions indicating sizes ranging from 8 to 48, you can let the program do this repetitive work for you. I could have created the pull-down at design-time, and then added the menu items dynamically, but I prefer showing you the complete code, so that you can apply it to other cases.

To create a new menu item (or pull-down) you simply call the `Create` constructor of the `TMenuItem` class:

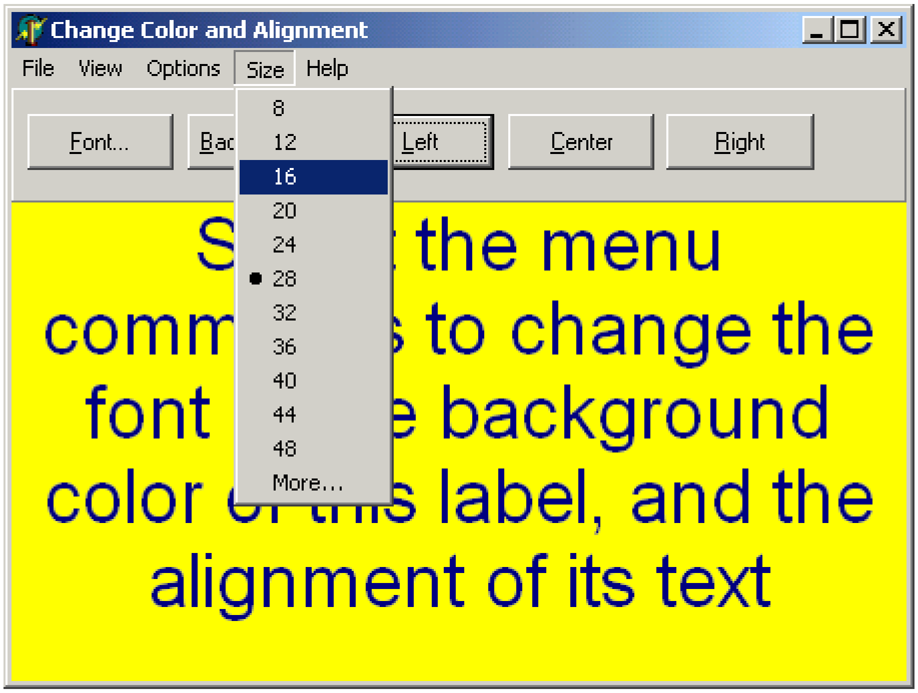
```
var
  PullDown: TMenuItem;
begin
  PullDown := TMenuItem.Create (self);
```

Then you can simply set its `Caption` and other properties, and finally insert it in the proper parent menu. The new pull-down should be inserted in `Items` of the `MainMenu1` component. You can calculate the position, knowing the index is zero-based, or you can ask the main menu component for the previous pull-down menu:

```
Position := MainMenu1.Items.IndexOf (Options1);
MainMenu1.Items.Insert (Position + 1, PullDown);
```

The menu items of this pull-down are created in a `while` loop (I don't use a `for` loop because I want to provide only one menu item for every four possible sizes: 8, 12, 16, and so on). The code to create each item is slightly more complex simply because I want to turn them into radio items, but the basic structure of the code is very simple:

```
var
  Item: TMenuItem;
  I: Integer;
begin
  ...
  I := 8;
  while I <= 48 do
  begin
    Item := TMenuItem.Create (self);
    Item.Caption := IntToStr (I);
    PullDown.Insert (PullDown.Count, Item);
    I := I + 4;
  end;
```



Change Color and Alignment

More...
S the menu comm to change the font background color label, and the alignment of its text

To insert an item at the end I call the Insert method passing the number of items (`PullDown.Count`) as a parameter. As you can see, the program adds one extra item at the end of the menu, used to set a different size than those listed. The `OnClick` event of this last menu item is handled by the `Font1Click` method, which shows the font selection dialog box:

```
Item := TMenuItem.Create (self);
Item.Caption := 'More...';
Item.OnClick := Font1Click;
PullDown.Insert (PullDown.Count, Item);
```

Also the `OnClick` events of the other menu items are connected with a method, but this time it is a method you have to define manually, by adding its declaration to the form class:

```
type
  TFormColorText = class(TForm)
    ...
  public
    procedure SizeItemClick(Sender: TObject);
end;
```

The method should have the proper signature (or parameters list). Here is the code of the method, which is based on the `Sender` parameter:

```
procedure TFormColorText.SizeItemClick(Sender: TObject);
begin
  with Sender as TMenuItem do
    Label1.Font.Size := StrToInt (Caption);
end;
```

As you can see, this code doesn't set the proper check mark (or radio item mark) next to the selected item. The reason is that the user can select a new size by changing the font. For this reason, we can use a different approach, and handle the `OnClick` event of the pull-down menu. This event is activated just before showing the pull-down menu, so we can use it to set the proper check mark at that time:

```
procedure TFormColorText.SizeClick (Sender: TObject);
```

```
var
  I: Integer;
  Found: Boolean;
begin
  Found := False;
  with Sender as TMenuItem do
  begin
    // look for a match, skipping the last item
    for I := 0 to Count - 2 do
      if StrToInt (Items [I].Caption) =
        Label1.Font.Size then
      begin
        Items [I].Checked := True;
        Found := True;
        System.Break; // skip the rest of the loop
      end;
    if not Found then
      Items [Count - 1].Checked := True;
  end;
end;
```

This code scans the items of the pull-down menu we have activated (the `Sender`), skipping only the final one, and checks whether the caption matches the current `Size` of the font of the label. If no match is found, the program checks the last menu item, to indicate that a different size is active.

Of course we have to set this `SizeClick` event handler at run-time, when the pull-down menu is created. So we can finally look at the complete source code of the `FormCreate` method, which sums up all the features I have discussed in this section:

```
procedure TFormColorText.FormCreate(Sender: TObject);
var
  PullDown, Item: TMenuItem;
  Position, I: Integer;
begin
  // create the new pulldown menu
  PullDown := TMenuItem.Create (self);
  PullDown.Caption := '&Size';
  PullDown.OnClick := SizeClick;
  // compute the position and add it
  Position := MainMenu1.Items.IndexOf (Options1);
  MainMenu1.Items.Insert (Position + 1, PullDown);

  // create menu items for various sizes
  I := 8;
  while I <= 48 do
  begin
    // create the new item
    Item := TMenuItem.Create (self);
    Item.Caption := IntToStr (I);
    // make it a radio item
    Item.GroupIndex := 1;
    Item.RadioItem := True;
    // handle click and insert
    Item.OnClick := SizeItemClick;
    PullDown.Insert (PullDown.Count, Item);
    I := I + 4;
  end;

  // add extra item at the end
  Item := TMenuItem.Create (self);
  Item.Caption := 'More...';
  // make it a radio item
  Item.GroupIndex := 1;
  Item.RadioItem := True;
  // handle click by showing the font dialog box
  Item.OnClick := Font1Click;
  PullDown.Insert (PullDown.Count, Item);
end;
```

Creating Menus and Menu Items Dynamically

When you want to create a menu or a menu item dynamically, you can use the corresponding components, as I've done in the MenuOne3 example. As an alternative, you can also use some global functions available in the Menus unit:

```
function NewMenu(Owner: TComponent; const AName: string;
  Items: array of TMenuItem): TMainMenu;
function NewPopupMenu(Owner: TComponent;
  const AName: string; Alignment: TPopupAlignment;
  AutoPopup: Boolean; Items: array of TMenuitem):
  TPopupMenu;
function NewSubMenu(const ACaption: string;
  hCtx: Word; const AName: string;
  Items: array of TMenuItem): TMenuItem;
function NewItem(const ACaption: string;
  AShortCut: TShortCut; AChecked, AEnabled: Boolean;
  AOnClick: TNotifyEvent; hCtx: Word;
  const AName: string): TMenuItem;
function NewLine: TMenuItem;
```

The `NewMenu` and `NewPopupMenu` functions, in particular, should be used to create brand-new menus. Calling the constructors of the corresponding classes, in fact, doesn't always work properly.

Short and Long Menus

If you don't like creating menu items dynamically, but still need to have a very flexible menu, there are a couple of good alternatives. You can create a large menu with all the items you need, then hide all the items and pull-down menus you do not want at the beginning. To add a new command you need only show it. This solution is a follow-up to what we have done up to now.

You can also create several menus, possibly with common elements, and exchange them as required. This approach is demonstrated in this section. A typical example of a form having two menus is one that uses two different sets of menus (long and short) for two different kinds of users (expert and inexperienced). This technique was common in major Windows applications for some years but has since been replaced by other approaches, such as letting each user redefine the whole structure of the menu.

The idea is simple and its implementation straightforward:

1. Prepare the full menu of the application, adding a menu item with the `Caption` *'Short'*.
2. Add this menu to the Delphi menu template.
3. Place a second MainMenu component on the form, and copy its structure from the template.
4. In the second menu, remove the items corresponding to advanced features and change the `Caption` of the special item from *'Short'* to *'Long'*.
5. In the Menu property of the form, set the MainMenu component you want to use when the application starts, choosing one of the two available. Note that this operation has an effect on the form at design-time, too.
6. Write the code for the Short and Long commands so that when they are selected, the menu changes.

If you follow these steps, you'll end up with an application similar to TwoMenus, which can change its menu at run-time. The example has two different MainMenu components, with useless "dummy" menu items, plus the Short and Long commands.

The application does nothing apart from changing the main menu when the Short Menu or Long Menu items are selected. Here is the code for the Short Menu item:

```
procedure TForm1.ShortMenus1Click(Sender: TObject);
begin
  {activate short menu}
  Form1.Menu := MainMenu2;
end;
```

Graphical Menu Items

Besides the run-time changes on a menu's structure I've listed so far, which are all directly available in Delphi, there are a number of operations you can perform on menus using the Windows API. In fact, there are several API functions referring to menus.

In particular, using Windows API functions for menus lets us add some graphics to them. We can customize the check mark, replace the strings with bitmaps, and even paint in the menu items.

Customizing the Menu Check Mark

As I've just mentioned, there are a number of ways to customize a menu in Windows. In this section, I'm going to show you how you can customize the check mark used by a menu item, using two bitmaps of your own. This example, NewCheck, involves using bitmaps and calling a Windows API function.

First I should explain why we need two bitmaps, not just one. If you look at a menu item, it can have either a check mark or nothing. In general, however, Windows uses two different bitmaps for the checked and unchecked menu item. I've prepared two bitmaps, of 16 x 14 pixels, using the Delphi Image Editor. You can easily run this program from the Tools menu, but you can prepare the bitmaps with any editor, including Windows Paintbrush. The bitmaps should be stored in two BMP files in the same directory as the project.

The NewCheck example has a very simple form, with just two components, a MainMenu and a label:

```
object Form1: TForm1
```

```
  Caption = 'New Check'
  Menu = MainMenu1
  OnCreate = FormCreate
  OnDestroy = FormDestroy
  object Label1: TLabel
    Alignment = taCenter
    AutoSize = False
    Caption = 'OFF'
    Font.Height = -96
    Font.Name = 'Arial'
    Font.Style = [fsBold]
  end
  object MainMenu1: TMainMenu
    object Command1: TMenuItem
      Caption = '&Command'
      OnClick = Command1Click
      object Toggle1: TMenuItem
        Caption = '&Toggle'
        OnClick = Toggle1Click
      end
    end
  end
end
```

As you can see in the listing above, the menu item has a single command (Toggle), which will be used to change the text of the label from *'ON'* to *'OFF'* and change the check mark, too:

```
procedure TForm1.Toggle1Click(Sender: TObject);
begin
  Toggle1.Checked := not Toggle1.Checked;
  if Toggle1.Checked then
    Label1.Caption := 'ON'
  else
    Label1.Caption := 'OFF';
end;
```

The most important portion of the code of this example is the call to the `SetMenuItemBitmaps` Windows API function:

```
function SetMenuItemBitmaps (Menu: HMenu;
  Position, Flags: Word;
  BitmapUnchecked, BitmapChecked: HBitmap): Bool;
```

This function has a number of parameters:

- The first parameter is the pull-down menu we refer to.
- The second parameter is the position of the menu item in that pull-down menu.
- The third parameter is a flag that determines how to interpret the previous parameter (Position).
- The last two parameters indicate the bitmaps that should be used.

Notice that this function changes the check mark bitmaps only for a specific menu item. Here is the code you can use in Delphi to call the function:

```
procedure TForm1.Command1Click(Sender: TObject);
begin
  SetMenuItemBitmaps (Command1.Handle,
    Toggle1.Command, MF_BYCOMMAND,
    Bmp2.Handle, Bmp1.Handle);
end;
```

This call uses two bitmap variables that are defined in the code and the names of some components (`Command1` is the name of the pull-down, and `Toggle1` is the name of the menu item). The code above shows that it is usually very easy to pass the handle of an element to a Windows function — just use its `Handle` property.

At first I thought this function could be called when the form was created, after the two bitmaps had been loaded from the file, but it cannot. Delphi changes the default Windows behavior somewhat, forcing the application to re-associate the bitmap with the menu items each time they are displayed. The solution I've found is to execute this call each time the pull-down menu is selected — that is, on the `OnClick` event of the pull-down.

The only thing left is to load the bitmaps. You need to add two fields of the `TBitmap` type to the form class, create an instance of the two objects, and then load the bitmaps from the two `BMP` files. This is done only once, when the form is created:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  Bmp1 := TBitmap.Create;
  Bmp2 := TBitmap.Create;
  Bmp1.LoadFromFile ('ok.bmp');
  Bmp2.LoadFromFile ('no.bmp');
end;
```

The two bitmaps should also be destroyed when the program terminates (in the handler of the `OnDestroy` event of the form):

```
procedure TForm1.FormDestroy(Sender: TObject);
begin
  Bmp1.Free;
  Bmp2.Free;
end;
```

Notice that to run this program, you need to have the two `BMP` files in the same directory as the executable file. The bitmaps, in fact, are loaded at run-time and are not embedded by Delphi in the `EXE` file. As an alternative I could have used two non-visible Image components to hold the images.

> You can indeed include a bitmap in the resources of an application and in its executable file in order to be able to ship the application in a single file. This process, however, is slightly more complex, so I've decided not to use it here.

Bitmap Menu Items

Instead of placing a bitmap close to a menu item to indicate the status of its `Checked` property, as we've done in the previous section, you can actually replace the text of a menu item with a bitmap. In specific cases this can make an application easier to use.

BitMenu is a very simple program. I've put a shape in the middle of a form and added a menu to set the kind of shape (rectangle, rounded rectangle, or ellipse), and its color. Here is the textual description of the form and its menu:

```
object Form1: TForm1
  Caption = ' Bitmap Menu'
  Menu = MainMenu1
  OnCreate = FormCreate
  OnDestroy = FormDestroy
  OnResize = FormResize
  object ShapeDemo: TShape...  // default properties
  object MainMenu1: TMainMenu
    object File1: TMenuItem...
      object Exit1: TMenuItem...
    end
    object Shape1: TMenuItem
      Caption = '&Shape'
      object Ellipse1: TMenuItem
        Caption = 'Ellipse'
        OnClick = Ellipse1Click
      end
      object RoundRec1: TMenuItem
        Caption = 'RoundRec'
        OnClick = RoundRec1Click
      end
      object Rectang1: TMenuItem
        Caption = 'Rectang'
        OnClick = Rectang1Click
      end
    end
    object Color1: TMenuItem
      Caption = '&Color'
      object Red1: TMenuItem
        Caption = 'Red'
        OnClick = Red1Click
      end
      object Green1: TMenuItem
        Caption = 'Green'
        OnClick = Green1Click
      end
      object Blue1: TMenuItem
        Caption = 'Blue'
        OnClick = Blue1Click
      end
    end
    object Help1: TMenuItem...
    object About1: TMenuItem...
  end
end
```

I've listed the complete description of the menu items because their captions will play an important role in the code, as you'll see shortly. As a second step I've made the program work, by handling the various menu commands. Here are two examples from the two main pull-down menus:

```
procedure TForm1.Red1Click(Sender: TObject);
begin
  ShapeDemo.Brush.Color := clRed;
end;

procedure TForm1.Ellipse1Click(Sender: TObject);
```

```
begin
  ShapeDemo.Shape := stEllipse;
end;
```

I've also written a handler for the `OnResize` event of the form, to resize the shape depending on the actual size of the form. Instead of setting its four positional properties (`Left`, `Top`, `Width`, and `Height`) I've called the `SetBounds` method. This approach leads to faster code.

Now that we've written the code of the program, it is time to turn the menu items into bitmaps. To accomplish this I've prepared a bitmap file for each of the three shapes and one for each of the three base colors. Technically these bitmaps can have any size, but to make them look nice they should generally be wide and low (the typical size of a menu item).

Having prepared the six bitmap files, each named with the caption of its menu items (plus the `.BMP` extension), I've written a handler for the `OnCreate` event of the form, and replaced the text of the items of the fake standard menu with bitmaps. This can be accomplished by calling the `ModifyMenu` API function:

```
function ModifyMenu (hMnu: HMENU;
  uPosition, uFlags, uIDNewItem: UINT;
  lpNewItem: PChar): BOOL; stdcall;
```

The first parameter is the handle of the menu we are working on (typically a pull-down menu), the second is the position of the item we want to modify, the third is some menu flags indicating the effect of other parameters, the fourth is the identifier of the menu item (stored by Delphi in the `Command` property), and the last is the new string for the menu item. How can we use this to set a bitmap, instead? We simply pass the handle of a bitmap in the last parameter (instead of the string), and use the `mf_Bitmap` menu flag among the values of the `uFlags` parameter.

Now you are ready to look at the source code, which is based on two `for` loops. I wanted to make the code as generic as possible, so that adding a new kind of shape or color will be pretty straightforward:

```
procedure TForm1.FormCreate(Sender: TObject);
var
  I: Integer;
  Bmp: TBitmap;
begin
  // load the bitmaps for the shapes
  for I := 0 to Shape1.Count - 1 do
  begin
    Bmp := TBitmap.Create;
    Bmp.LoadFromFile (Shape1.Items [I].Caption + '.bmp');
    ModifyMenu (Shape1.Handle,Shape1.Items [I].MenuIndex,
      mf_ByPosition or mf_Bitmap,
      Shape1.Items [I].Command, Pointer (Bmp.Handle));
    Shape1.Items [I].Tag := Integer (Bmp);
  end;

  // load the bitmaps for the colors
  for I := 0 to Color1.Count - 1 do
  begin
    Bmp := TBitmap.Create;
    Bmp.LoadFromFile (Color1.Items [I].Caption + '.bmp');
    ModifyMenu (Color1.Handle, Color1.Items [I].MenuIndex,
      mf_ByPosition or mf_Bitmap, Color1.Items [I].Command,
      Pointer (Bmp.Handle));
    Color1.Items [I].Tag := Integer (Bmp);
  end;
```

```
end;
```

> In the two calls to the `ModifyMenu` API function in the code above, we've used the `mf_ByPosition` flag in the third parameter, and passed the position of the item in the second parameter. However, we still need to pass the menu command as the fourth parameter, because this will be the command of the new menu item. If we don't, we'll lose the connection between the menu item and its Delphi event handler.

As you can see I save the reference to each bitmap object I create in the `Tag` property of the corresponding menu item. The only reason I have to save the bitmap objects is to be able to destroy them when the application terminates:

```
procedure TForm1.FormDestroy(Sender: TObject);
var
  I: Integer;
begin
  for I := 0 to Shape1.Count - 1 do
    TBitmap (Shape1.Items [I].Tag).Free;
  for I := 0 to Color1.Count - 1 do
    TBitmap (Color1.Items [I].Tag).Free;
end;
```

As an alternative I could have saved the bitmap objects in an array (declared as a field of the form), and then destroyed each of the objects of the array at the end.

When you run this program, the Shape pull-down menu looks nice. The Color pull-down menu, however, is not working properly. As soon as you select it, in fact, the colors are displayed properly. But when you move over a menu item (as you can see by running the program) its colors are reversed by the menu item selection. Reversing the color you are asking for results in a very odd user interface: to select the color blue you have to click on an item that has temporarily turned to yellow!

Basically, you can use only black-and-white or gray-scaled bitmaps in a menu item. Color bitmaps create a lot of problems. If you want to obtain this effect, you should use an owner-draw menu item, as described in the next section.

Owner-Draw Menu Items

In Windows, the system is usually responsible for painting buttons, list boxes, edit boxes, menu items, and similar elements. Basically these controls know how to paint themselves. As an alternative, however, the system allows the owner of these controls, generally a form, to paint them. This technique, available for buttons, list boxes, combo boxes, and menu items, is called *owner-draw*.

Actually in Delphi the situation is slightly more complex. The components can take care of painting themselves also in this case (as is the case for the `TBitBtn` class for bitmap buttons), and eventually activate corresponding events. If you don't think about the internal details, owner-draw techniques for list boxes and combo boxes require you simply to write the handler for a couple of events.

Delphi provides no support for owner-draw menu items, though. So in this case we have to use the standard Windows approach, and handle a couple of system messages in our form. Here is the definition of these methods in the source code of the ODMenu example, an extension of the BitMenu example discussed in the last section:

```
type
```

```
  TForm1 = class(TForm)
    ...
  public
    procedure WmMeasureItem (var Msg: TWmMeasureItem);
      message wm_MeasureItem;
    procedure WmDrawItem (var Msg: TWmDrawItem);
      message wm_DrawItem;
  end;
```

The `wm_MeasureItem` message is sent by Windows once for each menu item when the pull-down menu is displayed to determine the size of each item. The `wm_DrawItem` message is sent when an item has to be repainted. This happens when Windows first displays the items, and each time the status changes; for example, when the mouse moves over an item, it should become highlighted. In fact, to paint the menu items, we have to consider all the possibilities, including drawing the highlighted items with specific colors, drawing the check mark if required, and so on.

In the ODMenu example I'll handle the highlighted color, but skip other advanced aspects (such as the check marks). I've modified the `CreateForm` method to call the `ModifyMenu` API function passing the `mfOwnerDraw` menu flag. I also pass a code as the last parameter, to distinguish the various items. The other parameters are the same as in the previous version of the example:

```
procedure TForm1.FormCreate(Sender: TObject);
var
  I: Integer;
begin
  ...
  // turn the menu items into owner-draw items
  for I := 0 to Color1.Count - 1 do
  begin
    ModifyMenu (Color1.Handle, Color1.Items [I].MenuIndex,
      mf_ByPosition or mf_OwnerDraw,
      Color1.Items [I].Command, Pointer (I));
  end;
end;
```

Now we have to write the code of the two owner-draw message handlers. The `WmMeasureItem` method receives as a parameter (in the corresponding `TWmMeasureItem` structure) a pointer to the Windows `MeasureItemStruct` structure (you can see the details of this structure in the Windows API help file). From this last structure we use the `CtlType` field, which stores the type of element we are measuring, to check whether this operation pertains to a menu. If it does, we use the `ItemWidth` and `ItemHeight` fields to set the width and height of the item. Since all items have the same size, the code is quite simple. The last thing we have to do is to provide a return value for the message, indicating we have handled it, in the `Result` field of the message structure. Here is the complete code:

```
procedure TForm1.WmMeasureItem (var Msg: TWmMeasureItem);
begin
  inherited;
  with Msg.MeasureItemStruct^ do
    if CtlType = odt_Menu then
    begin
      ItemWidth := 80;
      ItemHeight := 30;
      Msg.Result := 1; // we've handled it
    end;
end;
```

Drawing a menu item is slightly more complex, since to write Delphi code we have to create a TCanvas object, which encapsulates a Windows *device context* handle. Since we have to free this object to avoid memory leaks, I've used a try-finally statement to destroy it even if an error occurs:

```
Canvas1 := TCanvas.Create;
Canvas1.Handle := hDC;
try
  ...
finally
  Canvas1.Free;
end;
```

The code assigns to the Handle property of this TCanvas object the hDC field passed by the message in the DrawItemStruct structure (there is, again, a pointer to this structure passed in one of the fields of the TWmDrawItem parameter of the message-handler method). This hDC field passes to our code the handle to the device context (the painting area, the Canvas) of the pull-down menu we are going to paint.

Once we have set up the drawing mechanism, we can start with the actual code. First we have to check the state of the menu item, stored in the ItemState field. If this includes the ods_Selected flag (a condition we can test by checking the result of a bitwise and expression); then we have to paint the background of the menu item using the Windows system color for the highlighted items, clHighlight. Otherwise, we use the standard color for menus, clMenu.

> Some of the Delphi constants for colors correspond to the Windows system color. These colors are not fixed, but reflect the current color setting made by the user.

Once we've assigned to the Brush of the canvas the background color, we can easily paint it by calling the FillRect method. This method has one single parameter, corresponding to the rectangle we have to erase. This information is available in the rcItem field of the DrawItemStruct structure. Notice, by the way, that if you don't limit your drawing area to this rectangle, you can paint over other menu items as well!

The second step is drawing the actual colored areas, which don't depend on the status of the menu item, since we want each color to show up properly even if the item is selected. By looking to the ItemData field, the code retrieves the code passed as the last parameter of the ModifyMenu function call, used to make the menu item owner-draw. Depending on the value of this field, the program sets a proper value for the Color of the Brush using a simple case statement. At this point we only have to paint the area, by calling the Rectangle function and passing, in the four parameters, a smaller area than the full surface of the menu item. In fact we need to reserve a border with the background color. In the example the border is 5 pixels wide.

Here, finally, is the complete source code of the WmDrawItem method:

```
procedure TForm1.WmDrawItem (var Msg: TWmDrawItem);
var
  Canvas1: TCanvas;
begin
  inherited;
  with Msg.DrawItemStruct^ do
    if CtlType = odt_Menu then
    begin
      // create a canvas for painting
      Canvas1 := TCanvas.Create;
      Canvas1.Handle := hDC;
      try
```

```
          // set the background color and draw it
          if (ods_Selected and ItemState <> 0) then
            Canvas1.Brush.Color := clHighlight
          else
            Canvas1.Brush.Color := clMenu;
          Canvas1.FillRect (rcItem);
          case ItemData of
            0: Canvas1.Brush.Color := clRed;
            1: Canvas1.Brush.Color := clLime;
            2: Canvas1.Brush.Color := clBlue;
          end;
          Canvas1.Rectangle (rcItem.Left + 5, rcItem.Top + 5,
            rcItem.Right - 10, rcItem.Bottom - 10);
        finally
          Canvas1.Free;
        end;
      end;
end;
```

I suggest you run this program along with the BitMenu program, to see the differences in the way the colored menu items are painted. Actually, looking at these two examples one might think of using the owner-draw technique also for menu items with black-and-white bitmaps.

Customizing the System Menu

In some circumstances, it is interesting to add menu commands to the system menu itself, instead of (or besides) having a menu bar. This might be useful for secondary windows, toolboxes, windows requiring a large area on the screen, and for "quick-and-dirty" applications. Adding a single menu item to the system menu is straightforward:

```
AppendMenu (GetSystemMenu (Handle, FALSE),
  MF_SEPARATOR, 0, '');
AppendMenu (GetSystemMenu (Handle, FALSE),
  MF_STRING, idSysAbout, '&About...');
```

The code fragment above (extracted from the SysMenu example) adds a separator and a new item to the system menu item. The GetSystemMenu API function, which requires as a parameter the handle of the form, returns a handle to the system menu. The AppendMenu API function is a general-purpose function you can use to add menu items or complete pull-down menus to any menu (the menu bar, the system menu, or an existing pull-down menu). When adding a menu item, you have to specify its text and a numeric identifier. In the example I've defined this identifier as:

```
const
  idSysAbout = 100;
```

In the SysMenu example, this code is executed in the OnCreate event handler, and it produces the new system menu. Adding a menu item to the system menu is easy, but how can we handle its selection? Selecting a normal menu generates the wm_Command Windows message. This is handled internally by Delphi, which activates the OnClick event of the corresponding menu item component. The selection of system menu commands, instead, generates a wm_SysCommand message, which is passed by Delphi to the default handler. Windows usually needs to do something in response to a system menu command.

We can intercept this command and check to see whether the command identifier (passed in the CmdType field of the TWmSysCommand parameter) of the menu item is our idSysAbout. Since there isn't a corresponding event in Delphi, we have to define a new message response method to the form class:

```
public
  procedure WMSysCommand (var Msg: TMessage);
    message wm_SysCommand;
```

The code of this procedure is not very complex. We just need to check whether the command is our own and call the default handler:

```
procedure TForm1.WMSysCommand (var Msg: TWMSysCommand);
begin
  if Msg.CmdType = idSysAbout then
    ShowMessage ('Mastering Delphi: SysMenu example');
  inherited;
end;
```

To build a more complex system menu, instead of adding and handling each menu item as we have just done, we can follow a different approach. Just add a MainMenu component to the form, create its structure (any structure will do), and write the proper event handlers. Then reset the value of the Menu property of the form, removing the menu bar. This way we have a MainMenu component but nothing on the screen.

Now we can add some code to the SysMenu example to add each of the items from the hidden menu to the system menu. This operation takes place when the button of the form is pressed. The corresponding handler uses generic code that doesn't depend on the structure of the menu we are appending to the system menu:

```
procedure TForm1.Button1Click(Sender: TObject);
var
  I: Integer;
begin
  // add a separator
  AppendMenu (GetSystemMenu (Handle, FALSE), MF_SEPARATOR, 0, '');
  // add the main menu to the system menu
  with MainMenu1 do
    for I := 0 to Items.Count - 1 do
      AppendMenu (GetSystemMenu (self.Handle, FALSE),
        mf_Popup, Items[I].Handle, PChar (Items[I].Caption));
  // disable the button
  Button1.Enabled := False;
end;
```

This code uses the expression self.Handle to access the handle of the form. This is required because we are currently working on the MainMenu1 component, as specified by the with statement.

The menu flag used in this case, mf_Popup, indicates that we are adding a pull-down menu. In this function call the fourth parameter is interpreted as the handle of the pull-down menu we are adding (in the previous example we passed the identifier of the menu, instead). Since we are adding to the system menu items with sub-menus, the final structure of the system menu will have two levels.

> The Windows API uses the terms *pop-up menu* and *pull-down menu* interchangeably. This is really odd, because most of us use the terms for two different things, the local menus and the secondary menus of the menu bar. Apparently, they've done this because these two elements are implemented with the same kind of internal windows; and the fact that they are two distinct user-interface elements is probably something that was later conceptually built over a single basic internal structure.

Once you have added the menu items to the system menu, you need to handle them. Of course you can check for each menu item in the `WMSysCommand` method, or you can try building a smarter approach. Since in Delphi it is easier to write a handler for the `OnClick` event of each item, as usual, we can look for the item corresponding to the given identifier in the menu structure. Delphi helps us by providing a `FindItem` method.

When we have found the menu item (and if we have found something), we can call its `Click` method (which invokes the `OnClick` handler). Here is the code I've added to the `WMSysCommand` method:

```
var
  Item: TMenuItem;
begin
  ...
  Item := MainMenu1.FindItem (Msg.CmdType, fkCommand);
  if Item <> nil then
    Item.Click;
```

In this code, The `CmdType` field of the message structure that is passed to the `WMSysCommand` procedure holds the command of the menu item being called.

You can also use a simple `if` or `case` statement to handle one of the system menu's predefined menu items that have special codes for this identifier, such as `sc_Close`, `sc_Minimize`, `sc_Maximize`, and so on. For more information, you can see the description of the `wm_SysCommand` message in the Windows API Help file, available in Delphi.

> This application works but has one glitch. If you click the right mouse button over the TaskBar icon representing the application, you get a plain system menu (actually even different than the default one). The reason is that this system menu belongs to a different window, the window of the `Application` global object.

Building a Complete Menu

Now that we know how to write a menu, disable and check menu items, and so on, we are ready to build the menu for a full-fledged application. Do you remember the RichNote example of the last chapter? It was a simple editor based on a RichEdit component. You could use it to write and change the font of the selected text, but that was all. Now we want to add a menu and implement a number of features, including a complete scheme for opening and saving the text files. In fact, we want to be able to ask the user to save any modified file before opening a new one, to avoid losing any changes. Sounds like a professional application, doesn't it?

First of all, we need to build the menu, following the standard. The main menu starts with two standard pull-down menus, File and Edit, with the typical menu items. Then there are two specific pull-down menus, Font and Paragraph, with menu items to set the text font and alignment. The last two pull-down menus, Options and Help, are *almost* standard: Their names are standard, but their menu items are not. The Options menu has commands to change the background color and to count the characters, and the Help menu has only the About menu item.

In this example, we want to implement most but not all of the commands of the menu, for example skipping the Clipboard commands. The following table shows the complete structure of the menu:

&File	&Edit	F&ont	&Paragraph	&Options	&Help
&New	Cu&t	&Times New Roman	&Left Aligned	&Backgroud Color	&About RichNote...
&Open...	&Copy	&Courier New	&Right Aligned	&Read Only	
&Save	&Paste	&Arial	&Centered	&Count chars...	
Save&As...		&Bold			
&Print...		&Italic			
E&xit		&Small			
		&Medium			
		&Large			
		More &Fonts...			

Having added a complete menu, we can now get rid of the simple panel and the font button of the RichNote example. The only visual component left in the form of the RichNot2 version will be the RichEdit component, which is aligned with the client area. Then there is the MainMenu component, and four components for standard dialog boxes (OpenDialog, SaveDialog, FontDialog, and ColorDialog).

The File Menu

As I mentioned when we began working through the RichNot2 example, the most complex part of this program is implementing the commands of the File pull-down menu—New, Open, Save, and Save As. In each case, we need to track whether the current file has changed, saving the file only if it has. We should prompt the user to save the file each time the program creates a new file, loads an existing one, or terminates.

To accomplish this, I've added two fields and three methods to the class describing the form of the application:

```
  private
    FileName: string;
    Modified: Boolean;
  public
    function SaveChanges: Boolean;
    function Save: Boolean;
    function SaveAs: Boolean;
```

The `FileName` string and the `Modified` flag are set when the form is created and changed when a new file is loaded or the user renames a file with the Save As command. These two flags are initialized when the form is first created:

```
procedure TFormRichNote.FormCreate(Sender: TObject);
begin
  FileName := '';
  Modified := False;
end;
```

The value of the flag changes as soon as you type new characters in the RichEdit control (in its `OnChange` event handler):

```
procedure TFormRichNote.RichEdit1Change(Sender: TObject);
begin
  Modified := True;
end;
```

When a new file is created, the program checks whether the text has been modified. If so, it calls the SaveChanges function, which asks the user whether to save the changes, discard them, or skip the current operation:

```
procedure TFormRichNote.New1Click(Sender: TObject);
begin
  if not Modified or SaveChanges then
  begin
    RichEdit1.Text := '';
    Modified := False;
    FileName := '';
    Caption := 'RichNote - [Untitled]';
  end;
end;
```

If the creation of a new file is confirmed, some simple operations take place, including using *'Untitled'* instead of the file name in the form's caption.

Short-Circuit Evaluation

The expression **if not** Modified **or** SaveChanges **then** requires some explanation. By default, Pascal performs what is called "short-circuit evaluation" of complex conditional expressions. The idea is simple: if the expression not Modified is true, we are sure that the whole expression is going to be true, and we don't need to evaluate the second expression. In this particular case, the second expression is a function call, and the function is called only if Modified is True. This behavior of or and and expressions can be changed by setting a Delphi compiler option called Complete Boolean Eval. You can find it on the Compiler page of the Project Options dialog box.

The message box displayed by the SaveChanges function has three options. If the user selects the Cancel button, the function returns False. If the user selects No, nothing happens (the file is not saved) and the function returns True, to indicate that although we haven't actually saved the file, the requested operation (such as creating a new file) can be accomplished. If the user selects Yes, the file is saved and the function returns True.

In the code of this function, notice in particular the call to the MessageDlg function used as the value of a case statement:

```
function TFormRichNote.SaveChanges: Boolean;
begin
  case MessageDlg (
    'The document ' + filename + ' has changed.' +
    #13#13 + 'Do you want to save the changes?',
    mtConfirmation, mbYesNoCancel, 0) of
  idYes:
    // call Save and return its result
    Result := Save;
  idNo:
    // don't save and continue
    Result := True;
  else // idCancel:
    // don't save and abort operation
    Resulht := False;
  end;
```

```
end;
```

> In the MessageDlg call above, I've added explicit newline characters (`#13`) to improve the readability of the output. As an alternative to using a numeric character constant, you can call `Chr(13)`.

To actually save the file, another function is invoked: `Save`. This method saves the file if it already has a proper file name or asks the user to enter a name, calling the `SaveAs` functions. These are two more internal functions, not directly connected with menu items:

```
function TFormRichNote.Save: Boolean;
begin
  if Filename = '' then
    Result := SaveAs // ask for a file name
  else
  begin
    RichEdit1.Lines.SaveToFile (FileName);
    Modified := False;
    Result := True;
  end;
end;

function TFormRichNote.SaveAs: Boolean;
begin
  SaveDialog1.FileName := Filename;
  if SaveDialog1.Execute then
  begin
    Filename := SaveDialog1.FileName;
    Save;
    Caption := 'RichNote - ' + Filename;
    Result := True;
  end
  else
    Result := False;
end;
```

I use two functions to perform the Save and SaveAs operations (and do not call the corresponding menu handler directly) because I need a way to report a request to cancel the operation from the user. To avoid code duplication, the handlers of the Save and SaveAs menu items call the two functions too, although they ignore the return value:

```
procedure TFormRichNote.Save1Click(Sender: TObject);
begin
  if Modified then
    Save;
end;

procedure TFormRichNote.Saveas1Click(Sender: TObject);
begin
  SaveAs;
end;
```

Opening a file is much simpler. Before loading a new file, the program checks whether the current file has changed, asking the user to save it with the `SaveChanges` function, as before. The `Open1Click` method is based on the OpenDialog component, another default dialog box provided by Windows and supported by Delphi:

```
procedure TFormRichNote.Open1Click(Sender: TObject);
begin
  if not Modified or SaveChanges then
    if OpenDialog1.Execute then
    begin
      Filename := OpenDialog1.FileName;
      RichEdit1.Lines.LoadFromFile (FileName);
      Modified := False;
      Caption := 'RichNote - ' + FileName;
    end;
end;
```

The only other detail related to file operations is that both the OpenDialog and SaveDialog components of the NotesForm have a particular value for their `Filter` and `DefaultExt` properties, as you can see in the following fragment from the textual description of the form:

```
object OpenDialog1: TOpenDialog
  DefaultExt = 'rtf'
  FileEditStyle = fsEdit
  Filter = 'Rich Text File (*.rtf)|*.rtf|Any file (*.*)|*.*'
  Options = [ofHideReadOnly, ofPathMustExist,ofFileMustExist]
end
```

The string used for the `Filter` property (which should be written on a single line) contains four pairs of substrings, separated by the | symbol. Each pair has a description of the type of file that will appear in the File Open or File Save dialog box, and the filter to be applied to the files in the directory, such as `*.RTF`. To set the filters in Delphi, you can simply invoke the editor of this property, which displays a list with two columns.

The file-related methods above are also called from the `FormCloseQuery` method (the handler of the `OnCloseQuery` event), which is called each time the user tries to close the form, terminating the program. We can make this happen in various ways — by double-clicking on the system menu icon, selecting the system menu's Close command, pressing the Alt+F4 keys, or calling the `Close` method in the code, as in the File | Exit menu command.

In `FormCloseQuery`, you can decide whether or not to actually close the application by setting the `CanClose` parameter, which is passed by reference. Again, if the current file has been modified, we call the `SaveChanges` function and use its return value. Again we can use the short-circuit evaluation technique:

```
procedure TFormRichNote.FormCloseQuery(Sender: TObject;
  var CanClose: Boolean);
begin
  CanClose := not Modified or SaveChanges;
end;
```

The last menu item of the File menu is the Print command. Since the RichEdit component includes print capabilities and they are very simple to use, I've decided to implement it anyway. Here is the code, which actually produces a very nice printout:

```
procedure TFormRichNote.Print1Click(Sender: TObject);
begin
  RichEdit1.Print (FileName);
end;
```

The Paragraph Menu

Compared to the File menu, the other pull-down menus of this example are simpler. The code of the Paragraph menu is based on some properties of its items. Here is their textual description (from the DFM file):

```
object Paragraph1: TMenuItem
  Caption = '&Paragraph'
  object LeftAligned1: TMenuItem
    Caption = '&Left Aligned'
    Checked = True
    GroupIndex = 1
    RadioItem = True
    OnClick = RightAligned1Click
  end
  object RightAligned1: TMenuItem
    Caption = '&Right Aligned'
    GroupIndex = 1
    RadioItem = True
    OnClick = RightAligned1Click
  end
  object Centered1: TMenuItem
    Caption = '&Centered'
    GroupIndex = 1
    RadioItem = True
    OnClick = RightAligned1Click
  end
end
```

As you can see, the program uses radio menu items, by giving to the three items the same value for the `GroupIndex` property and setting the `RadioItem` property to `True`. The menu items also share the same `RightAligned1Click` method for their `OnClick` event. Here is the code of the method, which is based on the correspondence between the position of the menu items in the pull-down (indicated by their `MenuIndex` property) and the order of the values of the `TAlignment` enumeration. It is a trick, but it works. Here is the code:

```
procedure TFormRichNote.RightAligned1Click(Sender: TObject);
begin
  RichEdit1.Paragraph.Alignment :=
    TAlignment ((Sender as TMenuItem).MenuIndex);
  (Sender as TMenuItem).Checked := True;
end;
```

First, this procedure sets the alignment of the current paragraph (the paragraph including the selected text or the editor cursor), then it checks the current menu item — the menu item that has activated the method (the `Sender` object). As you can see, this code relies on some controlled typecasts, based on the `as` keyword: this is what you have to do any time you want to write generic code (that is, to attach the same methods to events of different components).

Notice that setting the check mark for the current menu item is correct only until you change the selection or the current line in the text. For this reason, we can handle the `OnSelectionChange` event of the RichEdit component, and update the check mark of the Paragraph menu each time:

```
procedure TFormRichNote.RichEdit1SelectionChange(Sender: TObject);
begin
  Paragraph1.Items [Integer (RichEdit1.Paragraph.Alignment)].
    Checked := True;
```

```
end;
```

The Font Menu

The Font pull-down menu is built on the same concept, but it has two groups of radio items, plus items with a standard check mark. Each group, then, uses a different approach to handle the menu item selection with a single event response method. You can see the details of the properties of the menu items directly in the `RichForm.DFM` source code file (this listing was too long to reproduce here).

The code of the first group of menu items (used to select the font) is based on a simple trick: the name of the font to select corresponds to the `Caption` of the menu item, without the initial `&` character:

```
procedure TFormRichNote.TimesRoman1Click(Sender: TObject);
var
  FontName: string;
begin
  // get the font name and remove the &
  FontName := (Sender as TMenuItem).Caption;
  Delete (FontName, 1, 1);
  // change selected text font
  if RichEdit1.SelLength > 0 then
    RichEdit1.SelAttributes.Name := FontName;
  (Sender as TMenuItem).Checked := True;
end;
```

This code acts on the current selection (using the `SelAttributes` property of the RichEdit1 component), as the RichNote example in Chapter 8 did. Notice that you can easily extend this code by adding new menu items consisting of the name of the font preceded by the `&` character. Then you'll necessarily have to set the same value for the `GroupIndex` property of the previous items (in this case `1`). So if you simply set the `RadioItem` property to `True` and connect the `OnClick` event to the `TimesRoman1Click` method, they'll behave just like the existing font selection menu items.

The second group of items controls the selection of the bold and italic styles. This is accomplished by two similar but separate methods. Here is one of them:

```
procedure TFormRichNote.Bold1Click(Sender: TObject);
begin
  Bold1.Checked := not Bold1.Checked;
  if RichEdit1.SelLength > 0 then
    with RichEdit1.SelAttributes do
      if Bold1.Checked then
        Style := Style + [fsBold]
      else
        Style := Style - [fsBold];
end;
```

The last part of the menu has another group of radio menu items, used to set the size of the font. These menu items refer to a font size in the caption and have the same value stored in their `Tag` property. This makes the code very easy to write. Again, there is a single method for the three menu items, but you can add new items to this group with very little effort:

```
procedure TFormRichNote.Large1Click(Sender: TObject);
begin
  if RichEdit1.SelLength > 0 then
    RichEdit1.SelAttributes.Size :=(Sender as TMenuItem).Tag;
  (Sender as TMenuItem).Checked := True;
end;
```

The last item of this menu simply activates the Font dialog box. Notice that the font returned by this dialog box cannot be assigned directly to the `SelAttributes` property; we need to call the `Assign` method, instead:

```
procedure TFormRichNote.More1Click(Sender: TObject);
begin
  FontDialog1.Font := RichEdit1.Font;
  if FontDialog1.Execute then
    RichEdit1.SelAttributes.Assign (FontDialog1.Font);
  // update the check marks
  RichEdit1SelectionChange (self);
end;
```

All the commands of this menu affect the status of the current selection, setting the check boxes and radio items properly. The method above, instead, calls the `RichEdit1SelectionChange` method. This is the handler of the `OnSelectionChange` event of the RichEdit component.

This method scans some of the groups to determine which element has to be checked. As in other examples before, this code has been written so that you can easily extend it for new menu items (the listing also includes the code used to reset the paragraph alignment, discussed earlier):

```
procedure TFormRichNote.RichEdit1SelectionChange(Sender: TObject);
var
  FontName: string;
  I: Integer;
begin
  // check the font name radio menu item
  FontName := '&' + RichEdit1.SelAttributes.Name;
  for I := 0 to 2 do
    with Font1.Items [I] do
      if FontName = Caption then
        Checked := True;

  // check the bold and italic items
  Italic1.Checked :=
    fsItalic in RichEdit1.SelAttributes.Style;
  Bold1.Checked :=
    fsBold in RichEdit1.SelAttributes.Style;

  // check the font size
  for I := Small1.MenuIndex to Large1.MenuIndex do
    with Font1.Items [I] do
      if Tag = RichEdit1.SelAttributes.Size then
        Checked := True;

  // check the paragraph style
  Paragraph1.Items [Integer (RichEdit1.Paragraph.Alignment)].
    Checked := True;
end;
```

This method doesn't work perfectly. When you set a custom font, the selection doesn't change properly (because the current item remains selected). To fix it, we should remove any radio check mark when the value is not one of the possible selections, or add new menu items for this special case. The example is complex enough, so I think we can live with this minor inconvenience.

The Options Menu

The last pull-down menu of the RichNot2 example is the Options menu. This menu has three unrelated commands used to customize the user interface, and to determine and display the length of the text. The first command displays a color selection dialog box, used to change the color of the background of the RichEdit component:

```
procedure TFormRichNote.BackColor1Click(Sender: TObject);
begin
  ColorDialog1.Color := RichEdit1.Color;
  if ColorDialog1.Execute then
    RichEdit1.Color := ColorDialog1.Color;
end;
```

The second command can be used to mark the text as read-only. In theory this property should be set depending on the status of the file on the disk. In the example, instead, the user can toggle the read-only attribute manually:

```
procedure TFormRichNote.ReadOnly1Click(Sender: TObject);
begin
  RichEdit1.ReadOnly := not RichEdit1.ReadOnly;
  ReadOnly1.Checked := not ReadOnly1.Checked;
end;
```

The last menu item activates a method to count the number of characters in the text and display the total in a message box. The core of the method is the call to the `GetTextLen` function of the RichEdit control. The number is extracted and formatted into an output string:

```
procedure TFormRichNote.Countchars1Click(Sender: TObject);
begin
  MessageDlg (Format (
    'The text has %d characters', [RichEdit1.GetTextLen]),
    mtInformation, [mbOK], 0);
end;
```

The handler of the `OnClick` event of this last item of the Options menu terminates the example. As mentioned at the beginning, this was a rather long and complex example, but its purpose was to show you the implementation of the menu commands of a real-world application. In particular, I explained in detail the File pull-down menu because this is something you'll probably need to handle in any file-related application.

Now we are ready to delve into another topic involving menus, the use of local menus activated by the right mouse button click.

Pop-Up Menus

In Windows, it is common to see applications that have special local menus you activate by clicking the right mouse button. The menu that is displayed — a pop-up menu, in common Windows terminology — usually depends on the position of the mouse click. These menus tend to be easy to use since they group only the few commands related to the element that is currently selected. They are also usually faster to use than full-blown menus because you don't need to move the mouse up to the menu bar and then down again to go on working.

In Delphi, there are basically two ways to display pop-up menus, using the corresponding component. You can let Delphi handle them automatically or you can choose a manual technique. I'll explore both approaches, starting with the first, which is the simplest one.

To add a pop-up menu to a form, you need to perform a few simple operations. Create a PopupMenu component, add some menu items to it, and select the component as the value of the form's `PopupMenu` property. That's all. Of course, you should also add some handlers for the `OnClick` events of the local menu's various menu items, as you do with an ordinary menu.

An Automatic Local Menu

To show you how to create a local menu, I've built an example that is an extension of the Dragging example. The new example is named Local1. I've added a first PopupMenu component to its form and connected it using the `PopupMenu` property of the form itself. Once this is done, running the program and clicking the right mouse button on the form displays the local menu. Then, I've added a second pop-up menu component, with two levels, to the form, and I've attached it to the StaticText component on the right, `LabelTarget`. To connect a local menu to a specific component, you simply need to set its `PopupMenu` property. The four methods related to the first group of commands of the Colors pull-down menu just select a color:

```
procedure TDraggingForm.Aqua1Click(Sender: TObject);
begin
  LabelTarget.Color := clAqua;
end;
```

The Transparent command selects the color of the parent form as the current color, setting the value of the `ParentColor` property to `True`.

> The components of a form usually borrow some properties from the form. This is indicated by specific properties, such as `ParentColor` or `ParentFont`. When these properties are set to `True`, the current value of the component's property is ignored, and the value of the form is used instead. Usually, this is not a problem, because as soon as you set a property of the component (for example, the font), the corresponding property indicating the use of the parent attribute (`ParentFont`) is automatically set to `False`.

The last command of the pull-down menu, User Defined, presents the standard Color Selection dialog box to the user. The three commands of the pop-up menu's second pull-down change the alignment of the text of the big label and add a check mark near the current selection, deselecting the other two menu items. Here is one of the three methods:

```
procedure TDraggingForm.Center1Click(Sender: TObject);
begin
  LabelTarget.Alignment := taCenter;
  Left1.Checked := False;
  Center1.Checked := True;
  Right1.Checked := False;
end;
```

A pop-up menu, in fact, can use all the features of a main menu and can have checked, disabled, or hidden items, and more. I could have also used radio menu items for this pop-up menu, but this doesn't seem to be a very common approach.

Modifying a Pop-Up Menu When It Is Activated

Why not use the same technique to display a check mark near the selected color? It is possible, but it's not a very good solution. In fact, there are six menu items to consider, and the color can also change when a user drags it from one of the labels on the left of the form. For this reason, and to show you another technique, I've followed a different approach.

Each time a pop-up menu is displayed, the `OnPopup` event is sent to your application. In the code of the corresponding method, you can place the check mark on the current selection of the color, independently from the action used to set it:

```
procedure TDraggingForm.PopupMenu2Popup(Sender: TObject);
var
  I: Integer;
begin
  // unchecks all menu items (not required for radio menu items)
  with Colors1 do
    for I := 0 to Count - 1 do
      Items[I].Checked := False;

  // checks the proper item
  case LabelTarget.Color of
    clRed: Red1.Checked := True;
    clAqua: Aqua1.Checked := True;
    clGreen: Green1.Checked := True;
    clYellow: Yellow1.Checked := True;
  else
    if LabelTarget.ParentColor then
      Transparent1.Checked := True
    else
      UserDefined1.Checked := True;
  end;
end;
```

This method's code requires some explanation. At the beginning, the menu items are all unchecked by using a `for` loop on the `Items` array of the Colors1 menu. The advantage of this loop is that it operates on all the menu items, regardless of their number. Then the program uses a `case` statement to check the proper item.

Handling Pop-Up Menus Manually

In the Local1 example, we saw how to use automatic pop-up menus. As an alternative, you can set the `AutoPopup` property to `False` or not connect the pop-up menu to any component, and use the pop-up menu's `Popup` method to display it on the screen. This procedure requires two parameters: the *x* and *y* values of the position where the menu is going to be displayed. The problem is that you need to supply the *screen* coordinates of the point, not the client coordinates, which are the usual coordinates relative to the form's client area.

As an example, I've taken an existing application with a menu — the third version of the MenuOne example, described in this chapter — and added a peculiar pop-up menu. The idea is that there are two different pop-up menus, one to change the colors and the other to change the alignment of the text. Each time the user right-clicks on the caption, one of the two pop-up menus is displayed. In real applications, you'll probably have to decide which menu to display depending on the status of some variable. Here, I've followed a simple (and arbitrary) rule: Each time the right mouse button is clicked, the pop-up menu changes. My aim is to show you how to do this in the simplest possible way.

The two pop-up menus are very simple, and correspond to actions already available in the main menu (and connected with the same event handlers). Actually, I've built these pop-up menus by copying the main menu to a menu template and then pasting from it. The only change I've made is to remove the shortcut keys.

When the user clicks the right mouse button over the label, which takes up the whole surface of the form, a method displays one of the two menus. Instead of using the `OnClick` event, I've trapped the `OnMouseDown` event of the label. This second event passes as parameters the coordinates of the mouse click.

These coordinates are relative to the label, so you have to convert them to screen coordinates by calling the `ClientToScreen` method of the label:

```
procedure TFormColorText.Label1MouseDown(Sender: TObject;
  Button: TMouseButton; Shift: TShiftState; X, Y: Integer);
var
  ClientPoint, ScreenPoint: TPoint;
begin
  if Button = mbRight then
  begin
    ClientPoint.X := X;
    ClientPoint.Y := Y;
    ScreenPoint := Label1.ClientToScreen (ClientPoint);
    Inc (ClickCount);
    if Odd (ClickCount) then
      PopupMenu1.Popup (ScreenPoint.X, ScreenPoint.Y)
    else
      PopupMenu2.Popup (ScreenPoint.X, ScreenPoint.Y);
  end;
end;
```

In this procedure, you first have to check whether the right mouse button was clicked. The second step is to translate the coordinate of the position of the mouse click from client coordinates to screen coordinates. Screen coordinates are required by the PopupMenu component's `Popup` method.

The last thing we have to do is provide the proper check marks for the menu items of the second pop-up menu. A solution is to copy the current check marks of the main menu to the pop-up before displaying it:

```
if Odd (ClickCount) then
  PopupMenu1.Popup (ScreenPoint.X, ScreenPoint.Y)
else
begin
  {set the check marks as in the main menu}
  Left2.Checked := Left1.Checked;
  Center2.Checked := Center1.Checked;
  Right2.Checked := Right1.Checked;
  PopupMenu2.Popup (ScreenPoint.X, ScreenPoint.Y);
end;
```

An alternative solution—the one I've actually implemented in the Local2 example — is to set this check mark every time you set the check marks of the main menu, as in the following code:

```
procedure TFormColorText.Left1Click(Sender: TObject);
begin
  Label1.Alignment := taLeftJustify;
  Left1.Checked := True;
  Left2.Checked := True;
end;
```

In a more general application you might want to write a generic routine to apply the check marks more consistently, but in this example one of these two simple techniques will do.

What’s Next

In this chapter, we have seen how to create main menus and pop-up menus in Delphi. We’ve discussed the standard guidelines for the names of the pull-down menus and of the menu items, shortcut keys, check marks, graphical menus, local menus, and many other topics. You can explore in other directions, as well. For example, you can create a menu dynamically (at run-time) or copy portions of a menu to another menu, as in the SysMenu example.

The next step, however, is to explore a less common but very nice feature of Delphi programming, multimedia.

CHAPTER 6: MULTIMEDIA FUN

- Windows default sounds
- From a beep to music
- The Media Player component
- Playing sounds and running videos
- Applications for audio CD drives

Among the many devices, the multimedia subsystem focuses sound cards or CD-ROM drives. Of course, besides being physically connected to your computer, these devices must be properly installed in Windows for your Delphi applications to access them.

Windows provides a specific API, known as the *Multimedia API*, to handle external devices such as video, MIDI, and CD drives. Delphi includes a corresponding Help file along with an easy-to-use component, the Media Player, to manipulate most multimedia devices. Before discussing this component, which is the main topic of the chapter, we'll look at some simpler ways to produce sound in Windows, beyond the simple beeps we have used previously.

Windows Default Sounds

In the book's earlier examples, every time we wanted to notify the user of an error or a specific event, we called a Delphi system procedure (`Beep`) or a Windows API function (`MessageBeep`). The `Beep` procedure is defined in the Delphi run-time library as follows:

```
procedure Beep;
begin
  MessageBeep(0);
end;
```

It simply passes the value 0 to the `MessageBeep` API function. Besides the values 0 and `-1`, both used to produce a beep with the internal speaker of the computer, the `MessageBeep` function can also accept other values, and play the corresponding sounds with your sound board. Here are the acceptable constants and the corresponding Windows sounds they produce (these are the sound names available in Control Panel):

`mb_IconAsterisk`	SystemAsterisk sound
`mb_IconExclamation`	SystemExclamation sound
`mb_IconHand`	SystemHand sound
`mb_IconQuestion`	SystemQuestion sound
`mb_Ok`	SystemDefault sound

You can change the association between system events and sound files using the Control Panel, which lists the sounds under the names shown in the right column above. These associations are stored in the Windows System Registry.

Notice that these constants are also the possible values of the MessageBox API function, encapsulated in the MessageBox method of the TApplication class. It is common to produce the corresponding sound when the message box is displayed. This feature is not directly available in the Delphi MessageDlg function (which displays a message box with a corresponding icon), but we can extend it easily by building a SoundMessageDlg function, as demonstrated by the following example.

Every Box Has a Beep

To show you the capabilities of the MessageBeep API function, I've prepared a simple example, Beeps. The form of this example has a RadioGroup with some radio buttons from which the user can choose one of the five valid constants of the MessageBeep function. Here is the definition of the RadioGroup, from the textual description of the form:

```
object RadioGroup1: TRadioGroup
  Caption = 'Parameters'
  ItemIndex = 0
  Items.Strings = (
    'mb_IconAsterisk'
    'mb_IconExclamation'
    'mb_IconHand'
    'mb_IconQuestion'
    'mb_Ok')
end
```

The program plays the sound corresponding to the current selection when the user clicks on the Beep Sound button (one of the push buttons of the form). This button's OnClick event-handler first determines which radio button was selected, using a case statement, and then plays the corresponding sound:

```
procedure TForm1.BeepButtonClick(Sender: TObject);
var
  BeepConstant: Cardinal;
begin
  case RadioGroup1.ItemIndex of
    0: BeepConstant := mb_IconAsterisk;
    1: BeepConstant := mb_IconExclamation;
    2: BeepConstant := mb_IconHand;
    3: BeepConstant := mb_IconQuestion;
    4: BeepConstant := mb_Ok;
  else
    BeepConstant := 0;
  end;
  MessageBeep (BeepConstant);
end;
```

The else clause of the case statement is provided mainly to prevent an annoying (but not dangerous) compiler warning. To compare the selected sound with the default beep sound, click on the second button of the column (labeled *Beep –1*), which has the following code:

```
procedure TForm1.BeepOneButtonClick(Sender: TObject);
begin
  MessageBeep (Cardinal (-1));
end;
```

You can also pass the corresponding $FFFFFFFF hexadecimal value to the MessageBeep function. There is actually no difference between the two approaches. To test whether a sound driver is installed in your system (with or without a sound card, since it is possible to have a sound driver for the PC speaker), click on the first button (labeled *Test*), which uses a multimedia function, `WaveOutGetNumDevs`, to perform the test:

```
procedure TForm1.TestButtonClick(Sender: TObject);
begin
  if WaveOutGetNumDevs > 0 then
    SoundMessageDlg ('Sound is supported',
      mtInformation, [mbOk], 0)
  else
    SoundMessageDlg ('Sound is NOT supported',
      mtError, [mbOk], 0);
end;
```

To compile this function, you need to add the MmSystem unit to the `uses` clause. If your computer has no sound driver installed, you will hear only standard beeps, regardless of which sound is selected. The last two buttons have a similar aim: they both display a message box and play the corresponding sound.

The `OnClick` event handler of the Message Box button uses the traditional Windows approach. It calls the `MessageBeep` function and then the `MessageBox` method of the `Application` object soon afterward. The effect is that the sound is 1played when the message box is displayed. In fact (depending on the sound driver), playing a sound doesn't usually stop other Windows operations. Here is the code related to this fourth button:

```
procedure TForm1.BoxButtonClick(Sender: TObject);
var
  BeepConstant: Cardinal;
begin
  case RadioGroup1.ItemIndex of
    0: BeepConstant := mb_IconAsterisk;
    1: BeepConstant := mb_IconExclamation;
    2: BeepConstant := mb_IconHand;
    3: BeepConstant := mb_IconQuestion;
  else {including 4:}
    BeepConstant := mb_Ok;
  end;
  MessageBeep (BeepConstant);
  Application.MessageBox (
    PChar (RadioGroup1.Items [RadioGroup1.ItemIndex]),
    'Sound', BeepConstant);
end;
```

If you click on the last button, the program calls the `SoundMessageDlg` function, which is not an internal Delphi function. It's one I've added to the program, but you can use it in your applications. The only suggestion I have is to choose a shorter name if you want to use it frequently. `SoundMessageDlg` plays a sound, specified by its `AType` parameter, and then displays the Delphi standard message box:

```
function SoundMessageDlg (const Msg: string;
  AType: TMsgDlgType; AButtons: TMsgDlgButtons;
  HelpCtx: Longint): Integer;
var
  BeepConstant: Cardinal;
begin
  case AType of
    mtWarning: BeepConstant := mb_IconExclamation;
    mtError: BeepConstant := mb_IconHand;
    mtInformation: BeepConstant := mb_IconAsterisk;
    mtConfirmation: BeepConstant := mb_IconQuestion;
  else
    BeepConstant := mb_Ok;
  end;
  MessageBeep(BeepConstant);
  Result := MessageDlg (Msg, AType,
    AButtons, HelpCtx);
end;

procedure TForm1.MessDlgButtonClick(Sender: TObject);
var
  DlgType: TMsgDlgType;
begin
  case RadioGroup1.ItemIndex of
    0: DlgType := mtInformation;
    1: DlgType := mtWarning;
    2: DlgType := mtError;
    3: DlgType := mtConfirmation;
  else {including 4:}
    DlgType := mtCustom;
  end;
  SoundMessageDlg (
    RadioGroup1.Items [RadioGroup1.ItemIndex],
    DlgType, [mbOK], 0);
end;
```

SoundMessageDlg is a simple function, but your programs can really benefit from its use.

From Beeps to Music

When you use the MessageBeep function, your choice of sounds is limited to the default system sounds. Another Windows API function, PlaySound, can be used to play a system sound, as well as any other waveform file (WAV). Again, I've built a simple example to show you this approach. The example is named ExtBeep (for Extended Beep) and has the simple form.

The form's list box shows the names of some system sounds and some WAV files, available in the current directory (that is, the directory containing ExtBeep.exe itself). When the user clicks on the Play button, the PlaySound function (defined in the MmSystem unit) is called:

```
procedure TForm1.PlayButtonClick(Sender: TObject);
begin
  PlaySound (PChar (Listbox1.Items [ListBox1.ItemIndex]),
    0, snd_Async);
end;
```

The first parameter is the name of the sound—either a system sound, a WAV file, or a specific sound resource (see the Win32 API Help file for details). The second parameter specifies where to look for a resource sound, and the third contains a series of flags, in this case indicating that the function should return immediately and let the sound play asynchronously. (An alternative value for this parameter is snd_Sync. If you use this value, the function won't return until the sound has finished playing.) With asynchronous play, you can interrupt a long sound by calling the PlaySound function again, using nil for the first parameter:

```
procedure TForm1.StopButtonClick(Sender: TObject);
begin
  PlaySound (nil, 0, 0);
```

```
end;
```

This is the code executed by the ExtBeep example when the user clicks on the Stop button. This button is particularly useful for stopping the repeated execution of the sound started by the Loop button, which calls `PlaySound` passing as its last parameter `(snd_Async or snd_Loop)`.

The only other method of the example, `FormCreate`, selects the first item of the list box at startup, by setting its `ItemIndex` property to 0. This avoids run-time errors if the user clicks on the button before selecting an item from the list box. You can test this example by running it, and by adding the names of the other `WAV` files or system sounds (as listed in the registration database). I suggest you also test other values for the third parameter of the function (see the API help files for details).

The Media Player Component

Now let's move back to Delphi and use the Media Player component. The Delphi `TMediaPlayer` class encapsulates most of the capabilities of the Windows Media Control Interface (MCI), a high-level interface for controlling internal and external media devices.

Perhaps the most important property of the `TMediaPlayer` component is `DeviceType`. Its value can be `dtAutoSelect`, indicating that the type of the device depends on the file extension of the current file (the `FileName` property). As an alternative, you can select a specific device type, such as `dtAVIVideo`, `dtCDAudio`, `dtWaveAudio`, and many others.

Once the device type (and eventually the file) have been selected, you can open the corresponding device (or set `AutoOpen` to `True`), and the buttons of the Media Player component will be enabled. The component has a number of buttons, not all of which are appropriate for each media type. There are actually three properties referring to the buttons: `VisibleButtons`, `EnabledButtons`, and `ColoredButtons`. The first determines which of the buttons are present in the control, the second determines which buttons are enabled, and the third determines which buttons have colored marks. By using the first two of these properties, you can permanently or temporarily hide or disable some of the buttons.

The component has several events. The `OnClick` event is unusual because it contains one parameter indicating which button was pressed and a second parameter you can use to disable the button's default action. The `OnNotify` event later tells the component whether the action generated by the button was successful. Another event, `OnPostClick`, is sent either when the action starts or when it ends, depending on the value of the `Wait` property. This property determines whether the operation on the device should be synchronous.

Playing Sound Files

Our first example using the Media Player is very simple. The form of the MmSound example has some labels describing the current status, a button to select a new file, an OpenDialog component, and a Media Player component with the following settings:

```
object MediaPlayer1: TMediaPlayer
  VisibleButtons = [btPlay, btPause,
    btStop, btNext, btPrev]
  OnClick = MediaPlayer1Click
  OnNotify = MediaPlayer1Notify
```

```
end
```

When a user opens a new file, a wave table, or a MIDI file, the program enables the Media Player, and you can play the sound and use the other buttons, too:

```
procedure TForm1.NewButtonClick(Sender: TObject);
begin
  if OpenDialog1.Execute then
  begin
    FileLabel.Caption := OpenDialog1.Filename;
    MediaPlayer1.Filename := OpenDialog1.Filename;
    MediaPlayer1.Open;
    MediaPlayer1.Notify := True;
  end;
end;
```

Since I set the `Notify` property to `True`, the Media Player invokes the corresponding event handler, which outputs the information to a label:

```
procedure TForm1.MediaPlayer1Notify(Sender: TObject);
begin
  case MediaPlayer1.NotifyValue of
    nvSuccessful : NotifLabel.Caption := 'Success';
    nvSuperseded : NotifLabel.Caption := 'Superseded';
    nvAborted    : NotifLabel.Caption := 'Aborted';
    nvFailure    : NotifLabel.Caption := 'Failure';
  end;
  MediaPlayer1.Notify := True;
end;
```

Notice that you need to set the `Notify` property to `True` every time the `OnNotify` event handler is called in order to receive further notifications. Another label is updated to display the requested command.

```
procedure TForm1.MediaPlayer1Click(Sender: TObject;
  Button: TMPBtnType; var DoDefault: Boolean);
begin
  case Button of
    btPlay: ActionLabel.Caption := 'Playing';
    btPause: ActionLabel.Caption := 'Paused';
    btStop: ActionLabel.Caption := 'Stopped';
    btNext: ActionLabel.Caption := 'Next';
    btPrev: ActionLabel.Caption := 'Previous';
  end;
end;
```

Running Videos

So far, we have worked with sound only. Now it is time to move to another kind of media device: video. You indeed have a video device on your system, but to play video files (such as `AVI` files), you need a specific driver (directly available in Windows). If your computer can display videos, writing a Delphi application to do so is almost trivial: place a Media Player component in a form, select an `AVI` file in the `FileName` property, set the `AutoOpen` property to `True`, and run the program. As soon as you click on the Play button, the system opens a second window and shows the video in it.

Instead of playing the file in its own window, we can add a panel (or any other windowed component) to the form and use the name of this panel as the value of the Media Player's `Display` property. As an alternative, we can set the `Display` and the `DisplayRect` properties to indicate which portions of the output window the video should cover.

Although it is possible to create a similar program writing no code at all, to do so I would have to know which `AVI` files reside on your computer, and specify the full path of one of them in the `FileName` property of the Media Player component. As an alternative, I've written a simple routine to open and start playing a file automatically. You only have to click on the panel (as the caption suggests).

```
procedure TForm1.Panel1Click(Sender: TObject);
begin
  if OpenDialog1.Execute then
  begin
    MediaPlayer1.FileName := OpenDialog1.Filename;
    MediaPlayer1.Open;
    MediaPlayer1.Perform (wm_LButtonDown, 0, $00090009);
    MediaPlayer1.Perform (wm_LButtonUp, 0, $00090009);
  end;
end;
```

After opening the Media Player, I could have called its `Play` method immediately to start it. But that would not have enabled and disabled the buttons properly. So I decided to simulate a click in position 9 on the *x*-axis and 9 on the *y*-axis of the Media Player window (instead of building the 32-bit value including both coordinates with a function, you can use the hexadecimal value directly, as in the code above). To avoid errors, I disabled all the buttons at design-time, until the simulated click takes place. I also automatically close the player when the application is closed (in the `OnClose` event handler).

A Video in a Form

The Media Player component has some limits regarding the window it can use to produce the output. You can use many components, but not all of them. A strange thing you can try is to use the Media Player component itself as the video's output window. This works, but there are two problems. First, the Media Player component cannot be aligned, and it cannot be sized at will. If you try to use big buttons, their size will be reduced automatically at run-time. The second problem is that if you click on the Pause button, you'll see the button in front of the video, while the other buttons are still covered. (I suggest you try this approach, anyway, just for fun.)

One thing you cannot do easily is display the video in a form. In fact, although you cannot set the form as the value of the Media Player's `Display` property at design-time, you can set it at run-time. To try this, simply place a hidden Media Player component (set the `Visible` property to `False`) and an `OpenDialog` component in a form. Set a proper title and hint for the form itself, and enable the `ShowHints` property. Then write the following code to load, start, and stop the video when the user clicks on the form:

```
procedure TForm1.FormClick(Sender: TObject);
begin
  if MediaPlayer1.FileName = '' then
    if OpenDialog1.Execute then
    begin
      MediaPlayer1.FileName := OpenDialog1.FileName;
      MediaPlayer1.Open;
      Playing := False;
    end
    else
      exit; // stop if no file is selected
  if Playing then
  begin
    MediaPlayer1.Stop;
    Playing := False;
    Caption := 'MM Video (Stopped)';
    Hint := 'Click to play video';
  end
  else
  begin
    MediaPlayer1.Display := self;
    MediaPlayer1.DisplayRect := ClientRect;
    MediaPlayer1.Play;
    Playing := True;
    Caption := 'MMV (Playing)';
    Hint := 'Click to stop video';
  end;
end;
```

In this code, `Playing` is a private `Boolean` field of the form. Notice that the program shows the video using the full client area of the form. If the form is resized, you can simply enlarge the output rectangle accordingly:

```
procedure TForm1.FormResize(Sender: TObject);
begin
  MediaPlayer1.DisplayRect := ClientRect;
end;
```

The best way to view a video is to use its original size, but with this program you can actually stretch it, and even change its proportions. Of course, the Media Player can also stop when it reaches the end of a file or when an error occurs. In both cases, we receive a notification event:

```
procedure TForm1.MediaPlayer1Notify(Sender: TObject);
begin
  Playing := False;
  Caption := 'MMV (Stopped)';
  Hint := 'Click to play video';
end;
```

Working with a CD Drive

In addition to audio and video files, the MCI interface is generally used to operate external devices. There are many examples, but the most common MCI device connected to a PC is probably a CD-ROM drive. Most CD-ROM drives can also read audio CDs, sending the output to an external speaker or a sound card. You can use the MCI interface and the Media Player component to write applications that handle such a device. Basically, you need to set the `DeviceType` property to `dtCDAudio`, making sure no file is selected in the `FileName` property, and be ready with a CD player.

In fact, just by placing a Media Player component in a form, setting the above properties, and compiling and running the program, you end up with a fully functional audio CD player. When you start customizing the player, though, not everything is as simple as it seems at first glance. I've built an example using some more capabilities of this component and of Windows multimedia support related to audio CDs. The form of this program has a couple of buttons, some labels to show the current status, a timer, and a SpinEdit component you can use to choose a track from the disk.

The idea is to use the labels to inform the user of the number of tracks on a disk, the current track, the current position within a track, and the length of the track, monitoring the current situation using the timer.

In general, if you can, use the `tfTMSF` value (Track, Minute, Second, Frame) for the `TimeFormat` property of the Media Player component to access positional properties (such as `Position` and `Length`). Extracting the values is not too complex if you use the proper functions of the MmSystem unit, such as the following:

```
CurrentTrack := Mci_TMSF_Track (MediaPlayer1.Position);
```

Here are the two functions that compute the values for the whole disk and for the current track:

```
procedure TForm1.CheckDisk;
var
  NTracks, NLen: Integer;
begin
  NTracks := MediaPlayer1.Tracks;
  NLen := MediaPlayer1.Length;
  DiskLabel.Caption := Format (
    'Tracks: %.2d, Length:%.2d:%.2d', [NTracks,
    Mci_TMSF_Minute (NLen), Mci_TMSF_Second (NLen)]);
  SpinEdit1.MaxValue := NTracks;
end;

procedure TForm1.CheckPosition;
var
  CurrentTrack, CurrentPos, TrackLen: Integer;
begin
  CurrentPos := MediaPlayer1.Position;
  CurPosLabel.Caption := Format ('Position: %.2d:%.2d',
    [Mci_TMSF_Minute (CurrentPos),
    Mci_TMSF_Second (CurrentPos)]);
  CurrentTrack := Mci_TMSF_Track (CurrentPos);
  TrackLen := MediaPlayer1.TrackLength [CurrentTrack];
  TrackNumberLabel.Caption := Format (
    'Current track: %.2d, Length:%.2d:%.2d', [CurrentTrack,
    Mci_MSF_Minute (TrackLen), Mci_MSF_Second (TrackLen)]);
end;
```

The code seems complex only because of the many conversions it makes. Notice in particular that the length of the current track (stored in the `TrackLength` property) is not measured using the default format, as the online help suggests, but with the `MSF` (Minute Second Frame) format.

The global values for the disk are computed only at startup and when the New CD button is clicked:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  MediaPlayer1.TimeFormat := tfTMSF;
  MediaPlayer1.Open;
  CheckDisk;
  CheckPosition;
end;

procedure TForm1.NewButtonClick(Sender: TObject);
begin
  CheckDisk;
  CheckPosition;
end;
```

The values for the current track and position are computed this way each time the timer interval elapses, by calling the `CheckPosition` method. This is far from perfect, because if you want to play an audio CD while using other programs, a timer accessing the Media Player information often slows down the system too much. Of course, this mainly depends on your hardware. Besides telling the user what is going on, the form has the Media Player component to allow the user to start and stop playing, change tracks, and so on. The operations on this component activate and halt the timer:

```
procedure TForm1.MediaPlayer1PostClick(
  Sender: TObject; Button: TMPBtnType);
begin
  if MediaPlayer1.Mode = mpPlaying then
    Timer1.Enabled := True
  else
    Timer1.Enabled := False;
  CheckPosition;
end;
```

You can also use the Go button to jump to the track selected in the SpinEdit component, where the `MaxValue` property is set by the `CheckDisk` method. Here is the code I've written:

```
procedure TForm1.GoButtonClick(Sender: TObject);
var
  Playing: Boolean;
begin
  Playing := (MediaPlayer1.Mode = mpPlaying);
  if Playing then
    MediaPlayer1.Stop;
  MediaPlayer1.Position :=
    MediaPlayer1.TrackPosition[SpinEdit1.Value];
  CheckPosition;
  if Playing then
    MediaPlayer1.Play;
end;
```

A good extension to this program would be to connect it to a CD database with the title of each CD you own and the title of each track. (I would have done that if it hadn't been for the time it would have taken to enter the title and track of each of my disks.) Remember, anyway, that a similar program is already available in Windows.

What's Next

In this chapter, we have seen how to add some audio and video capabilities to Delphi applications. We have seen how to add sound effects to respond to user actions. We have also seen examples of how to use the Media Player with sound files, video files, and an external device (an audio CD). With computers and CD-ROM players becoming faster every year, video is becoming an important feature of many applications. Don't underestimate this area of programming simply because you are writing *serious* business programs.

EPILOGUE

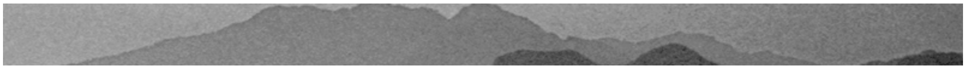
Delphi is a great programming environment. Now that you have learned about its core features, and seen the development of a number of programs, you might want to understand more about the language and fully master the internals of the VCL. This is where one of the books of the Mastering Delphi series I've written might help you. But you might also find more information in the other free e-books available on my web site.

As I mentioned in the Introduction, check the book page page, at

```
http://www.marcocantu.com/edelphi
```

for corrections and updates; the site has also links to other Delphi sites, documentation, simple wizards and components, and hosts also a newsgroup, which is the preferred way to report problems about this book (in the related section). It is possible to read the newsgroup also directly on the web from my site, and also sign-up to a mailing list in which I'll announce future edition of this and other volumes.

Again, as discussed in the introduction donations are welcome, also in the form of code examples, chapters for this and other books... but also offering cash, buying a printed book, or attending one of the Delphi classes I set up.



MASTERING™ DELPHI™ 6

Software License Agreement: Terms and Conditions

The media and/or any online materials accompanying this book that are available now or in the future contain programs and/or text files (the "Software") to be used in connection with the book. SYBEX hereby grants to you a license to use the Software, subject to the terms that follow. Your purchase, acceptance, or use of the Software will constitute your acceptance of such terms.

The Software compilation is the property of SYBEX unless otherwise indicated and is protected by copyright to SYBEX or other copyright owner(s) as indicated in the media files (the "Owner(s)"). You are hereby granted a single-user license to use the Software for your personal, noncommercial use only. You may not reproduce, sell, distribute, publish, circulate, or commercially exploit the Software, or any portion thereof, without the written consent of SYBEX and the specific copyright owner(s) of any component software included on this media.

In the event that the Software or components include specific license requirements or end-user agreements, statements of condition, disclaimers, limitations or warranties ("End-User License"), those End-User Licenses supersede the terms and conditions herein as to that particular Software component. Your purchase, acceptance, or use of the Software will constitute your acceptance of such End-User Licenses.

By purchase, use or acceptance of the Software you further agree to comply with all export laws and regulations of the United States as such laws and regulations may exist from time to time.

Reusable Code in This Book

The author created reusable code in this publication expressly for reuse for readers. Sybex grants readers permission to reuse for any purpose the code found in this publication or its accompanying CD-ROM so long as the author is attributed in any application containing the reusable code, and the code itself is never sold or commercially exploited as a stand-alone product.

Software Support

Components of the supplemental Software and any offers associated with them may be supported by the specific Owner(s) of that material but they are not supported by SYBEX. Information regarding any available support may be obtained from the Owner(s) using the information provided in the appropriate readme files or listed elsewhere on the media.

Should the manufacturer(s) or other Owner(s) cease to offer support or decline to honor any offer, SYBEX bears no responsibility. This notice concerning support for the Software is provided for your information only. SYBEX is not the agent or principal of the Owner(s), and SYBEX is in no way responsible for providing any support for the Software, nor is it liable or responsible for any support provided, or not provided, by the Owner(s).

Warranty

SYBEX warrants the enclosed media to be free of physical defects for a period of ninety (90) days after purchase. The Software is not available from SYBEX in any other form or media than that enclosed herein or posted to www.sybex.com. If you discover a defect in the media during this warranty period, you may obtain a replacement of identical format at no charge by sending the defective media, postage prepaid, with proof of purchase to:

SYBEX Inc.
Customer Service Department
1151 Marina Village Parkway
Alameda, CA 94501
(510) 523-8233
Fax: (510) 523-2373
e-mail: info@sybex.com
WEB: HTTP://WWW.SYBEX.COM

After the 90-day period, you can obtain replacement media of identical format by sending us the defective disk, proof of purchase, and a check or money order for $10, payable to SYBEX.

Disclaimer

SYBEX makes no warranty or representation, either expressed or implied, with respect to the Software or its contents, quality, performance, merchantability, or fitness for a particular purpose. In no event will SYBEX, its distributors, or dealers be liable to you or any other party for direct, indirect, special, incidental, consequential, or other damages arising out of the use of or inability to use the Software or its contents even if advised of the possibility of such damage. In the event that the Software includes an online update feature, SYBEX further disclaims any obligation to provide this feature for any specific duration other than the initial posting.

The exclusion of implied warranties is not permitted by some states. Therefore, the above exclusion may not apply to you. This warranty provides you with specific legal rights; there may be other rights that you may have that vary from state to state. The pricing of the book with the Software by SYBEX reflects the allocation of risk and limitations on liability contained in this agreement of Terms and Conditions.

Shareware Distribution

This Software may contain various programs that are distributed as shareware. Copyright laws apply to both shareware and ordinary commercial software, and the copyright Owner(s) retains all rights. If you try a shareware program and continue using it, you are expected to register it. Individual programs differ on details of trial periods, registration, and payment. Please observe the requirements stated in appropriate files.

Copy Protection

The Software in whole or in part may or may not be copy-protected or encrypted. However, in all cases, reselling or redistributing these files without authorization is expressly forbidden except as specifically provided for by the Owner(s) therein.

To Lella, the love of my life,
and Benedetta, our love come to life.

Acknowledgments

This edition of *Mastering Delphi* marks the seventh year of the Delphi era, as it took Borland two years to release the latest incarnation of Delphi (along with its Linux twin, Kylix). As it has for many other programmers, Delphi has been my primary interest throughout these years; and writing, consulting, teaching, and speaking at conferences about Delphi have absorbed more and more of my time, leaving other languages and programming tools in the dust of my office. Because my work and my life are quite intertwined, many people have been involved in both, and I wish I had enough space and time to thank them all as they deserve. Instead, I'll just mention a few particular people and say a warm "Thank You" to the entire Delphi community (especially for the Spirit of Delphi 1999 Award I've been happy to share with Bob Swart).

The first official thanks are for the Borland programmers and managers who made Delphi possible and continue to improve it: Chuck Jazdzewski, Danny Thorpe, Eddie Churchill, Allen Bauer, Steve Todd, Mark Edington, Jim Tierney, Ravi Kumar, Jörg Weingarten, Anders Ohlsson, and all the others I have not had a chance to meet. I'd also like to give particular mention to my friends Ben Riga (the current Delphi product manager), John Kaster and David Intersimone (at Borland's Developer Relations), and others who have worked at Borland, including Charlie Calvert, Zack Urlocker and Nan Borreson.

The next thanks are for the Sybex editorial and production crew, many of whom I don't even know. Special thanks go to Pete Gaughan, Leslie Light, Denise Santoro Lincoln, and Diane Lowery; I'd also like to thank Richard Mills, Kristine O'Callaghan, and Kris Warrenburg.

This edition of *Mastering Delphi* has once again had an incredibly picky and detailed review from Delphi R&D team member Danny Thorpe. His highlights and comments in this and past editions have improved the book in all areas: technical content, accuracy, examples, and even readability. Thanks a lot. Previous editions also had special contributions: Tim Gooch worked on Part V for *Mastering Delphi 4*, and Giuseppe Madaffari contributed database material for the Delphi 5 edition. For this edition, Guy Smith-Ferrier rewrote the chapter on ADO, and Nando Dessena helped me with the InterBase chapter. Many improvements to the text and sample programs were suggested by technical reviewers of past editions (Juancarlo Añez, Ralph Friedman, Tim Gooch, and Alain Tadros) and in other reviews over the years by Bob Swart, Giuseppe Madaffari, and Steve Tendon.

Special thanks go to my friends Bruce Eckel, Andrea Provaglio, Norm McIntosh, Johanna and Phil of the BUG-UK, Ray Konopka, Mark Miller, Cary Jensen, Chris Frizelle of *The Delphi Magazine*, Foo Say How, John Howe, Mike Orriss, Chad "Kudzu" Hower, Dan Miser, Marco Miotti, and the entire D&D Team (Paolo, Andrea, Uberto, Nando, Giuseppe, and Mr. Coke). Also, a very big "Thank You" to all the attendees of my Delphi programming courses, seminars, and conferences in Italy, the United States, France, the United Kingdom, Singapore, the Netherlands, Germany, Sweden…

My biggest thanks go to my wife Lella who had to endure yet another many-months-long book-writing session and too many late nights (after spending the evenings with our daughter, Benedetta—I'll thank her with a hug, as Daddy's book looks quite boring to her). Many of our friends (and their kids) provided healthy breaks in the work: Sandro and Monica with Luca, Stefano and Elena, Marco and Laura with Matteo, Bianca, Luca and Elena with Tommaso, Chiara and Daniele with Leonardo, Laura, Vito and Marika with Sofia. Our parents, brothers, sisters, and their families were very supportive, too. It was nice to spend some of our free time with them and our six nephews—Matteo, Andrea, Giacomo, Stefano, Andrea, and Pietro.

Finally, I would like to thank all of the people, many of them unknown, who enjoy life and help to build a better world. If I never stop believing in the future and in peace, it is also because of them.

Introduction

The first time Zack Urlocker showed me a yet-to-be-released product code-named Delphi, I realized that it would change my work—and the work of many other software developers. I used to struggle with C++ libraries for Windows, and Delphi was and still is the best combination of object-oriented programming and visual programming for Windows.

Delphi 6 simply builds on this tradition and on the solid foundations of the VCL to deliver another astonishing and all-encompassing software development tool. Looking for database, client/server, multitier, intranet, or Internet solutions? Looking for control and power? Looking for fast productivity? With Delphi 6 and the plethora of techniques and tips presented in this book, you'll be able to accomplish all this.

Six Versions and Counting

Some of the original Delphi features that attracted me were its form-based and object-oriented approach, its extremely fast compiler, its great database support, its close integration with Windows programming, and its component technology. But the most important element was the Object Pascal language, which is the foundation of everything else.

Delphi 2 was even better! Among its most important additions were these: the Multi-Record Object and the improved database grid, OLE Automation support and the variant data type, full Windows 95 support and integration, the long string data type, and Visual Form Inheritance. Delphi 3 added to this the code insight technology, DLL debugging support, component templates, the TeeChart, the Decision Cube, the WebBroker technology, component packages, ActiveForms, and an astonishing integration with COM, thanks to interfaces.

Delphi 4 gave us the AppBrowser editor, new Windows 98 features, improved OLE and COM support, extended database components, and many additions to the core VCL classes, including support for docking, constraining, and anchoring controls. Delphi 5 added to the picture many more improvements of the IDE (too many to list here), extended database support (with specific ADO and InterBase datasets), an improved version of MIDAS with Internet support, the TeamSource version-control tool, translation capabilities, the concept of frames, and new components.

Now Delphi 6 adds to all these features support for cross-platform development with the new Component Library for Cross-Platform (CLX), an extended run-time library, the new dbExpress database engine, Web services and exceptional XML support, a powerful Web development framework, more IDE enhancements, and a plethora of new components and classes, as you'll see in the following pages.

Delphi is a great tool, but it is also a complex programming environment that involves many elements. This book will help you master Delphi programming, including the Object Pascal language, Delphi components (both using the existing ones and developing your own), database and client/server support, the key elements of Windows and COM programming, and Internet and Web development.

You do not need in-depth knowledge of any of these topics to read this book, but you do need to know the basics of Pascal programming. Having some familiarity with Delphi will help you considerably, particularly after the introductory chapters. The book starts covering its topics in depth immediately; much of the introductory material from previous editions has been removed. Some of this material and an introduction to Pascal is available on the companion CD-ROM and on my Web site and can be a starting point if you are not confident with Delphi basics. Each new Delphi 6 feature is covered in the relevant chapters throughout the book.

The Structure of the Book

The book is divided into four parts:

- Part I, "Foundations," introduces new features of the Delphi 6 Integrated Development Environment (IDE) in Chapter 1, then moves to the Object Pascal language and to the run-time library (RTL) and Visual Component Library (VCL), providing both foundations and advanced tips.
- Part II, "Visual Programming," covers standard components, Windows common controls, graphics, menus, dialogs, scrolling, docking, multipage controls, Multiple Document Interface, the Action List and Action Manager architectures, and many other topics. The focus is on both the VCL and CLX libraries. The final chapters discuss the development of custom components and the use of libraries and packages.
- Part III, "Database Programming," covers plain database access, in-depth coverage of the data-aware controls, client/server programming, dbExpress, InterBase, ADO and dbGo, DataSnap (or MIDAS), and the development of custom data-aware controls and data sets.

- Part IV, “Beyond Delphi: Connecting with the World,” first discusses COM, OLE Automation, and COM+. Then it moves to Internet programming, covering TCP/IP sockets, Internet protocols and Indy, Web server-side extensions (with WebBroker and WebSnap), XML, and the development of Web services.

As this brief summary suggests, the book covers topics of interest to Delphi users at nearly all levels of programming expertise, from “advanced beginners” to component developers.

In this book, I’ve tried to skip reference material almost completely and focus instead on techniques for using Delphi effectively. Because Delphi provides extensive online documentation, to include lists of methods and properties of components in the book would not only be superfluous, it would also make it obsolete as soon as the software changes slightly. I suggest that you read this book with the Delphi Help files at hand, to have reference material readily available.

However, I’ve done my best to allow you to read the book away from a computer if you prefer. Screen images and the key portions of the listings should help in this direction. The book uses just a few conventions to make it more readable. All the source code elements, such as keywords, properties, classes, and functions, appear in `this font`, and code excerpts are formatted as they appear in the Delphi editor, with boldfaced keywords and italic comments and strings.

Free Source Code on CD (and the Web)

This book focuses on examples. After the presentation of each concept or Delphi component, you’ll find a working program example (sometimes more than one) that demonstrates how the feature can be used. All told, there are about 300 examples presented in the book. These programs are directly available on the companion CD-ROM. The same material is also available on my Web site (`www.marcocantu.com`), where you’ll also find updates and examples from past editions. Inside the back cover of the book, you’ll find more information about the CD. Most of the examples are quite simple and focus on a single feature. More complex examples are often built step-by-step, with intermediate steps including partial solutions and incremental improvements.

NOTE Some of the database examples also require you to have the Delphi sample database DBDEMOS installed; it is part of the default Delphi installation. Others require the InterBase EMPLOYEE sample database.

Beside the source code files, the CD hosts the ready-to-use compiled programs. There is also an HTML version of the source code, with full syntax highlighting, along with a complete cross-reference of keywords and identifiers (class, function, method, and property names, among others). The cross-reference is an HTML file, so you'll be able to use your browser to easily find all the programs that use a Delphi keyword or identifier you're looking for (not a full search engine, but close enough).

The directory structure of the sample code is quite simple. Basically, each chapter of the book has its own folder, with a subfolder for each example (e.g., `06\Borders`). In the text, the examples are simply referenced by name (e.g., Borders).

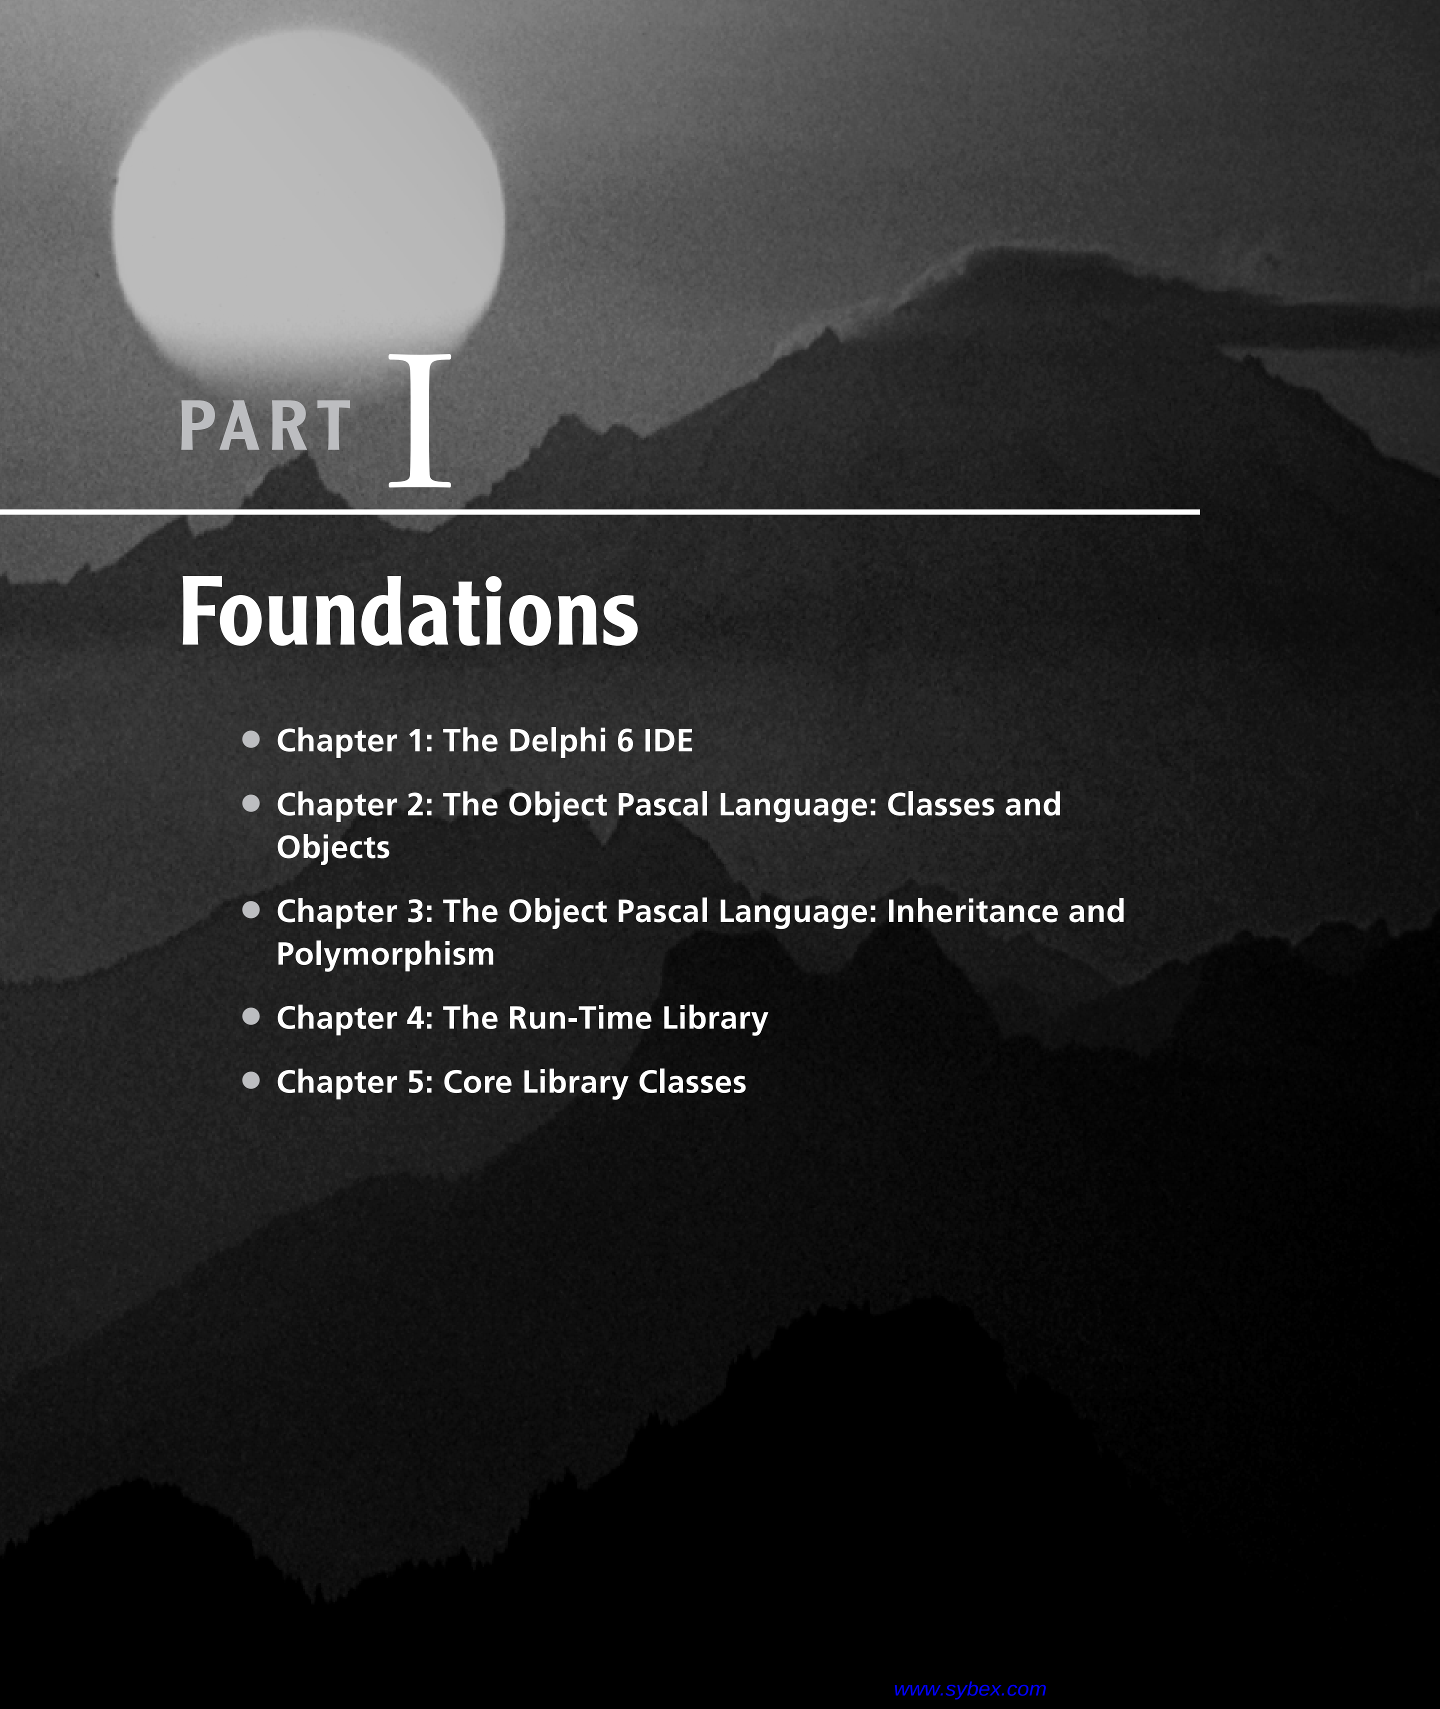
TIP To change an example, first copy it (or the entire `md6code` folder) to your hard disk, but before opening it remember to set the read-only flag to False (it is True by default on the read-only media)

NOTE Be sure to read the source code archive's Readme file, which contains important information about using the software legally and effectively.

How to Reach the Author

If you find any problems in the text or examples in this book, both the publisher and I would be happy to hear from you. Besides reporting errors and problems, please give us your unbiased opinion of the book and tell us which examples you found most useful and which you liked least. There are several ways you can provide this feedback:

- On the Sybex Web site (`www.sybex.com`), you'll find updates to the text or code as necessary. To comment on this book, click the Contact Sybex link and then choose Book Content Issues. This link displays a form where you can enter your comments.
- My own Web site (`www.marcocantu.com`) hosts further information about the book and about Delphi, where you might find answers to your questions. The site has news and tips, technical articles, free online books, white papers, Delphi links, and my collection of Delphi components and tools.
- I have also set up a newsgroup section specifically devoted to my books and to general Delphi Q&A. Refer to my Web site for a list of the newsgroup areas and for the instructions to subscribe to them. (In fact, these newsgroups are totally free but require a login password.) The newsgroups can also be accessed via a Web interface you can find on my site.
- Finally, you can reach me via e-mail at `marco@marcocantu.com`. For technical questions, please try using the newsgroups first, as you might get answers earlier and from multiple people. My mailbox is usually quite full and, regretfully, I cannot reply promptly to every request. (Please write to me in English or Italian.)



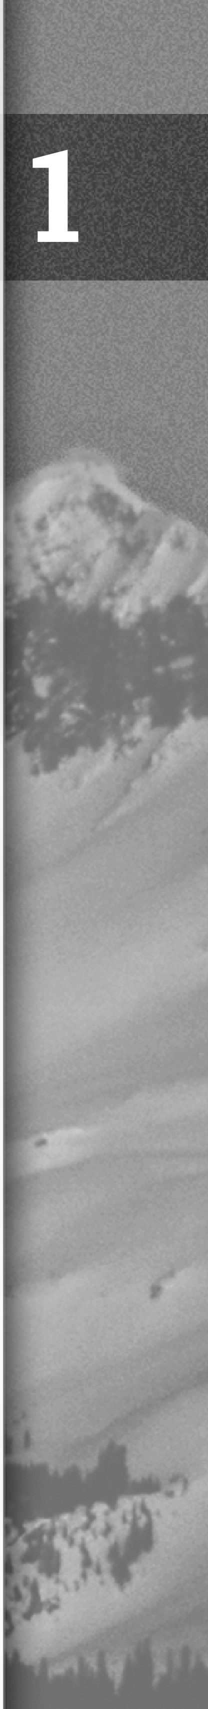
PART I

Foundations

- Chapter 1: The Delphi 6 IDE
- Chapter 2: The Object Pascal Language: Classes and Objects
- Chapter 3: The Object Pascal Language: Inheritance and Polymorphism
- Chapter 4: The Run-Time Library
- Chapter 5: Core Library Classes

CHAPTER 1

The Delphi 6 IDE



- Object TreeView and Designer view
- The AppBrowser editor
- The code insight technology
- Designing forms
- The Project Manager
- Delphi files

In a visual programming tool such as Delphi, the role of the environment is at times even more important than the programming language. Delphi 6 provides many new features in its visual development environment, and this chapter covers them in detail. This chapter isn't a complete tutorial but mainly a collection of tips and suggestions aimed at the average Delphi user. In other words, it's not for newcomers. I'll be covering the new features of the Delphi 6 Integrated Development Environment (IDE) and some of the advanced and little-known features of previous versions as well, but in this chapter I won't provide a step-by-step introduction. Throughout this book, I'll assume you already know how to carry out the basic hands-on operations of the IDE, and all the chapters after this one focus on programming issues and techniques.

If you *are* a beginning programmer, don't be afraid. The Delphi Integrated Development Environment is quite intuitive to use. Delphi itself includes a manual (available in Acrobat format on the Delphi CD) with a tutorial that introduces the development of Delphi applications. You can also find a step-by-step introduction to the Delphi IDE on my Web site, **`http://www.marcocantu.com`**. The short online book *Essential Delphi* is based on material from the first chapters of earlier editions of *Mastering Delphi*.

Editions of Delphi 6

Before delving into the details of the Delphi programming environment, let's take a side step to underline two key ideas. First, there isn't a single edition of Delphi; there are many of them. Second, any Delphi environment can be customized. For these reasons, Delphi screens you see illustrated in this chapter may differ from those on your own computer. Here are the current editions of Delphi:

- The "Personal" edition is aimed at Delphi newcomers and casual programmers and has support for neither database programming nor any of the other advanced features of Delphi 6.
- The "Professional" edition is aimed at professional developers. It includes all the basic features, plus database programming support (including ADO support), basic Web server support (WebBroker), and some of the external tools. This book generally assumes you are working with at least the Professional edition.
- The "Enterprise" edition is aimed at developers building enterprise applications. It includes all the new XML and advanced Web services technologies, internationalization, three-tier architecture, and many other tools. Some chapters of this book cover features included only in Delphi Enterprise; these sections are specifically identified.

NOTE In the past, some of the features of Delphi Enterprise have been available as an "up-sell" to owners of Delphi Professional. This might also happen for this version.

Besides the different editions available, there are ways to customize the Delphi environment. In the screen illustrations throughout the book, I've tried to use a standard user interface (as it comes out of the box); however, I have my preferences, of course, and I generally install many add-ons, which might be reflected in some of the screen shots.

The Delphi 6 IDE

The Delphi 6 IDE includes large and small changes that will really improve a programmer's productivity. Among the key features are the introduction of the Object TreeView for every designer, an improved Object Inspector, extended code completion, and loadable views, including diagrams and HTML.

Most of the features are quite easy to grasp, but it's worth examining them with some care so that you can start using Delphi 6 at its full potential right away. You can see an overall image of Delphi 6 IDE, highlighting some of the new features, in Figure 1.1.

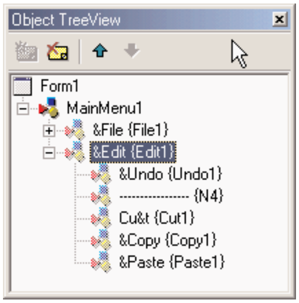
The Object TreeView

Delphi 5 introduced a TreeView for data modules, where you could see the relations among nonvisual components, such as datasets, fields, actions, and so on. Delphi 6 extends the idea by providing an Object TreeView for every designer, including plain forms. The Object TreeView is placed by default above the Object Inspector; use the View ➢ Object TreeView command in case it is hidden.

The Object TreeView shows all of the components and objects on the form in a tree, representing their relations. The most obvious is the parent/child relation: Place a panel on a form, a button inside it and one outside of the panel. The tree will show the two buttons, one under the form and the other under the panel, as in Figure 1.1. Notice that the TreeView is synchronized with the Object Inspector and Form Designer, so as you select an item and change the focus in any one of these three tools, the focus changes in the other two tools.

Besides parent/child, the Object TreeView shows also other relations, such as owner/owned, component/subobject, collection/item, plus various specific ones, including dataset/connection and data source/dataset relations. Here, you can see an example of the structure of a menu in the tree.



```
Object TreeView
Form1
  MainMenu1
    &File {File1}
    &Edit {Edit1}
      &Undo {Undo1}
      --------------- {N4}
      Cu&t {Cut1}
      &Copy {Copy1}
      &Paste {Paste1}
```

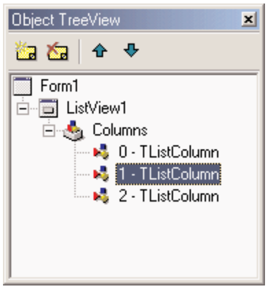
At times, the TreeView also displays “dummy” nodes, which do not correspond to an actual object but do correspond to a predefined one. As an example of this behavior, drop a Table component (from the BDE page) and you’ll see two grayed icons for the session and the alias. Technically, the Object TreeView uses gray icons for components that do not have design-time persistence. They are real components (at design time and at run time), but because they are default objects that are constructed at run time and have no persistent data that can be edited at design time, the Data Module Designer does not allow you to edit their properties. If you drop a Table on the form, you’ll also see items with a red question mark enclosed in a yellow circle next to them. This symbol indicates partially undefined items (there used to be a red square around those items in Delphi 5).

The Object TreeView supports multiple types of *dragging*:

- You can select a component from the palette (by clicking it, not actually dragging it), move the mouse over the tree, and click a component to drop it there. This allows you to drop a component in the proper container (form, panel, and others) regardless of the fact that its surface might be totally covered by other components, something that prevents you from dropping the component in the designer without first rearranging those components.
- You can drag components within the TreeView—for example, moving a component from one container to another—something that, with the Form Designer, you can do only with cut and paste techniques. Moving instead of cutting provides the advantage that if you have connections among components, these are not lost, as happens when you delete the component during the cut operation.
- You can drag components from the TreeView to the Diagram view, as we'll see later.

Right-clicking any element of the TreeView displays a shortcut menu similar to the component menu you get when the component is in a form (and in both cases, the shortcut menu may include items related to the custom component editors). You can even delete items from the tree.

The TreeView doubles also as a collection editor, as you can see here for the `Columns` property of a ListView control. In this case, you can not only rearrange and delete items, but also add new items to the collection.



TIP You can print the contents of the Object TreeView for documentation purposes. Simply select the window and use the File ➢ Print command, as there is no Print command in the shortcut menu.

Loadable Views

Another important change has taken place in the Code Editor window. For any single file loaded in the IDE, the editor can now show multiple views, and these views can be defined programmatically and added to the system, then loaded for given files—hence the name *loadable* views.

The most frequently used view is the Diagram page, which was already available in Delphi 5 data modules, although it was less powerful. Another set of views is available in Web applications, including an HTML Script view, an HTML Result preview, and many others discussed in Chapter 22.

The Diagram View

Along with the TreeView, another feature originally introduced in Delphi 5 Data Modules and now available for every designer is the Diagram view. This view shows dependencies among components, including parent/child relations, ownership, linked properties, and generic relations. For dataset components, it also supports master/detail relations and lookup connections. You can even add your comments in text blocks linked to specific components.

The Diagram is not built automatically. You must drag components from the TreeView to the diagram, which will automatically display the existing relations among the components you drop there. In Delphi 6, you can now select multiple items from the Object TreeView and drag them all at once to the Diagram page.

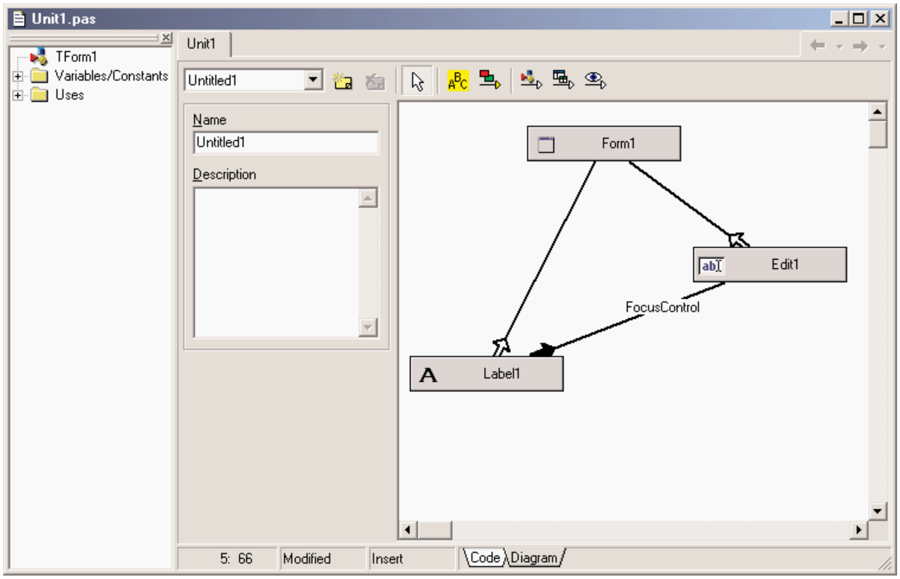
What's nice is that you can set properties by simply drawing arrows between the components. For example, after moving an edit and a label to Diagram, you can select the Property Connector icon, click the label, and drag the mouse cursor over the edit. When you release the mouse button, the Diagram will set up a property relation based on the `FocusControl` property, which is the only property of the label referring to an edit control. This situation is depicted in Figure 1.2.

As you can see, setting properties is *directional*: If you drag the property relation line from the edit to the label, you end up trying to use the label as the value of a property of the edit box. Because this isn't possible, you'll see an error message indicating the problem and offering to connect the components in the opposite way.

In Delphi 6, the Diagram view allows you to create multiple diagrams for each Delphi unit—that is, for each form or data module. Simply give a name to the diagram and possibly add a description, click the New Diagram button, prepare another diagram, and you'll be able to switch back and forth between diagrams using the combo box available in the toolbar of the Diagram view.

FIGURE 1.2:

The Diagram view allows you to connect components using the Property connector.



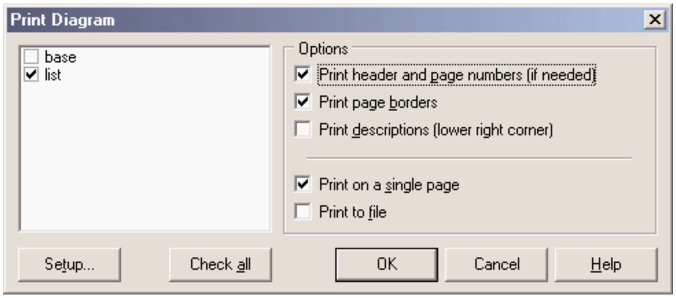
Name: Untitled1

Description:

Although you can use the Diagram view to set up relations, its main role is to document your design. For this reason, it is important to be able to print the content of this view. Using the standard File ➢ Print command while the Diagram is active, Delphi prompts you for options, as you can see in Figure 1.3, allowing you to customize the output in many ways.

FIGURE 1.3:

The Print Options for the Diagram view



Print Diagram

- □ base
- ☑ list

Options

- ☑ Print header and page numbers (if needed)
- ☑ Print page borders
- □ Print descriptions (lower right corner)
- ☑ Print on a single page
- □ Print to file

The information in the Data Diagram view is saved in a separate file, not as part of the DFM file. Delphi 5 used design-time information (DTI) files, which had a structure similar to INI files. Delphi 6 can still read the older .DTI format, but uses the new Delphi Diagram Portfolio format (.DDP). These files apparently use the DFM binary format (or a similar one), so they are not editable as text. All of these files are obviously useless at run time (it makes no sense to include them in the compilation of the executable file).

An IDE for Two Libraries

Another very important change I just want to introduce here is the fact that Delphi 6, for the first time, allows you to use to different component libraries, VCL (Visual Components Library) and CLX (Component Library for Cross-Platform). When you create a new project, you simply choose which of the two libraries you want to use, starting with the File ➢ New ➢ Application command for a classic VCL-based Windows program and with the File ➢ New ➢ CLX Application command for a new CLX-based portable application.

Creating a new project or opening an existing one, the Component Palette is rearranged to show only the controls related to the current library (although most of them are actually shared). This topic is fully covered in Chapter 6, so I don't want to get into the details here; I'll just underline that you can use Delphi 6 to build applications you can compile right away for Linux using Kylix. The effect of this change on the IDE is really quite large, as many things "under the hood" had to be reengineered. Only programmers using the ToolsAPI and other advanced elements will notice all these internal differences, as they are mostly transparent to most users.

Smaller Enhancements

Besides this important change and others I'll discuss in later sections, such as the update of the Object Inspector and of code completion, there are small (but still quite important) changes in the Delphi 6 IDE. Here is a list of these changes:

- There is a new Window menu in the IDE. This menu lists the open windows, something you could obtain in the past using the Alt+0 keys. This is really very handy, as windows often end up behind others and are hard to find. (Thanks, Borland, for listening to this and other simple but effective requests from users.)

TIP Two entries of the Main Window registry section of Delphi (under `\Software\Borland\Delphi\6.0` for the current user) allow you to hide this menu and disable its alphabetic sort order. This registry keys use strings (in place of Boolean values) where "-1" indicates true and "0" false.

- The File menu doesn't include specific items for creating new forms or applications. These commands have been increased in number and grouped under the File ➢ New secondary menu. The Other command of this menu opens the New Item dialog box (the Object Repository) as the File ➢ New command did in the past.
- The Component Palette local menu has a submenu listing all of the palette pages in alphabetic order. You can use it to change the active page, particularly when it is not visible on the screen.

TIP

The order of the entries in the Tabs submenu of the Component Palette local menu can be set in the same order as the palette itself, and not sorted alphabetically. This is accomplished by setting to "0" (false) the value of the Sort Palette Tabs Menu key of the Main Window registry section of Delphi (under `\Software\Borland\Delphi\6.0` for the current user).

- There is a new toolbar, the Internet toolbar, which is initially disabled. This toolbar supports WebSnap applications.

Updated Environment Options Dialog Box

Quite a few small changes relate to the commonly used Environment Options dialog box. The pages of this dialog box have been rearranged, moving the Form Designer options from the Preferences page to the new Designer page. There are also a few new options and pages:

- The Preferences page of the Environment Options dialog box has a new check box that prevents Delphi windows from automatically docking with each other. This is a very welcome addition!
- A new page, Environment Variables, allows you to see system environment variables (such as the standard path names and OS settings) and set user-defined variables. The nice point is that you can use both system- and user-defined environment variables in each of the dialog boxes of the IDE—for example, you can avoid hard-coding commonly used path names, replacing them with a variable. In other words, the environment variables work similarly to the $DELPHI variable, referring to Delphi's base directory, but can be defined by the user.
- Another new page is called Internet. In this page, you can choose the default file extensions used for HTML and XML files (mainly by the WebSnap framework) and also associate an external editor with each extension.

Delphi Extreme Toys

At times, the Delphi team comes up with small enhancements of the IDE that aren't included in the product because they either aren't of general use or will require time to be improved in quality, user interface, or robustness. Some of these internal wizards and IDE extensions have now been made available, with the collective name of Delphi Extreme Toys, to registered Delphi 6 users. You should automatically get this add-on as you register your copy of the product (online or through a Borland office).

There isn't an official list of the content of the Extreme Toys, as Borland plans to keep extending them. The initial release includes an IDE-based search engine for seeking answers on Delphi across the Internet, a wizard for turning on and off specific compiler warnings, and an “invokamatic” wizard for accelerating the creation of Web services. The Extreme Toys will, in essence, be *unofficial* wizards, code utilities, and components from the Delphi team—or useful stuff from various people.

Recent IDE Additions

Delphi 5 provided a huge number of new features to the IDE. In case you’ve only used versions of Delphi prior to 5, or need to brush up on some useful added information, this is a short summary of the most important of the features introduced in Delphi 5.

Saving the Desktop Settings

The Delphi IDE allows programmers to customize it in various ways—typically, opening many windows, arranging them, and docking them to each other. However, programmers often need to open one set of windows at design time and a different set at debug time. Similarly, programmers might need one layout when working with forms and a completely different layout when writing components or low-level code using only the editor. Rearranging the IDE for each of these needs is a tedious task.

For this reason, Delphi allows you to save a given arrangement of IDE windows (called a *desktop*) with a name and restore it easily. Also, you can make one of these groupings your default debugging setting, so that it will be restored automatically when you start the debugger. All these features are available in the Desktops toolbar. You can also work with desktop settings using the View ➢ Desktops menu.

Desktop setting information is saved in DST files, which are INI files in disguise. The saved settings include the position of the main window, the Project Manager, the Alignment Palette, the Object Inspector (including its new property category settings), the editor windows (with the status of the Code Explorer and the Message View), and many others, plus the docking status of the various windows.

Here is a small excerpt from a DST file, which should be easily readable:

```
[Main Window]
Create=1
Visible=1
State=0
Left=0
Top=0
Width=1024
Height=105
ClientWidth=1016
ClientHeight=78
```

```
[ProjectManager]
Create=1
Visible=0
State=0
...
Dockable=1

[AlignmentPalette]
Create=1
Visible=0
...
```

Desktop settings override project settings. This helps eliminate the problem of moving a project between machines (or between developers) and having to rearrange the windows to your liking. Delphi 5 separates per-user and per-machine preferences from the project settings, to better support team development.

TIP

If you open Delphi and cannot see the form or other windows, I suggest you try checking (or deleting) the desktop settings. If the project desktop was last saved on a system running in a high-resolution video mode (or a multimonitor configuration) and opened on a different system with lower screen resolution or fewer monitors, some of the windows in the project might be located off-screen on the lower-resolution system. The simplest ways to fix that are either to load your own named desktop configuration after opening the project, thus overriding the project desktop settings, or just delete the DST file that came with the project files.

The To-Do List

Another feature added in Delphi 5 was the to-do list. This is a list of tasks you still have to do to complete a project, a collection of notes for the programmer (or programmers, as this tool can be very handy in a team). While the idea is not new, the key concept of the to-do list in Delphi is that it works as a two-way tool.

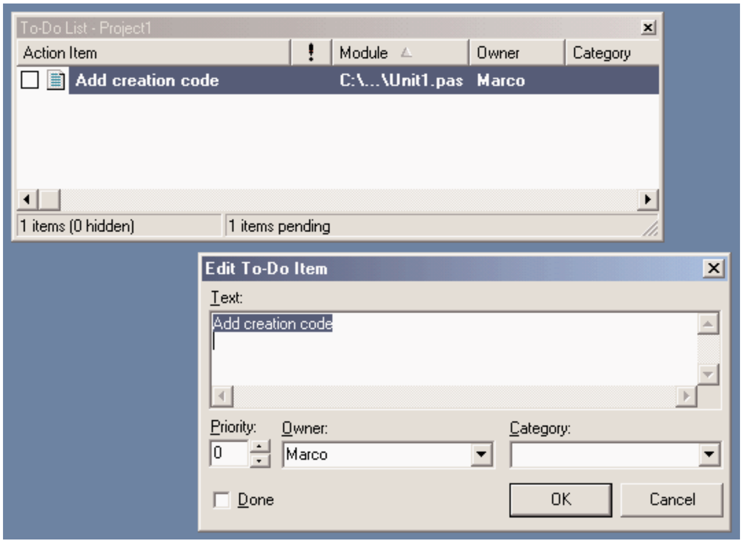
In fact, you can add or modify to-do items by adding special TODO comments to the source code of any file of a project; you'll then see the corresponding entries in the list. But you can also visually edit the items in the list to modify the corresponding source code comment. For example, here is how a to-do list item might look like in the source code:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  // TODO -oMarco: Add creation code
end;
```

The same item can be visually edited in the window shown in Figure 1.4.

FIGURE 1.4:

The Edit To-Do Item window can be used to modify a to-do item, an operation you can also do directly in the source code.



To-Do List - Project1

	Action Item	!	Module	Owner	Category
□	Add creation code		C:\...\Unit1.pas	Marco	

1 items (0 hidden) 1 items pending

Edit To-Do Item

Text: Add creation code

Priority: 0

Owner: Marco

Category:

□ Done

The exception to this two-way rule is the definition of project-wide to-do items. You must add these items directly to the list. To do that, you can either use the Ctrl+A key combination in the To-Do List window or right-click in the window and select Add from the shortcut menu. These items are saved in a special file with the .TODO extension.

You can use multiple options with a `TODO` comment. You can use `–o` (as in the code excerpt above) to indicate the owner, the programmer who entered the comment; the `–c` option to indicate a category; or simply a number from 1 to 5 to indicate the priority (0, or no number, indicates that no priority level is set). For example, using the Add To-Do Item command on the editor's shortcut menu (or the Ctrl+Shift+T shortcut) generated this comment:

```
{ TODO 2 -oMarco : Button pressed }
```

Delphi treats everything after the colon, up to the end of line or the closing brace, depending on the type of comment, as the text of the to-do item. Finally, in the To-Do List window you can check off an item to indicate that it has been done. The source code comment will change from `TODO` to `DONE`. You can also change the comment in the source code manually to see the check mark appear in the To-Do List window.

One of the most powerful elements of this architecture is the main To-Do List window, which can automatically collect to-do information from the source code files as you type them, sort and filter them, and export them to the Clipboard as plain text or an HTML table.

The AppBrowser Editor

The editor included with Delphi hasn't changed recently, but it has many features that many Delphi programmers don't know and use. It's worth briefly examining this tool. The Delphi editor allows you to work on several files at once, using a "notebook with tabs" metaphor, and you can also open multiple editor windows. You can jump from one page of the editor to the next by pressing Ctrl+Tab (or Shift+Ctrl+Tab to move in the opposite direction).

TIP In Delphi 6, you can drag-and-drop the tabs with the unit names in the upper portion of the editor to change their order, so that you can use a single Ctrl+Tab to move between the units you are mostly interested in. The local menu of the editor has also a Pages command, which lists all of the available pages in a submenu, a handy feature when many units are loaded.

Several options affect the editor, located in the new Editor Properties dialog box. You have to go to the Preferences page of the Environment Options dialog box, however, to set the editor's AutoSave feature, which saves the source code files each time you run the program (preventing data loss in case the program crashes badly).

I won't discuss the various settings of the editor, as they are quite intuitive and are described in the online Help. A tip to remember is that using the Cut and Paste commands is not the only way to move source code. You can also select and drag words, expressions, or entire lines of code. You can also copy text instead of moving it, by pressing the Ctrl key while dragging.

The Code Explorer

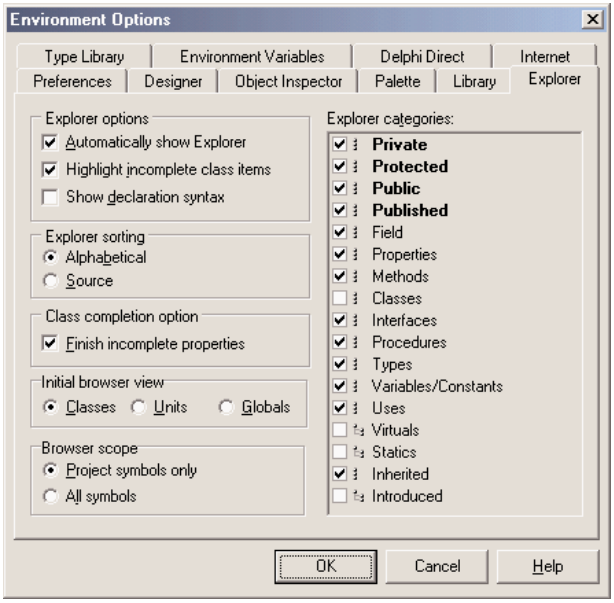
The Code Explorer window, which is generally docked on the side of the editor, simply lists all of the types, variables, and routines defined in a unit, plus other units appearing in `uses` statements. For complex types, such as classes, the Code Explorer can list detailed information, including a list of fields, properties, and methods. All the information is updated as soon as you start typing in the editor. You can use the Code Explorer to navigate in the editor. If you double-click one of the entries in the Code Explorer, the editor jumps to the corresponding declaration.

TIP In Delphi 6 you can modify variables, properties, and method names directly in the Code Explorer.

While all that is quite obvious after you've used Delphi for a few minutes, some features of the Code Explorer are not so intuitive. One important point is that you have full control of the layout of the information, and you can reduce the depth of the tree usually displayed in this window by customizing the Code Explorer. Collapsing the tree can help you make your selections more quickly. You can configure the Code Explorer by using the corresponding page of the Environment Options, as shown in Figure 1.5.

FIGURE 1.5:

You can configure the Code Explorer in the Environment Options dialog box.



Explorer options
☑ Automatically show Explorer
☑ Highlight incomplete class items
□ Show declaration syntax

Explorer sorting
● Alphabetical
○ Source

Class completion option
☑ Finish incomplete properties

Initial browser view
● Classes ○ Units ○ Globals

Browser scope
● Project symbols only
○ All symbols

Explorer categories:
☑ **Private**
☑ **Protected**
☑ **Public**
☑ **Published**
☑ Field
☑ Properties
☑ Methods
□ Classes
☑ Interfaces
☑ Procedures
☑ Types
☑ Variables/Constants
☑ Uses
□ Virtuals
□ Statics
☑ Inherited
□ Introduced

Notice that when you deselect one of the Explorer Categories items on the right side of this page of the dialog box, the Explorer doesn't remove the corresponding elements from view—it simply adds the node in the tree. For example, if you deselect the Uses check box, Delphi doesn't hide the list of the used units from the Code Explorer. On the contrary, the used units are listed as main nodes instead of being kept in the `Uses` folder. I generally disable the Types, Classes, and Variables selections.

Because each item of the Code Explorer tree has an icon marking its type, arranging by field and method seems less important than arranging by access specifier. My preference is to show all items in a single group, as this requires the fewest mouse clicks to reach each item. Selecting items in the Code Explorer, in fact, provides a very handy way of navigating the source code of a large unit. When you double-click a method in the Code Explorer, the focus moves to the definition in the class declaration (in the interface portion of the unit). You can use the Ctrl+Shift combination with the Up or Down arrow keys to jump from the definition of a method or procedure in the interface portion of a unit to its complete definition in the implementation portion (or back again).

NOTE Some of the Explorer Categories shown in Figure 1.5 are used by the Project Explorer, rather than by the Code Explorer. These include, among others, the Virtuals, Statics, Inherited, and Introduced grouping options.

Browsing in the Editor

Another feature of the AppBrowser editor is *Tooltip symbol insight*. Move the mouse over a symbol in the editor, and a Tooltip will show you where the identifier is declared. This feature can be particularly important for tracking identifiers, classes, and functions within an application you are writing, and also for referring to the source code of the Visual Component Library (VCL).

WARNING Although it may seem a good idea at first, you cannot use Tooltip symbol insight to find out which unit declares an identifier you want to use. If the corresponding unit is not already included, in fact, the Tooltip won't appear.

The real bonus of this feature, however, is that you can turn it into a navigational aid. When you hold down the Ctrl key and move the mouse over the identifier, Delphi creates an active link to the definition instead of showing the Tooltip. These links are displayed with the blue color and underline style that are typical of Web browsers, and the pointer changes to a hand whenever it's positioned on the link.

For example, you can Ctrl+click the `TLabel` identifier to open its definition in the VCL source code. As you select references, the editor keeps track of the various positions you've jumped to, and you can move backward and forward among them—again as in a Web browser. You can also click the drop-down arrows near the Back and Forward buttons to view a detailed list of the lines of the source code files you've already jumped to, for more control over the backward and forward movement.

How can you jump directly to the VCL source code if it is not part of your project? The AppBrowser editor can find not only the units in the Search path (which are compiled as part of the project), but also those in Delphi's Debug Source, Browsing, and Library paths. These directories are searched in the order I've just listed, and you can set them in the Directories/Conditionals page of the Project Options dialog box and in the Library page of the Environment Options dialog box. By default, Delphi adds the VCL source code directories in the Browsing path of the environment.

Class Completion

The third important feature of Delphi's AppBrowser editor is *class completion*, activated by pressing the Ctrl+Shift+C key combination. Adding an event handler to an application is a fast operation, as Delphi automatically adds the declaration of a new method to handle the event in the class and provides you with the skeleton of the method in the implementation portion of the unit. This is part of Delphi's support for visual programming.

Newer versions of Delphi also simplify life in a similar way for programmers who write a little extra code behind event handlers. The new code-generation feature, in fact, applies to general methods, message-handling methods, and properties. For example, if you type the following code in the class declaration:

```
public
  procedure Hello (MessageText: string);
```

and then press Ctrl+Shift+C, Delphi will provide you with the definition of the method in the implementation section of the unit, generating the following lines of code:

```
{ TForm1 }
procedure TForm1.Hello(MessageText: string);
begin
end;
```

This is really handy, compared with the traditional approach of many Delphi programmers, which is to copy and paste one or more declarations, add the class names, and finally duplicate the `begin...end` code for every method copied.

Class completion can also work the other way around. You can write the implementation of the method with its code directly, and then press Ctrl+Shift+C to generate the required entry in the class declaration.

Code Insight

Besides the Code Explorer, class completion, and the navigational features, the Delphi editor supports the *code insight* technology. Collectively, the code insight techniques are based on a constant background parsing, both of the source code you write and of the source code of the system units your source code refers to.

Code insight comprises five capabilities: code completion, code templates, code parameters, Tooltip expression evaluation, and Tooltip symbol insight. This last feature was already covered in the section "Browsing in the Editor"; the other four will be discussed in the following subsections. You can enable, disable, and configure each of these features in the Code Insight page of the Editor Options dialog box.

Code Completion

Code completion allows you to choose the property or method of an object simply by looking it up on a list or by typing its initial letters. To activate this list, you just type the name of an object, such as `Button1`, then add the dot, and wait. To force the display of the list, press Ctrl+spacebar; to remove it when you don't want it, press Esc. Code completion also lets you look for a proper value in an assignment statement.

In Delphi 6, as you start typing, the list filters its content according to the initial portion of the element you've inserted. The code completion list uses colors and shows more details to help you distinguish different items. Another new feature is that in the case of functions with parameters, parentheses are included in the generated code, and the parameters list hint is displayed immediately.

As you type `:=` after a variable or property, Delphi will list all the other variables or objects of the same type, plus the objects having properties of that type. While the list is visible, you can right-click it to change the order of the items, sorting either by scope or by name, and you can also resize the window.

In Delphi 6, code completion also works in the interface section of a unit. If you press Ctrl+spacebar while the cursor is inside the class definition, you'll get a list of: virtual methods you can override (including abstract methods), the methods of implemented interfaces, the base class properties, and eventually system messages you can handle. Simply selecting one of them will add the proper method to the class declaration. In this particular case, the code completion list allows multiple selection.

TIP

When the code you've written is incorrect, code insight won't work, and you may see just a generic error message indicating the situation. It is possible to display specific code insight errors in the Message pane (which must already be open; it doesn't open automatically to display compilation errors). To activate this feature, you need to set an undocumented registry entry, setting the string key `\Delphi\6.0\Compiling\ShowCodeInsiteErrors` to the value '1'.

There are advanced features of Delphi 6 code completion that aren't easy to spot. One that I found particularly useful relates to the discovery of symbols in units not used by your project. As you invoke it (with Ctrl+spacebar) over a blank line, the list also includes symbols from common units (such as Math, StrUtils, and DateUtils) not already included in the `uses` statement of the current one. By selecting one of these *external* symbols, Delphi adds the unit to the `uses` statement for you. This feature (which doesn't work inside expressions) is driven by a customizable list of extra units, stored in the registry key `\Delphi\6.0\CodeCompletion\ExtraUnits`.

Code Templates

Code templates allow you to insert one of the predefined code templates, such as a complex statement with an inner begin...end block. Code templates must be activated manually, by typing Ctrl+J to show a list of all of the templates. If you type a few letters (such as a keyword) before pressing Ctrl+J, Delphi will list only the templates starting with those letters.

You can add your own custom code templates, so that you can build your own shortcuts for commonly used blocks of code. For example, if you use the MessageDlg function often, you might want to add a template for it. In the Code Insight page of the Environment Options dialog box, click the Add button in the Code Template area, type in a new template name (for example, **mess**), type a description, and then add the following text to the template body in the Code memo control:

```
MessageDlg ('|', mtInformation, [mbOK], 0);
```

Now every time you need to create a message dialog box, you simply type **mess** and then press Ctrl+J, and you get the full text. The vertical line (or pipe) character indicates the position within the source code where the cursor will be in the editor after expanding the template. You should choose the position where you want to start typing to complete the code generated by the template.

Although code templates might seem at first sight to correspond to language keywords, they are in fact a more general mechanism. They are saved in the DELPHI32.DCI file, so it should be possible to copy this file to make your templates available on different machines. Merging two code template files is not documented, though.

Code Parameters

Code parameters display, in a hint or Tooltip window, the data type of a function's or method's parameters while you are typing it. Simply type the function or method name and the open (left) parenthesis, and the parameter names and types appear immediately in a pop-up hint window. To force the display of code parameters, you can press Ctrl+Shift+spacebar. As a further help, the current parameter appears in bold type.

Tooltip Expression Evaluation

Tooltip expression evaluation is a debug-time feature. It shows you the value of the identifier, property, or expression that is under the mouse cursor.

More Editor Shortcut Keys

The editor has many more shortcut keys that depend on the editor style you've selected. Here are a few of the less-known shortcuts, most of which are useful:

- Ctrl+Shift plus a number key from 0 to 9 activates a bookmark, indicated in a "gutter" margin on the side of the editor. To jump back to the bookmark, press the Ctrl key plus the number key. The usefulness of bookmarks in the editor is limited by the facts that a new bookmark can override an existing one and that bookmarks are not persistent; they are lost when you close the file.
- Ctrl+E activates the incremental search. You can press Ctrl+E and then directly type the word you want to search for, without the need to go through a special dialog box and click the Enter key to do the actual search.
- Ctrl+Shift+I indents multiple lines of code at once. The number of spaces used is the one set by the Block Indent option in the General page of the Editor Properties dialog box. Ctrl+Shift+U is the corresponding key for unindenting the code.
- Ctrl+O+U toggles the case of the selected code; you can also use Ctrl+K+E to switch to lowercase and Ctrl+K+F to switch to uppercase.
- Ctrl+Shift+R starts recording a macro, which you can later play by using the Ctrl+Shift+P shortcut. The macro records all the typing, moving, and deleting operations done in the source code file. Playing the macro simply repeats the sequence—an operation that might have little meaning once you've moved on to a different source code file. Editor macros are quite useful for performing multistep operations over and over again, such as reformatting source code or arranging data more legibly in source code.
- Holding down the Alt key, you can drag the mouse to select rectangular areas of the editor, not just consecutive lines and words.

The Form Designer

Another Delphi window you'll interact with very often is the Form Designer, a visual tool for placing components on forms. In the Form Designer, you can select a component directly with the mouse or through the Object Inspector, a handy feature when a control is behind another one or is very small. If one control covers another completely, you can use the Esc key to select the parent control of the current one. You can press Esc one or more times to select the form, or press and hold Shift while you click the selected component. This will deselect the current component and select the form by default.

There are two alternatives to using the mouse to set the position of a component. You can either set values for the Left and Top properties, or you can use the arrow keys while holding down Ctrl. Using arrow keys is particularly useful for fine-tuning an element's position. (The Snap To Grid option works only for mouse operations.) Similarly, by pressing the arrow keys while you hold down Shift, you can fine-tune the size of a component. (If you press Shift+Ctrl along with an arrow key, the component will be moved only at grid intervals.) Unfortunately, during these fine-tuning operations, the component hints with the position and size are not displayed.

To align multiple components or make them the same size, you can select several components and set the Top, Left, Width, or Height property for all of them at the same time. To select several components, you can click them with the mouse while holding down the Shift key, or, if all the components fall into a rectangular area, you can drag the mouse to "draw" a rectangle surrounding them. When you've selected multiple components, you can also set their relative position using the Alignment dialog box (with the Align command of the form's shortcut menu) or the Alignment Palette (accessible through the View ➢ Alignment Palette menu command).

When you've finished designing a form, you can use the Lock Controls command of the Edit menu to avoid accidentally changing the position of a component in a form. This is particularly helpful, as Undo operations on forms are limited (only an Undelete one), but the setting is not persistent.

Among its other features, the Form Designer offers several Tooltip hints:

- As you move the pointer over a component, the hint shows you the name and type of the component. Delphi 6 offers extended hints, with details on the control position, size, tab order, and more. This is an addition to the Show Component Captions environment setting, which I keep active.
- As you resize a control, the hint shows the current size (the Width and Height properties). Of course, this feature is available only for controls, not for nonvisual components (which are indicated in the Form Designer by icons).
- As you move a component, the hint indicates the current position (the Left and Top properties).

Finally, you can save DFM (Delphi Form Module) files in plain text instead of the traditional binary resource format. You can toggle this option for an individual form with the Form Designer's shortcut menu, or you can set a default value for newly created forms in the

Designer page of the Environment Options dialog box. In the same page, you can also specify whether the secondary forms of a program will be automatically created at startup, a decision you can always reverse for each individual form (using the Forms page of the Project Options dialog box).

Having DFM files stored as text was a welcome addition in Delphi 5; it lets you operate more effectively with version-control systems. Programmers won't get a real advantage from this feature, as you could already open the binary DFM files in the Delphi editor with a specific command of the shortcut menu of the designer. Version-control systems, on the other hand, need to store the textual version of the DFM files to be able to compare them and capture the differences between two versions of the same file.

In any case, note that if you use DFM files as text, Delphi will still convert them into a binary resource format before including them in the executable file of your programs. DFMs are linked into your executable in binary format to reduce the executable size (although they are not really compressed) and to improve run-time performance (they can be loaded faster).

NOTE Text DFM files are more portable between versions of Delphi than their binary version. While an older version of Delphi might not accept a new property of a control in a DFM created by a newer version of Delphi, the older Delphis will still be able to read the rest of the text DFM file. If the newer version of Delphi adds a new data type, though, older Delphis will be unable to read the newer Delphi's binary DFMs at all. Even if this doesn't sound likely, remember that 64-bit operating systems are just around the corner. When in doubt, save in text DFM format. Also note that all versions of Delphi support text DFMs, using the command-line tool Convert in the `bin` directory.

The Object Inspector in Delphi 6

Delphi 5 provided new features to the Object Inspector, and Delphi 6 includes even more additions to it. As this is a tool programmers use all the time, along with the editor and the Form Designer, its improvements are really significant.

The most important change in Delphi 6 is the ability of the Object Inspector to expand component references in-place. Properties referring to other components are now displayed in a different color and can be expanded by selecting the + symbol on the left, as it happens with internal subcomponents. You can then modify the properties of that other component without having to select it. See Figure 1.6 for an example.

NOTE This interface-expansion feature also supports subcomponents, as demonstrated by the new LabeledEdit control.

FIGURE 1.6: A connected component (a pop-up menu) expanded in the Object Inspector while working on another component (a list box)

TIP A related feature of the Object Inspector is the ability to select the component referenced by a property. To do this, double-click the property value with the left mouse button while keeping the Ctrl key pressed. For example, if you have a MainMenu component in a form and you are looking at the properties of the form in the Object Inspector, you can select the MainMenu component by moving to the MainMenu property of the form and Ctrl+double-clicking the value of this property. This selects the main menu indicated as the value of the property in the Object Inspector.

Here are some other relevant changes of the Object Inspector:

- The list at the top of the Object Inspector shows the type of the object and can be removed to save some space (and considering the presence of the Object TreeView).
- The properties that reference an object are now a different color and may be expanded without changing the selection.
- You can optionally also view read-only properties in the Object Inspector. Of course, they are grayed out.
- The Object Inspector has a new Properties dialog box (see Figure 1.7), which allows you to customize the colors of the various types of properties and the overall behavior of this window.

- Since Delphi 5, the drop-down list for a property can include graphical elements. This is used for properties such as `Color` and `Cursor`, and is particularly useful for the `ImageIndex` property of components connected with an ImageList.

NOTE

Interface properties can now be configured at design time using the Object Inspector. This makes use of the Interfaced Component Reference model introduced in Kylix/Delphi 6, where components may implement and hold references to interfaces as long as the interfaces are implemented by components. Interfaced Component References work like plain old component references, except that interface properties can be bound to any component that implements the necessary interface. Unlike component properties, interface properties are not limited to a specific component type (a class or its derived classes). When you click the drop-down list in the Object Inspector editor for an interface property, all components on the current form (and linked forms) that implement the interface are shown.

Drop-Down Fonts in the Object Inspector

The Delphi Object Inspector has graphical drop-down lists for several properties. You might want to add one showing the actual image of the font you are selecting, corresponding to the `Name` subproperty of the `Font` property. This capability is actually built into Delphi, but it has been disabled because most computers have a large number of fonts installed and rendering

Continued on next page

them can really slow down the computer. If you want to enable this feature, you have to install in Delphi a package that enables the `FontNamePropertyDisplayFontNames` global variable of the new VCLEditors unit. I've done this in the OiFontPk package, which you can find among the program examples for this chapter on the companion CD-ROM.

Once this package is installed, you can move to the `Font` property of any component and use the graphical Name drop-down menu, as displayed here:

2 hidden

There is a second, more complex customization of the Object Inspector that I like and use frequently: a custom font for the entire Object Inspector, to make its text more visible. This feature is particularly useful for public presentations. You can find the package to install custom fonts in the Object Inspector on my Web site, `www.marcocantu.com`.

Property Categories

Delphi 5 also introduced the idea of property categories, activated by the Arrange option of the local menu of the Object Inspector. If you set it, properties won't be listed alphabetically but arranged by group, with each property possibly appearing in multiple groups.

Categories have the benefit of reducing the complexity of the Object Inspector. You can use the View submenu from the shortcut menu to hide properties of given categories, regardless of the way they are displayed (that is, even if you prefer the traditional arrangement by name, you can still hide the properties of some categories).

Secrets of the Component Palette

The Component Palette is very simple to use, but there are a few things you might not know. There are four simple ways to place a component on a form:

- After selecting a control in the palette, click within the form to set the position for the control, and press-and-drag the mouse to size it.
- After selecting any component, simply click within the form to place it with the default height and width.
- Double-click the icon in the palette to add a component of that type in the center of the form.
- Shift-click the component icon to place several components of the same kind in the form. To stop this operation, simply click the standard selector (the arrow icon) on the left side of the Component Palette.

You can select the Properties command on the shortcut menu of the palette to completely rearrange the components in the various pages, possibly adding new elements or just moving them from page to page. In the resulting Properties page, you can simply drag a component from the Components list box to the Pages list box to move that component to a different page.

TIP When you have too many pages in the Component Palette, you'll need to scroll them to reach a component. There is a simple trick you can use in this case: Rename the pages with shorter names, so that all the pages will fit on the screen. Obvious—once you've thought about it.

The real undocumented feature of the Component Palette is the "hot-track" activation. By setting special keys of the Registry, you can simply select a page of the palette by moving over the tab, without any mouse click. The same feature can be applied to the component scrollers on both sides of the palette, which show up when a page has too many components. To activate this hidden feature, you must add an `Extras` key under `HKEY_CURRENT_USER\Software\Borland\Delphi\6.0`. Under this key enter two string values, `AutoPaletteSelect` and `AutoPaletteScroll`, and set each value to the string '1'.

Defining Event Handlers

There are several techniques you can use to define a handler for an event of a component:

- Select the component, move to the Events page, and either double-click in the white area on the right side of the event or type a name in that area and press the Enter key.
- For many controls, you can double-click them to perform the default action, which is to add a handler for the `OnClick`, `OnChange`, or `OnCreate` events.

When you want to remove an event handler you have written from the source code of a Delphi application, you could delete all of the references to it. However, a better way is to delete all of the code from the corresponding procedure, leaving only the declaration and the `begin` and `end` keywords. The text should be the same as what Delphi automatically generated when you first decided to handle the event. When you save or compile a project, Delphi removes any empty methods from the source code and from the form description (including the reference to them in the Events page of the Object Inspector). Conversely, to keep an event handler that is still empty, consider adding a comment to it (even just the `//` characters), so that it will not be removed.

Copying and Pasting Components

An interesting feature of the Form Designer is the ability to copy and paste components from one form to another or to duplicate the component in the form. During this operation, Delphi duplicates all the properties, keeps the connected event handlers, and, if necessary, changes the name of the control (which must be unique in each form).

It is also possible to copy components from the Form Designer to the editor and vice versa. When you copy a component to the Clipboard, Delphi also places the textual description there. You can even edit the text version of a component, copy the text to the Clipboard, and then paste it back into the form as a new component. For example, if you place a button on a form, copy it, and then paste it into an editor (which can be Delphi's own source-code editor or any word processor), you'll get the following description:

```
object Button1: TButton
  Left = 152
  Top = 104
  Width = 75
  Height = 25
  Caption = 'Button1'
  TabOrder = 0
end
```

Now, if you change the name of the object, its caption, or its position, for example, or add a new property, these changes can be copied and pasted back to a form. Here are some sample changes:

```
object Button1: TButton
  Left = 152
  Top = 104
  Width = 75
  Height = 25
  Caption = 'My Button'
  TabOrder = 0
  Font.Name = 'Arial'
end
```

Copying this description and pasting it into the form will create a button in the specified position with the caption *My Button* in an Arial font.

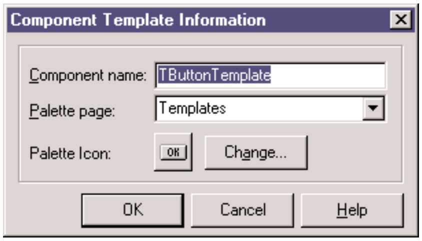
To make use of this technique, you need to know how to edit the textual representation of a component, what properties are valid for that particular component, and how to write the values for string properties, set properties, and other special properties. When Delphi interprets the textual description of a component or form, it might also change the values of other properties related to those you've changed, and it might change the position of the component so that it doesn't overlap a previous copy. Of course, if you write something completely wrong and try to paste it into a form, Delphi will display an error message indicating what has gone wrong.

You can also select several components and copy them all at once, either to another form or to a text editor. This might be useful when you need to work on a series of similar components. You can copy one to the editor, replicate it a number of times, make the proper changes, and then paste the whole group into the form again.

From Component Templates to Frames

When you copy one or more components from one form to another, you simply copy all of their properties. A more powerful approach is to create a *component template*, which makes a copy of both the properties and the source code of the event handlers. As you paste the template into a new form, by selecting the pseudo-component from the palette, Delphi will replicate the source code of the event handlers in the new form.

To create a component template, select one or more components and issue the Component ➢ Create Component Template menu command. This opens the Component Template Information dialog box, where you enter the name of the template, the page of the Component Palette where it should appear, and an icon.



Component Template Information

Component name: TButtonTemplate

Palette page: Templates

Palette Icon:

By default, the template name is the name of the first component you've selected followed by the word *Template*. The default template icon is the icon of the first component you've selected, but you can replace it with an icon file. The name you give to the component template will be used to describe it in the Component Palette (when Delphi displays the pop-up hint).

All the information about component templates is stored in a single file, DELPHI32.DCT, but there is apparently no way to retrieve this information and edit a template. What you can do, however, is place the component template in a brand-new form, edit it, and install it again as a component template *using the same name*. This way you can overwrite the previous definition.

TIP A group of Delphi programmers can share component templates by storing them in a common directory, adding to the Registry the entry `CCLibDir` under the key `\Software\Borland\Delphi\6.0\Component Templates`.

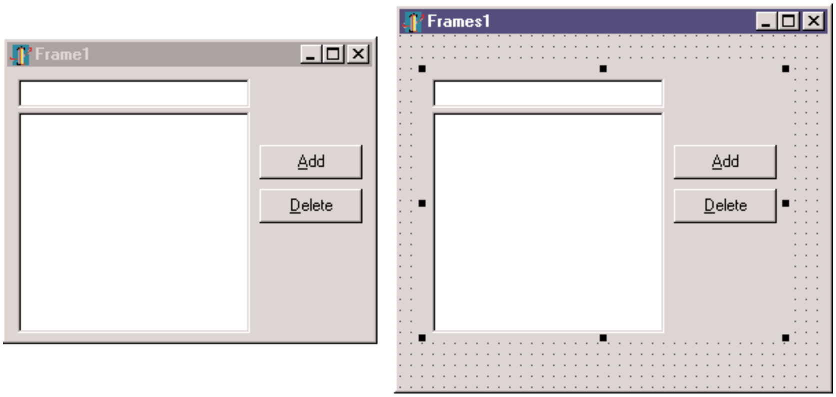
Component templates are handy when different forms need the same group of components and associated event handlers. The problem is that once you place an instance of the template in a form, Delphi makes a copy of the components and their code, which is no longer related to the template. There is no way to modify the template definition itself, and it is certainly not possible to make the same change effective in all the forms that use the template. Am I asking too much? Not at all. This is what the *frames* technology in Delphi does.

A frame is a sort of panel you can work with at design time in a way similar to a form. You simply create a new frame, place some controls in it, and add code to the event handlers. After the frame is ready, you can open a form, select the Frame pseudo-component from the Standard page of the Component Palette, and choose one of the available frames (of the current project). After placing the frame in a form, you'll see it as if the components were copied to it. If you modify the original frame (in its own designer), the changes will be reflected in each of the instances of the frame.

You can see a simple example, called Frames1, in Figure 1.8 (its code is available on the companion CD). A screen snapshot doesn't really mean much; you should open the program or rebuild a similar one if you want to start playing with frames. Like forms, frames define classes, so they fit within the VCL object-oriented model much more easily than component templates. Chapter 4 provides an in-depth look at VCL and includes a more detailed description of frames. As you might imagine from this short introduction, frames are a powerful new technique.

FIGURE 1.8:

The Frames1 example demonstrates the use of frames. The frame (on the left) and its instance inside a form (on the right) are kept in synch.



Managing Projects

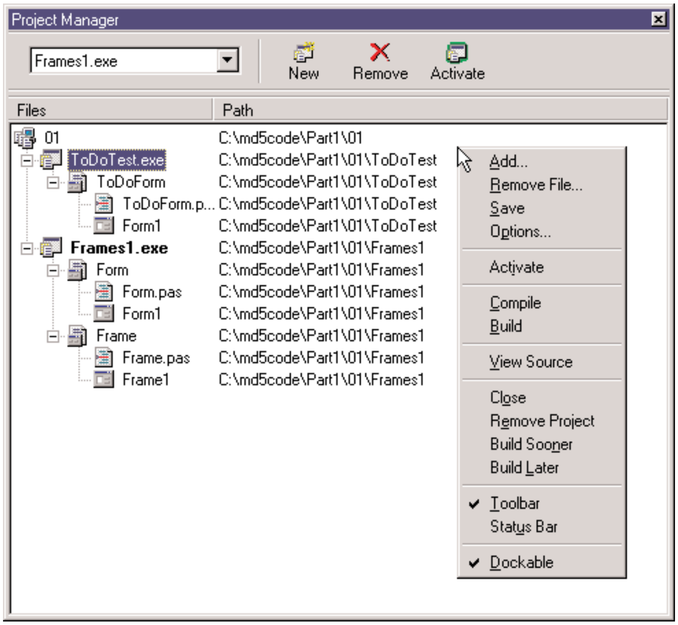
Delphi's multitarget Project Manager (View ➢ Project Manager) works on a project *group*, which can have one or more projects under it. For example, a project group can include a DLL and an executable file, or multiple executable files.

TIP In Delphi 6, all open packages will show up as projects in the Project Manager view, even if they haven't been added to the project group.

In Figure 1.9, you can see the Project Manager with the project group for the current chapter. As you can see, the Project Manager is based on a tree view, which shows the hierarchical structure of the project group, the projects, and all of the forms and units that make up each project. You can use the simple toolbar and the more complex shortcut menus of the Project Manager to operate on it. The shortcut menu is context-sensitive; its options depend on the selected item. There are menu items to add a new or existing project to a project group, to compile or build a specific project, or to open a unit.

Of all the projects in the group, only one is active, and this is the project you operate upon when you select a command such as Project ➢ Compile. The Project pull-down of the main menu has two commands you can use to compile or build all the projects of the group. (Strangely enough, these commands are not available in the shortcut menu of the Project Manager for the project group.) When you have multiple projects to build, you can set a relative order by using the Build Sooner and Build Later commands. These two commands basically rearrange the projects in the list.

FIGURE 1.9:
Delphi's multitarget Project Manager



Files	Path
01	C:\md5code\Part1\01
ToDoTest.exe	C:\md5code\Part1\01\ToDoTest
ToDoForm	C:\md5code\Part1\01\ToDoTest
ToDoForm.p...	C:\md5code\Part1\01\ToDoTest
Form1	C:\md5code\Part1\01\ToDoTest
Frames1.exe	C:\md5code\Part1\01\Frames1
Form	C:\md5code\Part1\01\Frames1
Form.pas	C:\md5code\Part1\01\Frames1
Form1	C:\md5code\Part1\01\Frames1
Frame	C:\md5code\Part1\01\Frames1
Frame.pas	C:\md5code\Part1\01\Frames1
Frame1	C:\md5code\Part1\01\Frames1

Among its advanced features, you can drag source code files from Windows folders or Windows Explorer onto a project in the Project Manager window to add them to that project.

The Project Manager automatically selects as the current project the one you are working with—for example, opening a file. You can easily see which project is selected and change it by using the combo box on the top of the form.

TIP

Besides adding Pascal files and projects, you can add Windows resource files to the Project Manager; they are compiled along with the project. Simply move to a project, select the Add shortcut menu, and choose Resource File (*.rc) as the file type. This resource file will be automatically bound to the project, even without a corresponding `$R` directive.

Delphi saves the project groups with the new .BPG extension, which stands for Borland Project Group. This feature comes from C++Builder and from past Borland C++ compilers, a history that is clearly visible as you open the source code of a project group, which is basically that of a makefile in a C/C++ development environment. Here is a simple example:

```
#------------------------------
VERSION = BWS.01
#------------------------------
!ifndef ROOT
ROOT = $(MAKEDIR)\..
```

```
!endif
#------------------------------
MAKE = $(ROOT)\bin\make.exe -$(MAKEFLAGS) -f$**
DCC = $(ROOT)\bin\dcc32.exe $**
BRCC = $(ROOT)\bin\brcc32.exe $**
#------------------------------
PROJECTS = Project1.exe
#------------------------------
default: $(PROJECTS)
#------------------------------
Project1.exe: Project1.dpr
  $(DCC)
```

Project Options

The Project Manager doesn't provide a way to set the options of two different projects at one time. What you can do instead is invoke the Project Options dialog from the Project Manager for each project. The first page of Project Options (Forms) lists the forms that should be created automatically at program startup and the forms that are created manually by the program. The next page (Application) is used to set the name of the application and the name of its Help file, and to choose its icon. Other Project Options choices relate to the Delphi compiler and linker, version information, and the use of run-time packages.

There are two ways to set compiler options. One is to use the Compiler page of the Project Options dialog. The other is to set or remove individual options in the source code with the `{$X+}` or `{$X-}` commands, where you'd replace *X* with the option you want to set. This second approach is more flexible, since it allows you to change an option only for a specific source-code file, or even for just a few lines of code. The source-level options override the compile-level options.

All project options are saved automatically with the project, but in a separate file with a .DOF extension. This is a text file you can easily edit. You should not delete this file if you have changed any of the default options. Delphi also saves the compiler options in another format in a CFG file, for command-line compilation. The two files have similar content but a different format: The *dcc* command-line compiler, in fact, cannot use .DOF files, but needs the .CFG format.

Another alternative for saving compiler options is to press Ctrl+O+O (press the O key twice while keeping Ctrl pressed). This inserts, at the top of the current unit, compiler directives that correspond to the current project options, as in the following listing:

```
{$A+,B-,C+,D+,E-,F-,G+,H+,I+,J+,K-,L+,M-,N+,O+,P+,Q-,R-,S-,T-,U-,V+,
W-,X+,Y+,Z1}

{$MINSTACKSIZE $00004000}
```

```
{$MAXSTACKSIZE $00100000}

{$IMAGEBASE $00400000}

{$APPTYPE GUI}
```

Compiling and Building Projects

There are several ways to compile a project. If you run it (by pressing F9 or clicking the Run toolbar icon), Delphi will compile it first. When Delphi compiles a project, it compiles only the files that have changed.

If you select Compile ➢ Build All instead, every file is compiled, even if it has not changed. You should only need this second command infrequently, since Delphi can usually determine which files have changed and compile them as required. The only exception is when you change some project options, in which case you have to use the Build All command to put the new options into effect.

To build a project, Delphi first compiles each source code file, generating a Delphi compiled unit (DCU). (This step is performed only if the DCU file is not already up-to-date.) The second step, performed by the linker, is to merge all the DCU files into the executable file, optionally with compiled code from the VCL library (if you haven't decided to use packages at run time). The third step is binding into the executable file any optional resource files, such as the RES file of the project, which hosts its main icon, and the DFM files of the forms. You can better understand the compilation steps and follow what happens during this operation if you enable the Show Compiler Progress option (in the Preferences page of the Environment Options dialog box).

WARNING Delphi doesn't always properly keep track of when to rebuild units based on other units you've modified. This is particularly true for the cases (and there are many) in which user intervention confuses the compiler logic. For example, renaming files, modifying source files outside the IDE, copying older source files or DCU files to disk, or having multiple copies of a unit source file in your search path can break the compilation. Every time the compiler shows some strange error message, the first thing you should try is the Build All command to resynchronize the make feature with the current files on disk.

The Compile command can be used only when you have loaded a project in the editor. If no project is active and you load a Pascal source file, you cannot compile it. However, if you load the source file *as if it were a project*, that will do the trick and you'll be able to compile the file. To do this, simply select the Open Project toolbar button and load a PAS file. Now you can check its syntax or compile it, building a DCU.

I've mentioned before that Delphi allows you to use run-time packages, which affect the distribution of the program more than the compilation process. Delphi packages are dynamic link libraries (DLLs) containing Delphi components. By using packages, you can make an executable file much smaller. However, the program won't run unless the proper dynamic link libraries (such as `vcl50.bpl`, which is quite large) are available on the computer where you want to run the program.

If you add the size of this dynamic library to that of the small executable file, the total amount of disk space required by the apparently smaller program built with run-time packages is much larger than the space required by the apparently bigger stand-alone executable file. Of course, if you have multiple applications on a single system, you'll end up saving a lot, both in disk space and memory consumption at run time. The use of packages is often but not always recommended. I'll discuss all the implications of packages in detail in Chapter 12.

In both cases, Delphi executables are extremely fast to compile, and the speed of the resulting application is comparable to that of a C or C++ program. Delphi compiled code runs at least five times faster than the equivalent code in interpreted or "semicompiled" tools.

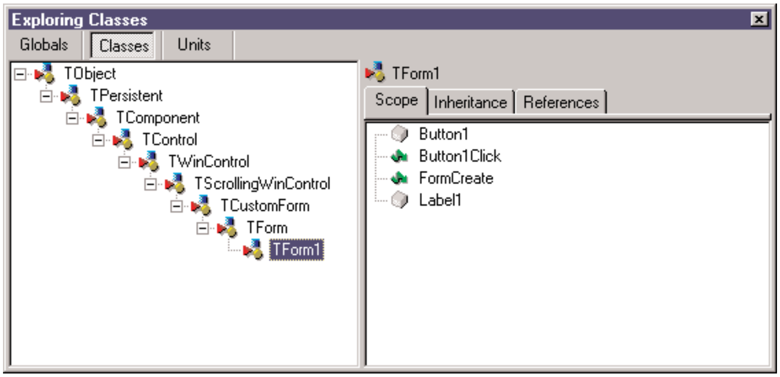
Exploring a Project

Past versions of Delphi included an Object Browser, which you could use when a project was compiled to see a hierarchical structure of its classes and to look for its symbols and the source-code lines where they are referenced. Delphi now includes a similar but enhanced tool, called Project Explorer. Like the Code Explorer, it is updated automatically as you type, without recompiling the project.

The Project Explorer allows you to list Classes, Units, and Globals, and lets you choose whether to look only for symbols defined within your project or for those from both your project and VCL. You can see an example with only project symbols in Figure 1.10.

FIGURE 1.10:

The Project Explorer



You can change the settings of this Explorer and those of the Code Explorer in the Explorer page of the Environment Options or by selecting the Properties command in the shortcut menu of the Project Explorer. Some of the Explorer categories you see in this window are specific to the Project Explorer; others relate to both tools.

Additional and External Delphi Tools

Besides the IDE, when you install Delphi you get other, external tools. Some of them, such as the Database Desktop, the Package Collection Editor (`PCE.exe`), and the Image Editor (`ImagEdit.exe`), are available from Tools menu of the IDE. In addition, the Enterprise edition has a link to the SQL Monitor (`SqlMon.exe`).

Other tools that are not directly accessible from the IDE include many command-line tools you can find in the `bin` directory of Delphi. For example, there is a command-line Delphi compiler (`DCC.exe`), a Borland resource compiler (`BRC32.exe` and `BRCC32.exe`), and an executable viewer (`TDump.exe`).

Finally, some of the sample programs that ship with Delphi are actually useful tools that you can compile and keep at hand. I'll discuss some of these tools in the book, as needed. Here are a few of the useful and higher-level tools, mostly available in the `\Delphi6\bin` folder and in the Tools menu:

Web App Debugger (`WebAppDbg.exe`) is the debugging Web server introduced in Delphi 6. It is used to keep track of the requests send to your applications and debug them. I'll discuss this tool in Chapter 21.

XML Mapper (`XmlMapper.exe`), again new in Delphi 6, is a tool for creating XML transformations to be applied to the format produced by the ClientDataSet component. More on this topic in Chapter 22.

External Translation Manager (`etm60.exe`) is the stand-alone version of the Integrated Translation Manager. This external tool can be given to external translators and is available for the first time in Delphi 6.

Borland Registry Cleanup Utility (`D6RegClean.exe`) helps you remove all of the Registry entries added by Delphi 6 to a computer.

TeamSource is an advanced version-control system provided with Delphi, starting with version 5. The tool is very similar to its past incarnation and is installed separately from Delphi.

WinSight (Ws.exe) is a Windows "message spy" program available in the bin directory.

Database Explorer can be activated from the Delphi IDE or as a stand-alone tool, using the DBExplor.exe program of the bin directory.

OpenHelp (oh.exe) is the tool you can use to manage the structure of Delphi's own Help files, integrating third-party files into the help system.

Convert (Convert.exe) is a command-line tool you can use to convert DFM files into the equivalent textual description and vice versa.

Turbo Grep (Grep.exe) is a command-line search utility, much faster than the embedded Find In Files mechanism but not so easy to use.

Turbo Register Server (TRegSvr.exe) is a tool you can use to register ActiveX libraries and COM servers. The source code of this tool is available under \Demos\ActiveX\TRegSvr.

Resource Explorer is a powerful resource viewer (but not a full-blown resource editor) you can find under \Demos\ResXplor.

Resource Workshop The Delphi 5 CD also includes a separate installation for Resource Workshop. This is an old 16-bit resource editor that can also manage Win32 resource files. It was formerly included in Borland C++ and Pascal compilers for Windows and was much better than the standard Microsoft resource editors then available. Although its user interface hasn't been updated and it doesn't handle long filenames, this tool can still be very useful for building custom or special resources. It also lets you explore the resources of existing executable files.

The Files Produced by the System

Delphi produces various files for each project, and you should know what they are and how they are named. Basically, two elements have an impact on how files are named: the names you give to a project and its units, and the predefined file extensions used by Delphi. Table 1.1 lists the extensions of the files you'll find in the directory where a Delphi project resides. The table also shows when or under what circumstances these files are created and their importance for future compilations.

TABLE 1.1: Delphi Project File Extensions

Extension	File Type and Description	Creation Time	Required to Compile?
.BMP, .ICO, .CUR	Bitmap, icon, and cursor files: standard Windows files used to store bitmapped images.	Development: Image Editor	Usually not, but they might be needed at run time and for further editing.
.BPG	Borland Project Group: the files used by the new multiple-target Project Manager. It is a sort of makefile.	Development	Required to recompile all the projects of the group at once.
.BPL	Borland Package Library: a DLL including VCL components to be used by the Delphi environment at design time or by applications at run time. (These files used a .DPL extension in Delphi 3.)	Compilation: Linking	You'll distribute packages to other Delphi developers and, optionally, to end-users.
.CAB	The Microsoft Cabinet compressed-file format used for Web deployment by Delphi. A CAB file can store multiple compressed files.	Compilation	Distributed to users.
.CFG	Configuration file with project options. Similar to the DOF files.	Development	Required only if special compiler options have been set.
.DCP	Delphi Component Package: a file with symbol information for the code that was compiled into the package. It doesn't include compiled code, which is stored in DCU files.	Compilation	Required when you use packages. You'll distribute it only to other developers along with DPL files.
.DCU	Delphi Compiled Unit: the result of the compilation of a Pascal file.	Compilation	Only if the source code is not available. DCU files for the units you write are an intermediate step, so they make compilation faster.
.DDP	The new Delphi Diagram Portfolio, used by the Diagram view of the editor (was .DTI in Delphi 5)	Development	No. This file stores "design-time only" information, not required by the resulting program but very important for the programmer.

TABLE 1.1 continued: Delphi Project File Extensions

Extension	File Type and Description	Creation Time	Required to Compile?
.DFM	Delphi Form File: a binary file with the description of the properties of a form (or a data module) and of the components it contains.	Development	Yes. Every form is stored in both a PAS and a DFM file.
.~DF	Backup of Delphi Form File (DFM).	Development	No. This file is produced when you save a new version of the unit related to the form and the form file along with it.
.DFN	Support file for the Integrated Translation Environment (there is one DFN file for each form and each target language).	Development (ITE)	Yes (for ITE). These files contain the translated strings that you edit in the Translation Manager.
.DLL	Dynamic Link Library: another version of an executable file.	Compilation: Linking	See .EXE.
.DOF	Delphi Option File: a text file with the current settings for the project options.	Development	Required only if special compiler options have been set.
.DPK	Delphi Package: the project source code file of a package.	Development	Yes.
.DPR	Delphi Project file. (This file actually contains Pascal source code.)	Development	Yes.
.~DP	Backup of the Delphi Project file (.DPR).	Development	No. This file is generated automatically when you save a new version of a project file.
.DSK	Desktop file: contains information about the position of the Delphi windows, the files open in the editor, and other Desktop settings.	Development	No. You should actually delete it if you copy the project to a new directory.

TABLE 1.1 continued: Delphi Project File Extensions

Extension	File Type and Description	Creation Time	Required to Compile?
.DSM	Delphi Symbol Module: stores all the browser symbol information.	Compilation (but only if the Save Symbols option is set)	No. Object Browser uses this file, instead of the data in memory, when you cannot recompile a project.
.EXE	Executable file: the Windows application you've produced.	Compilation: Linking	No. This is the file you'll distribute. It includes all of the compiled units, forms, and resources.
.HTM	Or .HTML, for Hypertext Markup Language: the file format used for Internet Web pages.	Web deployment of an ActiveForm	No. This is not involved in the project compilation.
.LIC	The license files related to an OCX file.	ActiveX Wizard and other tools	No. It is required to use the control in another development environment.
.OBJ	Object (compiled) file, typical of the C/C++ world.	Intermediate compilation step, generally not used in Delphi	It might be required to merge Delphi with C++ compiled code in a single project.
OCX	OLE Control Extension: a special version of a DLL, containing ActiveX controls or forms.	Compilation: Linking	See .EXE.
.PAS	Pascal file: the source code of a Pascal unit, either a unit related to a form or a stand-alone unit.	Development	Yes.
.~PA	Backup of the Pascal file (.PAS).	Development	No. This file is generated automatically by Delphi when you save a new version of the source code.
.RES, .RC	Resource file: the binary file associated with the project and usually containing its icon. You can add other files of this type to a project. When you create custom resource files you might use also the textual format, .RC.	Development Options dialog box. The ITE (Integrated Translation Environment) generates resource files with special comments.	Yes. The main RES file of an application is rebuilt by Delphi according to the information in the Application page of the Project Options dialog box.

TABLE 1.1 continued: Delphi Project File Extensions

Extension	File Type and Description	Creation Time	Required to Compile?
.RPS	Translation Repository (part of the Integrated Translation Environment).	Development (ITE)	No. Required to manage the translations.
.TLB	Type Library: a file built automatically or by the Type Library Editor for OLE server applications.	Development	This is a file other OLE programs might need.
TODO	To-do list file, holding the items related to the entire project.	Development	No. This file hosts notes for the programmers.
.UDL	Microsoft Data Link.	Development	Used by ADO to refer to a data provider. Similar to an alias in the BDE world (see Chapter 12).

Besides the files generated during the development of a project in Delphi, there are many others generated and used by the IDE itself. In Table 1.2, I've provided a short list of extensions worth knowing about. Most of these files are in proprietary and undocumented formats, so there is little you can do with them.

TABLE 1.2: Selected Delphi IDE Customization File Extensions

Extension	File Type
.DCI	Delphi code templates
.DRO	Delphi's Object Repository (The repository should be modified with the Tools ➢ Repository command.)
.DMT	Delphi menu templates
.DBI	Database Explorer information
.DEM	Delphi edit mask (files with country-specific formats for edit masks)
.DCT	Delphi component templates
.DST	Desktop settings file (one for each desktop setting you've defined)

Looking at Source Code Files

I've just listed some files related to the development of a Delphi application, but I want to spend a little time covering their actual format. The fundamental Delphi files are Pascal source code files, which are plain ASCII text files. The bold, italic, and colored text you see in the editor depends on syntax highlighting, but it isn't saved with the file. It is worth noting that there is one single file for the whole code of the form, not just small code fragments.

TIP In the listings in this book, I've matched the bold syntax highlighting of the editor for keywords and the italic for strings and comments.

For a form, the Pascal file contains the form class declaration and the source code of the event handlers. The values of the properties you set in the Object Inspector are stored in a separate form description file (with a .DFM extension). The only exception is the `Name` property, which is used in the form declaration to refer to the components of the form.

The DFM file is a binary and, in Delphi, can be saved either as a plain-text file or in the traditional Windows Resource format. You can set the default format you want to use for new projects in the Designerpage of the Environment Options dialog box, and you can toggle the format of individual forms with the Text DFM command of a form's shortcut menu. A plain-text editor can read only the text version. However, you can load DFM files of both types in the Delphi editor, which will, if necessary, first convert them into a textual description. The simplest way to open the textual description of a form (whatever the format) is to select the View As Text command on the shortcut menu in the Form Designer. This closes the form, saving it if necessary, and opens the DFM file in the editor. You can later go back to the form using the View As Form command on the shortcut menu in the editor window.

You can actually edit the textual description of a form, although this should be done with extreme care. As soon as you save the file, it will be turned back into a binary file. If you've made incorrect changes, compilation will stop with an error message and you'll need to correct the contents of your DFM file before you can reopen the form. For this reason, you shouldn't try to change the textual description of a form manually until you have good knowledge of Delphi programming.

TIP In the book, I often show you excerpts of DFM files. In most of these excerpts, I only show the most relevant components or properties; generally, I have removed the positional properties, the binary values, and other lines providing little useful information.

In addition to the two files describing the form (PAS and DFM), a third file is vital for rebuilding the application. This is the Delphi project file (DPR), which is another Pascal source code file. This file is built automatically, and you seldom need to change it manually. You can see this file with the Project -> View Source menu command.

Some of the other, less relevant files produced by the IDE use the structure of Windows INI files, in which each section is indicated by a name enclosed in square brackets. For example, this is a fragment of an option file (DOF):

```
[Compiler]
A=1
B=0
ShowHints=1
ShowWarnings=1

[Linker]
MinStackSize=16384
MaxStackSize=1048576
ImageBase=4194304

[Parameters]
RunParams=
HostApplication=
```

The same structure is used by the Desktop files (DSK), which store the status of the Delphi IDE for the specific project, listing the position of each window. Here is a small excerpt:

```
[MainWindow]
Create=1
Visible=1
State=0
Left=2
Top=0
Width=800
Height=97
```

NOTE A lot of information related to the status of the Delphi environment is saved in the Windows Registry, as well as in DSK and other files. I've already indicated a few special undocumented entries of the Registry you can use to activate specific features. You should explore the `HKEY_CURRENT_USER\Software\Borland\Delphi\6.0` section of the Registry to examine all the settings of the Delphi IDE (including all those you can modify with the Project Options and the Environment Options dialog boxes, as well as many others).

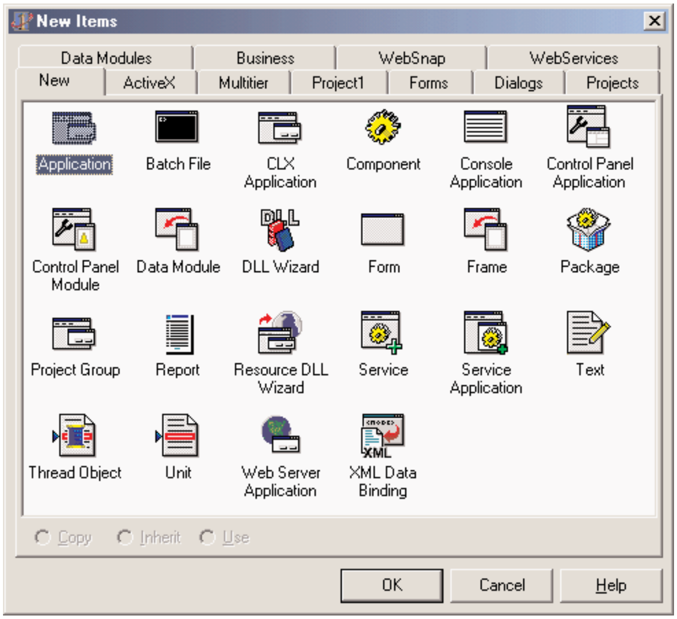
The Object Repository

Delphi has menu commands you can use to create a new form, a new application, a new data module, a new component, and so on. These commands are located in the File ➢ New menu and in other pull-down menus. What happens if you simply select File ➢ New ➢ Other? Delphi opens the Object Repository, which is used to create new elements of any kind: forms, applications, data modules, thread objects, libraries, components, automation objects, and more.

The New dialog box (shown in Figure 1.11) has several pages, hosting all the new elements you can create, existing forms and projects stored in the Repository, Delphi wizards, and the forms of the current project (for visual form inheritance). The pages and the entries in this tabbed dialog box depend on the specific version of Delphi, so I won't list them here.

FIGURE 1.11:

The first page of the New dialog box, generally known as the "Object Repository"



TIP The Object Repository has a shortcut menu that allows you to sort its items in different ways (by name, by author, by date, or by description) and to show different views (large icons, small icons, lists, and details). The Details view gives you the description, the author, and the date of the tool, information that is particularly important when looking at wizards, projects, or forms that you've added to the Repository.

The simplest way to customize the Object Repository is to add new projects, forms, and data modules as templates. You can also add new pages and arrange the items on some of them (not including the New and "current project" pages). Adding a new template to Delphi's Object Repository is as simple as using an existing template to build an application. When you have a working application you want to use as a starting point for further development of similar programs, you can save the current status to a template, ready to use later on. Simply use the Project ➢ Add To Repository command, and fill in its dialog box.

Just as you can add new project templates to the Object Repository, you can also add new form templates. Simply move to the form that you want to add and select the Add To Repository command of its shortcut menu. Then indicate the title, description, author, page, and icon in its dialog box.

You might want to keep in mind that as you copy a project or form template to the repository and then copy it back to another directory, you are simply doing a copy and paste operation. This isn't much different than copying the files manually.

The Empty Project Template

When you start a new project, it automatically opens a blank form, too. If you want to base a new project on one of the form objects or Wizards, this is not what you want, however. To solve this problem, you can add an Empty Project template to the Gallery.

The steps required to accomplish this are simple:

1. Create a new project as usual.
2. Remove its only form from the project.
3. Add this project to the templates, naming it *Empty Project*.

When you select this project from the Object Repository, you gain two advantages: You have your project without a form, and you can pick a directory where the project template's files will be copied. There is also a disadvantage—you have to remember to use the File ➢ Save Project As command to give a new name to the project, because saving the project any other way automatically uses the default name in the template.

To further customize the Repository, you can use the Tools ➢ Repository command. This opens the Object Repository dialog box, which you can use to move items to different pages, to add new elements, or to delete existing ones. You can even add new pages, rename or delete them, and change their order. An important element of the Object Repository setup is the use of defaults:

- Use the New Form check box below the list of objects to designate a form as the one to be used when a new form is created (File ➢ New Form).
- The Main Form check box indicates which type of form to use when creating the main form of a new application (File ➢ New Application) when no special New Project is selected.
- The New Project check box, available when you select a project, marks the default project that Delphi will use when you issue the File ➢ New Application command.

Only one form and only one project in the Object Repository can have each of these three settings marked with a special symbol placed over its icon. If no project is selected as New Project, Delphi creates a default project based on the form marked as Main Form. If no form is marked as the main form, Delphi creates a default project with an empty form.

When you work on the Object Repository, you work with forms and modules saved in the `OBJREPOS` subdirectory of the Delphi main directory. At the same time, if you use a form or any other object directly without copying it, then you end up having some files of your project in this directory. It is important to realize how the Repository works, because if you want to modify a project or an object saved in the Repository, the best approach is to operate on the original files, without copying data back and forth to the Repository.

Installing New DLL Wizards

Technically, new wizards come in two different forms: They may be part of components or packages, or they may be distributed as stand-alone DLLs. In the first case, they would be installed the same way you install a component or a package. When you've received a stand-alone DLL, you should add the name of the DLL in the Windows Registry under the key `\Software\Borland\Delphi\6.0\Experts`. Simply add a new string key under this key, choose a name you like (it doesn't really matter what it is), and use as text the path and filename of the wizard DLL. You can look at the entries already present under the `Experts` key to see how the path should be entered.

What's Next?

This chapter has presented an overview of the new and more advanced features of the Delphi 6 programming environment, including tips and suggestions about some lesser-known features that were already available in previous Delphi versions. I didn't provide a step-by-step description of the IDE, partly because it is generally simpler to start *using* Delphi than it is to read about how to use it. Moreover, there is a detailed Help file describing the environment and the development of a new simple project; and you might already have some exposure to one of the past versions of Delphi or a similar development environment.

Now we are ready to spend the next two chapters looking into the Object Pascal language and then proceed by studying the RTL and the class library included in Delphi 6.

CHAPTER 2

The Object Pascal Language: Classes and Objects

- The Pascal language
- New conditional compilation and hint directives
- Classes and objects
- The *Self* keyword
- Class methods and overloading
- Encapsulation: *private* and *public*
- Using properties
- Constructors
- Objects and memory

Most modern programming languages support *object-oriented programming* (OOP). OOP languages are based on three fundamental concepts: encapsulation (usually implemented with classes), inheritance, and polymorphism (or late binding).

You can write Delphi applications even without knowing the details of Object Pascal. As you create a new form, add new components, and handle events, Delphi prepares most of the related code for you automatically. But knowing the details of the language and its implementation will help you to understand precisely what Delphi is doing and to master the language completely.

A single chapter doesn't allow space for a full introduction to the principles of object-oriented programming and the Object Pascal language. Instead, I will outline the key OOP features of the language and show how they relate to everyday Delphi programming. Even if you don't have a precise knowledge of OOP, the chapter will introduce each of the key concepts so that you won't need to refer to other sources.

The Pascal Language

The Object Pascal language used by Delphi is an OOP extension of the classic Pascal language, which Borland pushed forward for many years with its Turbo Pascal compilers. The syntax of the Pascal language is known to be quite verbose and more readable than, for example, the C language. Its OOP extension follows the same approach, delivering the same power of the recent breed of OOP languages, from Java to C#.

In this chapter, I'll discuss only the object-oriented extensions of the Pascal language available in Delphi. However, I'll highlight recent additions Borland has done to the core language. These features have been introduced in Delphi 6 and are, at least partially, related to the Linux version of Delphi.

New Pascal features include the `$IF` and `$ELSEIF` directives for conditional compilation, the `$WARN` and `$MESSAGE` directives, and the `platform`, `library`, and `deprecated` hint directives. These topics are discussed in the following sections. Changes to the assembler (with new directives, support for MMX and Pentium Pro instructions, and many more features) are really beyond the scope of this book.

Other relatively minor changes in the language include a change in the default value for the `$WRITEABLECONST` compiler switch, which is now disabled. This option allows programs to modify the value of typed constants and should generally be left disabled, using variables instead of constants for modifyable values. Another change is the support for the `Int64` data type in variants. Finally, you can assign specific values to the elements of an enumeration (as in the C/C++ language), instead of using the default sequence of values.

The New *$IF* Compiler Directive

Delphi has always had a $IFDEF directive you could use to test whether a specific symbol was defined. (Delphi also has a $IFNDEF directive, with the opposite test.) This is used to obtain conditional compilation, as in

```
{$IFDEF DEBUG}
  // executes only if the DEBUG directive is set
  ShowMessage ('Executing critical code');
{$ENDIF}
```

By setting or not setting the DEBUG directive and recompiling, the extra line of code will be included or skipped by the compiler.

This code directive is powerful, but checking for multiple versions of Delphi and operating systems can force you to use multiple-nested $IFDEF directives, making the code totally unreadable. For this reason, Borland has introduced a new and more powerful directive for conditional compilation, $IF. Inside the directive you can use the Defined function to check whether a conditional symbol is defined, or use the Declared function to see whether a language constant is defined and use these constants within a constant Boolean expression. Here is some code that shows how to use a constant within the $IF directive (you can find this and other code excerpts of this and the next section in the IfDirective example on the companion CD):

```
const
  DebugControl = 2;

{$IF Defined(DEBUG) and (DebugControl > 3)}
  ShowMessage ('Executing critical code');
{$IFEND}
```

Notice that the statement is closed by a $IFEND and that you can also have an optional $ELSE branch. You can also concatenate conditions with the $ELSEIF directive, followed by another condition and evaluated only as an alternative to the $IF directive it refers to:

```
{$IF one}
  ...
{$ELSEIF two}
  ...
{$ELSE}
  ...
{$IFEND}
```

Within the expressions of the $IF directive, you can use only untyped constants, which are really and invariably treated as constants by the compiler. You can follow the general rules of Pascal constant expressions. You can use all the language operators, the and, or, xor, and not Boolean operators, and mathematical ones including div, mod, +, -, *, /, > and <, to mention just a few common ones. You can also use predefined functions such as SizeOf, High, Low, Prev, Succ, and others listed in the Delphi Help page “Constant expressions.” The expression can use constant symbols of any type, including floats and strings, so long as the expression itself ultimately evaluates to a True or False value.

WARNING In these constant expressions, it is not possible to use type constants, which can be optionally modified in the code depending on the status of the writeable-typed constants directive ($J or $WRITEABLECONST). In any case, using constants you can modify is quite a bad idea in the first place.

Delphi provides a few predefined conditional symbols, including compiler version, the operating system, the GUI environment, and so on. I’ve listed the most important ones in Table 2.1. You can also use the RTLVersion constant defined in the System unit to test which version of Delphi (and its run-time library) you are compiling on. The predefined symbol ConditionalExpressions can be used to shield the new directives from older versions of Delphi:

```
{$IFDEF ConditionalExpressions}
   {$IF System.RTLVersion > 14.0}
      // do something
   {$IFEND}
{$ENDIF}
```

TABLE 2.1: Commonly Used Predefined Conditional Symbols

Symbol	Description
VER140	Compiling with Delphi 6, which is the 14.0 version of the Borland Pascal compiler; Delphi 5 used VER130, with lower numbers for past versions.
MSWINDOWS	Compiling on the Windows platform (new in Delphi 6).
LINUX	Compiling on the Linux platform. On Kylix, there are also the LINUX32, POSIX, and ELF predefined symbols.
WIN32	Compiling only on the 32-bit Windows platform. This symbol was introduced in Delphi 2 to distinguish from 16-bit Windows compilations (Delphi 1 defined the WINDOWS symbol). You should use WIN32 only to mark code specifically for Win32, not Win16 or future Win64 platforms (for which the WIN64 symbol has been reserved). Use MSWINDOWS, instead, to distinguish between Windows and other operating systems.
CONSOLE	Compiling a console application, and not a GUI one. This symbol is meaningful only under Windows, as all Linux applications are console applications.
BCB	Defined when the C++Builder IDE invokes the Pascal compiler.
ConditionalExpressions	Indicates that the $IF directive is available. It is defined in Kylix and Delphi 6, but not in earlier versions.

TIP I recommend using conditional compilation sparingly and only when it is really required. It is generally better, whenever possible, to write code that can adapt to different situations—for example, adding different versions of the same class (or different inherited classes) to the same program. Excessive use of conditional compilation makes a program hard to read and to debug.

WARNING Remember to issue a Build All command when you change a conditional symbol or a constant, which can affect a conditional compilation; otherwise the affected units won't be recompiled unless their source code changes.

New Hint Directives

Supporting multiple operating systems within the same source code base implies a number of compatibility issues. Besides a modified run-time library and a wholly new component library (discussed in Chapter 4, "The Run-Time Library," and Chapter 5, "Core Library Classes"), Delphi 6 includes special directives Borland uses to mark special portions of the code. As they introduced the idea of custom warnings and messages (described in the previous section), they've added a few special predefined ones.

The *platform* Directive

The first directive of this group is the `platform` directive, used to mark nonportable code. This directive can be used to mark procedures, variables, types, and almost any defined symbol. Borland uses `platform` in its libraries, so that when you use a platform-specific capability (for example, calling the `IncludeTrailingBackslash` function of the `SysUtils` unit), you'll receive a warning message, such as:

```
Symbol 'IncludeTrailingBackslash' is specific to a platform.
```

This warning is a hint for developers who plan to port their code between the Linux and Windows platforms, even in the future. In many cases, you'll be able to find an alternative approach that is fully platform independent. Check the help file (or eventually the library source code) for hints in this direction. In the case of the `IncludeTrailingBackslash` function, there is now a new version, called `IncludeTrailingDelimiter`, that is also portable to a Unix-based file system.

Of course you can use the `platform` directive to mark your code, for example, if you write a component or library that has platform-specific features. Here are a few examples:

```
var
  windowsversion: Integer = 2000 platform;
```

```
procedure Test; platform;
begin
  Beep;
end;

type
  TWinClass = class
    x: Integer;
  end platform;
```

The code fragments of this section are available, for your experiments, in the IfDirective example on the companion CD.

NOTE The position of semicolons for hint directives can be quite confusing at first. The rule is that a hint directive must appear before the semicolon following the symbol it modifies. But a procedure, function, or unit header declaration can be followed only by reserved words, so its hint directive can appear following the semicolon. A type, variable, or constant declaration can be followed by another identifier, so the hint directive must come before the semicolon closing its declaration. Part of the rationale behind this is that the hint directives are not reserved words, so they can be used as the name of an identifier.

The *deprecated* Directive

The `deprecated` directive works in a similar way to the `platform` directive; the only real differences are that it is used in a different context and produces a different compiler warning. The role of `deprecated` is to mark identifiers that are still part of the system for compatibility reasons, but either are going to be removed in the future or expose you to risks of incompatibility. This symbol is used sparingly in the Delphi library.

The *library* Directive

The `library` directive works in a similar way to `deprecated` and `platform`; its role is to mark out code or components that are specific to a library (either VCL or CLX) and are not portable among them. However, apparently this symbol is never used within the Delphi library.

The *$WARN* Directive

The `$WARNINGS` directive (and the corresponding compiler option) allows you to turn off all the warning messages. Most programmers like to keep the messages on and tend to work with programs that compile with no hints and warnings. With the advent of the three hint directives discussed in the last section, however, there are programs specifically aimed for a platform, which cannot compile without compatibility warnings.

To overcome this situation, Delphi 6 introduces the $WARN directive, specifically aimed at disabling hint directives. As an example, you'll disable platform hints by writing this code:

```
{$WARN SYMBOL_PLATFORM OFF}
```

The $WARN directive has five different parameters, related to the three hint directives, and can use the ON and OFF values for each:

- SYMBOL_PLATFORM and UNIT_PLATFORM can be used to disable the platform directive in the current unit or in the unit where the directive is specified. The warning, in fact, is issued while compiling the code that uses the symbol, not while compiling the code with the definition.
- SYMBOL_LIBRARY and UNIT_LIBRARY work on the library directive in the same manner as the platform-related parameters above.
- SYMBOL_DEPRECATED can be used to disable the deprecated directive.

The *$MESSAGE* Directive

The compiler has now the ability to generate warnings in many different situations, so that the developer of a library or a portion of a program can let other programmers know of a given problem or risk in using a given feature, when the program can still legally compile. An extension to this idea is to let programmers insert custom warning messages in the code, with this syntax:

```
{$MESSAGE 'Old version of the unit: consider using the updated version'}
```

Compiling this code will issue a hint message with the text provided. This feature can be used to indicate possible problems, suggest alternative approaches, mark unfinished code, and more. This is probably more reliable than using a TODO item (discussed in the preceding chapter), because a programmer might not open the To-Do List window but the compiler will remind him of the pending problem. However, it is the compiler that issues the message, so you'll see it even if the given portion of the code is not really used by the program because the linker will remove it from the executable file.

These type of free messages, like the hint directives, become very useful to let the developer of a component communicate with the programmers using it, warning of potential pitfalls.

Introducing Classes and Objects

The cornerstone of the OOP extensions available in Object Pascal is represented by the class keyword, which is used inside type declarations. Classes define the blueprint of the objects you create in Delphi. As the terms *class* and *object* are commonly used and often misused, let's be sure we agree on their definitions.

A *class* is a user-defined data type, which has a state (its representation) and some operations (its behavior). A class has some internal data and some methods, in the form of procedures or functions, and usually describes the generic characteristics and behavior of some similar objects.

An *object* is an instance of a class, or a variable of the data type defined by the class. Objects are *actual* entities. When the program runs, objects take up some memory for their internal representation. The relationship between object and class is the same as the one between variable and type.

To declare a new class data type in Object Pascal, with some local data fields and some methods, use the following syntax:

```
type
  TDate = class
    Month, Day, Year: Integer;
    procedure SetValue (m, d, y: Integer);
    function LeapYear: Boolean;
  end;
```

NOTE The convention in Delphi is to use the letter *T* as a prefix for the name of every class you write and every other type (*T* stands for *Type*). This is just a convention—to the compiler, *T* is just a letter like any other—but it is so common that following it will make your code easier to understand.

The following is a complete class definition, with two methods declared and not yet fully defined. The definition of these two methods (the `LeapYear` function and the `SetValue` procedure) must be present in the same unit of the class declaration and are written with this syntax:

```
procedure TDate.SetValue (m, d, y: Integer);
begin
  Month := m;
  Day := d;
  Year := y;
end;

function TDate.LeapYear: Boolean;
begin
  // call IsLeapYear in SysUtils.pas
  Result := IsLeapYear (Year);
end;
```

The method names are prefixed with the class name (using the dot-notation), because a unit can hold multiple classes, possibly with methods having the same names. You can actually avoid retyping the method names and parameter list by using the class completion feature of the editor. Simply type or modify the class definition and press Ctrl+Shift+C while the cursor is within the class definition itself; this will allow Delphi to generate a skeleton of the definition of the methods, including the `begin` and `end` statements.

Once the class has been defined, we can create an object and use it as follows:

```
var
  ADay: TDate;
begin
  // create an object
  ADay := TDate.Create;
  // use the object
  ADay.SetValue (1, 1, 2000);
  if ADay.LeapYear then
    ShowMessage ('Leap year: ' + IntToStr (ADay.Year));
  // destroy the object
  ADay.Free;
end;
```

Notice that `ADay.LeapYear` is an expression similar to `ADay.Year`, although the first is a function call and the second a direct data access. You can optionally add parentheses after the call of a function with no parameters. You can find the code snippets above in the source code of the Date1 example; the only difference is that the program creates a date based on the year provided in an edit box.

Classes, Objects, and Visual Programming

When I teach classes about OOP in Delphi, I always tell my students that regardless of how much OOP you know and how much you use it, Delphi forces you in the OOP direction. Even if you simply create a new application with a form and place a button over it to execute some code when the button is pressed, you are building an object-oriented application. In fact, the form is an object of a new class (by default `TForm1`, which inherits from the base `TForm` class provided by Borland), and the button is an instance of the `TButton` class, provided by Borland, as you can see in the following code snippet:

```
type
  TForm1 = class(TForm)
    Button1: TButton;
  end;
```

Given these premises, it would be very hard to build a Delphi application without using classes and objects. Yes, I know it is technically possible, but I doubt it would make a lot of sense. Not using objects and classes with Delphi would probably be more difficult than using them, as you have to give up all of the design-time tools for visual programming.

In any case, the real challenge is using OOP properly, something I'll try to teach you in this chapter (and in the rest of the book), along with an introduction to the key elements of the Object Pascal language.

The *Self* Keyword

Methods are very similar to procedures and functions. The real difference is that methods have an implicit parameter, which is a reference to the current object. Within a method you can refer to this parameter—the current object—using the `Self` keyword. This extra hidden parameter is needed when you create several objects of the same class, so that each time you apply a method to one of the objects, the method will operate only on its own data and not affect sibling objects.

For example, in the `SetValue` method of the `TDate` class, listed earlier, we simply use `Month`, `Year`, and `Day` to refer to the fields of the current object, something you might express as

```
Self.Month := m;
Self.Day := d;
```

This is actually how the Delphi compiler translates the code, *not* how you are supposed to write it. The `Self` keyword is a fundamental language construct used by the compiler, but at times it is used by programmers to resolve name conflicts and to make tricky code more readable.

NOTE The C++ and Java languages have a similar feature based on the keyword `this`.

All you really need to know about `Self` is that the technical implementation of a call to a method differs from that of a call to a generic subroutine. Methods have an extra hidden parameter, `Self`. Because all this happens behind the scenes, you do not need to know how `Self` works at this time.

If you look at the definition of the `TMethod` data type in the System unit, you'll see that it is a record with a `Code` field and a `Data` field. The first is a pointer to the function's address in memory; the second the value of the `Self` parameter to use when calling that function address. We'll discuss method pointers in Chapter 5.

Overloaded Methods

Object Pascal supports overloaded functions and methods: you can have multiple methods with the same name, provided that the parameters are different. By checking the parameters, the compiler can determine which of the versions of the routine you want to call.

There are two basic rules:

- Each version of the method must be followed by the `overload` keyword.
- The differences must be in the number or type of the parameters or both. The return type cannot be used to distinguish between two methods.

Overloading can be applied to global functions and procedures and to methods of a class. As an example of overloading, I've added to the `TDate` class two different versions of the `SetValue` method:

```
type
  TDate = class
  public
    procedure SetValue (y, m, d: Integer); overload;
    procedure SetValue (NewDate: TDateTime); overload;
...//the rest of the class declaration

procedure TDate.SetValue (y, m, d: Integer);
begin
  fDate := EncodeDate (y, m, d);
end;

procedure TDate.SetValue(NewDate: TDateTime);
begin
  fDate := NewDate;
end;
```

NOTE In Delphi 6, the compiler has been enhanced to improve the resolution of overloaded methods, allowing the compilation of calls that were considered ambiguous. In particular, the compiler handles the difference between `AnsiString` and `WideString` types. The overload resolution also has better support for variant-type parameters (which will provide matches in case there is no exact match for another overloaded version) and interfaces (which are given precedence to object types). Finally, the compiler allows the `nil` value to match an interface-type parameter. Some of these improvements were already introduced in the Kylix compiler.

Creating Components Dynamically

In Delphi, the `Self` keyword is often used when you need to refer to the current form explicitly in one of its methods. The typical example is the creation of a component at run time, where you must pass the owner of the component to its `Create` constructor and assign the same value to its `Parent` property. (The difference between `Owner` and `Parent` properties is discussed in the next chapter.) In both cases, you have to supply the current form as parameter or value, and the best way to do this is to use the `Self` keyword.

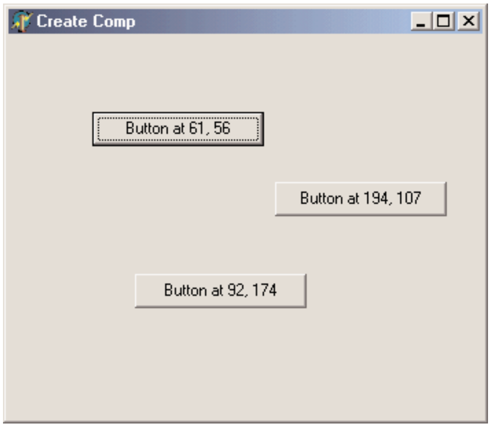
To demonstrate this kind of code, I've written the CreateC example (the name stands for *Create Component*) included on the companion CD. This program has a simple form with no components and a handler for its OnMouseDown event. I've used OnMouseDown because it receives as its parameter the position of the mouse click (unlike the OnClick event). I need this information to create a button component in that position. Here is the code of the method:

```
procedure TForm1.FormMouseDown (Sender: TObject;
  Button: TMouseButton; Shift: TShiftState; X, Y: Integer);
var
  Btn: TButton;
begin
  Btn := TButton.Create (Self);
  Btn.Parent := Self;
  Btn.Left := X;
  Btn.Top := Y;
  Btn.Width := Btn.Width + 50;
  Btn.Caption := Format ('Button at %d, %d', [X, Y]);
end;
```

The effect of this code is to create buttons at mouse-click positions, with a caption indicating the exact location, as you can see in Figure 2.1. In the code above, notice in particular the use of the Self keyword, as the parameter of the Create method and as the value of the Parent property. I'll discuss these two elements (ownership and the Parent property) in Chapter 5.

FIGURE 2.1:

The output of the CreateC example, which creates Button components at run time



It is very common to write code like the above method using a with statement, as in the following listing:

```
procedure TForm1.FormMouseDown (Sender: TObject;
  Button: TMouseButton; Shift: TShiftState; X, Y: Integer);
```

```
begin
  with TButton.Create (Self) do
  begin
    Parent := Self;
    Left := X;
    Top := Y;
    Width := Width + 50;
    Caption := Format ('Button in %d, %d', [X, Y]);
  end;
end;
```

TIP When writing a procedure like the code you've just seen, you might be tempted to use the `Form1` variable instead of `Self`. In this specific example, that change wouldn't make any practical difference, but if there are multiple instances of a form, using `Form1` would be an error. In fact, if the `Form1` variable refers to the first form of that type being created, by clicking in another form of the same type, the new button will always be displayed in the first form. Its `Owner` and `Parent` will be `Form1` and not the form the user has clicked. In general, referring to a particular instance of a class when the current object is required is bad OOP practice.

Class Methods and Class Data

When you define a field in a class, you actually specify that the field should be added to each object of that class. Each instance has its own independent representation (referred to by the `Self` pointer). In some cases, however, it might be useful to have a field that is shared by all the objects of a class.

Other object-oriented programming languages have formal constructs to express this, while in Object Pascal we can simulate this feature using the encapsulation provided at the unit level. You can simply add a variable in the `implementation` portion of a unit, to obtain a class variable—a single memory location shared by all of the objects of a class.

If you need to access this value from outside the unit, you might use a method of the class. However, this forces you to apply this method to one of the instances of the class. An alternative solution is to declare a *class method*. A class method cannot access the data of any single object but can be applied to a class as a whole rather than to a particular instance.

To declare a class method in Object Pascal, you simply add the `class` keyword in front of it:

```
type
  MyClass = class
    class function ClassMeanValue: Integer;
```

The use of class methods is not very common in Object Pascal, because you can obtain the same effect by adding a procedure or function to a unit declaring a class. Object-oriented purists, however, will definitely prefer the use of a class method over a routine unrelated to a class. For example, an OOP purist would add a class method for getting the current date to a `TDate` class instead of using a global function (also because some OOP languages, including Java, don't have the notion of global functions).

We'll see several class methods in the next chapter, when we'll examine the structure of the `TObject` class.

TIP Contrary to other OOP languages, Delphi class methods can also be virtual, so they can be overridden and used to obtain polymorphism (a technique discussed later in this chapter).

Encapsulation

A class can have any amount of data and any number of methods. However, for a good object-oriented approach, data should be hidden, or *encapsulated*, inside the class using it. When you access a date, for example, it makes no sense to change the value of the day by itself. In fact, changing the value of the day might result in an invalid date, such as February 30. Using methods to access the internal representation of an object limits the risk of generating erroneous situations, as the methods can check whether the date is valid and refuse to modify the new value if it is not. Encapsulation is important because it allows the class writer to modify the internal representation in a future version.

The concept of encapsulation is often indicated by the idea of a "black box," where you don't know about the internals: You only know how to interface with it or how to use it regardless of its internal structure. The "how to use" portion, called the *class interface*, allows other parts of a program to access and use the objects of that class. However, when you use the objects, most of their code is hidden. You seldom know what internal data the object has, and you usually have no way to access the data directly. Of course, you are supposed to use methods to access the data, which is shielded from unauthorized access. This is the object-oriented approach to a classical programming concept known as *information hiding*.

Delphi implements this class-based encapsulation but still supports the classic module-based encapsulation using the structure of units. Because the two are strictly related, let me recap the traditional approach first.

Encapsulation and Units

A unit in Object Pascal is a secondary source-code file, with the main source-code file being represented by the project source code. Every unit has two main sections, called `interface` and `implementation`, as well as two optional ones for `initialization` and `finalization` code. I want to focus here on the information hiding implemented by units.

In short, every identifier (type, routine, variable, and so on) that you declare in the interface portion of a unit becomes visible to any other unit of the program, provided there is a uses statement referring back to the unit that defines the identifier. All the routines and methods you declare in the interface portion of the unit must later be fully defined in the implemented portion of the same unit. In the interface section of a unit, however, you cannot write any actual statements to execute.

On the other hand, any identifier you declare in the implementation portion of the unit is local to the unit and is not visible outside it. A unit can have local data, local support functions, and even local types that the rest of the program is not allowed to access. This provides a direct way to hide the implementation details of an abstraction from its users, so you can later change your code without affecting other units of the program (and without even having to notify the changes to other programmers writing those units).

When you write classes in a unit, you'll generally define them in the interface portion of a unit, but some special keywords allow you to hide portions of this class interface.

Private, Protected, and Public

For class-based encapsulation, the Object Pascal language has three access specifiers: private, protected, and public. A fourth, published, controls RTTI and design time information and will be discussed in more detail in Chapter 5. Here are the three *classic* access specifiers:

- The private directive denotes fields and methods of a class that are not accessible outside the unit (the source code file) that declares the class.
- The protected directive is used to indicate methods and fields with limited visibility. Only the current class and its subclasses can access protected elements. We'll discuss this keyword again in the "Protected Fields and Encapsulation" section.
- The public directive denotes fields and methods that are freely accessible from any other portion of a program as well as in the unit in which they are defined.

Generally, the fields of a class should be private; the methods are usually public. However, this is not always the case. Methods can be private or protected if they are needed only internally to perform some partial computation. Fields can be protected so that you can manipulate them in subclasses, but only if you are fairly sure that their type definition is not going to change. Access specifiers only restrict code outside your unit from accessing certain members of classes declared in the interface section of your unit. This means that if two classes are in the same unit, there is no protection for their private fields. Only by placing a class in the interface portion of a unit will you limit the visibility from classes and functions in other units to the public method and fields of the class.

As an example, consider this new version of the TDate class:

```
type
  TDate = class
  private
    Month, Day, Year: Integer;
  public
    procedure SetValue (y, m, d: Integer); overload;
    procedure SetValue (NewDate: TDateTime); overload;
    function LeapYear: Boolean;
    function GetText: string;
    procedure Increase;
  end;
```

In this version, the fields are now declared to be private, and there are some new methods. The first, GetText, is a function that returns a string with the date. You might think of adding other functions, such as GetDay, GetMonth, and GetYear, which simply return the corresponding private data, but similar direct data-access functions are not always needed. Providing access functions for each and every field might reduce the encapsulation and make it harder to modify the internal implementation of a class. Access functions should be provided only if they are part of the logical interface of the class you are implementing.

Another new method is the Increase procedure, which increases the date by one day. This is far from simple, because you need to consider the different lengths of the various months as well as leap and non–leap years. What I'll do to make it easier to write the code is change the internal implementation of the class to Delphi's TDateTime type for the internal implementation. The class definition will change to (the complete code will be in the next example, DateProp):

```
type
  TDate = class
  private
    fDate: TDateTime;
  public
    procedure SetValue (y, m, d: Integer); overload;
    procedure SetValue (NewDate: TDateTime); overload;
    function LeapYear: Boolean;
    function GetText: string;
    procedure Increase;
  end;
```

Notice that because the only change is in the private portion of the class, you won't have to modify any of your existing programs that use it. This is the advantage of encapsulation!

NOTE The TDateTime type is actually a floating-point number. The integral portion of the number indicates the date since 12/30/1899, the same base date used by OLE Automation and Microsoft applications. (Use negative values to express previous years.) The decimal portion indicates the time as a fraction. For example, a value of 3.75 stands for the second of January 1900, at 6:00 A.M. (three-quarters of a day). To add or subtract dates, you can add or subtract the number of days, which is much simpler than adding days with a day/month/year representation.

Encapsulating with Properties

Properties are a very sound OOP mechanism, or a very well thought out application of the idea of encapsulation. Essentially, you have a name that completely hides its implementation details. This allows you to modify the class extensively without affecting the code using it. A good definition of properties is that of *virtual fields*. From the perspective of the user of the class that defines them, properties look exactly like fields, as you can generally read or write their value. For example, you can read the value of the Caption property of a button and assign it to the Text property of an edit box with the following code:

```
Edit1.Text := Button1.Caption;
```

This looks like we are reading and writing fields. However, properties can be directly mapped to data, as well as to access methods, for reading and writing the value. When properties are mapped to methods, the data they access can be part of the object or outside of it, and they can produce side effects, such as repainting a control after you change one of its values. Technically, a property is an identifier that is mapped to data or methods using a read and a write clause. For example, here is the definition of a Month property for a date class:

```
property Month: Integer read FMonth write SetMonth;
```

To access the value of the Month property, the program reads the value of the private field FMonth, while to change the property value it calls the method SetMonth (which must be defined inside the class, of course). Different combinations are possible (for example, we could also use a method to read the value or directly change a field in the write directive), but the use of a method to change the value of a property is very common. Here are two alternative definitions for the property, mapped to two access methods or mapped directly to data in both directions:

```
property Month: Integer read GetMonth write SetMonth;
property Month: Integer read FMonth write FMonth;
```

TIP When you write code that accesses a property, it is important to realize that a method might be called. The issue is that some of these methods take some time to execute; they can also produce side effects, often including a (slow) repainting of the component on the screen. Although side effects of properties are seldom documented, you should be aware that they exist, particularly when you are trying to optimize your code.

Often, the actual data and access methods are private (or protected) while the property is public. This means you must use the property to have access to those methods or data, a technique that provides both an extended and a simplified version of encapsulation. It is an *extended* encapsulation because not only can you change the representation of the data and its access functions, but you can also add or remove access functions without changing the calling code at all. A user only needs to recompile the program using the property.

Class Completion for Properties

Properties provide a *simplified* encapsulation because when extra code is not required, you map the properties directly to fields, without writing tedious and useless access methods. And even when you want to write those methods, the IDE can use class completion (the Ctrl+Shift+C key combination) to generate the skeleton of the access methods of the properties for you. If you simply type in a class (say TMyClass),

```
property X: Integer;
```

and activate class completion, Delphi generates a SetX method for the property and adds the FX field to the class. The resulting code looks like this:

```
type
  TMyClass = class(TForm)
  private
    FX: Integer;
    procedure SetX(const Value: Integer);
  public
    property X: Integer read FX write SetX;
  end;

implementation

procedure TMyClass.SetX(const Value: Integer);
begin
  FX := Value;
end;
```

This really saves a lot of typing. You can even partially control how class completion generates Set and Get methods for the property. In fact, if you first type the property declaration including the read and write directives, as in

```
property X: Integer read GetX write SetX;
```

Class completion will generate the requested methods or add the field definition. If you want both the field and the methods, type in only the property name and its data type (as in the first example above), and let Delphi expand the declaration. At this point, fix the expanded declaration by replacing the FX field with a GetX method in the read portion, and invoke class completion a second time.

Properties for the *TDate* Class

As an example, I've added properties for accessing the year, the month, and the day to an object of the TDate class discussed earlier. These properties are not mapped to specific fields, but they all map to the single fDate field storing the entire date information. This is the new definition of the class:

```
type
  TDate = class
  private
    fDate: TDateTime;
    procedure SetDay(const Value: Integer);
    procedure SetMonth(const Value: Integer);
    procedure SetYear(const Value: Integer);
    function GetDay: Integer;
    function GetMonth: Integer;
    function GetYear: Integer;
  public
    procedure SetValue (y, m, d: Integer); overload;
    procedure SetValue (NewDate: TDateTime); overload;
    function LeapYear: Boolean;
    function GetText: string;
    procedure Increase;
    property Year: Integer read GetYear write SetYear;
    property Month: Integer read GetMonth write SetMonth;
    property Day: Integer read GetDay write SetDay;
  end;
```

Each of the Get and Set methods is easily implemented using functions available in the new DateUtils unit (discuss in more detail in Chapter 4). Here is the code for two of them (the others are very similar):

```
function TDate.GetYear: Integer;
begin
  Result := YearOf (fDate);
end;

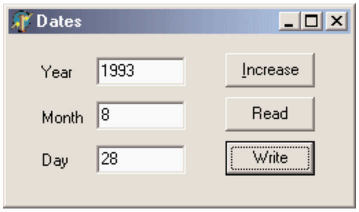
procedure TDate.SetYear(const Value: Integer);
begin
  fDate := RecodeYear (fDate, Value);
end;
```

The code for this class is available in the DateProp example. The program uses a secondary unit for the definition of the TDate class to enforce encapsulation and creates a single-date object stored in a form variable and kept in memory for the entire execution of the program. Using a standard approach, the object is created in the form OnCreate event handler and destroyed in the form OnDestroy event handler.

The form of the program (see Figure 2.2) has three edit boxes and buttons to copy the values of these edit boxes to and from the properties of the date object:

FIGURE 2.2:

The form of the DateProp example



Year: 1993
Month: 8
Day: 28

```
procedure TDateForm.BtnReadClick(Sender: TObject);
begin
  EditYear.Text := IntToStr (TheDay.Year);
  EditMonth.Text := IntToStr (TheDay.Month);
  EditDay.Text := IntToStr (TheDay.Day);
end;
```

WARNING When writing the values, the program uses the `SetValue` method instead of setting each of the properties. In fact, assigning the month and the day separately can cause you trouble when the month is not valid for the current day. For example, the day is currently January 31, and you want to assign to it February 20. If you assign the month first, this part of the assignment will fail, as February 31 does not exist. If you assign the day first, the problem will arise when doing the reverse assignment. Due to the validity rules for dates, it is better to assign everything at once.

Advanced Features of Properties

Properties have several advanced features I'll focus on in future chapters, specifically the introduction to the base classes of the library in Chapter 5 and writing custom Delphi components in Chapter 11, "Creating Components." This is a short summary of these more advanced features:

- The `write` directive of a property can be omitted, making it a *read-only* property. The compiler will issue an error if you try to change it. You can also omit the `read` directive and define a *write-only* property, but that doesn't make much sense and is used infrequently.
- The Delphi IDE gives special treatment to *design-time* properties, declared with the `published` access specifier and generally displayed in the Object Inspector for the selected component. More on the `published` keyword and its effect is in Chapter 5.
- The other properties, often called *run-time only* properties, are those declared with the `public` access specifier. These properties can be used in the program code.

- You can define *array-based* properties, which use the typical notation with square brackets to access an element of a list. The *string list–based* properties, such as the `Lines` of a list box, are a typical example of this group.
- Properties have special directives, including `stored` and `default`, which control the *component streaming system*, introduced in Chapter 5 and detailed in Chapter 11.

NOTE You can usually assign a value to a property or read it, and you can even use properties in expressions, but you cannot always pass a property as a parameter to a procedure or method. This is because a property is not a memory location, so it cannot be used as a `var` parameter; it cannot be passed by reference.

Encapsulation and Forms

One of the key ideas of encapsulation is to reduce the number of global variables used by a program. A global variable can be accessed from every portion of a program. For this reason, a change in a global variable affects the whole program. On the other hand, when you change the representation of a class's field, you only need to change the code of some methods of that class and nothing else. Therefore, we can say that information hiding refers to *encapsulating changes*.

Let me clarify this idea with an example. When you have a program with multiple forms, you can make some data available to every form by declaring it as a global variable in the interface portion of the unit of one of the forms:

```
var
  Form1: TForm1;
  nClicks: Integer;
```

This works but has two problems. First, the data is not connected to a specific instance of the form, but to the entire program. If you create two forms of the same type, they'll share the data. If you want every form of the same type to have its own copy of the data, the only solution is to add it to the form class:

```
type
  TForm1 = class(TForm)
  public
    nClicks: Integer;
  end;
```

The second problem is that if you define the data as a global variable or as a public field of a form, you won't be able to modify its implementation in the future without affecting the code that uses the data. For example, if you only have to read the current value from other forms, you can declare the data as private and provide a method to read the value:

```
type
  TForm1 = class(TForm)
  public
    function GetClicks: Integer;
  private
    nClicks: Integer;
  end;

function TForm1.GetClicks: Integer;
begin
  Result := nClicks;
end;
```

Adding Properties to Forms

An even better solution is to add a property to the form. Every time you want to make some information of a form available to other forms, you should really use a property, for all the reasons discussed in the previous section. Simply change the field declaration of the form, shown in the preceding listing, by adding the keyword `property` in front of it and then press Ctrl+Shift+C to activate code completion. Delphi will automatically generate all of the extra code you need. In the form, you also need to handle the `OnClick` event, increasing the value of the property (and showing it in the form caption):

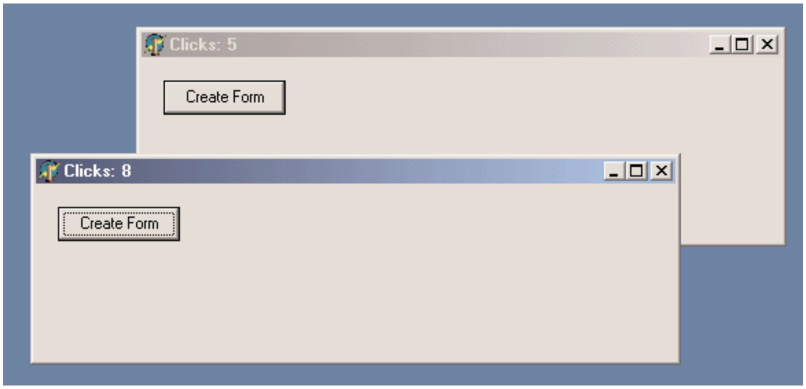
```
procedure TForm1.FormClick(Sender: TObject);
begin
  Inc (FClicks);
  Caption := 'Clicks: ' + IntToStr (FClicks);
end;
```

The complete code for this form class is available in the FormProp example and illustrated in Figure 2.3. The program can create multi-instances of the form (that is, multiple objects based on the same form class), each with its own click count. Clicking the Create Form button creates the secondary forms, using the following code:

```
procedure TForm1.btnCreateFormClick(Sender: TObject);
begin
  with TForm1.Create (Self) do
    Show;
end;
```

FIGURE 2.3:

Two forms of the FormProp example at run time



NOTE Notice that adding a property to a form doesn't add to the list of the form properties in the Object Inspector.

In my opinion, properties should also be used in the form classes to encapsulate the access to the components of a form. For example, if you have a main form with a status bar used to display some information (and with the `SimplePanel` property set to `True`) and you want to modify the text from a secondary form, you might be tempted to write:

```
Form1.StatusBar1.SimpleText := 'new text';
```

This is a standard practice in Delphi, but it's not a good one, because it doesn't provide any encapsulation of the form structure or components. If you have similar code in many places throughout an application, and you later decide to modify the user interface of the form (replacing `StatusBar` with another control or activating multiple panels), you'll have to fix the code in many places. The alternative is to use a method or, even better, a property to hide the specific control. Simply type

```
property StatusText: string read GetText write SetText;
```

and press the Ctrl+Shift+C combination again, to let Delphi add the definition of both methods for reading and writing the property:

```
function TForm1.GetText: string;
begin
  Result := StatusBar1.SimpleText;
end;

procedure TForm1.SetText(const Value: string);
begin
  StatusBar1.SimpleText := Value;
end;
```

In the other forms of the program, you can simply refer to the StatusText property of the form, and if the user interface changes, only the Set and Get methods of the property are affected.

NOTE See Chapter 5 for a detailed discussion of how you can avoid having published form fields for components, which will improve encapsulation. But don't rush there: the description requires a good knowledge of Delphi, and the technique discussed has a few drawbacks!

Constructors

As I've mentioned, to allocate the memory for the object, we call the Create method. This is a *constructor*, a special method that you can apply to a class to allocate memory for an instance of that class. The instance is returned by the constructor and can be assigned to a variable for storing the object and using it later on. The default TObject.Create constructor initializes all the data of the new instance to zero.

If you want your instance data to start out with a nonzero value, then you need to write a custom constructor to do that. The new constructor can be called Create, or it can have any other name; use the constructor keyword in front of it. Notice that you don't need to call TObject.Create: it is Delphi that allocates the memory for the new object, not the class constructor. All you have to do is to initialize the class base.

If you create objects without initializing them, calling methods later may result in odd behavior or even a run-time error. A consistent use of constructors to initialize objects' data is an important *preventive* technique to avoid these errors in the first place. For example, we must call the SetValue procedure of the TDate class after we've created the object. As an alternative, we can provide a customized constructor, which creates the object and gives it an initial value.

Although you can use any name for a constructor, you should stick to the standard name, Create. If you use a name other than Create, the Create constructor of the base TObject class will still be available, but a programmer calling this default constructor might bypass the initialization code you've provided because they don't recognize the name.

By defining a Create constructor with some parameters, you replace the default definition with a new one and make its use compulsory. For example, after you define

```
type
  TDate = class
  public
    constructor Create (y, m, d: Integer);
constructor TDate.Create (y, m, d: Integer);
begin
  fDate := EncodeDate (y, m, d);
end;
```

you'll be able to call this constructor and not the standard `Create`:

```
var
  ADay: TDate;
begin
  // Error, does not compile:
  ADay := TDate.Create;
  // OK:
  ADay := TDate.Create (1, 1, 2000);
```

The rules for writing constructors for custom components are different, as we'll see in Chapter 11. In short, when you inherit from `TComponent`, you should override the default `Create` constructor with one parameter and avoid disabling it.

Overloaded Constructors

Overloading is particularly relevant for constructors, because we can add to a class multiple constructors and call them all `Create`, which makes them easy to remember.

NOTE Historically, overloading was added to C++ to allow the use of multiple constructors that have the same name (the name of the class). In Object Pascal, this feature was considered unnecessary because multiple constructors can have different specific names. The increased integration of Delphi with C++Builder has motivated Borland to make this feature available in both languages, starting with Delphi 4. Technically, when C++Builder constructs an instance of a Delphi VCL class, it looks for a Delphi constructor named `Create` and nothing but `Create`. If the Delphi class has constructors by other names, they cannot be used from C++Builder code. Therefore, when creating classes and components you intend to share with C++Builder programmers, you should be careful to name all your constructors `Create` and distinguish between them by their parameter lists (using `overload`). Delphi does not require this, but it is required for C++Builder to use your Delphi classes.

As an example, I've added to the class two separate `Create` constructors: one with no parameters, which hides the default constructor, and one with the initialization values. The constructor with no parameter uses as the default value today's date:

```
type
  TDate = class
  public
    constructor Create; overload;
    constructor Create (y, m, d: Integer); overload;
constructor TDate.Create (y, m, d: Integer);
begin
  fDate := EncodeDate (y, m, d);
end;

constructor TDate.Create;
begin
  fDate := Date;
end;
```

Having these two constructors makes it possible to define a new `TDate` object in two different ways:

```
var
  Day1, Day2: TDate;
begin
  Day1 := TDate.Create (2001, 12, 25);
  Day2 := TDate.Create; // today
```

See the section “The Complete *TDate* Class” later in this chapter for the DateView example, which includes the code of these constructors.

Destructors

In the same way that a class can have a custom constructor, it can have a custom destructor, a method declared with the `destructor` keyword and called `Destroy`, which can perform some resource cleanup before an object is destroyed. Just as a constructor call allocates memory for the object, a destructor call frees the memory.

We can write code for a destructor, generally overriding the default `Destroy` destructor, to let the object execute some code before it is destroyed. Destructors are needed only for objects that acquire resources in their constructors or during their lifetime. In your code, of course, you don’t have to handle memory de-allocation—this is something Delphi does for you.

`Destroy` is a virtual destructor of the `TObject` class. Most of the classes that require custom clean-up code when the objects are destroyed override this virtual method. The reason you should never define a new destructor is that objects are usually destroyed by calling the `Free` method, and this method calls the `Destroy` virtual destructor of the specific class (virtual methods will be discussed later in this chapter).

Free (and *nil*)

`Free` is a method of the `TObject` class, inherited by all other classes. The `Free` method basically checks whether the current object (`Self`) is not `nil` before calling the `Destroy` virtual destructor. Here is its pseudocode (the actual Delphi code is written in assembler):

```
procedure TObject.Free;
begin
  if Self <> nil then
    Destroy;
end;
```

By looking at this code, you can see that calling `Free` doesn't set the object to `nil` automatically; this is something you should do yourself! The reason is that the object doesn't know which variables may be referring to it, so it has no way to set them all to `nil`.

NOTE Automatically setting an object to `nil` is not possible. You might have several references to the same object, and Delphi doesn't track them. At the same time, within a method (such as `Free`) we can operate on the object, but we know nothing about the object reference—the memory address of the variable we've used to call the method. In other words, inside the `Free` method or any other method of a class, we know the memory address of the object (`Self`), but we don't know the memory location of the variable referring to the object.

Delphi 5 introduced a `FreeAndNil` procedure you can use to free an object and set its reference to `nil` at the same time. Simply call

```
FreeAndNil (Obj1)
```

instead of writing

```
Obj1.Free;
Obj1 := nil;
```

The `FreeAndNil` procedure knows about the object reference, passed as a parameter, and can act on it. Here is Delphi code for `FreeAndNil`:

```
procedure FreeAndNil(var Obj);
var
  P: TObject;
begin
  P := TObject(Obj);
  // clear the reference before destroying the object
  TObject(Obj) := nil;
  P.Free;
end;
```

NOTE There's more on this topic in the section "Destroying Objects Only Once" later in this chapter.

The Complete *TDate* Class

In the initial portion of this chapter, I've shown you bits and pieces of the source code for different versions of a TDate class. In Listing 2.1 is the complete interface portion of the unit that defines the TDate class.

Listing 2.1: The *TDate* class, from the ViewDate example

```
unit Dates;

interface

type
  TDate = class
  private
    fDate: TDateTime;
    procedure SetDay(const Value: Integer);
    procedure SetMonth(const Value: Integer);
    procedure SetYear(const Value: Integer);
    function GetDay: Integer;
    function GetMonth: Integer;
    function GetYear: Integer;
  public
    constructor Create; overload;
    constructor Create (y, m, d: Integer); overload;
    procedure SetValue (y, m, d: Integer); overload;
    procedure SetValue (NewDate: TDateTime); overload;
    function LeapYear: Boolean;
    procedure Increase (NumberOfDays: Integer = 1);
    procedure Decrease (NumberOfDays: Integer = 1);
    function GetText: string;
    property Year: Integer read GetYear write SetYear;
    property Month: Integer read GetMonth write SetMonth;
    property Day: Integer read GetDay write SetDay;
  end;

implementation

uses
  SysUtils, DateUtils;

procedure TDate.SetValue (y, m, d: Integer);
begin
  fDate := EncodeDate (y, m, d);
end;

function TDate.LeapYear: Boolean;
begin
  Result := IsInLeapYear(fDate);
end;
```

```
procedure TDate.Increase (NumberOfDays: Integer = 1);
begin
  fDate := fDate + NumberOfDays;
end;

function TDate.GetText: string;
begin
  GetText := DateToStr (fDate);
end;

procedure TDate.Decrease (NumberOfDays: Integer = 1);
begin
  fDate := fDate - NumberOfDays;
end;

constructor TDate.Create (y, m, d: Integer);
begin
  fDate := EncodeDate (y, m, d);
end;

constructor TDate.Create;
begin
  fDate := Date;
end;

procedure TDate.SetValue(NewDate: TDateTime);
begin
  fDate := NewDate;
end;

procedure TDate.SetDay(const Value: Integer);
begin
  fDate := RecodeDay (fDate, Value);
end;

procedure TDate.SetMonth(const Value: Integer);
begin
  fDate := RecodeMonth (fDate, Value);
end;

procedure TDate.SetYear(const Value: Integer);
begin
  fDate := RecodeYear (fDate, Value);
end;

function TDate.GetDay: Integer;
begin
  Result := DayOf (fDate);
end;
```

```
function TDate.GetMonth: Integer;
begin
  Result := MonthOf (fDate);
end;

function TDate.GetYear: Integer;
begin
  Result := YearOf (fDate);
end;

end.
```

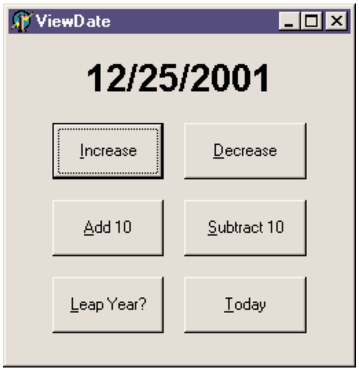
The aim of the Increase and Decrease methods, which have a default value for their parameter, is quite easy to understand. If called with no parameter, they change the value of the date to the next or previous day. If a NumberOfDays parameter is part of the call, they add or subtract that number.

GetText returns a string with the formatted date, using the DateToStr function.

The form of the example I've built to show you how to use the TDate class, as illustrated in Figure 2.4, has a caption to display a date and six buttons, which can be used to modify the date. To make the label component look nice, I've given it a big font, made it as wide as the form, set its Alignment property to taCenter, and set its AutoSize property to False.

FIGURE 2.4:

The output of the ViewDate example at startup



The startup code of this program is in the OnCreate event handler. In the corresponding method, we create an instance of the TDate class, initialize this object, and then show its textual description in the Caption of the label.

```
procedure TDateForm.FormCreate(Sender: TObject);
begin
  TheDay := TDate.Create (2001, 12, 25);
  LabelDate.Caption := TheDay.GetText;
end;
```

TheDay is a private field of the class of the form, TDateForm. (By the way, the name for the form class is automatically chosen by Delphi when we change the Name property of the form to DateForm.) The object is then destroyed along with the form:

```
procedure TDateForm.FormDestroy(Sender: TObject);
begin
  TheDay.Free;
end;
```

When the user clicks one of the six buttons, we need to apply the corresponding method to the TheDay object and then display the new value of the date in the label:

```
procedure TDateForm.BtnTodayClick(Sender: TObject);
begin
  TheDay.SetValue (Date);
  LabelDate.Caption := TheDay.GetText;
end;
```

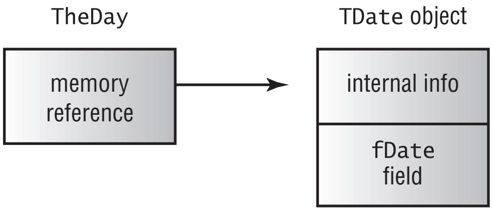
Notice that in this code we reuse an existing object, assigning a new date to it. We could also create a new object and assign it to the existing TheDate variable, but this can lead to confusing situations, as explained in the next section.

Delphi's Object Reference Model

In some OOP languages, declaring a variable of a class type creates an instance of that class. Object Pascal, instead, is based on an *object reference model*. The idea is that a variable of a class type, such as the TheDay variable in the preceding ViewDate example, does not hold the value of the object. Rather, it contains a reference, or a *pointer*, to indicate the memory location where the object has been stored. You can see this structure depicted in Figure 2.5.

FIGURE 2.5:

A representation of the structure of an object in memory, with a variable referring to it



The only problem with this approach is that when you declare a variable, you don't create an object in memory; you only reserve the memory location for a reference to an object. Object instances must be created manually, at least for the objects of the classes you define. Instances of the components you place on a form are built automatically by Delphi.

You've seen how to create an instance of an object by applying a constructor to its class. Once you have created an object and you've finished using it, you need to dispose of it (to avoid filling up memory you don't need any more, which causes what is known as a *memory leak*). This can be accomplished by calling the Free method. As long as you create objects when you need them and free them when you're finished with them, the object reference model works without a glitch. The object reference model has many consequences on assigning object and on managing memory, as we'll see in the next two sections.

Assigning Objects

If a variable holding an object only contains a reference to the object in memory, what happens if you copy the value of that variable? Suppose we write the BtnTodayClick method of the ViewDate example in the following way:

```
procedure TDateForm.BtnTodayClick(Sender: TObject);
var
  NewDay: TDate;
begin
  NewDay := TDate.Create;
  TheDay := NewDay;
  LabelDate.Caption := TheDay.GetText;
end;
```

This code copies the memory address of the NewDay object to the TheDay variable (as shown in Figure 2.6); it doesn't copy the data of an object into the other. In this particular circumstance, this is not a very good approach, as we keep allocating memory for a new object every time the button is pressed, but we never release the memory of the object the TheDay variable was previously pointing to. This specific issue can be solved by freeing the old object, as in the following code (which is also simplified, without the use of an explicit variable for the newly created object):

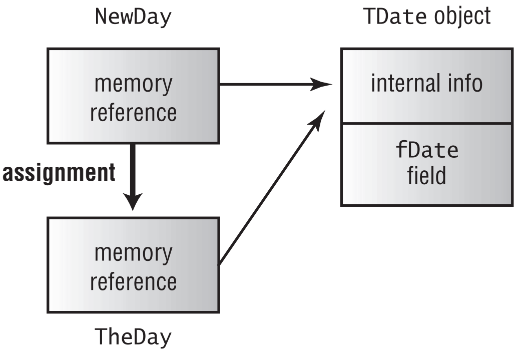


FIGURE 2.6:

A representation of the operation of assigning an object reference to another one. This is different from copying the actual content of an object to another.

```
procedure TDateForm.BtnTodayClick(Sender: TObject);
begin
  TheDay.Free;
  TheDay := TDate.Create;
```

The important thing to keep in mind is that, when you assign an object to another object, Delphi copies the reference to the object in memory to the new object/reference. You should not consider this a negative: In many cases, being able to define a variable referring to an existing object can be a plus. For example, you can store the object returned by calling a function or accessing a property and use it in subsequent statements, as this code snippet indicates:

```
var
  ADay: TDate;
begin
  ADay: UserInformation.GetBirthDate;
  // use a ADay
```

The same happens if you pass an object as a parameter to a function: You don't create a new object, but you refer to the same one in two different places of the code. For example, by writing this procedure and calling it as follows, you'll modify the `Caption` property of the `Button1` object, not of a copy of its data in memory (which would be totally useless):

```
procedure CaptionPlus (Button: TButton);
begin
  Button.Caption := Button.Caption + '+';
end;

// call...
CaptionPlus (Button1)
```

What if you really want to change the data inside an existing object, so that it matches the data of another object? You have to copy each field of the object, which is possible only if they are all public, or provide a specific method to copy the internal data. Some classes of the VCL have an `Assign` method, which does this copy operation. To be more precise, most of the VCL classes inheriting from `TPersistent`, but not inheriting from `TComponent`, have the `Assign` method. Other `TComponent`-derived classes have this method but raise an exception when it is called.

In the DateCopy example, slightly modified from the ViewDate program, I've added an `Assign` method to the `TDate` class, and I've called it from the Today button, with the following code:

```
procedure TDate.Assign (Source: TDate);
begin
  fDate := Source.fDate;
end;
```

```
procedure TDateForm.BtnTodayClick(Sender: TObject);
var
  NewDay: TDate;
begin
  NewDay := TDate.Create;
  TheDay.Assign(NewDay);
  LabelDate.Caption := TheDay.GetText;
  NewDay.Free;
end;
```

Objects and Memory

Memory management in Delphi is subject to three rules: Every object must be created before it can be used; every object must be destroyed after it has been used; and every object must be destroyed only once. Whether you have to do these operations in your code, or you can let Delphi handle memory management for you, depends on the model you choose among the different approaches provided by Delphi.

Delphi supports three types of memory management for dynamic elements (that is, elements not in the stack and the global memory area):

- Every time you create an object explicitly, in the code of your application, you should also free it. If you fail to do so, the memory used by that object won't be released for other objects until the program terminates.
- When you create a component, you can specify an owner component, passing the owner to the component constructor. The owner component (often a form) becomes responsible for destroying all the objects it owns. In other words, when you free the form, it frees all the components it owns. So, if you create a component and give it an owner, you don't have to remember to destroy it. This is the standard behavior of the components you create at design time by placing them on a form or data module.
- When you allocate memory for strings, dynamic arrays, and objects referenced by interface variables (discussed in Chapter 3), Delphi automatically frees the memory when the reference goes out of scope. You don't need to free a string: when it becomes unreachable, its memory is released.

Destroying Objects Only Once

Another problem is that if you call the `Destroy` destructor of an object twice, you get an error. If you remember to set the object to `nil`, you can call `Free` twice with no problem.

NOTE You might wonder why you can safely call Free if the object reference is nil, but you can't call Destroy. The reason is that Free is a known method at a given memory location, whereas the virtual function Destroy is determined at run time by looking at the type of the object, a very dangerous operation if the object doesn't exist any more.

To sum things up, here are a couple of guidelines:

- Always call Free to destroy objects, instead of calling the Destroy destructor.
- Use FreeAndNil, or set object references to nil after calling Free, unless the reference is going out of scope immediately afterward.

In general, you can also check whether an object is nil by using the Assigned function. So the following two statements are equivalent, at least in most cases:

```
if Assigned (ADate) then ...
if ADate <> nil then ...
```

Notice that these statements test only whether the pointer is not nil; they do not check whether it is a valid pointer. If you write the following code, the test will be satisfied, and you'll get an error on the line with the call to the method of the object:

```
ToDestroy.Free;
if ToDestroy <> nil then
  ToDestroy.DoSomething;
```

It is important to realize that calling Free doesn't set the object to nil.

What's Next?

In this chapter, we have discussed the foundations of object-oriented programming (OOP) in Object Pascal. We have considered the definition of classes, the use of methods, encapsulation, and memory management, but also some more advanced concepts such as properties and the dynamic creation of components.

This is certainly a lot of information if you are a newcomer, but if you are fluent in another OOP language or if you've already used past versions of Delphi, you should be able to apply the topics covered in this chapter to your programming.

The next chapter continues on the same line, highlighting inheritance in particular, along with virtual functions and interfaces. It also includes a discussion on exception handling and class references, so that at the end you'll have a complete overview of the language. At that point, you'll be ready to start focusing on the libraries the compiler relies on, and we'll get back to see how properties are used by Delphi and its IDE (in Chapter 5). Other chapters will provide further information on applying the OOP concepts to Delphi programming. You'll find OOP tips throughout the entire book, but particularly in Chapter 11, devoted to writing custom Delphi components.

CHAPTER 3

The Object Pascal Language: Inheritance and Polymorphism

- Inheritance
- Virtual methods
- Polymorphism
- Type-safe down-casting (run-time type information)
- Interfaces
- Working with exceptions
- Class references

After the introduction to classes and objects we've seen over the last chapter, let's move on to another key element of the language, *inheritance*. Deriving a class from an existing one is the real revolutionary idea of object-oriented programming, and it goes along with polymorphism, virtual functions, abstract functions, and many other topics discussed in this chapter.

We'll focus also on interfaces, another intriguing idea of the most recent OOP languages, and we'll cover a few more elements of Object Pascal, such as exception handling and class references. Together with the previous chapter, this will provide an almost complete roundup of the language.

Inheriting from Existing Types

We often need to use a slightly different version of an existing class that we have written or that someone has given to us. For example, you might need to add a new method or slightly change an existing one. You can do this easily by modifying the original code, unless you want to be able to use the two different versions of the class in different circumstances. Also, if the class was originally written by someone else (including Borland), you might want to keep your changes separate.

A typical alternative is to make a copy of the original type definition, change its code to support the new features, and give a new name to the resulting class. This might work, but it also might create problems: In duplicating the code you also duplicate the bugs; and if you want to add a new feature, you'll need to add it two or more times, depending on the number of copies of the original code you've made. This approach results in two completely different data types, so the compiler cannot help you take advantage of the similarities between the two types.

To solve these kinds of problems in expressing similarities between classes, Object Pascal allows you to define a new class directly from an existing one. This technique is known as *inheritance* (or *subclassing*) and is one of the fundamental elements of object-oriented programming languages. To inherit from an existing class, you only need to indicate that class at the beginning of the declaration of the subclass. For example, Delphi does this automatically each time you create a new form:

```
type
  TForm1 = class(TForm)
  end;
```

This simple definition indicates that the `TForm1` class inherits all the methods, fields, properties, and events of the `TForm` class. You can apply any public method of the `TForm` class to an object of the `TForm1` type. `TForm`, in turn, inherits some of its methods from another class, and so on, up to the `TObject` base class.

As an example of inheritance, we can change the ViewDate program, deriving a new class from TDate and modifying its GetText function. You can find this code in the DATES.PAS file of the NewDate example on the companion CD.

```
type
  TNewDate = class (TDate)
  public
    function GetText: string;
  end;
```

In this example, the TNewDate class is derived from TDate. It is common to say that TDate is an *ancestor* class or *parent* class of TNewDate and that TNewDate is a *subclass*, *descendant* class, or *child* class of TDate.

To implement the new version of the GetText function, I used the FormatDateTime function, which uses (among other features) the predefined month names available in Windows; these names depend on the user's regional and language settings. Many of these regional settings are actually copied by Delphi into constants defined in the library, such as LongMonthNames, ShortMonthNames, and many others you can find under the "Currency and date/time formatting variables" topic in the Delphi Help file. Here is the GetText method, where '*dddddd*' stands for the long date format:

```
function TNewDate.GetText: string;
begin
  GetText := FormatDateTime ('dddddd', fDate);
end;
```

TIP Using regional information, the NewDate program automatically adapts itself to different Windows user settings. If you run this same program on a computer with regional settings referring to a language other than English, it will automatically show month names in that language. To test this behavior, you just need to change the regional settings; you don't need a new version of Windows. Notice that regional-setting changes immediately affect the running programs.

Once we have defined the new class, we need to use this new data type in the code of the form of the NewDate example. Simply define the TheDay object of type TNewDate, and call its constructor in the FormCreate method:

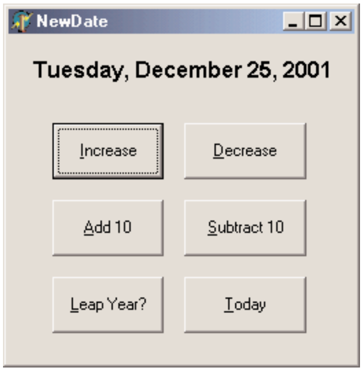
```
type
  TDateForm = class(TForm)
    ...
  private
    TheDay: TNewDate; // updated declaration
  end;
```

```
procedure TDateForm.FormCreate(Sender: TObject);
begin
  TheDay := TNewDate.Create (2001, 12, 25); // updated
  DateLabel.Caption := TheDay.GetText;
end;
```

Without any other changes, the new NewDate example will work properly. The TNewDate class inherits the methods to increase the date, add a number of days, and so on. In addition, the older code calling these methods still works. Actually, to call the new version of the GetText method, we don't need to change the source code! The Delphi compiler will automatically bind that call to a new method. The source code of all the other event handlers remains exactly the same, although its meaning changes considerably, as the new output demonstrates (see Figure 3.1).

FIGURE 3.1:

The output of the NewDate program, with the name of the month and of the day depending on Windows regional settings



Tuesday, December 25, 2001

Protected Fields and Encapsulation

The code of the GetText method of the TNewDate class compiles only if it is written in the same unit as the TDate class. In fact, it accesses the fDate private field of the ancestor class. If we want to place the descendant class in a new unit, we must either declare the fDate field as protected or add a protected access method in the ancestor class to read the value of the private field.

Many developers believe that the first solution is always the best, because declaring most of the fields as protected will make a class more extensible and will make it easier to write subclasses. However, this violates the idea of encapsulation. In a large hierarchy of classes, changing the definition of some protected fields of the base classes becomes as difficult as changing some global data structures. If ten derived classes are accessing this data, changing its definition means potentially modifying the code in each of the ten classes.

In other words, flexibility, extension, and encapsulation often become conflicting objectives. When this happens, you should try to favor encapsulation. If you can do so without sacrificing flexibility, that will be even better. Often this intermediate solution can be obtained by using a virtual method, a topic I'll discuss in detail later in the section "Late Binding and Polymorphism." If you choose not to use encapsulation in order to obtain faster coding of the subclasses, then your design might not follow the object-oriented principles.

Accessing Protected Data of Other Classes

We've seen that in Delphi, the `private` and `protected` data of a class is accessible to any functions or methods that appear *in the same unit as the class*. For example, consider this class (part of the Protection example on the companion CD):

```
type
  TTest = class
  protected
    ProtectedData: Integer;
  public
    PublicData: Integer;
    function GetValue: string;
  end;
```

The `GetValue` method simply returns a string with the two integer values:

```
function TTest.GetValue: string;
begin
  Result := Format ('Public: %d, Protected: %d',
    [PublicData, ProtectedData]);
end;
```

Once you place this class in its own unit, you won't be able to access its protected portion from other units directly. Accordingly, if you write the following code,

```
procedure TForm1.Button1Click(Sender: TObject);
var
  Obj: TTest;
begin
  Obj := TTest.Create;
  Obj.PublicData := 10;
  Obj.ProtectedData := 20;  // won't compile
  ShowMessage (Obj.GetValue);
  Obj.Free;
end;
```

the compiler will issue an error message, "Undeclared identifier: 'ProtectedData.'"

Continued on next page

At this point, you might think there is no way to access the protected data of a class defined in a different unit. (This is what Delphi manuals and most Delphi books say.) However, there is a way around it. Consider what happens if you create an apparently useless derived class, such as

```
type
  TFake = class (TTest);
```

Now, if you make a direct cast of the object to the new class and access the protected data through it, this is how the code will look:

```
procedure TForm1.Button2Click(Sender: TObject);
var
  Obj: TTest;
begin
  Obj := TTest.Create;
  Obj.PublicData := 10;
  TFake (Obj).ProtectedData := 20; // compiles!
  ShowMessage (Obj.GetValue);
  Obj.Free;
end;
```

This code compiles and works properly, as you can see by running the Protection program. How is it possible for this approach to work? Well, if you think about it, the `TFake` class automatically inherits the protected fields of the `TTest` base class, and because the `TFake` class is in the same unit as the code that tries to access the data in the inherited fields, the protected data is accessible. As you would expect, if you move the declaration of the `TFake` class to a secondary unit, the program won't compile any more.

Now that I've shown you how to do this, I must warn you that violating the class-protection mechanism this way is likely to cause errors in your program (from accessing data that you really shouldn't), and it runs counter to good OOP technique. However, there are times when using this technique is the best solution, as you'll see by looking at the VCL source code and the code of many Delphi components. Two examples that come to mind are accessing the `Text` property of the `TControl` class and the `Row` and `Col` positions of the `DBGrid` control. These two ideas are demonstrated by the TextProp and DBGridCol examples, respectively. (These examples are quite advanced, so I suggest that only programmers with a good background of Delphi programming read them at this point in the text—other readers might come back later.) Although the first example shows a reasonable example of using the typecast *cracker,* the DBGrid example of `Row` and `Col` is actually a counterexample, one that illustrates the risks of accessing bits that the class writer chose not to expose. The row and column of a `DBGrid` do not mean the same thing as they do in a `DrawGrid` or `StringGrid` (the base classes). First, `DBGrid` does not count the fixed cells as actual cells (it distinguishes data cells

Continued on next page

from decoration), so your row and column indexes will have to be adjusted by whatever decorations are currently in effect on the grid (and those can change on the fly). Second, the `DBGrid` is a virtual view of the data. When you scroll up in a `DBGrid`, the data may move underneath it, but the currently selected row might not change.

This technique—declaring a local type only so that you can access protected data members of a class—is often described as a *hack,* and it should be avoided whenever possible. The problem is not accessing protected data of a class in the same unit but declaring a class for the sole purpose of accessing protected data of an existing object of a different class! The danger of this technique is in the hard-coded typecast of an object from a class to a different one.

Inheritance and Type Compatibility

Pascal is a strictly typed language. This means that you cannot, for example, assign an integer value to a `Boolean` variable, unless you use an explicit typecast. The rule is that two values are type-compatible only if they are of the same data type, or (to be more precise) if their data type refers to a single type definition.

WARNING If you redefine the same data type in two different units, they won't be compatible, even if their name is identical. A program using two equally named types of two different units will be a nightmare to compile and debug.

There is an important exception to this rule in the case of class types. If you declare a class, such as `TAnimal`, and derive from it a new class, say `TDog`, you can then assign an object of type `TDog` to a variable of type `TAnimal`. That is because a dog is an animal! So, although this might surprise you, the following constructor calls are both legal:

```
var
  MyAnimal1, MyAnimal2: TAnimal;
begin
  MyAnimal1 := TAnimal.Create;
  MyAnimal2 := TDog.Create;
```

As a general rule, you can use an object of a descendant class any time an object of an ancestor class is expected. However, the reverse is not legal; you cannot use an object of an ancestor class when an object of a descendant class is expected. To simplify the explanation, here it is again in code terms:

```
type
  TDog = class (TAnimal)
    ...
  end;
```

```
var
  MyAnimal: TAnimal;
  MyDog: TDog;

begin
  MyAnimal := MyDog;  // This is OK
  MyDog := MyAnimal;  // This is an error!!!
```

Before we look at the implications of this important feature of the language, you can try out the Animals1 example from the companion CD, which defines the two `TAnimal` and `TDog` classes:

```
type
  TAnimal = class
  public
    constructor Create;
    function GetKind: string;
  private
    Kind: string;
  end;

  TDog = class (TAnimal)
  public
    constructor Create;
  end;
```

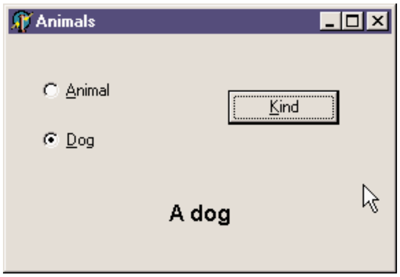
The two `Create` methods set the value of `Kind`, which is returned by the `GetKind` function. The form displayed by this example, shown in Figure 3.2, has a private field `MyAnimal` of type `TAnimal`. An instance of this class is created and initialized when the form is created and each time one of the radio buttons is selected:

```
procedure TFormAnimals.FormCreate(Sender: TObject);
begin
  MyAnimal := TAnimal.Create;
end;

procedure TFormAnimals.RadioDogClick(Sender: TObject);
begin
  MyAnimal.Free;
  MyAnimal := TDog.Create;
end;
```

FIGURE 3.2:

The form of the Animals1 example



Finally, the Kind button calls the `GetKind` method for the current animal and displays the result in the label:

```
procedure TFormAnimals.BtnKindClick(Sender: TObject);
begin
  KindLabel.Caption := MyAnimal.GetKind;
end;
```

Late Binding and Polymorphism

Pascal functions and procedures are usually based on *static* or *early binding*. This means that a method call is resolved by the compiler and linker, which replace the request with a call to the specific memory location where the function or procedure resides. (This is known as the *address* of the function.) OOP languages allow the use of another form of binding, known as *dynamic* or *late binding*. In this case, the actual address of the method to be called is determined at run time based on the type of the instance used to make the call.

The advantage of this technique is known as *polymorphism*. Polymorphism means you can write a call to a method, applying it to a variable, but which method Delphi actually calls depends on the type of the object the variable relates to. Delphi cannot determine until run time the actual class of the object the variable refers to, because of the type-compatibility rule discussed in the previous section.

NOTE The term *polymorphism* is quite a mouthful. A glance at the dictionary tells us that in a general sense, it refers to something having more than one form. In the OOP sense, then, it refers to the facts that there may be several versions of a given method across several related classes and that a single method call on an object instance of a particular class type can refer to one of these versions. Which version of the method gets called depends on the type of the object instance used to make the call at run time.

For example, suppose that a class and its subclass (let's say TAnimal and TDog) both define a method, and this method has late binding. Now you can apply this method to a generic variable, such as MyAnimal, which at run time can refer either to an object of class TAnimal or to an object of class TDog. The actual method to call is determined at run time, depending on the class of the current object.

The Animals2 example extends the Animals1 program to demonstrate this technique. In the new version, the TAnimal and the TDog classes have a new method: Voice, which means to output the sound made by the selected animal, both as text and as sound. This method is defined as virtual in the TAnimal class and is later overridden when we define the TDog class, by the use of the virtual and override keywords:

```
type
  TAnimal = class
  public
    function Voice: string; virtual;

  TDog = class (TAnimal)
  public
    function Voice: string; override;
```

Of course, the two methods also need to be implemented. Here is a simple approach:

```
uses
  MMSystem;

function TAnimal.Voice: string;
begin
  Voice := 'Voice of the animal';
  PlaySound ('Anim.wav', 0, snd_Async);
end;

function TDog.Voice: string;
begin
  Voice := 'Arf Arf';
  PlaySound ('dog.wav', 0, snd_Async);
end;
```

TIP This example uses a call to the PlaySound API function, defined in the MMSystem unit. The first parameter of this function is the name of the WAV sound file or the system sound you want to execute. The second parameter indicates an optional resource file containing the sound. The third parameter indicates (among other options) whether the call should be synchronous or asynchronous; that is, whether the program should wait for the sound to finish before continuing with the following statements.

Now what is the effect of the call `MyAnimal.Voice`? It depends. If the `MyAnimal` variable currently refers to an object of the `TAnimal` class, it will call the method `TAnimal.Voice`. If it refers to an object of the `TDog` class, it will call the method `TDog.Voice` instead. This happens only because the function is `virtual` (as you can experiment by removing this keyword and recompiling).

The call to `MyAnimal.Voice` will work for an object that is an instance of any descendant of the `TAnimal` class, even classes that are defined in other units—or that haven't been written yet! The compiler doesn't need to know about all the descendants in order to make the call compatible with them; only the ancestor class is needed. In other words, this call to `MyAnimal.Voice` is compatible with all future `TAnimal` subclasses.

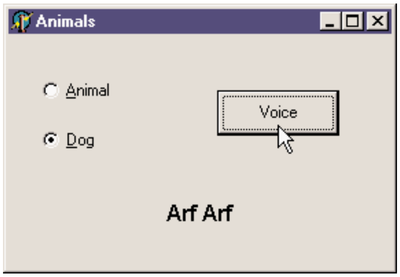
NOTE This is the key technical reason why object-oriented programming languages favor reusability. You can write code that uses classes within a hierarchy without any knowledge of the specific classes that are part of that hierarchy. In other words, the hierarchy—and the program—is still extensible, even when you've written thousands of lines of code using it. Of course, there is one condition: the ancestor classes of the hierarchy need to be designed very carefully.

The Animals2 program demonstrates the use of these new classes and has a form similar to that of the previous example. This code is executed by clicking the button:

```
procedure TFormAnimals.BtnVerseClick(Sender: TObject);
begin
  LabelVoice.Caption := MyAnimal.Voice;
end;
```

In Figure 3.3, you can see an example of the output of this program. By running it, you'll also hear the corresponding sounds produced by the `PlaySound` API call.

FIGURE 3.3: The output of the Animals2 example



Overriding and Redefining Methods

As we have just seen, to override a late-bound method in a descendant class, you need to use the override keyword. Note that this can take place only if the method was defined as virtual in the ancestor class. Otherwise, if it was a static method, there is no way to activate late binding, other than by changing the code of the ancestor class.

The rules are simple: A method defined as static remains static in every subclass, unless you hide it with a new virtual method having the same name. A method defined as virtual remains late-bound in every subclass. There is no way to change this, because of the way the compiler generates different code for late-bound methods.

NOTE The new C# programming language proposed by Microsoft (which is in essence a clone of Java) has the same notion as the Object Pascal language of marking the overridden version of a method with a specific keyword.

To redefine a static method, you add a method to a subclass having the same parameters or different parameters than the original one, without any further specifications. To override a virtual method, you must specify the same parameters and use the override keyword:

```
type
  MyClass = class
    procedure One; virtual;
    procedure Two; {static method}
  end;

  MySubClass = class (MyClass)
    procedure One; override;
    procedure Two;
  end;
```

There are typically two ways to override a method. One is to replace the method of the ancestor class with a new version. The other is to add some more code to the existing method. This can be accomplished by using the inherited keyword to call the same method of the ancestor class. For example, you can write

```
procedure MySubClass.One;
begin
  // new code
  ...
  // call inherited procedure MyClass.One
  inherited One;
end;
```

You might wonder why you need to use the override keyword. In other languages, when you redefine a method in a subclass, you automatically override the original one. However, having a specific keyword allows the compiler to check the correspondence between the names of the methods of the ancestor class and the subclass (misspelling a redefined function is a common error in other OOP languages), check that the method was virtual in the ancestor class, and so on.

When you override an existing virtual method of a base class, you must use the same parameters. When you introduce a new version of a method in a descendent class, you can declare it with the parameters you want. In fact, this will be a new method unrelated to the ancestor method of the same name. They only happen to use the same name. Here is an example:

```
type
  TMyClass = class
    procedure One;
  end;

  TMySubClass = class (TMyClass)
    procedure One (S: string);
  end;
```

NOTE Using the class definitions above, when you create an object of the `TMySubClass` class, you can apply to it the `One` method with the string parameter, but not the parameter-less version defined in the base class. If this is what you need, it can be accomplished by marking the re-declared method (the one in the derived class) with the `overload` keyword. If the method has different parameters than the version in the base class, it becomes effectively an overloaded method; otherwise it replaces the base class method. Notice that the method doesn't need to be marked as `overload` in the base class. However, if the method in the base class is virtual, the compiler issues the warning "Method 'One' hides virtual method of base type 'TMyClass.'" To avoid this message and to instruct the compiler more precisely on your intentions, you can use the `reintroduce` directive. If you are interested in this advanced topic, you can find this code in the Reintr example on the companion CD and experiment with it further.

Virtual versus Dynamic Methods

In Delphi, there are two different ways to activate late binding. You can declare the method as `virtual`, as we have seen before, or declare it as `dynamic`. The syntax of these two keywords is exactly the same, and the result of their use is also the same. What is different is the internal mechanism used by the compiler to implement late binding.

`virtual` methods are based on a *virtual method table* (VMT, also known as a *vtable*), which is an array of method addresses. For a call to a `virtual` method, the compiler generates code to jump to an address stored in the *n*th slot in the object's virtual method table.

Virtual method tables allow fast execution of the method calls. Their main drawback is that they require an entry for each `virtual` method for each descendant class, even if the method is not overridden in the subclass. At times, this has the effect of propagating VMT entries throughout a class hierarchy (even for methods that aren't redefined). This might require a lot of memory just to store the same method address multiple times.

`Dynamic` method calls, on the other hand, are dispatched using a unique number indicating the method. The search for the corresponding function is generally slower than the one-step table lookup for `virtual` methods. The advantage is that dynamic method entries only propagate in descendants when the descendants override the method. For large or deep object hierarchies, using `dynamic` methods instead of `virtual` methods can result in significant memory savings with only a minimal speed penalty.

From a programmer's perspective, the difference between these two approaches lies only in a different internal representation and slightly different speed or memory usage. Apart from this, `virtual` and `dynamic` methods are the same.

Message Handlers

A late-bound method can be used to handle a Windows message, too, although the technique is somewhat different. For this purpose Delphi provides yet another directive, `message`, to define message-handling methods, which must be procedures with a single `var` parameter. The `message` directive is followed by the number of the Windows message the method wants to handle.

WARNING The `message` directive is also available in Delphi for Linux and is fully supported by the language and the RTL. However, the visual portion of the CLX application framework does not use message methods to dispatch notifications to controls. For this reason, whenever possible, you should use a virtual method provided by the library rather than handle a Windows message directly. Of course, this matters only if you want your code to be more portable.

For example, the following code allows you to handle a user-defined message, with the numeric value indicated by the `wm_User` Windows constant:

```
type
  TForm1 = class(TForm)
    ...
    procedure WmUser (var Msg: TMessage);
      message wm_User;
  end;
```

The name of the procedure and the actual type of the parameters are up to you, although there are several predefined record types for the various Windows messages. You could later send this message, invoking the corresponding method, by writing:

```
PostMessage (Form1.Handle, wm_User, 0, 0);
```

This technique can be extremely useful for veteran Windows programmers, who know all about Windows messages and API functions. You can also dispatch a message to an object by calling the TObject.Dispatch method on the object. This will be a synchronous message call, not asynchronous like PostMessage. TObject.Dispatch is fully platform independent.

The ability to handle Windows messages and call API functions as you do when you are programming Windows with the C language may horrify some programmers and delight others. But in Delphi, when writing Windows applications, you will seldom need to use message methods or call Windows APIs directly. Obviously, these techniques will also affect the portability of your code to other platforms.

Abstract Methods

The abstract keyword is used to declare methods that will be defined only in subclasses of the current class. The abstract directive fully defines the method; it is not a forward declaration. If you try to provide a definition for the method, the compiler will complain. In Object Pascal, you can create instances of classes that have abstract methods. However, when you try to do so, Delphi's 32-bit compiler issues the warning message "Constructing instance of <class name> containing abstract methods." If you happen to call an abstract method at run time, Delphi will raise an exception, as demonstrated by the following Animals3 example.

NOTE C++ and Java use a more strict approach: in these languages, you cannot create instances of classes containing abstract methods.

You might wonder why you would want to use abstract methods. The reason lies in the use of polymorphism. If class TAnimal has the abstract method Voice, every subclass can redefine it. The advantage is that you can now use the generic MyAnimal object to refer to each animal defined by a subclass and invoke this method. If this method was not present in the interface of the TAnimal class, the call would not have been allowed by the compiler, which performs static type checking. Using a generic MyAnimal object, you can call only the method defined by its own class, TAnimal.

You cannot call methods provided by subclasses, unless the parent class has at least the declaration of this method—in the form of an abstract method. The next example, Animals3, demonstrates the use of abstract methods and the abstract call error. In Listing 3.1, you can see the interfaces of the classes of this new example. (Here TAnimal is an abstract class.)

Listing 3.1: Declaration of the three classes of the Animals3 example

```
type
  TAnimal = class
  public
    constructor Create;
    function GetKind: string;
    function Voice: string; virtual; abstract;
  private
    Kind: string;
  end;

  TDog = class (TAnimal)
  public
    constructor Create;
    function Voice: string; override;
    function Eat: string; virtual;
  end;

  TCat = class (TAnimal)
  public
    constructor Create;
    function Voice: string; override;
    function Eat: string; virtual;
  end;
```

The most interesting portion of Listing 3.1 is the definition of the class TAnimal, which includes a virtual abstract method: Voice. It is also important to notice that each derived class overrides this definition and adds a new virtual method, Eat. What are the implications of these two different approaches? To call the Voice function, we can write the same code as in the previous version of the program:

```
LabelVoice.Caption := MyAnimal.Voice;
```

How can we call the Eat method? We cannot apply it to an object of the TAnimal class. The statement

```
LabelVoice.Caption := MyAnimal.Eat;
```

generates the compiler error “Field identifier expected.”

To solve this problem, you can use run-time type information (RTTI) to cast the TAnimal object to a TCat or TDog object; but without the proper cast, the program will raise an exception. You will see an example of this approach in the next section. Adding the method definition to the TAnimal class is a typical solution to the problem, and the presence of the abstract keyword favors this choice.

NOTE What happens if a method overriding an abstract method calls `inherited`? In past versions of Delphi, this resulted in an abstract method call. In Delphi 6, the compiler has been enhanced to notice the presence of the abstract method and simply skip the `inherited` call. This means you can safely always use `inherited` in every overridden method, unless you specifically want to disable executing some code of the base class.

Type-Safe Down-Casting

The Object Pascal type-compatibility rule for descendant classes allows you to use a descendant class where an ancestor class is expected. As I mentioned earlier, the reverse is not possible.

Now suppose that the `TDog` class has an `Eat` method, which is not present in the `TAnimal` class. If the variable `MyAnimal` refers to a dog, it should be possible to call the function. But if you try, and the variable is referring to another class, the result is an error. By making an explicit typecast, we could cause a nasty run-time error (or worse, a subtle memory overwrite problem), because the compiler cannot determine whether the type of the object is correct and the methods we are calling actually exist.

To solve the problem, we can use techniques based on *run-time type information* (RTTI, for short). Essentially, because each object “knows” its type and its parent class, and we can ask for this information with the `is` operator or using the `InheritsFrom` method of the `TObject` class. The parameters of the `is` operator are an object and a class type, and the return value is a Boolean:

```
if MyAnimal is TDog then ...
```

The `is` expression evaluates as `True` only if the `MyAnimal` object is currently referring to an object of class `TDog` or a type descendant from `TDog`. This means that if you test whether a `TDog` object is of type `TAnimal`, the test will succeed. In other words, this expression evaluates as `True` if you can safely assign the object (`MyAnimal`) to a variable of the data type (`TDog`).

Now that you know for sure that the animal is a dog, you can make a safe typecast (or type conversion). You can accomplish this direct cast by writing the following code:

```
var
  MyDog: TDog;
begin
  if MyAnimal is TDog then
  begin
    MyDog := TDog (MyAnimal);
    Text := MyDog.Eat;
  end;
```

This same operation can be accomplished directly by the second RTTI operator, `as`, which converts the object only if the requested class is compatible with the actual one. The parameters of the `as` operator are an object and a class type, and the result is an object converted to the new class type. We can write the following snippet:

```
MyDog := MyAnimal as TDog;
Text := MyDog.Eat;
```

If we only want to call the `Eat` function, we might also use an even shorter notation:

```
(MyAnimal as TDog).Eat;
```

The result of this expression is an object of the `TDog` class data type, so you can apply to it any method of that class. The difference between the traditional cast and the use of the `as` cast is that the second raises an exception if the type of the object is incompatible with the type you are trying to cast it to. The exception raised is `EInvalidCast` (exceptions are described at the end of this chapter).

To avoid this exception, use the `is` operator and, if it succeeds, make a plain typecast (in fact, there is no reason to use `is` and `as` in sequence, doing the type check twice):

```
if MyAnimal is TDog then
  TDog(MyAnimal).Eat;
```

Both RTTI operators are very useful in Delphi because you often want to write generic code that can be used with several components of the same type or even of different types. When a component is passed as a parameter to an event-response method, a generic data type is used (`TObject`), so you often need to cast it back to the original component type:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  if Sender is TButton then
    ...
end;
```

This is a common technique in Delphi, and I'll use it in examples throughout the book. The two RTTI operators, `is` and `as`, are extremely powerful, and you might be tempted to consider them as standard programming constructs. Although they are indeed powerful, you should probably limit their use to special cases. When you need to solve a complex problem involving several classes, try using polymorphism first. Only in special cases, where polymorphism alone cannot be applied, should you try using the RTTI operators to complement it. *Do not use RTTI instead of polymorphism.* This is bad programming practice, and it results in slower programs. RTTI, in fact, has a negative impact on performance, because it must walk the hierarchy of classes to see whether the typecast is correct. As we have seen, virtual method calls require just a memory lookup, which is much faster.

NOTE There is actually more to run-time type information (RTTI) than the `is` and `as` operators. You can access to detailed class and type information at run time, particularly for published properties, events, and methods. More on this topic in Chapter 5.

Using Interfaces

When you define an abstract class to represent the base class of a hierarchy, you can come to a point in which the abstract class is so abstract that it only lists a series of virtual functions without providing any actual implementation. This kind of *purely abstract class* can also be defined using a specific technique, an `interface`. For this reason, we refer to these classes as *interfaces*.

Technically, an interface is not a class, although it may resemble one. Interfaces are not classes, because they are considered a totally separate element with distinctive features:

- Interface type objects are reference-counted and automatically destroyed when there are no more references to the object. This mechanism is similar to how Delphi manages long strings and makes memory management almost automatic.
- A class can inherit from a single base class, but it can implement multiple interfaces.
- As all classes descend from `TObject`, all interfaces descend from `IInterface`, forming a totally separate hierarchy.

The base interface class used to be `IUnknown` until Delphi 5, but Delphi 6 introduces a new name for it, `IInterface`, to mark even more clearly the fact that this language feature is separate from Microsoft's COM. In fact, Delphi interfaces are available also in the Linux version of the product.

You can use this rule: Interface types describing things that relate to COM and the related operating-system services should inherit from `IUnknown`. Interface types that describe things that do not necessarily require COM (for example, interfaces used for the internal application structure) should inherit from `IInterface`. Doing this consistently in your applications will make it easier to identify which portions of your application probably assume or require the Windows operating system and which portions are probably OS-independent.

NOTE Borland introduced interfaces in Delphi 3 along with the support COM programming. Though the interface language syntax may have been created to support COM, interfaces do not require COM. You can use interfaces to implement abstraction layers within your applications, without building COM server objects. For example, the Delphi IDE uses interfaces extensively in its internal architecture. COM is discussed in Chapter 19.

From a more general point of view, interfaces support a slightly different object-oriented programming model than classes. Objects implementing interfaces are subject to polymorphism for each of the interfaces they support. Indeed, the interface-based model is powerful. But having said that, I'm not interested in trying to assess which approach is better in each case. Certainly, interfaces favor encapsulation and provide a looser connection between classes than inheritance. Notice that the most recent OOP languages, from Java to C#, have the notion of interfaces.

Here is the syntax of the declaration of an interface (which, by convention, starts with the letter *I*):

```
type
  ICanFly = interface
    ['{EAD9C4B4-E1C5-4CF4-9FA0-3B812C880A21}']
    function Fly: string;
  end;
```

The above interface has a GUID, a numeric ID following its declaration and based on Windows conventions. You can generate these identifiers (called GUIDs in jargon) by pressing Ctrl+Shift+G in the Delphi editor.

Although you can compile and use interfaces even without specifying a GUID (as in the code above) for them, you'll generally want to do it, as this is required to perform `QueryInterface` or dynamic `as` typecasts using that interface type. Since the whole point of interfaces is (usually) to take advantage of greatly extended type flexibility at run time, if compared with class types, interfaces without GUIDs are not very useful.

Once you've declared an interface, you can define a class to implement it, as in:

```
type
  TAirplane = class (TInterfacedObject, ICanFly)
    function Fly: string;
  end;
```

The RTL already provides a few base classes to implement the basic behavior required by the `IInterface` interface. The simplest one is the `TInterfacedObject` class I've used in this code.

You can implement interface methods with static methods (as in the code above) or with virtual methods. You can override virtual methods in subclasses by using the `override` directive. If you don't use virtual methods, you can still provide a new implementation in a subclass by redeclaring the interface type in the subclass, rebinding the interface methods to new versions of the static methods. At first sight, using virtual methods to implement interfaces seems to allow for smoother coding in subclasses, but both approaches are equally powerful and flexible. However, the use of virtual methods affects code size and memory.

NOTE The compiler has to generate stub routines to fix up the interface call entry points to the matching method of the implementing class, and adjust the `self` pointer. The interface method stubs for static methods are very simple: adjust `self` and jump to the real method in the class. The interface method stubs for virtual methods are much more complicated, requiring about four times more code (20 to 30 bytes) in each stub than the static case. Also, adding more virtual methods to the implementing class just bloats the virtual method table (VMT) that much more in the implementing class and all its descendents. Interfaces already have their own VMT, and redeclaring interfaces in descendents to rebind the interface to new methods in the descendent is just as polymorphic as using virtual methods, but much smaller in code size.

Now that we have defined an implementation of the interface, we can write some code to use an object of this class, as usual:

```
var
  Airplane1: TAirplane;
begin
  Airplane1 := TAirplane.Create;
  Airplane1.Fly;
  Airplane1.Free;
end;
```

But we can also use an interface-type variable:

```
var
  Flyer1: ICanFly;
begin
  Flyer1 := TAirplane.Create;
  Flyer1.Fly;
end;
```

As soon as you assign an object to an interface-type variable, Delphi automatically checks to see whether the object implements that interface, using the `as` operator. You can explicitly express this operation as follows:

```
Flyer1 := TAirplane.Create as ICanFly;
```

NOTE The compiler generates different code for the `as` operator when used with interfaces or with classes. With classes, the compiler introduces run-time checks to verify that the object is effectively "type-compatible" with the given. With interfaces, the compiler sees at compile time that it can extract the necessary interface from the available class type, so it does. This operation is like a "compile-time `as`," not something that exists at run time.

Whether we use the direct assignment or the `as` statement, Delphi does one extra thing: it calls the `_AddRef` method of the object (defined by `IInterface` and implemented by `TInterfacedObject`), increasing its reference count. At the same time, as soon as the

Flyer1 variable goes out of scope, Delphi calls the _Release method (again part of IInterface), which decreases the reference count, checks whether the reference count is zero, and if necessary, destroys the object. For this reason in the listing above, there is no code to free the object we've created.

In other words, in Delphi, objects referenced by interface variables are reference-counted, and they are automatically de-allocated when no interface variable refers to them any more.

WARNING When using interface-based objects, you should generally access them only with object variables or only with interface variables. Mixing the two approaches breaks the reference counting scheme provided by Delphi and can cause memory errors that are extremely difficult to track. In practice, if you've decided to use interfaces, you should probably use exclusively interface-based variables.

Interface Properties, Delegation, Redefinitions, Aggregation, and Reference Counting Blues

To demonstrate a few technical elements related to interfaces, I've written the IntfDemo example. This example is based on two different interfaces, IWalker and IJumper, defined as follows:

```
IWalker = interface
  ['{0876F200-AAD3-11D2-8551-CCA30C584521}']
  function Walk: string;
  function Run: string;
  procedure SetPos (Value: Integer);
  function GetPos: Integer;
property Position: Integer read GetPos write SetPos;
end;

IJumper = interface
  ['{0876F201-AAD3-11D2-8551-CCA30C584521}']
  function Jump: string;
  function Walk: string;
  procedure SetPos (Value: Integer);
  function GetPos: Integer;
property Position: Integer read GetPos write SetPos;
end;
```

Notice that the first interface also defines a property. An interface property is just a name mapped to a read and a write method. You cannot map an interface property to a field, simply because an interface cannot have a data field.

Here comes a sample implementation of the `IWalker` interface. Notice that you don't have to define the property, only its access methods:

```
TRunner = class (TInterfacedObject, IWalker)
private
  Pos: Integer;
public
  function Walk: string;
  function Run: string;
  procedure SetPos (Value: Integer);
  function GetPos: Integer;
end;
```

The code is trivial, so I'm going to skip it (you can find it in the IntfDemo example, where there is also a destructor showing a message, used to verify that reference counting works properly). I've implemented the same interface also in another class, `TAthlete`, that I'll discuss in a second.

As I want to implement also the `IJumper` interface in two different classes, I've followed a different approach. Delphi allows you to delegate the implementation of an interface inside a class to an object exposed with a property. In other words, I want to share the actual implementation code for an interface implemented by several unrelated classes.

To support this technique, Delphi has a special keyword, `implements`. For example, you can write:

```
TMyJumper = class (TInterfacedObject, IJumper)
private
  fJumpImpl: IJumper;
public
  constructor Create;
  property Jumper: IJumper read fJumpImpl implements IJumper;
end;
```

In this case the property refers to an interface variable, but you can also use a plain object variable (my preferred approach). The constructor is required for initializing the internal *implementation* object:

```
constructor TMyJumper.Create;
begin
  fJumpImpl := TJumperImpl.Create;
end;
```

As a first attempt (and in the last edition of the book), I defined the implementation class as follows:

```
TJumperImpl = class (TInterfacedObject, IJumper)
private
  Pos: Integer;
public
  function Jump: string;
```

```
    function Walk: string;
    procedure SetPos (Value: Integer);
    function GetPos: Integer;
  end;
```

If you try this code, the program will compile and everything will run smoothly, until you try to check out what happens with reference counting. It won't work, period. The problem lies in the fact that when the program extracts the `IJumper` interface from the `TMyJumper` object, it actually increases and decreases the reference counting of the inner object, instead of the external one. In other words, you have a single compound object and two separate reference counts going on. This can lead to objects being both kept in memory and released too soon.

The solution to this problem is to have a single reference count, by redirecting the `_AddRef` and `_Release` calls of the internal object to the external one (actually we need to do the same also for `QueryInterface`). In the example, I've used the `TAggregatedObject` provided in Delphi 6 by the system unit; refer to the sidebar "Implementing Aggregates" for more details.

As a result of this approach, the implementation class is now defined as follows:

```
    TJumperImpl = class (TAggregatedObject, IJumper)
    private
      Pos: Integer;
    public
      function Jump: string;
      function Walk: string;
      procedure SetPos (Value: Integer);
      function GetPos: Integer;

      property Position: Integer read GetPos write SetPos;
    end;
```

An object using this class for implementing the `IJumper` interface must have a `Create` constructor, to create the internal object, and a destructor, to destroy it. The constructor of the aggregate object requires the container object as parameter, so that it can redirect back the `IInterface` calls. The key element, of course, is the property mapped to the interface with the `implements` keyword:

```
    TMyJumper = class (TInterfacedObject, IJumper)
    private
      fJumpImpl: TJumperImpl;
    public
      constructor Create;
      property Jumper: TJumperImpl read fJumpImpl implements IJumper;
      destructor Destroy; override;
    end;

  constructor TMyJumper.Create;
  begin
    fJumpImpl := TJumperImpl.Create (self);
  end;
```

This example is simple, but in general, things get more complex as you start to modify some of the methods or add other methods that still operate on the data of the internal fJumpImpl object. This final step is demonstrated, along with other features, by the TAthlete class, which implements both the IWalker and IJumper interfaces:

```
TAthlete = class (TInterfacedObject, IWalker, IJumper)
private
  fJumpImpl: TJumperImpl;
public
  constructor Create;
  destructor Destroy; override;
  function Run: string; virtual;
  function Walk1: string; virtual;
  function IWalker.Walk = Walk1;
  procedure SetPos (Value: Integer);
  function GetPos: Integer;

  property Jumper: TJumperImpl read fJumpImpl implements IJumper;
end;
```

One of the interfaces is implemented directly, whereas the other is delegated to the internal fJumpImpl object. Notice also that by implementing two interfaces that have a method in common, we end up with a name clash. The solution is to rename one of the methods, with the statement

```
function IWalker.Walk = Walk1;
```

This declaration indicates that the class implements the Walk method of the IWalker interface with a method called Walk1 (instead of with a method having the same name). Finally, in the implementation of all of the methods of this class, we need to refer to the Position property of the fJumpImpl internal object. By declaring a new implementation for the Position property, we'll end up with two positions for a single athlete, a rather odd situation. Here are a couple of examples:

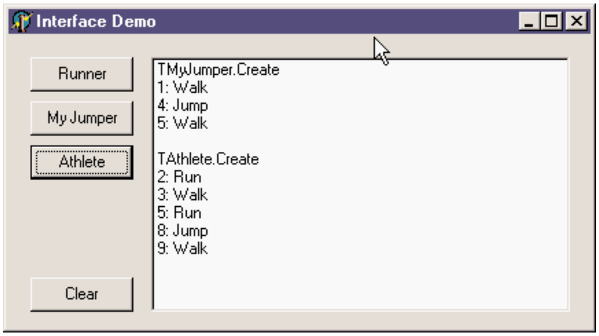
```
function TAthlete.GetPos: Integer;
begin
  Result := fJumpImpl.Position;
end;

function TAthlete.Run: string;
begin
  fJumpImpl.Position := fJumpImpl.Position + 2;
  Result := IntToStr (fJumpImpl.Position) + ': Run';
end;
```

You can further experiment with the IntfDemo example, which has a simple form with buttons to create and call methods of the various objects. Nothing fancy, though, as you can see in Figure 3.4. Simply keep in mind that each call returns the position after the requested movement and a description of the movement itself. Also, each object notifies with a message when it is destroyed.

FIGURE 3.4:

The IntfDemo example



```
TMyJumper.Create
1: Walk
4: Jump
5: Walk

TAthlete.Create
2: Run
3: Walk
5: Run
8: Jump
9: Walk
```

Implementing Aggregates

As mentioned, when you want to use an internal object to implement an interface, you are faced with reference counting problems. Of course, you can provide your own version of the _AddRef and _Release methods of IInterface, but having a ready-to-use solution might help. In fact, QueryInterface on the internal object must also be reflected to the outer object. The user of the interface (whether it works on the outer object or the internal one) should never be able to discern any difference in behavior between _AddRef, _Release, and QueryInterface calls on the aggregated interface and any other interface obtained from the implementing class.

Borland provides a solution to this problem with the TAggregatedObject class. In past version of Delphi, this was defined in the ComObj unit, but now it has been moved into the System unit, to make this feature also available to Linux and to separate it completely from COM support.

The TAggregatedObject class keeps a reference to the controller, the external object, passed as parameter in the constructor. This *weak reference* is kept using a pointer type variable to avoid artificially increasing the reference count of the controller from the aggregated object, something that will prevent the object's reference count from reaching zero. You create an object of this type (used as internal object) passing the reference to the controller (the external object), and all of the IInterface methods are passed back to the controller. A similar class, TContainedObject, lets the controller resolve reference counting, but handles the QueryInterface call internally, limiting the type resolution only to interfaces supported by the internal object.

Working with Exceptions

Another key feature of Object Pascal I'll cover in this chapter is the support for *exceptions*. The idea of exceptions is to make programs more robust by adding the capability of handling software or hardware errors in a uniform way. A program can survive such errors or terminate gracefully, allowing the user to save data before exiting. Exceptions allow you to separate the error-handling code from your normal code, instead of intertwining the two. You end up writing code that is more compact and less cluttered by maintenance chores unrelated to the actual programming objective.

Another benefit is that exceptions define a uniform and universal error-reporting mechanism, which is also used by Delphi components. At run time, Delphi raises exceptions when something goes wrong (in the run-time code, in a component, in the operating system). From the point of the code in which it is raised, the exception is passed to its calling code, and so on. Ultimately, if no part of your code handles the exception, Delphi handles it, by displaying a standard error message and trying to continue the program, by handing the next system message or user request.

The whole mechanism is based on four keywords:

try delimits the beginning of a protected block of code.

except delimits the end of a protected block of code and introduces the exception-handling statements, with this syntax form:

```
on exception-type do statement
```

finally is used to specify blocks of code that must always be executed, even when exceptions occur. This block is generally used to perform cleanup operations that should always be executed, such as closing files or database tables, freeing objects, and releasing memory and other resources acquired in the same program block.

raise is the statement used to generate an exception. Most exceptions you'll encounter in your Delphi programming will be generated by the system, but you can also `raise` exceptions in your own code when it discovers invalid or inconsistent data at run time. The `raise` keyword can also be used inside a handler to *re-raise* an exception; that is, to propagate it to the next handler.

The most important element to notice up front is that exception handling is no substitute for `if` statements or for tests on input parameters of functions. So *in theory* we could write this code:

```
function DivideTwicePlusOne (A, B: Integer): Integer;
begin
  try
    // error if B equals 0
    Result := A div B;
    // do something else... skip if exception is raised
    Result := Result div B;
    Result := Result + 1;
  except
    on EDivByZero do
      Result := 0;
  end;
end;
```

In practice, however, this is certainly not a good way of writing your programs. The except block above, like most of the except blocks of the simple examples presented here, has almost no sense at all. In the code above, you should probably not handle the exception but let the program display the error message to the user. An algorithm calling this DivideTwicePlusOne function should not continue (with a meaningless zero value) when this internal error is encountered.

Program Flow and the *finally* Block

But how do we stop the algorithm? The power of exceptions in Delphi relates to the fact that they are "passed" from a routine or method to the calling one, up to a global handler (if the program provides one, as Delphi applications generally do). So the real problem you might have is not how to stop an exception but how to execute some code when an exception is raised.

Consider this method (part of the TryFinally example from the CD), which performs some time-consuming operations and uses the hourglass cursor to show the user that it's doing something:

```
procedure TForm1.BtnWrongClick(Sender: TObject);
var
  I, J: Integer;
begin
  Screen.Cursor := crHourglass;
  J := 0;
  // long (and wrong) computation...
  for I := 1000 downto 0 do
    J := J + J div I;
  MessageDlg ('Total: ' + IntToStr (J), mtInformation, [mbOK], 0);
  Screen.Cursor := crDefault;
end;
```

Because there is an error in the algorithm (as the variable I can reach a value of 0 and is also used in a division), the program will break, but it won't reset the default cursor. This is what a try/finally block is for:

```
procedure TForm1.BtnTryFinallyClick(Sender: TObject);
var
  I, J: Integer;
begin
```

```
    Screen.Cursor := crHourglass;
    J := 0;
    try
      // long (and wrong) computation...
      for I := 1000 downto 0 do
        J := J + J div I;
      MessageDlg ('Total: ' + IntToStr (J), mtInformation, [mbOK], 0);
    finally
      Screen.Cursor := crDefault;
    end;
  end;
```

When the program executes this function, it always resets the cursor, whether an exception (of any sort) occurs or not.

This code doesn't handle the exception; it merely makes the program robust in case an exception is raised. As a `try` block can be followed by either an `except` or a `finally` statement, but not both of them at the same time, the typical solution if you want to also handle the exception is to use two nested `try` blocks. In this case, you associate the internal one with a `finally` statement and the external one with an `except` statement, or vice versa as the situation requires. Here is the code of this third button of the TryFinally example:

```
  procedure TForm1.BtnTryTryClick(Sender: TObject);
  var
    I, J: Integer;
  begin
    Screen.Cursor := crHourglass;
    J := 0;
    try try
      // long (and wrong) computation...
      for I := 1000 downto 0 do
        J := J + J div I;
      MessageDlg ('Total: ' + IntToStr (J), mtInformation, [mbOK], 0);
    finally
      Screen.Cursor := crDefault;
    end;
    except
      on E: EDivByZero do
      begin
        // re-raise the exception with a new message
        raise Exception.Create ('Error in Algorithm');
      end;
    end;
  end;
```

Every time you have some finalization code at the end of a method, you should place this code in a `finally` block. You should always, invariably, and continuously (how can I stress this more?) protect your code with `finally` statements, to avoid resource or memory leaks in case an exception is raised.

TIP

Handling the exception is generally much less important than using finally blocks, since Delphi can survive most of them. And too many exception-handling blocks in your code probably indicate errors in the program flow and possibly a misunderstanding of the role of exceptions in the language. In the examples in the rest of the book you'll see many try/finally blocks, a few raise statements, and almost no try/except blocks.

Exception Classes

In exception-handling statements shown earlier, we caught the EDivByZero exception, which is defined by Delphi's RTL. Other such exceptions refer to run-time problems (such as a wrong dynamic cast), Windows resource problems (such as out-of-memory errors), or component errors (such as a wrong index). Programmers can also define their own exceptions; you can create a new subclass of the default exception class or one of its subclasses:

```
type
  EArrayFull = class (Exception);
```

When you add a new element to an array that is already full (probably because of an error in the logic of the program), you can raise the corresponding exception by creating an object of this class:

```
if MyArray.Full then
  raise EArrayFull.Create ('Array full');
```

This Create method (inherited from the Exception class) has a string parameter to describe the exception to the user. You don't need to worry about destroying the object you have created for the exception, because it will be deleted automatically by the exception-handler mechanism.

The code presented in the previous excerpts is part of a sample program, called Exception1. Some of the routines have actually been slightly modified, as in the following DivideTwicePlusOne function:

```
function DivideTwicePlusOne (A, B: Integer): Integer;
begin
  try
    // error if B equals 0
    Result := A div B;
    // do something else... skip if exception is raised
    Result := Result div B;
    Result := Result + 1;
  except
    on EDivByZero do
    begin
      Result := 0;
      MessageDlg ('Divide by zero corrected.', mtError, [mbOK], 0);
    end;
    on E: Exception do
    begin
      Result := 0;
```

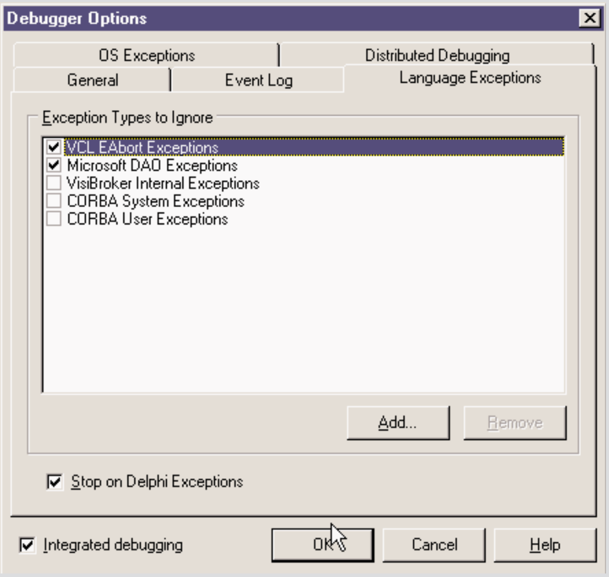
```
   MessageDlg (E.Message, mtError, [mbOK], 0);
  end;
 end; // end except
end;
```

Debugging and Exceptions

When you start a program from the Delphi environment (for example, by pressing the F9 key), you'll generally run it within the debugger. When an exception is encountered, the debugger will stop the program by default. This is normally what you want, of course, because you'll know where the exception took place and can see the call of the handler step-by-step. You can also use the Stack Trace feature of Delphi to see the sequence of function and method calls, which caused the program to raise an exception.

In the case of the Exception1 test program, however, this behavior will confuse the program's execution. In fact, even if the code is prepared to properly handle the exception, the debugger will stop the program execution at the source code line closest to where the exception was raised. Then, moving step-by-step through the code, you can see how it is handled.

If you just want to let the program run when the exception is properly handled, run the program from Windows Explorer, or temporarily disable the Stop on Delphi Exceptions options in the Language Exceptions page of the Debugger Options dialog box (activated by the Tools ➢ Debugger Options command), shown in the Language Exceptions page of the Debugger Options dialog box shown here.



Exception Types to Ignore

☑ VCL EAbort Exceptions
☑ Microsoft DAO Exceptions
☐ VisiBroker Internal Exceptions
☐ CORBA System Exceptions
☐ CORBA User Exceptions

☑ Stop on Delphi Exceptions

☑ Integrated debugging

In the Exception1 code there are two different exception handlers after the same try block. You can have any number of these handlers, which are evaluated in sequence. For this reason, you need to place the broader handlers (the handlers of the ancestor Exception classes) at the end.

In fact, using a hierarchy of exceptions, a handler is also called for the subclasses of the type it refers to, as any procedure will do. This is polymorphism in action again. But keep in mind that using a handler for every exception, such as the one above, is not usually a good choice. It is better to leave unknown exceptions to Delphi. The default exception handler in the VCL displays the error message of the exception class in a message box, and then resumes normal operation of the program. You can actually modify the normal exception handler with the Application.OnException event, as demonstrated in the ErrorLog example later in this chapter.

Another important element of the code above is the use of the exception object in the handler (see on E: Exception do). The object E of class Exception receives the value of the exception object passed by the raise statement. When you work with exceptions, remember this rule: You raise an exception by creating an object and handle it by indicating its type. This has an important benefit, because as we have seen, when you handle a type of exception, you are really handling exceptions of the type you specify as well as any descendant type.

Delphi defines a hierarchy of exceptions, and you can choose to handle each specific type of exception in a different way or handle groups of them together.

Logging Errors

Most of the time, you don't know which operation is going to raise an exception, and you cannot (and should not) wrap each and every piece of code in a try/except block. The general approach is to let Delphi handle all the exceptions and eventually pass them all to you, by handling the OnException event of the global Application object. This can be done rather easily with the ApplicationEvents component.

In the ErrorLog example, I've added to the main form a copy of the ApplicationEvents component and added a handler for its OnException event:

```
procedure TFormLog.LogException(Sender: TObject; E: Exception);
var
  Filename: string;
  LogFile: TextFile;
begin
  // prepares log file
  Filename := ChangeFileExt (Application.Exename, '.log');
  AssignFile (LogFile, Filename);
  if FileExists (FileName) then
    Append (LogFile) // open existing file
  else
    Rewrite (LogFile); // create a new one
  // write to the file and show error
```

```
    Writeln (LogFile, DateTimeToStr (Now) + ':' + E.Message);
    if not CheckBoxSilent.Checked then
      Application.ShowException (E);
    // close the file
    CloseFile (LogFile);
  end;
```

NOTE The ErrorLog example uses the text file support provided by the traditional Turbo Pascal TextFile data type. You can assign a text file variable to an actual file and then read or write it. You can find more on TextFile operations in Chapter 12 of *Essential Pascal*, available on the companion CD.

In the global exceptions handler, you can write to the log, for example, the date and time of the event, and also decide whether to show the exception as Delphi usually does (executing the `ShowException` method of the `TApplication` class). In fact, Delphi by default executes `ShowException` only if there is no `OnException` handler installed.

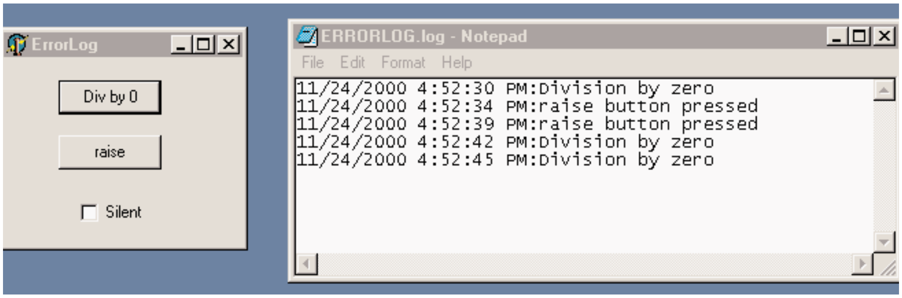
Finally, remember to close the file, flushing the buffers, every time the exception is handled or when the program terminates. I've chosen the first approach to avoid keeping the log file open for the lifetime of the application, potentially making it difficult to work on it. You can accomplish this in the `OnDestroy` event handler of the form:

```
procedure TFormLog.FormDestroy(Sender: TObject);
begin
  CloseFile (LogFile);
end;
```

The form of the program includes a check box to determine its behavior and two buttons generating exceptions. In Figure 3.5, you can see the ErrorLog program running and a sample exceptions log open in Notepad.

FIGURE 3.5:

The ErrorLog example and the log it produces



```
11/24/2000 4:52:30 PM:Division by zero
11/24/2000 4:52:34 PM:raise button pressed
11/24/2000 4:52:39 PM:raise button pressed
11/24/2000 4:52:42 PM:Division by zero
11/24/2000 4:52:45 PM:Division by zero
```

Class References

The final language feature I want to discuss in this chapter is *class references*, which implies the idea of manipulating classes themselves (not just class instances) within your code. The first point to keep in mind is that a class reference isn't a class, it isn't an object, and it isn't a reference to an object; it is simply a reference to a class type.

A class reference type determines the type of a class reference variable. Sounds confusing? A few lines of code might make this a little clearer. Suppose you have defined the class `TMyClass`. You can now define a new class reference type, related to that class:

```
type
  TMyClassRef = class of TMyClass;
```

Now you can declare variables of both types. The first variable refers to an object, the second to a class:

```
var
  AClassRef: TMyClassRef;
  AnObject: TMyClass;
begin
  AClassRef := TMyClass;
  AnObject := TMyClass.Create;
```

You may wonder what class references are used for. In general, class references allow you to manipulate a class data type at run time. You can use a class reference in any expression where the use of a data type is legal. Actually, there are not many such expressions, but the few cases are interesting. The simplest case is the creation of an object. We can rewrite the two lines above as follows:

```
AClassRef := TMyClass;
AnObject := AClassRef.Create;
```

This time I've applied the `Create` constructor to the class reference instead of to an actual class; I've used a class reference to create an object of that class.

NOTE Class references remind us of the concept of *metaclass* available in other OOP languages. In Object Pascal, however, a class reference is not itself a class but only a type pointer. Therefore, the analogy with metaclasses (classes describing other classes) is a little misleading. Actually, `TMetaclass` is also the term used in Borland C++Builder.

Class reference types wouldn't be as useful if they didn't support the same type-compatibility rule that applies to class types. When you declare a class reference variable, such as `MyClassRef` above, you can then assign to it that specific class and any subclass. So if `MyNewClass` is a subclass of my class, you can also write

```
AClassRef := MyNewClass;
```

Delphi declares a lot of class references in the run-time library and the VCL, including the following:

```
TClass = class of TObject;
ExceptClass = class of Exception;
TComponentClass = class of TComponent;
TControlClass = class of TControl;
TFormClass = class of TForm;
```

In particular, the `TClass` class reference type can be used to store a reference to any class you write in Delphi, because every class is ultimately derived from `TObject`. The `TFormClass` reference, instead, is used in the source code of most Delphi projects. The `CreateForm` method of the `Application` object, in fact, requires as parameter the class of the form to create:

```
Application.CreateForm(TForm1, Form1);
```

The first parameter is a class reference; the second is a variable that stores a reference to the created object instance.

Finally, when you have a class reference you can apply to it the class methods of the related class. Considering that each class inherits from `TObject`, you can apply to each class reference some of the methods of `TObject`, as we'll see in the next chapter.

Creating Components Using Class References

What is the *practical* use of class references in Delphi? Being able to manipulate a data type at run time is a fundamental element of the Delphi environment. When you add a new component to a form by selecting it from the Component Palette, you select a data type and create an object of that data type. (Actually, that is what Delphi does for you behind the scenes.) In other words, class references give you polymorphism for object construction.

To give you a better idea of how class references work, I've built an example named ClassRef. The form displayed by this example is quite simple. It has three radio buttons, placed inside a panel in the upper portion of the form. When you select one of these radio buttons and click the form, you'll be able to create new components of the three types indicated by the button labels: radio buttons, push buttons, and edit boxes.

To make this program run properly, you need to change the names of the three components. The form must also have a class reference field:

```
private
  ClassRef: TControlClass;
  Counter: Integer;
```

The first field stores a new data type every time the user clicks one of the three radio buttons. Here is one of the three methods:

```
procedure TForm1.RadioButtonRadioClick(Sender: TObject);
begin
  ClassRef := TRadioButton;
end;
```

The other two radio buttons have OnClick event handlers similar to this one, assigning the value TEdit or TButton to the ClassRef field. A similar assignment is also present in the handler of the OnCreate event of the form, used as an initialization method.

The interesting part of the code is executed when the user clicks the form. Again, I've chosen the OnMouseDown event of the form to hold the position of the mouse click:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
var
  NewCtrl: TControl;
  MyName: String;
begin
  // create the control
  NewCtrl := ClassRef.Create (Self);
  // hide it temporarily, to avoid flickering
  NewCtrl.Visible := False;
  // set parent and position
  NewCtrl.Parent := Self;
  NewCtrl.Left := X;
  NewCtrl.Top := Y;
  // compute the unique name (and caption)
  Inc (Counter);
  MyName := ClassRef.ClassName + IntToStr (Counter);
  Delete (MyName, 1, 1);
  NewCtrl.Name := MyName;
  // now show it
  NewCtrl.Visible := True;
end;
```

The first line of the code for this method is the key. It creates a new object of the class data type stored in the ClassRef field. We accomplish this simply by applying the Create constructor to the class reference. Now you can set the value of the Parent property, set the position of the new component, give it a name (which is automatically used also as Caption or Text), and make it visible.

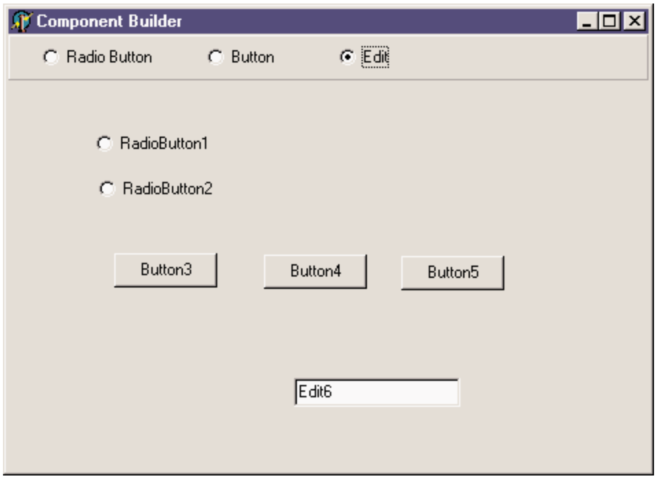
Notice in particular the code used to build the name; to mimic Delphi's default naming convention, I've taken the name of the class with the expression ClassRef.ClassName, using a class method of the TObject class. Then I've added a number at the end of the name and removed the initial letter of the string. For the first radio button, the basic string is TRadioButton, plus the *1* at the end, and minus the *T* at the beginning of the class name—RadioButton1. Sound familiar?

You can see an example of the output of this program in Figure 3.6. Notice that the naming is not exactly the same as used by Delphi. Delphi uses a separate counter for each type of control; I've used a single counter for all of the components. If you place a radio button, a push button, and an edit box in a form of the ClassRef example, their names will be RadioButton1, Button2, and Edit3.

NOTE For polymorphic construction to work, the base class type of the class reference must have a virtual constructor. If you use a virtual constructor (as in the example), the constructor call applied to the class reference will call the constructor of the type that the class reference variable *currently refers to*. But without a virtual constructor, your code will call the constructor of *fixed class type* indicated in the class reference declaration. Virtual constructors are required for polymorphic construction in the same way that virtual methods are required for polymorphism.

FIGURE 3.6:

An example of the output of the ClassRef example



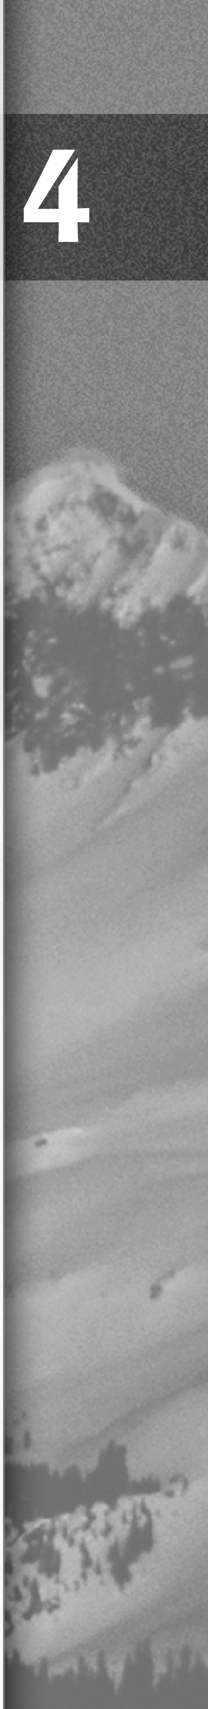
What's Next?

In this chapter, we have discussed the more advanced elements of object-oriented programming in Object Pascal. We have considered inheritance, virtual and abstract methods, polymorphism, safe typecasting, interfaces, exceptions, and class references.

Understanding the secrets of Object Pascal and the structure of the Delphi library is vital for becoming an expert Delphi programmer. These topics form the foundation of working with the VCL and CLX class libraries; after exploring them in the next two chapters, we'll *finally* go on in Part II of the book to explore the development of real applications using all the various components provided by Delphi.

In the meantime, the next chapter will give you an over view of the Delphi run-time library, mainly a collection of functions with little OOP involved. The RTL is an assorted collection of routines and tasks for performing basic tasks with Delphi, and it has been largely extended in Delphi 6.

Chapter 5 will give you more information about the Object Pascal language, discussing features related to the structure of the Delphi class library, such as the effect of the `published` keyword and the role of events. The chapter, as a whole, will discuss the overall architecture of the component library.



CHAPTER 4

The Run-Time Library

- Overview of the RTL
- New Delphi 6 RTL functions
- The conversion engine
- Dates, strings, and other new RTL units
- The *TObject* class
- Showing class information at run time

Delphi uses Object Pascal as its programming language and favors an object-oriented approach, tied with a visual development style. This is where Delphi shines, and we will cover component-based and visual development in this book; however, I want to underline the fact that a lot of ready-to-use features of Delphi come from its run-time library, or RTL for short. This is a large collection of functions you can use to perform simple tasks, as well as some complex ones, within your Pascal code. (I use "Pascal" here, because the run-time library mainly contains procedures and functions and not classes and objects.)

There is actually a second reason to devote this chapter of the book to the run-time library: Delphi 6 sees a large number of enhancements to this area. There are new groups of functions, functions have been moved to new units, and other elements have changed, creating a few incompatibilities with existing code. So even if you've used past versions of Delphi and feel confident with the RTL, you should still read at least portions of this chapter.

The Units of the RTL

As I mentioned above, in Delphi 6 the RTL (run-time library) has a new structure and several new units. The reason for adding new units is that many new functions were added. In most cases, you'll find the existing functions in the units where they used to be, but the new functions will appear in specific units. For example, new functions related to dates are now in the DateUtils unit, but existing date functions have not been moved away from SysUtils in order to avoid incompatibilities with existing code.

The exception to this rule relates to some of the variant support functions, which were moved out of the System unit to avoid unwanted linkage of specific Windows libraries, even in programs that didn't use those features. These variant functions are now part of the new Variants unit, described later in the chapter.

WARNING Some of your existing Delphi code might need to use this new Variants unit to recompile. Delphi 6 is smart enough to acknowledge this and auto-include the Variants unit in projects that use the `Variant` type, issuing only a warning.

A little bit of fine-tuning has also been applied to reduce the minimum size of an executable file, at times enlarged by the unwanted inclusion of global variables or initialization code.

Executable Size under the Microscope

While touching up the RTL, Borland engineers have been able to trim a little "fat" out of each and every Delphi application. Reducing the minimum program size of a few KB seems quite odd, with all the bloated applications you find around these days, but it is a good service to developers. There are cases in which even few KB (multiplied by many applications) can reduce size and eventually download time.

Continued on next page

As a simple test, I've built the MiniSize program, which is not an attempt to build the smallest possible program, but rather an attempt to build a very small program that does something interesting: It reports the size of its own executable file. All of the code of this example is in the source code on the companion CD:

```
program MiniSize;

uses
  Windows;

{$R *.RES}

var
  nSize: Integer;
  hFile: THandle;
  strSize: String;

begin
  // open the current file and read the size
  hFile := CreateFile (PChar (ParamStr (0)),
    0, FILE_SHARE_READ, nil, OPEN_EXISTING, 0, 0);
  nSize := GetFileSize (hFile, nil);
  CloseHandle (hFile);

  // copy the size to a string and show it
  SetLength (strSize, 20);
  Str (nSize, strSize);
  MessageBox (0, PChar (strSize),
    'Mini Program', MB_OK);
end.
```

The program opens its own executable file, after retrieving its name from the first command-line parameter (`ParamStr (0)`), extracts the size, converts it into a string using the simple `Str` function, and shows the result in a message. The program does not have top-level windows. Moreover, I use the `Str` function for the integer-to-string conversion to avoid including SysUtils, which defines all the more complex formatting routines and would impose a little extra overhead.

If you compile this program with Delphi 5, you obtain an executable size of 18,432 bytes. Delphi 6 reduces this size to only 15,360 bytes, trimming about 3 KB. Replacing the long string with a short string, and modifying the code a little, you can trim down the program further, up to 9,216 bytes. This is because you'll end up removing the string support routines and also the memory allocator, something possible only in programs using exclusively low-level calls. You can find both versions in the source code of the example.

Continued on next page

Notice, anyway, that decisions of this type always imply a few trade-offs. In eliminating the overhead of variants from Delphi applications that don't use them, for example, Borland added a little extra burden to applications that do. The real advantage of this operation, though, is in the reduced memory footprint of Delphi applications that do not use variants, as a result of not having to bring in several megabytes of the Ole2 system libraries.

What is really important, in my opinion, is the size of full-blown Delphi applications based on run-time packages. A simple test with a do-nothing program, the MiniPack example, shows an executable size of 15,972 bytes.

In the following sections is a list of the RTL units in Delphi 6, including all the units available (with the complete source code) in the `Source\Rtl\Sys` subfolder of the `Delphi` directory and some of those available in the new subfolder `Source\Rtl\Common`. This new directory hosts the source code of units that make up the new RTL package, which comprises both the function-based library and the core classes, discussed in the next chapter.

NOTE The VCL50 package has now been split into the VCL and RTL packages, so that nonvisual applications using run-time packages don't have the overhead of also deploying visual portions of the VCL. Also, this change helps with Linux compatibility, as the new package is shared between the VCL and CLX libraries. Notice also that the package names in Delphi 6 don't have the version number in their name anymore. When they are compiled, though, the BPL does have the version in its file name, as discussed in more detail in Chapter 12.

I'll give a short overview of the role of each unit and an overview of the groups of functions included. I'll also devote more space to the new Delphi 6 units. I won't provide a detailed list of the functions included, because the online help includes similar reference material. However, I've tried to pick a few interesting or little-known functions, and I will discuss them shortly.

The System and SysInit Units

System is the core unit of the RTL and is automatically included in any compilation (considering an automatic and implicit `uses` statement referring to it). Actually, if you try adding the unit to the `uses` statement of a program, you'll get the compile-time error:

```
[Error] Identifier redeclared: System
```

The System unit includes, among other things:

- The `TObject` class, the base class of any class defined in the Object Pascal language, including all the classes of the VCL. (This class is discussed later in this chapter.)

- The IUnknown and IDispatch interfaces as well as the simple implementation class TInterfacedObject. There are also the new IInterface and IInvokable interfaces. IInterface was added to underscore the point that the interface type in Delphi's Object Pascal language definition is in no way dependent on the Windows operating system (and never has been). IInvokable was added to support SOAP-based invocation. (Interfaces and related classes were introduced in the last chapter and will be discussed further in multiple sections of the book.)
- Some variant support code, including the variant type constants, the TVarData record type and the new TVariantManager type, a large number of variant conversion routines, and also variant records and dynamic arrays support. This area sees a lot of changes compared to Delphi 5. The basic information on variants is provided in Chapter 10 of *Essential Pascal* (available on the companion CD), while an introduction to custom variants is available later in this chapter.
- Many base data types, including pointer and array types and the TDateTime type I've already described in the last chapter.
- Memory allocation routines, such as GetMem and FreeMem, and the actual memory manager, defined by the TMemoryManager record and accessed by the GetMemoryManager and SetMemoryManager functions. For information, the GetHeapStatus function returns a THeapStatus data structure. Two new global variables (AllocMemCount and AllocMemSize) hold the number and total size of allocated memory blocks. There is more on memory and the use of these functions in Chapter 10.
- Package and module support code, including the PackageInfo pointer type, the GetPackageInfoTable global function, and the EnumModules procedure (packages internals are discussed in Chapter 12).
- A rather long list of global variables, including the Windows application instance MainInstance; IsLibrary, indicating whether the executable file is a library or a stand-alone program; IsConsole, indicating console applications; IsMultiThread, indicating whether there are secondary threads; and the command-line string CmdLine. (The unit includes also the ParamCount and ParamStr for an easy access to command-line parameters.) Some of these variables are specific to the Windows platform.
- Thread-support code, with the BeginThread and EndThread functions; file support records and file-related routines; wide string and OLE string conversion routines; and many other low-level and system routines (including a number of automatic conversion functions).

The companion unit of System, called SysInit, includes the system initialization code, with functions you'll seldom use directly. This is another unit that is always implicitly included, as it is used by the System unit.

New in System Unit

I've already described some interesting new features of the System unit in the list above, and most of the changes relate to making the core Delphi RTL more cross-platform portable, replacing Windows-specific features with generic implementations. Along this line, there are new names for interface types, totally revised support for variants, new pointer types, dynamic array support, and functions to customize the management of exception objects.

Another addition for compatibility with Linux relates to line breaks in text files. There is a new `DefaultTextLineBreakStyle` variable, which can be set to either tlbsLF or tlbsCRLF, and a new `sLineBreak` string constant, which has the value #13#10 in the Windows version of Delphi and the value #10 in the Linux version. The line break style can also be set on a file-by-file basis with `SetTextLineBreakStyle` function.

Finally, the System unit now includes the `TFileRec` and `TTextRec` structures, which were defined in the SysUtils unit in earlier versions of Delphi.

The SysUtils and SysConst Units

The SysConst unit defines a few constant strings used by the other RTL units for displaying messages. These strings are declared with the `resourcestring` keyword and saved in the program resources. As other resources, they can be translated by means of the Integrated Translation Manager or the External Translation Manager.

The SysUtils unit is a collection of system utility functions of various types. Different from other RTL units, it is in large part an operating system–dependent unit. The SysUtils unit has no specific focus, but it includes a bit of everything, from string management to locale and multibyte-characters support, from the `Exception` class and several other derived exception classes to a plethora of string-formatting constants and routines.

Some of the features of SysUtils are used every day by every programmer as the `IntToStr` or `Format` string-formatting functions; other features are lesser known, as they are the Windows version information global variables. These indicate the Windows platform (Window 9*x* or NT/2000), the operating system version and build number, and the eventual service pack installed on NT. They can be used as in the following code, extracted from the WinVersion example on the companion CD:

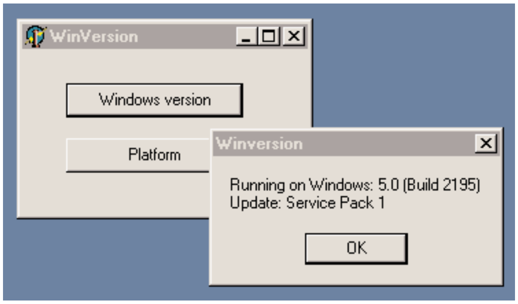
```
case Win32Platform of
  VER_PLATFORM_WIN32_WINDOWS:  ShowMessage ('Windows 9x');
  VER_PLATFORM_WIN32_NT:       ShowMessage ('Windows NT');
end;

ShowMessage ('Running on Windows: ' + IntToStr (Win32MajorVersion) + '.' +
  IntToStr (Win32MinorVersion) + ' (Build ' + IntToStr (Win32BuildNumber) +
  ') ' + #10#13 + 'Update: ' + Win32CSDVersion);
```

The second code fragment produces a message like the one in Figure 4.1, depending, of course, on the operating-system version you have installed.

FIGURE 4.1:

The version information displayed by the WinVersion example



WinVersion

Winversion

Running on Windows: 5.0 (Build 2195)
Update: Service Pack 1

Another little-known feature, but one with a rather long name, is a class that supports multithreading: `TMultiReadExclusiveWriteSynchronizer`. This class allows you to work with resources that can be used by multiple threads at the same time for reading (multiread) but must be used by one single thread when writing (exclusive-write). This means that the writing cannot start until all the reading threads have terminated.

NOTE The multi-read synchronizer is unique in that it supports recursive locks and promotion of read locks to write locks. The main purpose of the class is to allow multiple threads easy, fast access to read from a shared resource, but still allow one thread to gain exclusive control of the resource for relatively infrequent updates. There are other synchronization classes in Delphi, declared in the SyncObjs unit and closely mapped to operating-system synchronization objects (such as events and critical sections in Windows).

New SysUtils Functions

Delphi 6 has some new functions within the `SysUtils` unit. One of the new areas relates to Boolean to string conversion. The `BoolToStr` function generally returns '-1' and '0' for true and false values. If the second optional parameter is specified, the function returns the first string in the `TrueBoolStrs` and `FalseBoolStrs` arrays (by default 'TRUE' and 'FALSE'):

```
BoolToStr (True) // returns '-1'
BoolToStr (False, True) // returns 'FALSE' by default
```

The reverse function is `StrToBool`, which can convert a string containing either one of the values of two Boolean arrays mentioned above or a numeric value. In the latter case, the result will be true unless the numeric value is zero. You can see a simple demo of the use of the Boolean conversion functions in the StrDemo example, later in this chapter.

Other new functions of SysUtils relate to floating-point conversions to currency and date time types: `FloatToCurr` and `FloatToDateTime` can be used to avoid an explicit type cast. The `TryStrToFloat` and `TryStrToCurr` functions try to convert a string into a floating point or currency value and will return False in case of error instead of generating an exception (as the classic `StrToFloat` and `StrToCurr` functions do).

There is an `AnsiDequotedStr` function, which removes quotes from a string, matching the `AnsiQuoteStr` function added in Delphi 5. Speaking of strings, Delphi 6 has much-improved support for wide strings, with a series of new routines, including `WideUpperCase`, `WideLowerCase`, `WideCompareStr`, `WideSameStr`, `WideCompareText`, `WideSameText`, and `WideFormat`. All of these functions work like their `AnsiString` counterparts.

Three functions (`TryStrToDate`, `TryEncodeDate`, and `TryEncodeTime`) try to convert a string to a date or to encode a date or time, without raising an exception, similarly to the `Try` functions previously mentioned. In addition, the `DecodeDateFully` function returns more detailed information, such as the day of the week, and the `CurrentYear` function returns the year of today's date.

There is a portable, friendly, overloaded version of the `GetEnvironmentVariable` function. This new version uses string parameters instead of PChar parameters and is definitely easier to use:

```
function GetEnvironmentVariable(Name: string): string;
```

Other new functions relate to interface support. Two new overloaded versions of the little-known `Support` function allow you to check whether an object or a class supports a given interface. The function corresponds to the behavior of the `is` operator for classes and is mapped to the `QueryInterface` method. Here's an example in the code of the IntfDemo program from Chapter 3:

```
var
  W1: IWalker;
  J1: IJumper;
begin
  W1 := TAthlete.Create;
  // more code...
  if Supports (w1, IJumper) then
  begin
    J1 := W1 as IJumper;
    Log (J1.Walk);
  end;
```

There are also an `IsEqualGUID` function and two functions for converting strings to GUIDs and vice versa. The function `CreateGUID` has been moved to SysUtils, as well, to make it also available on Linux (with a custom implementation, of course).

Finally, Delphi 6 has some more Linux-compatibility functions. The AdjustLineBreaks function can now do different types of *adjustments* to carriage-return and line-feed sequences, along with the introduction of new global variables for text files in the System unit, as described earlier. The FileCreate function has an overloaded version in which you can specify file-access rights *the Unix way*. The ExpandFileName function can locate files (on case-sensitive file systems) even when their cases don't exactly correspond. The functions related to path delimiters (backslash or slash) have been made more generic and renamed accordingly. (For example, the IncludeTralingBackslash function is now better known as IncludingTrailingPathDelimiter.)

The Math Unit

The Math unit hosts a collection of mathematical functions: about forty trigonometric functions, logarithmic and exponential functions, rounding functions, polynomial evaluations, almost thirty statistical functions, and a dozen financial functions.

Describing all of the functions of this unit would be rather tedious, although some readers are probably very interested in the mathematical capabilities of Delphi. Here are some of the newer math functions.

New Math Functions

Delphi 6 adds to the Math unit quite a number of new features. There is support for infinite constants (Infinity and NegInfinity) and related comparison functions (IsInfinite and IsNan). There are new trigonometric functions for cosecants and cotangents and new angle-conversion functions.

A handy feature is the availability of an overloaded IfThen function, which returns one of two possible values depending on a Boolean expression. (A similar function is now available also for strings.) You can use it, for example, to compute the minimum of two values:

```
nMin := IfThen (nA < nB, na, nB);
```

NOTE The IfThen function is similar to the ?: operator of the C/C++ language, which I find very handy because you can replace a complete if/then/else statement with a much shorter expression, writing less code and often declaring fewer temporary variables.

The RandomRange and RandomFrom can be used instead of the traditional Random function to have more control on the random values produced by the RTL. The first function returns a number within two extremes you specify, while the second selects a random value from an array of possible numbers you pass to it as a parameter.

The InRange Boolean function can be used to check whether a number is within two other values. The EnsureRange function, instead, forces the value to be within the specified range.

The return value is the number itself or the lower limit or upper limit, in the event the number is out of range. Here is an example:

```
// do something only if value is within min and max
if InRange (value, min, max) then
  ...

// make sure the value is between min and max
value := EnsureRange (value, min, max);
...
```

Another set of very useful functions relates to comparisons. Floating-point numbers are fundamentally inexact; a floating-point number is an approximation of a theoretical real value. When you do mathematical operations on floating-point numbers, the inexactness of the original values accumulates in the results. Multiplying and dividing by the same number might not return exactly the original number but one that is very close to it. The `SameValue` function allows you to check whether two values are close enough in value to be considered equal. You can specify how close the two numbers should be or let Delphi compute a reasonable error range for the representation you are using. (This is why the function is overloaded.) Similarly, the `IsZero` function compares a number to zero, with the same "fuzzy logic."

The `CompareValue` function uses the same rule for floating-point numbers but is available also for integers; it returns one of the three constants `LessThanValue`, `EqualsValue`, and `GreaterThanValue` (corresponding to –1, 0, and 1). Similarly, the new `Sign` function returns –1, 0, and 1 to indicate a negative value, zero, or a positive value.

The `DivMod` function is equivalent to both div and mod operations, returning the result of the integer division and the remainder (or modulus) at once. The `RoundTo` function allows you to specify the rounding digit—allowing, for example, rounding to the nearest thousand or to two decimals:

```
RoundTo (123827, 3);   // result is 124,000
RoundTo (12.3827, -2); // result is 12.38
```

WARNING Notice that the `RoundTo` function uses a positive number to indicate the power of ten to round to (for example, `2` for hundreds) or a negative number for the number of decimal places. This is exactly the opposite of the `Round` function used by spreadsheets such as Excel.

There are also some changes to the standard rounding operations provided by the `Round` function: You can now control how the FPU (the floating-point unit of the CPU) does the rounding by calling the `SetRoundMode` function. There are also functions to control the FPU precision mode and its exceptions.

The New ConvUtils and StdConvs Units

The new ConvUtils unit contains the core of the conversion engine. It uses the conversion constants defined by a second unit, StdConvs. I'll cover these two units later in this chapter, showing you also how to extend them with new measurement units.

The New DateUtils Unit

The DateUtils unit is a new collection of date and time-related functions. It includes new functions for picking values from a TDateTime variable or counting values from a given interval, such as

```
// pick value
function DayOf(const AValue: TDateTime): Word;
function HourOf(const AValue: TDateTime): Word;
// value in range
function WeekOfYear(const AValue: TDateTime): Integer;
function HourOfWeek(const AValue: TDateTime): Integer;
function SecondOfHour(const AValue: TDateTime): Integer;
```

Some of these functions are actually quite odd, such as MilliSecondOfMonth or SecondOfWeek, but Borland developers have decided to provide a complete set of functions, no matter how impractical they sound. I actually used some of these functions in Chapter 2, to build the TDate class.

There are functions for computing the initial or final value of a given time interval (day, week, month, year) including the current date, and for range checking and querying; for example:

```
function DaysBetween(const ANow, AThen: TDateTime): Integer;
function WithinPastDays(const ANow, AThen: TDateTime;
  const ADays: Integer): Boolean;
```

Other functions cover incrementing and decrementing by each of the possible time intervals, encoding and "recoding" (replacing one element of the TDateTime value, such as the day, with a new one), and doing "fuzzy" comparisons (approximate comparisons where a difference of a millisecond will still make two dates equal). Overall, DateUtils is quite interesting and not terribly difficult to use.

The New StrUtils Unit

The StrUtils unit is a new unit with some new string-related functions. One of the key features of this unit is the availability of many new string comparison functions. There are functions based on a "soundex" algorithm (AnsiResembleText), some providing lookup in arrays of strings (AnsiMatchText and AnsiIndexText), sub-string location, and replacement (including AnsiContainsText and AnsiReplaceText).

NOTE *Soundex* is an algorithm to compare names based on how they sound rather then how they are spelled. The algorithm computes a number for each word sound, so that comparing two such numbers you can determine whether two names sound similar. The system was first applied 1880 by the U.S. Bureau of the Census, patented in 1918, and is now in the public domain. The soundex code is an indexing system that translates names into a four-character code consisting of one letter and three numbers. More information is at `www.nara.gov/genealogy/coding.html`.

Beside comparisons, other functions provide a two-way test (the nice `IfThen` function, similar to the one we've already seen for numbers), duplicate and reverse strings, and replace sub-strings. Most of these string functions were added as a convenience to Visual Basic programmers migrating to Delphi.

I've used some of these functions in the StrDemo example on the companion CD, which uses also some of the new Boolean-to-string conversions defined within the SysUtils unit. The program is actually a little more than a test for a few of these functions. For example, it uses the "soundex" comparison between the strings entered in two edit boxes, converting the resulting Boolean into a string and showing it:

```
ShowMessage (BoolToStr (AnsiResemblesText
  (EditResemble1.Text, EditResemble2.Text), True));
```

The program also showcases the `AnsiMatchText` and `AnsiIndexText` functions, after filling a dynamic array of strings (called `strArray`) with the values of the strings inside a list box. I could have used the simpler `IndexOf` method of the `TStrings` class, but this would have defeated the purpose of the example. The two list comparisons are done as follows:

```
procedure TForm1.ButtonMatchesClick(Sender: TObject);
begin
  ShowMessage (BoolToStr (AnsiMatchText(EditMatch.Text, strArray), True));
end;

procedure TForm1.ButtonIndexClick(Sender: TObject);
var
  nMatch: Integer;
begin
  nMatch := AnsiIndexText(EditMatch.Text, strArray);
  ShowMessage (IfThen (nMatch >= 0, 'Matches the string number ' +
    IntToStr (nMatch), 'No match'));
end;
```

Notice the use of the `IfThen` function in the last few lines of code, with two alternative output strings, depending on the result of the initial test (`nMatch <= 0`).

Three more buttons do simple calls to three other new functions, with the following lines of code (one for each):

```
// duplicate (3 times) a string
ShowMessage (DupeString (EditSample.Text, 3));
// reverse the string
ShowMessage (ReverseString (EditSample.Text));
// choose a random string
ShowMessage (RandomFrom (strArray));
```

The New Types Unit

The Types unit is a new Pascal file holding data types common to multiple operating systems. In past versions of Delphi, the same types were defined by the Windows unit; now they've been moved to this common unit, shared by Delphi and Kylix. The types defined here are simple ones and include, among others, the `TPoint`, `TRect`, and `TSmallPoint` record structures plus their related pointer types.

The New Variants and VarUtils Units

Variants and VarUtils are two new variant-related units. The Variants unit contains generic code for variants. As mentioned earlier, some of the routines in this unit have been moved here from the System unit. Functions include generic variant support, variant arrays, variant copying, and dynamic array to variant array conversions. There is also the `TCustomVariantType` class, which defines customizable variant data types.

The Variants unit is totally platform independent and uses the VarUtils unit, which contains OS-dependent code. In Delphi, this unit uses the system APIs to manipulate variant data, while in Kylix it uses some custom code provided by the RTL library.

Custom Variants and Complex Numbers

The possibility to extend the type system with custom variants is brand new in Delphi 6. It allows you to define a new data type that, contrary to a class, overloads standard arithmetic operators.

In fact, a variant is a type holding both type specification and the actual value. A variant can contain a string, another can contain a number. The system defines automatic conversions among variant types, allowing you to mix them inside operations (including custom variants). This flexibility comes at a high cost: operations on variants are much slower than on native types, and variants use extra memory.

As an example of a custom variant type, Delphi 6 ships with an interesting definition for complex numbers, found in the VarCmplx unit (available in source-code format in the

Rtl\Common folder). You can create complex variants by using one of the overloaded VarComplexCreate functions and use them in any expression, as the following code fragment demonstrates:

```
var
  v1, v2: Variant;
begin
  v1 := VarComplexCreate (10, 12);
  v2 := VarComplexCreate (10, 1);
  ShowMessage (v1 + v2 + 5);
```

The complex numbers are actually defined using classes, but they are surfaced as variants by inheriting a new class from the TCustomVariantType class (defined in the Variants unit), overriding a few virtual abstract functions, and creating a global object that takes care of the registration within the system.

Beside these internal definitions, the unit includes a long list of routines for operating on variant, including mathematical and trigonometric operations. I'll leave them to your study, as not all readers may be interested in complex numbers for their programs.

WARNING Building a custom variant is certainly not an easy task, and I can hardly find reasons for using them instead of objects and classes. In fact, with a custom variant you gain the advantage of using operator overloading on your own data structures, but you lose compile-time checking, make the code much slower, miss several OOP features, and have to write a lot of rather complex code.

The DelphiMM and ShareMem Units

The DelphiMM and ShareMem units relate to memory management. The actual Delphi memory manager is declared in the System unit. The DelphiMM unit defines an alternative memory manager library to be used when passing strings from an executable to a DLL (a Windows dynamic linking library), both built with Delphi.

The interface to this memory manager is defined in the ShareMem unit. This is the unit you must include (compulsory as first unit) in the projects of both your executable and library (or libraries). Then, you'll also need to distribute and install the Borlndmm.dll library file along with your program.

COM-Related Units

ComConts, ComObj, and ComServ provide low-level COM support. As these units are not really part of the RTL, from my point of view, I won't discuss them here in any detail. You can refer to Chapter 20 for all the related information. In any case, these units have not changed a lot since the last version of Delphi.

Converting Data

Delphi 6 includes a new conversion engine, defined in the ConvUtils unit. The engine by itself doesn't include any definition of actual measurement units; instead, it has a series of core functions for end users.

The key function is the actual conversion call, the `Convert` function. You simply provide the amount, the units it is expressed in, and the units you want it converted into. The following would convert a temperature of 31 degrees Celsius to Fahrenheit:

```
Convert (31, tuCelsius, tuFahrenheit)
```

An overloaded version of the `Convert` function allows converting values that have two units, such as speed (which has both a length and a time unit). For example, you can convert miles per hours to meters per second with this call:

```
Convert (20, duMiles, tuHours, duMeters, tuSeconds)
```

Other functions in the unit allow you to convert the result of an addition or a difference, check if conversions are applicable, and even list the available conversion families and units.

A predefined set of measurement units is provided in the StdConvs unit. This unit has conversion families and an impressive number of actual values, as in the following reduced excerpt:

```
  // Distance Conversion Units
  // basic unit of measurement is meters
  cbDistance: TConvFamily;

  duAngstroms: TConvType;
  duMicrons: TConvType;
  duMillimeters: TConvType;
  duMeters: TConvType;
  duKilometers: TConvType;
  duInches: TConvType;
  duMiles: TConvType;
  duLightYears: TConvType;
  duFurlongs: TConvType;
  duHands: TConvType;
  duPicas: TConvType;
```

This family and the various units are registered in the conversion engine in the initialization section of the unit, providing the conversion ratios (saved in a series of constants, as `MetersPerInch` in the code below):

```
cbDistance := RegisterConversionFamily('Distance');
duAngstroms := RegisterConversionType(cbDistance, 'Angstroms', 1E-10);
duMillimeters := RegisterConversionType(cbDistance, 'Millimeters', 0.001);
duInches := RegisterConversionType(cbDistance, 'Inches', MetersPerInch);
```

To test the conversion engine, I built a generic example (ConvDemo on the companion CD) that allows you to work with the entire set of available conversions. The program fills a combo box with the available conversion families and a list box with the available units of the active family. This is the code:

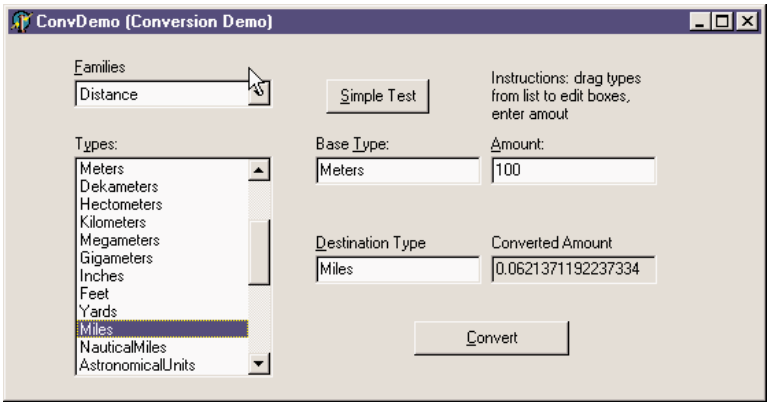
```
procedure TForm1.FormCreate(Sender: TObject);
var
  i: Integer;
begin
  GetConvFamilies (aFamilies);
  for i := Low(aFamilies) to High(aFamilies) do
    ComboFamilies.Items.Add (ConvFamilyToDescription (aFamilies[i]));
  // get the first and fire event
  ComboFamilies.ItemIndex := 0;
  ChangeFamily (self);
end;

procedure TForm1.ChangeFamily(Sender: TObject);
var
  aTypes: TConvTypeArray;
  i: Integer;
begin
  ListTypes.Clear;
  CurrFamily := aFamilies [ComboFamilies.ItemIndex];
  GetConvTypes (CurrFamily, aTypes);
  for i := Low(aTypes) to High(aTypes) do
    ListTypes.Items.Add (ConvTypeToDescription (aTypes[i]));
end;
```

The `aFamilies` and `CurrFamily` variables are declared in the private section of the form as follows:

```
aFamilies: TConvFamilyArray;
CurrFamily: TConvFamily;
```

At this point, a user can enter two measurement units and an amount in the corresponding edit boxes of the form, as you can see in Figure 4.2. To make the operation faster, it is actually possible to select a value in the list and drag it to one of the two Type edit boxes. The dragging support is described in the sidebar "Simple Dragging in Delphi."



ConvDemo (Conversion Demo)

Instructions: drag types from list to edit boxes, enter amout

Families: Distance

Types:

Meters
Dekameters
Hectometers
Kilometers
Megameters
Gigameters
Inches
Feet
Yards
Miles
NauticalMiles
AstronomicalUnits

Base Type: Meters

Amount: 100

Destination Type: Miles

Converted Amount: 0.0621371192237334

FIGURE 4.2: The ConvDemo example at run time

Simple Dragging in Delphi

The ConvDemo example I've built to show how to use the new conversion engine of Delphi 6 uses an interesting technique: dragging. In fact, you can move the mouse over the list box, select an item, and then keep the left mouse button pressed and drag the item over one of the edit boxes in the center of the form.

To accomplish this, I had to set the `DragMode` property of the list box (the source component) to dmAutomatic and implement the `OnDragOver` and `OnDragDrop` events of the target edit boxes (the two edit boxes are connected to the same event handlers, sharing the same code). In the first method, the program indicates that the edit boxes always accept the dragging operation, regardless of the source. In the second method, the program copies the text selected in the list box (the `Source` control of the dragging operation) to the edit box that fired the event (the `Sender` object). Here is the code for the two methods:

```
procedure TForm1.EditTypeDragOver(Sender, Source: TObject;
  X, Y: Integer; State: TDragState; var Accept: Boolean);
begin
  Accept := True;
end;

procedure TForm1.EditTypeDragDrop(Sender, Source: TObject;
  X, Y: Integer);
begin
  (Sender as TEdit).Text := (Source as TListBox).Items
    [(Source as TListBox).ItemIndex];
end;
```

The units must match those available in the current family. In case of error, the text of the Type edit boxes is shown in red. This is the effect of the first part of the DoConvert method of the form, which is activated as soon as the value of one of the edit boxes for the units or the amount changes. After checking the types in the edit boxes, the DoConvert method does the actual conversion, displaying the result in the fourth, grayed edit box. In case of errors, you'll get a proper message in the same box. Here is the code:

```
procedure TForm1.DoConvert(Sender: TObject);
var
  BaseType, DestType: TConvType;
begin
  // get and check base type
  if not DescriptionToConvType(CurrFamily, EditType.Text, BaseType) then
    EditType.Font.Color := clRed
  else
    EditType.Font.Color := clBlack;

  // get and check destination type
  if not DescriptionToConvType(CurrFamily, EditDestination.Text,
      DestType) then
    EditDestination.Font.Color := clRed
  else
    EditDestination.Font.Color := clBlack;

  if (DestType = 0) or (BaseType = 0) then
    EditConverted.Text := 'Invalid type'
  else
    EditConverted.Text := FloatToStr (Convert (
      StrToFloat (EditAmount.Text), BaseType, DestType));
end;
```

If all this is not interesting enough for you, consider that the conversion types provided serve only as a demo: You can fully customize the engine, by providing the measurement units you are interested in, as described in the next section.

What About Currency Conversions?

Converting currencies is not exactly the same as converting measurement units, as currency rates change at very high speed. In theory, you can register a conversion rate with Delphi's conversion engine. From time to time, you check the new rate exchange, unregister the existing conversion, and register a new one. However, keeping up with the actual rate means changing the conversion so often that the operation might not make a lot of sense. Also, you'll have to triangulate conversions: you have to define a base unit (probably the U.S. dollar if you live in America) and convert to and from this currency even for converting between two different ones.

What's more interesting is to use the engine for converting member currencies of the euro, for two reasons. First, conversion rates are fixed (until the single euro currency actually takes over). Second, the conversion among euro currencies is legally done by converting a currency to euros first and then from the euro amount to the other currency, the exact behavior of Delphi's conversion engine. There is only a small problem, as you should apply a rounding algorithm at every step of the conversion. I'll consider this problem after I've provided the base code for integrating euro currencies with Delphi 6 conversion engine.

NOTE The ConvertIt demo of Delphi 6 provides support for euro conversions, using a slightly different rounding approach (which might be more correct or not, I'm not really sure). I've decided to keep this example anyway, as it is instructive in showing how to create a new measurement system (and I lacked another example as good).

The example, called EuroConv, is actually meant to teach how to register any new measurement unit with the engine. Following the template provided by the StdConvs unit, I've created a new unit (called EuroConvConst) and in the interface portion I've declared variables for the family and the specific units, as follows:

```
interface

var
  // Euro Currency Conversion Units
  cbEuroCurrency: TConvFamily;

  cuEUR: TConvType;
  cuDEM: TConvType; // Germany
  cuESP: TConvType; // Spain
  cuFRF: TConvType; // France
  cuIEP: TConvType; // Ireland
  cuITL: TConvType; // Italy
  // and so on...
```

In the implementation portion of the unit, I've defined constants for the various official conversion rates:

```
implementation

const
  DEMPerEuros = 1.95583;
  ESPPerEuros = 166.386;
  FRFPerEuros = 6.55957;
  IEPPerEuros =  0.787564;
  ITLPerEuros =  1936.27;
  // and so on...
```

Finally, in the unit initialization code I've registered the family and the various currencies, each with its own conversion rate and a readable name:

```
initialization
  // Euro Currency's family type
  cbEuroCurrency := RegisterConversionFamily('EuroCurrency');

  cuEUR := RegisterConversionType(
    cbEuroCurrency, 'EUR', 1);
  cuDEM := RegisterConversionType(
    cbEuroCurrency, 'DEM', 1 / DEMPerEuros);
  cuESP := RegisterConversionType(
    cbEuroCurrency, 'ESP', 1 / ESPPerEuros);
  cuFRF := RegisterConversionType(
    cbEuroCurrency, 'FRF', 1 / FRFPerEuros);
  cuIEP := RegisterConversionType(
    cbEuroCurrency, 'IEP', 1 / IEPPerEuros);
  cuITL := RegisterConversionType(
    cbEuroCurrency, 'ITL', 1 / ITLPerEuros);
```

NOTE The engine uses as a conversion factor the amount of the base unit to obtain the secondary ones, with a constant like `MetersPerInch`, for example. The standard rate of euro currencies is defined in the opposite way. For this reason, I've decided to keep the conversion constants with the official values (as `DEMPerEuros above`) and pass them to the engine as fractions (`1/DEMPerEuros`).

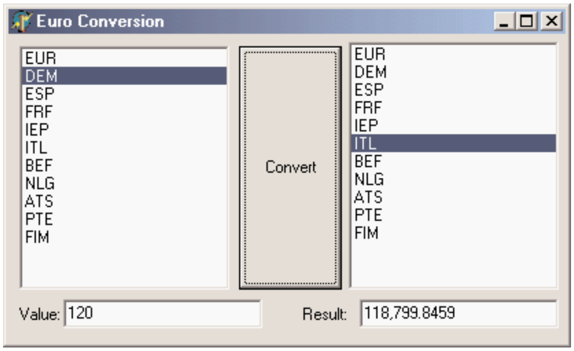
Having registered this unit, we can now convert 120 German marks to Italian liras by writing:

```
Convert (120, cuDEM, cuITL)
```

The demo program actually does a little more, providing two list boxes with the available currencies, extracted as in the previous example, and edit boxes for the input value and final result. You can see the form at run time in Figure 4.3.

FIGURE 4.3:

The output of the EuroConv unit, showing the use of Delphi's conversion engine with a custom measurement unit



Value: 120

Result: 118,799.8459

The program works nicely but is not perfect, as the proper rounding is not applied. In fact, you should round not only the final result of the conversion but also the intermediate value. Using the conversion engine to accomplish this directly is not easy. The engine allows you to provide either a custom conversion function or a conversion rate. But writing identical conversion functions for the all the various currencies seems a bad idea, so I've decided to go a different path. (You can see examples of custom conversion functions in the StdConvs unit, in the portion related to temperatures.)

In the EuroConv example, I've added to the unit with the conversion rates a custom function, called `EuroConv`, that does the proper conversion. Simply calling this function instead of the standard `Convert` function does the trick (and I really see no drawback to this approach, because in programs like this, you'll hardly mix currencies with meters or temperatures). As an alternative, I could inherit a new class from `TConvTypeFactor`, providing a new version of the `FromCommon` and `ToCommon` methods, or I could have called the overloaded versions of the `RegisterConversionType` that accepts these two functions as parameters. None of these techniques, however, would have allowed me to handle special cases, such as the conversion of a currency to itself.

This is the code of the `EuroConv` function, which uses the internal `EuroRound` function for rounding to the number of digits specified in the `Decimals` parameter (which must be between 3 and 6, according with the official rules):

```
type
  TEuroDecimals = 3..6;

function EuroConvert (const AValue: Double;
  const AFrom, ATo: TConvType;
  const Decimals: TEuroDecimals = 3): Double;

  function EuroRound (const AValue: Double): Double;
  begin
    Result := AValue * Power (10, Decimals);
    Result := Round (Result);
    Result := Result / Power (10, Decimals);
  end;

begin
  // check special case: no conversion
  if AFrom = ATo then
    Result := AValue
  else
  begin
    // convert to Euro, then round
    Result := ConvertFrom (AFrom, AValue);
    Result := EuroRound (Result);
```

```
      // convert to currency then round again
      Result := ConvertTo (Result, ATo);
      Result := EuroRound (Result);
    end;
  end;
```

Of course, you might want to extend the example by providing conversion to other non-euro currencies, eventually picking the values automatically from a Web site. I'll leave this as a rather complex exercise.

The *TObject* Class

As mentioned earlier, a key element of the System unit is the definition of the `TObject` class, the *mother of all Delphi classes*. Every class in the system is a subclass of the `TObject` class, either directly (for example, if you indicate no base class) or indirectly. The whole hierarchy of the classes of an Object Pascal program has a single root. This allows you to use the `TObject` data type as a replacement for the data type of any class type in the system.

For example, event handlers of components usually have a `Sender` parameter of type `TObject`. This simply means that the `Sender` object can be of any class, since every class is ultimately derived from `TObject`. The typical drawback of such an approach is that to work on the object, you need to know its data type. In fact, when you have a variable or a parameter of the `TObject` type, you can apply to it only the methods and properties defined by the `TObject` class itself. If this variable or parameter happens to refer to an object of the `TButton` type, for example, you cannot directly access its `Caption` property. The solution to this problem lies in the use of the safe down-casting or run-time type information (RTTI) operators (`is` and `as`) discussed in Chapter 3.

There is another approach. For any object, you can call the methods defined in the `TObject` class itself. For example, the `ClassName` method returns a string with the name of the class. Because it is a class method (see Chapter 2 for details), you can actually apply it both to an object and to a class. Suppose you have defined a `TButton` class and a `Button1` object of that class. Then the following statements have the same effect:

```
Text := Button1.ClassName;
Text := TButton.ClassName;
```

There are occasions when you need to use the name of a class, but it can also be useful to retrieve a class reference to the class itself or to its base class. The class reference, in fact, allows you to operate on the class at run time (as we've seen in the preceding chapter), while the class name is just a string. We can get these class references with the `ClassType` and `ClassParent` methods. The first returns a class reference to the class of the object, the second to its base class. Once you have a class reference, you can apply to it any class methods of TObject—for example, to call the ClassName method.

Another method that might be useful is InstanceSize, which returns the run-time size of an object. Although you might think that the SizeOf global function provides this information, that function actually returns the size of an object reference—a pointer, which is invariably four bytes—instead of the size of the object itself.

In Listing 4.1, you can find the complete definition of the TObject class, extracted from the System unit. Beside the methods I've already mentioned, notice InheritsFrom, which provides a test very similar to the is operator but that can be applied also to classes and class references (while the first argument of is must be an object).

Listing 4.1: The definition of the *TObject* class (in the System RTL unit)

```
type
  TObject = class
    constructor Create;
    procedure Free;
    class function InitInstance(Instance: Pointer): TObject;
    procedure CleanupInstance;
    function ClassType: TClass;
    class function ClassName: ShortString;
    class function ClassNameIs(
      const Name: string): Boolean;
    class function ClassParent: TClass;
    class function ClassInfo: Pointer;
    class function InstanceSize: Longint;
    class function InheritsFrom(AClass: TClass): Boolean;
    class function MethodAddress(const Name: ShortString): Pointer;
    class function MethodName(Address: Pointer): ShortString;
    function FieldAddress(const Name: ShortString): Pointer;
    function GetInterface(const IID: TGUID;out Obj): Boolean;
    class function GetInterfaceEntry(
      const IID: TGUID): PInterfaceEntry;
    class function GetInterfaceTable: PInterfaceTable;
    function SafeCallException(ExceptObject: TObject;
      ExceptAddr: Pointer): HResult; virtual;
    procedure AfterConstruction; virtual;
    procedure BeforeDestruction; virtual;
    procedure Dispatch(var Message); virtual;
    procedure DefaultHandler(var Message); virtual;
    class function NewInstance: TObject; virtual;
    procedure FreeInstance; virtual;
    destructor Destroy; virtual;
  end;
```

NOTE The ClassInfo method returns a pointer to the internal run-time type information (RTTI) of the class, introduced in the next chapter.

These methods of TObject are available for objects of every class, since TObject is the common ancestor class of every class. Here is how we can use these methods to access class information:

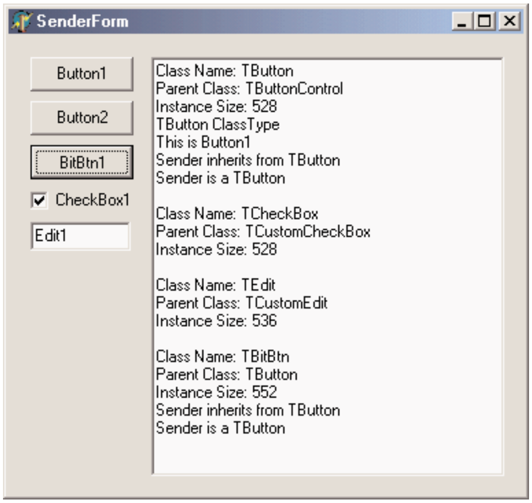
```
procedure TSenderForm.ShowSender(Sender: TObject);
begin
  Memo1.Lines.Add ('Class Name: ' + Sender.ClassName);

  if Sender.ClassParent <> nil then
    Memo1.Lines.Add ('Parent Class: ' + Sender.ClassParent.ClassName);

  Memo1.Lines.Add ('Instance Size: ' + IntToStr (Sender.InstanceSize));
end;
```

The code checks to see whether the ClassParent is nil in case you are actually using an instance of the TObject type, which has no base type. This ShowSender method is part of the IfSender example on the companion CD. The method is connected with the OnClick event of several controls: three buttons, a check box, and an edit box. When you click each control, the ShowSender method is invoked with the corresponding control as sender (more on events in the next chapter). One of the buttons is actually a Bitmap button, an object of a TButton subclass. You can see an example of the output of this program at run time in Figure 4.4.

FIGURE 4.4: The output of the IfSender example



```
Class Name: TButton
Parent Class: TButtonControl
Instance Size: 528
TButton ClassType
This is Button1
Sender inherits from TButton
Sender is a TButton

Class Name: TCheckBox
Parent Class: TCustomCheckBox
Instance Size: 528

Class Name: TEdit
Parent Class: TCustomEdit
Instance Size: 536

Class Name: TBitBtn
Parent Class: TButton
Instance Size: 552
Sender inherits from TButton
Sender is a TButton
```

You can use other methods to perform tests. For example, you can check whether the Sender object is of a specific type with the following code:

```
if Sender.ClassType = TButton then ...
```

You can also check whether the Sender parameter corresponds to a given object, with this test:

```
if Sender = Button1 then...
```

Instead of checking for a particular class or object, you'll generally need to test the type compatibility of an object with a given class; that is, you'll need to check whether the class of the object is a given class *or* one of its subclasses. This lets you know whether you can operate on the object with the methods defined for the class. This test can be accomplished using the InheritsFrom method, which is also called when you use the is operator. The following two tests are equivalent:

```
if Sender.InheritsFrom (TButton) then ...
if Sender is TButton then ...
```

Showing Class Information

I've extended the IfSender example to show a complete list of base classes of a given object or class. Once you have a class reference, in fact, you can add all of its base classes to the ListParent list box with the following code:

```
with ListParent.Items do
begin
  Clear;
  while MyClass.ClassParent <> nil do
  begin
    MyClass := MyClass.ClassParent;
    Add (MyClass.ClassName);
  end;
end;
```

You'll notice that we use a class reference at the heart of the while loop, which tests for the absence of a parent class (so that the current class is TObject). Alternatively, we could have written the while statement in either of the following ways:

```
while not MyClass.ClassNameIs ('TObject') do...
while MyClass <> TObject do...
```

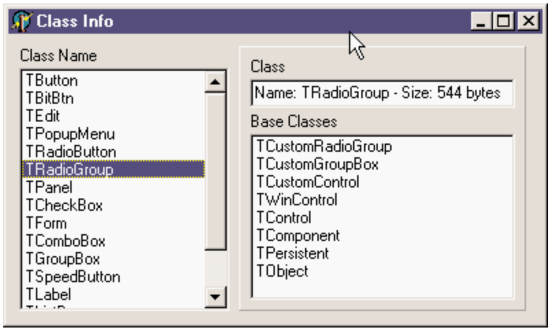
The code in the with statement referring to the ListParent list box is part of the ClassInfo example (see the companion CD), which displays the list of parent classes and some other information about a few components of the VCL, basically those on the Standard page of the Component Palette. These components are manually added to a dynamic array holding classes and declared as

```
private
  ClassArray: array of TClass;
```

When the program starts, the array is used to show all the class names in a list box. Selecting an item from the list box triggers the visual presentation of its details and its base classes, as you can see in the output of the program, in Figure 4.5.

FIGURE 4.5:

The output of the ClassInfo example



```
TButton
TBitBtn
TEdit
TPopupMenu
TRadioButton
TRadioGroup
TPanel
TCheckBox
TForm
TComboBox
TGroupBox
TSpeedButton
TLabel
```

Name: TRadioGroup - Size: 544 bytes

```
TCustomRadioGroup
TCustomGroupBox
TCustomControl
TWinControl
TControl
TComponent
TPersistent
TObject
```

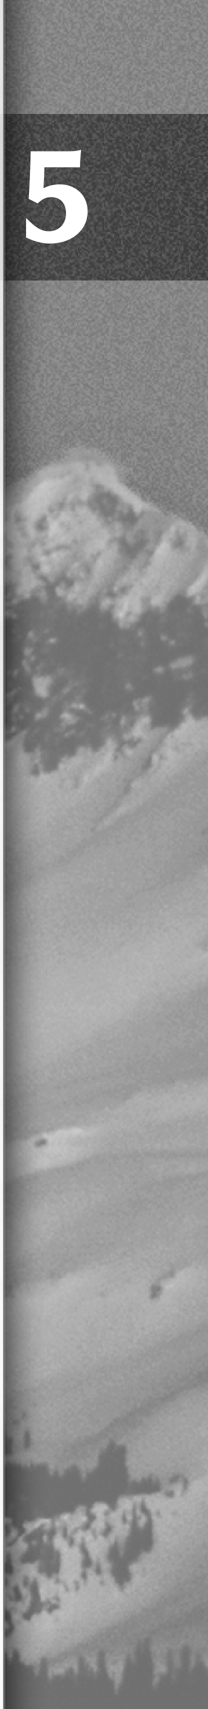
NOTE As a further extension to this example, it is possible to create a tree with all of the base classes of the various components in a hierarchy. To do that, I've created the VclHierarchy program, which you can find on my Web site, `www.marcocantu.com`, in the CanTools section.

What's Next?

In this chapter I've focused my attention on new features of the Delphi 6 function-based run-time library. I have provided only a summary of the entire RTL, not a complete overview, as this would have taken too much space. You can find more examples of the basic RTL functions of Delphi in my free electronic book *Essential Pascal*, which is featured on the companion CD.

In the next chapter, we'll start moving from the function-based RTL to the class-based RTL, which is the core of Delphi's class library. I won't debate whether the core classes common to the VCL and CLX, such as `TObject`, actually belong to the RTL or the class library. I've covered everything defined in System, SysUtils, and other units hosting functions and procedures in this chapter, while the next chapter focuses on the Classes unit and other core units defining classes.

Along with the preceding two chapters on the Object Pascal language, this will provide a foundation for discussing visual- and database-oriented classes, or components, if you prefer. Looking to the various library units, we'll find many more global functions, which don't belong to the core RTL but are still quite useful!



Chapter 5

Core Library Classes

- The RTL package, CLX, and VCL
- *TPersistent* and *published*
- The *TComponent* base class and its properties
- Components and ownership
- Events
- Lists, container classes, and collections
- Streaming
- Summarizing the units of the RTL package

We saw in the preceding chapter that Delphi includes a large number of functions and procedures, but the real power of Delphi's visual programming lies in the huge class library it comes with. Delphi's standard class library contains hundreds of classes, with thousands of methods, and it is so large that I certainly cannot provide a detailed reference in this book. What I'll do, instead, is explore various areas of this library starting with this chapter and continuing through the following ones.

This first chapter is devoted to the core classes of the library as well as to some standard programming techniques, such as the definition of events. We'll explore some commonly used classes, such as lists, string lists, collections, and streams. We'll devote most of our time to exploring the content of the Classes unit, but we'll devote time also to other core units of the library.

Delphi classes can be used either entirely in code or within the visual form designer. Some of them are component classes, which show up in the Component Palette, while others are more general-purpose. The terms *class* and *component* can be used almost as synonyms in Delphi. Components are the central elements of Delphi applications. When you write a program, you basically choose a number of components and define their interactions. That's all there is to Delphi visual programming.

Before reading this chapter, you need to have a good understanding of the Object Pascal programming language, including inheritance, properties, virtual methods, class references, and so on, as discussed in Chapters 2 and 3 of this book.

The RTL Package, VCL, and CLX

Until version 5, Delphi's class library was known as VCL, which stands for Visual Components Library. Kylix, the Delphi version for Linux, introduced a new component library, called CLX (pronounced "clicks" and standing for Component Library for X-Platform or Cross Platform). Delphi 6 includes both the VCL and CLX libraries. For visual components, the two class libraries are alternative one to the other. However, the core classes and the database and Internet portions of the two libraries are basically shared.

VCL was considered as a single large library, although programmers used to refer to different parts of it (components, controls, nonvisual components, data sets, data-aware controls, Internet components, and so on). CLX introduces a distinction in four parts: BaseCLX, VisualCLX, DataCLX, and NetCLX. Only in VisualCLX does the library use a totally different approach between the two platforms, with the rest of the code being inherently portable to Linux. In the following section, I discuss the sections of these two libraries, while the rest of the chapter focuses on the common core classes.

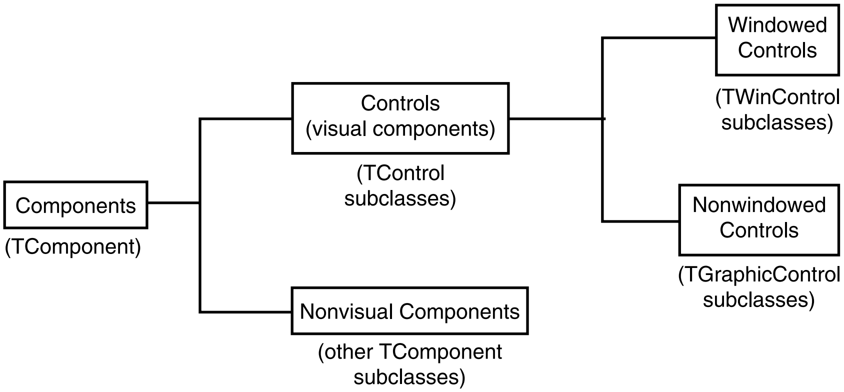
In Delphi 6, this distinction is underlined by the fact that the core non-visual components and classes of the library are part of the new RTL package, which is used by both VCL and CLX. Moreover, using this package in non-visual applications (for example, Web server programs) allows you to reduce the size of the files to deploy and load in memory considerably.

Traditional Sections of VCL

Delphi programmers use to refer to different sections of VCL with names Borland originally suggested in its documentation, and names that became common afterwards for different groups of components. Technically, components are subclasses of the `TComponent` class, which is one of the root classes of the hierarchy, as you can see in Figure 5.1. Actually the `TComponent` class inherits from the `TPersistent` class; the role of these two classes will be explained in the next section.

FIGURE 5.1:

A graphical representation of the main groups of components of VCL



Besides components, the library includes classes that inherit directly from `TObject` and from `TPersistent`. These classes are collectively known as *Objects* in portions of the documentation, a rather confusing name for me. These noncomponent classes are often used for values of properties or as utility classes used in code; not inheriting from `TComponent`, these classes cannot be used directly in visual programming.

NOTE To be more precise, noncomponent classes cannot be made available in the Component Palette and cannot be dropped directly into a form, but they can be visually managed with the Object Inspector, as subproperties of other properties or items of collections of various types. So even noncomponent classes are often easily used when interacting with the Form Designer.

The component classes can be further divided into two main groups: controls and nonvisual components. Controls groups all the classes that descend from `TControl`.

Controls have a position and a size on the screen and show up in the form at design time in the same position they'll have at run time. Controls have two different subspecifications, window-based or graphical, but I'll discuss them in more detail in the next chapter.

Nonvisual components are all the components that are not controls—all the classes that descend from `TComponent` but not from `TControl`. At design time, a nonvisual component appears on the form as an icon (optionally with a caption below it). At run time, some of these components may be visible (for example, the standard dialog boxes), and others are always invisible (for example, the database table component).

TIP You can simply move the mouse cursor over a control or component in the Form Designer to see a Tooltip with its name and class type (and, in Delphi 6, some extended information). You can also use an environment option, Show Component Captions, to see the name of a nonvisual component right under its icon.

The Structure of CLX

This is the traditional subdivision of VCL, which is very common for Delphi programmers. Even with the introduction of CLX and some new naming schemes, the traditional names will probably survive and merge into Delphi programmers' jargon.

Borland now refers to different portions of the CLX library using one terminology under Linux and a slightly different (and less clear) naming structure in Delphi. This is the subdivision of the Linux-compatible library:

BaseCLX forms the core of the class library, the topmost classes (such as `TComponent`), and several general utility classes (including lists, containers, collections, and streams). Compared to the corresponding classes of VCL, BaseCLX is largely unchanged and is highly portable between the Windows and Linux platforms. This chapter is largely devoted to exploring BaseCLX and the common VCL core classes.

VisualCLX is the collection of visual components, generally indicated as controls. This is the portion of the library that is more tightly related to the operating system: VisualCLX is implemented on top of the Qt library, available both on Windows and on Linux. Using VisualCLX allows for full portability of the visual portion of your application between Delphi on Windows and Kylix on Linux. However, most of the VisualCLX components have corresponding VCL controls, so that you can also easily move your code from one library to the other. I'll discuss VisualCLX and the controls of VCL in the next chapter.

DataCLX comprises all the database-related components of the library. Actually, DataCLX is the front end of the new dbExpress database engine included in Delphi 6 and Kylix. Delphi includes also the traditional BDE front end, dbGo, and InterBase Express (IBX). If we can consider all these components as part of DataCLX, only the dbExpress front end and IBX are portable between Windows and Linux. DataCLX includes also the ClientDataSet component, now indicated as MyBase, and other related classes. Delphi's data access components are discussed in Part III of the book.

NetCLX includes the Internet-related components, from the WebBroker framework, to the HTML producer components, from Indy (Internet Direct) to Internet Express, from the new Site Express to XML support. This part of the library is, again, highly portable between Windows and Linux. Internet support is discussed in the last part of the book.

VCL-Specific Sections of the Library

The preceding areas of the library are available, with the differences I've mentioned, on both Delphi and Kylix. In Delphi 6, however, there are other sections of VCL, which for one reason or another are specific to Windows only:

- The Delphi ActiveX (DAX) framework provides support for COM, OLE Automation, ActiveX, and other COM-related technologies. See Chapter 16 for more information on this area of Delphi.
- The Decision Cube components provide OLAP support but have ties with the BDE and haven't been updated recently. Decision Cube is not discussed in the book.

Finally, the default Delphi 6 installation includes some third-party components, such as TeeChart for business graphics and QuickReport for reporting. These components will be mentioned in the book but are not discussed in detail.

The *TPersistent* Class

The first core class of the Delphi library we'll look at is the `TPersistent` class, which is quite a strange one: it has very little code and almost no direct use, but it provides a foundation for the entire idea of visual programming. You can see the definition of the class in Listing 5.1.

Listing 5.1: The definition of the *TPersistent* class, from the Classes unit

```
{$M+}
TPersistent = class(TObject)
  private
    procedure AssignError(Source: TPersistent);
  protected
    procedure AssignTo(Dest: TPersistent); virtual;
    procedure DefineProperties(Filer: TFiler); virtual;
    function  GetOwner: TPersistent; dynamic;
  public
    destructor Destroy; override;
    procedure Assign(Source: TPersistent); virtual;
    function  GetNamePath: string; dynamic;
  end;
```

As the name implies, this class handles persistency—that is, saving the value of an object to a file to be used later to re-create the object in the same state and with the same data. Persistency is a key element of visual programming. In fact (as we saw in Chapter 1) at design time in Delphi you manipulate actual objects, which are saved to DFM files and re-created at run time when the specific component container—form or data module—is created.

The streaming support, though, is not embedded in the `TPersistent` class but is provided by other classes, which target `TPersistent` and its descendants. In other words, you can "persist" with Delphi default streaming-only objects of classes inheriting from `TPersistent`. One of the reasons for this behavior lies in the fact that the class is compiled with a special option turned on, `{$M+}`. This flag activates the generation of extended RTTI information for the published portion of the class.

Delphi's streaming system, in fact, doesn't try to save the in-memory data of an object, which would be complex because of the many pointers to other memory locations, totally meaningless when the object would be reloaded. Instead, Delphi saves objects by listing the value of all of properties marked with a special keyword, `published`. When a property refers to another object, Delphi saves the name of the object or the entire object (with the same mechanism) depending on its type and relationship with the main object.

Of the methods of the `TPersistent` class, the only one you'll generally use is the `Assign` procedure, which can be used for copying the actual value of an object. In the library, this method is implemented by many noncomponent classes but by very few components. Actually, most subclasses reimplement the virtual protected `AssignTo` method, called by the default implementation of `Assign`.

NOTE Other methods include `DefineProperties`, used for customizing the streaming system and adding extra information (pseudo-properties), and the `GetOwner` and `GetNamePath` methods used by collections and other special classes to identify themselves to the Object Inspector.

The *published* Keyword

Along with the public, protected, and private access directives, you can use a fourth one, called published. For any published field, property, or method, the compiler generates extended RTTI information, so that Delphi's run time environment or a program can query a class for its published interface. For example, every Delphi component has a published interface that is used by the IDE, in particular the Object Inspector. A regular use of published fields is important when you write components. Usually, the published part of a component contains no fields or methods but properties and events.

When Delphi generates a form or data module, it places the definitions of its components and methods (the event handlers) in the first portion of its definition, before the public and private keywords. These fields and methods of the initial portion of the class are published. The default is published when no special keyword is added before an element of a component class.

To be more precise, published is the default keyword only if the class was compiled with the $M+ compiler directive or is descended from a class compiled with $M+. As this directive is used in the TPersistent class, most classes of VCL and all of the component classes default to published. However, noncomponent classes in Delphi (such as TStream and TList) are compiled with $M- and default to public visibility.

The methods assigned to any event should be published methods, and the fields corresponding to your components in the form should be published to be automatically connected with the objects described in the DFM file and created along with the form. (We'll see later in this chapter the details of this situation and the problems it generates.)

Accessing Published Fields and Methods

As I've mentioned, there are three different declarations that make sense in the published section of a class: fields, methods, and properties. I'll discuss properties in the section "Accessing Properties by Name," while here I'll introduce possible ways of interacting with fields and methods first. The TObject class, in fact, has three interesting methods for this area: MethodAddress, MethodName, and FieldAddress.

The first function, MethodAddress, returns the memory address of the compiled code (a sort of function pointer) of the method passed as parameter in a string. By assigning this method address to the Code field of a TMethod structure and assigning an object to the Data field, you can obtain a complete method pointer. At this point, to call the method you'll need to cast it to

Continued on next page

the proper method pointer type. This is a code fragment highlighting the key points of this technique:

```
var
  Method: TMethod;
  Evt: TNotifyEvent;
begin
  Method.Code := MethodAddress ('Button1Click');
  Method.Data := Self;
  Evt := TNotifyEvent(Method);
  Evt (Sender); // call the method
end;
```

Delphi uses similar code to assign an event handler when it loads a DFM file, as these files store the name of the methods used to handle the events, while the components actually store the method pointer. The second method, `MethodName`, does the opposite transformation, returning the name of the method at a given memory address. This can be used to obtain the name of an event handler, given its value, something Delphi does when streaming a component into a DFM file.

Finally, the `FieldAddress` method of `TObject` returns the memory location of a published field, given its name. This is used by Delphi to connect components created from the DFM files with the fields of their owner (for example, a form) having the same name.

Notice that these three methods are seldom used in "normal" programs but play a key role to make Delphi work as it actually does and are strictly related to the streaming system. You'll need to use these methods only when writing extremely dynamic programs or special-purpose wizards or other Delphi extensions.

Accessing Properties by Name

The Object Inspector displays a list of an object's published properties, even for components you've written. To do this, it relies on the RTTI information generated for published properties. Using some advanced techniques, an application can retrieve a list of the published properties of an object and use them.

Although this capability is not very well known, in Delphi it is possible to access properties by name simply by using the string with the name of the property and then retrieving its value. Access to the RTTI information of properties is provided through a group of undocumented subroutines, part of the TypInfo unit.

WARNING These subroutines have always been undocumented in past versions of Delphi, so that Borland remained free to change them. However, from Delphi 1 to Delphi 5, changes were actually very limited and related only to the data structures declared in TypInfo, not the functions provided by the unit. In Delphi 5 Borland actually added many more goodies, and a few "helper" routines, that are officially promoted (even if still not fully documented in the help file but only with comments provided in the unit).

Rather than explore the entire TypInfo unit here, we will look at only the minimal code required to access properties by name. Prior to Delphi 5 it was necessary to use the GetPropInfo function to retrieve a pointer to some internal property information and then apply one of the access functions, such as GetStrProp, to this pointer. You also had to check for the existence and the type of the property.

Delphi 5 introduced a new set of TypInfo routines, including the handy GetPropValue, which returns a variant with the value of the property or varNULL if the property doesn't exist. You simply pass to this function the object and a string with the property name. A further optional parameter allows you to choose the format for returning values of properties of the set type.

For example, we can call

```
ShowMessage (GetPropValue (Button1, 'Caption'));
```

This call has the same effect as calling ShowMessage, passing as parameter Button1.Caption. The only real difference is that this version of the code is much slower, since the compiler generally resolves normal access to properties in a more efficient way. The advantage of the run-time access is that you can make it very flexible, as in the following RunProp example (also available on the companion CD).

This program displays in a list box the value of a property of any type for each component of a form. The name of the property we are looking for is provided in an edit box. This makes the program very flexible. Besides the edit box and the list box, the form has a button to generate the output and some other components added only to test their properties. When you click the button, the following code is executed:

```
uses
  TypInfo;

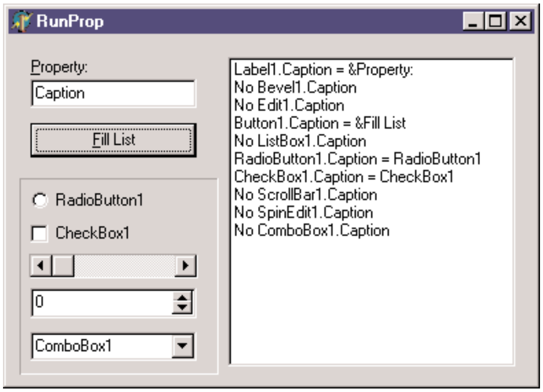
procedure TForm1.Button1Click(Sender: TObject);
var
  I: Integer;
  Value: Variant;
begin
  ListBox1.Clear;
```

```
for I := 0 to ComponentCount -1 do
begin
  if IsPublishedProp (Components[I], Edit1.Text) then
  begin
    Value := GetPropValue (Components[I], Edit1.Text);
    ListBox1.Items.Add (Components[I].Name + '.' + Edit1.Text + ' = ' + string (Value));
  end
  else
    ListBox1.Items.Add ('No ' + Components[I].Name + '.' + Edit1.Text);
```

You can see the effect of pressing the Fill List button while using the default *Caption* value in the edit box in Figure 5.2. You can try with any other property name. Numbers will be converted to strings by the variant conversion. Objects (such as the value of the `Font` property) will be displayed as memory addresses.

FIGURE 5.2:

The output of the RunProp example, which accesses properties by name at run time



```
Label1.Caption = &Property:
No Bevel1.Caption
No Edit1.Caption
Button1.Caption = &Fill List
No ListBox1.Caption
RadioButton1.Caption = RadioButton1
CheckBox1.Caption = CheckBox1
No ScrollBar1.Caption
No SpinEdit1.Caption
No ComboBox1.Caption
```

WARNING Do not use regularly the TypInfo unit instead of polymorphism and other property-access techniques. Use base-class property access first, or use the safe `as` typecast when required, and reserve RTTI access to properties as a very last resort. Using TypInfo techniques makes your code slower, more complex, and more prone to human error; in fact, it skips the compile-time type-checking.

The *TComponent* Class

If the `TPersistent` class is really more important than it seems at first sight, the key class at the heart of Delphi's component-based class library is `TComponent`, which inherits from

TPersistent (and from TObject). The TComponent class defines many core elements of components, but it is not as complex as you might think, as the base classes and the language already provide most of what's actually needed.

I won't explore all of the details of the TComponent class, some of which are more important for component designers than they are for component users. I'll just discuss ownership (which accounts for some public properties of the class) and the two published properties of the class, Name and Tag.

Ownership

One of the core features of the TComponent class is the definition of ownership. When a component is created, it can be assigned an owner component, which will be responsible for destroying it. So every component can have an owner and can also be the owner of other components. Several public methods and properties of the class are actually devoted to handling the *two sides* of ownership. Here is a list, extracted from the class declaration (in the Classes unit of VCL):

```
type
  TComponent = class(TPersistent, IInterface, IInterfaceComponentReference)
  public
    constructor Create(AOwner: TComponent); virtual;
    procedure DestroyComponents;
    function FindComponent(const AName: string): TComponent;
    procedure InsertComponent(AComponent: TComponent);
    procedure RemoveComponent(AComponent: TComponent);

    property Components[Index: Integer]: TComponent read GetComponent;
    property ComponentCount: Integer read GetComponentCount;
    property ComponentIndex: Integer
      read GetComponentIndex write SetComponentIndex;
    property Owner: TComponent read FOwner;
```

If you create a component giving it an owner, this will be added to the list of components (InsertComponent), which is accessible using the Components array property. The specific component has an Owner and knows its position in the owner components list, with the ComponentIndex property. Finally, the destructor of the owner will take care of the destruction of the object it owns, calling DestroyComponents. There are a few more protected methods involved, but this should give you the overall picture.

What is important to emphasize is that component ownership can solve a large part of the memory management problems of your applications, if used properly. If you always create components with an owner—the default operation if you use the visual designers of the IDE—you only need to remember to destroy these component containers when they are not needed anymore, and you can forget about the components they contain. For example, you delete a form to destroy all of the components it contains at once, which is a large simplification compared to having to remember to free each and every object individually.

The Components Array

The Components property can also be used to access one component owned by another—let's say, a form. This can be very handy (compared to using directly a specific component) for writing generic code, acting on all or many components at a time. For example, you can use the following code to add to a list box the names of all the components of a form (this code is actually part of the ChangeOwner example, presented in the next section):

```
procedure TForm1.Button1Click(Sender: TObject);
var
  I: Integer;
begin
  ListBox1.Items.Clear;
  for I := 0 to ComponentCount - 1 do
    ListBox1.Items.Add (Components [I].Name);
end;
```

This code uses the ComponentCount property, which holds the total number of components owned by the current form, and the Components property, which is actually the list of the owned components. When you access a value from this list you get a value of the TComponent type. For this reason you can directly use only the properties common to all components, such as the Name property. To use properties specific to particular components, you have to use the proper type-downcast (as).

NOTE In Delphi, some components are also component containers: the GroupBox, Panel, PageControl, and, of course, Form components. When you use these controls, you can add other components inside them. In this case, the container is the parent of the components (as indicated by the Parent property), while the form is their owner (as indicated by the Owner property). You can use the Controls property of a form or group box to navigate the child controls, and you can use the Components property of the form to navigate all the owned components, regardless of their parent.

Using the Components property, we can always access each component of a form. If you need access to a specific component, however, instead of comparing each name with the name of the component you are looking for, you can let Delphi do this work, by using the FindComponent method of the form. This method simply scans the Components array looking for a name match. More information about the role of the Name property for a component is in a later section.

Changing the Owner

We have seen that almost every component has an owner. When a component is created at design time (or from the resulting DFM file), its owner will invariably be its form. When you create a component at run time, the owner is passed as a parameter to the `Create` constructor.

`Owner` is a read-only property, so you cannot change it. The owner is set at creation time and should generally not change during the lifetime of a component. To understand why you should not change the owner of a component at design time nor freely change its name, read the following discussion. Be warned, that the topic covered is not simple, so if you're only starting with Delphi, you might want to come back to this section at a later time.

To change the owner of a component, you can call the `InsertComponent` and `RemoveComponent` methods of the owner itself, passing the current component as parameter. Using these methods you can change a component's owner. However, you cannot apply them directly in an event handler of a form, as we attempt to do here:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  RemoveComponent (Button1);
  Form2.InsertComponent (Button1);
end;
```

This code produces a memory access violation, because when you call `RemoveComponent`, Delphi disconnects the component from the form field (`Button1`), setting it to `nil`. The solution is to write a procedure like this:

```
procedure ChangeOwner (Component, NewOwner: TComponent);
begin
  Component.Owner.RemoveComponent (Component);
  NewOwner.InsertComponent (Component);
end;
```

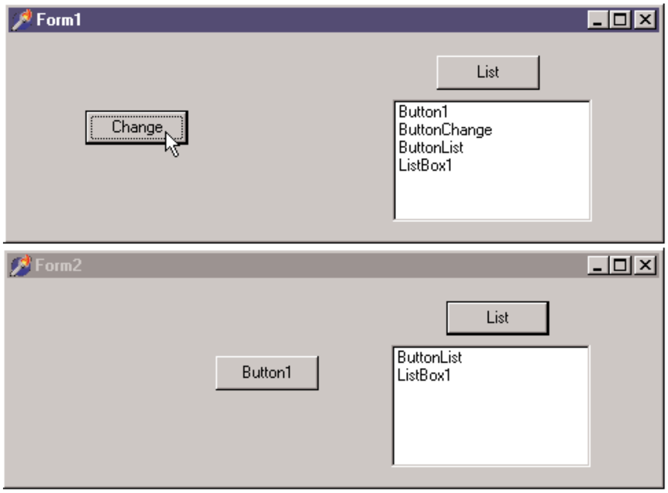
This method (extracted from the ChangeOwner example) changes the owner of the component. It is called along with the simpler code used to change the parent component; the two commands combined move the button *completely* to another form, changing its owner:

```
procedure TForm1.ButtonChangeClick(Sender: TObject);
begin
  if Assigned (Button1) then
  begin
    // change parent
    Button1.Parent := Form2;
    // change owner
    ChangeOwner (Button1, Form2);
  end;
end;
```

The method checks whether the Button1 field still refers to the control, because while moving the component, Delphi will set Button1 to nil. You can see the effect of this code in Figure 5.3.

FIGURE 5.3:

In the ChangeOwner example, clicking the Change button moves the Button1 component to the second form.



To demonstrate that the Owner of the Button1 component actually changes, I've added another feature to both forms. The List button fills the list box with the names of the components each form owns, using the procedure shown in the previous section. Click the two List buttons before and after moving the component, and you'll see what happens behind the scenes. As a final feature, the Button1 component has a simple handler for its OnClick event, to display the caption of the owner form:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  ShowMessage ('My owner is ' + ((Sender as TButton).Owner as TForm).Caption);
end;
```

The *Name* Property

Every component in Delphi should have a name. The name must be unique within the owner component, which is generally the form into which you place the component. This means that an application can have two different forms, each with a component with the same name, although you might want to avoid this practice to prevent confusion. It is generally better to keep component names unique throughout an application.

Setting a proper value for the Name property is very important: If it's too long, you'll need to type a lot of code to use the object; if it's too short, you may confuse different objects.

Usually the name of a component has a prefix with the component type; this makes the code more readable and allows Delphi to group components in the combo box of the Object Inspector, where they are sorted by name. There are three important elements related to the Name property of the components:

- First, the value of the Name property is used to define the name of the object in the declaration of the form class. This is the name you're generally going to use in the code to refer to the object. For this reason, the value of the name property must be a legal Pascal identifier (it has to be without spaces and must start with a letter, not a number).
- Second, if you set the Name property of a control before changing its Caption or Text property, the new name is often copied to the caption. That is, if the name and the caption are identical, then changing the name will also change the caption.
- Third, Delphi uses the name of the component to create the default name of the methods related to its events. If you have a Button1 component, its default OnClick event handler will be called Button1Click, unless you specify a different name. If you later change the name of the component, Delphi will modify the names of the related methods accordingly. For example, if you change the name of the button to MyButton, the Button1Click method automatically becomes MyButtonClick.

As mentioned earlier, if you have a string with the name of a component, you can get its instance by calling the FindComponent of its owner, which returns nil in case the component is not found. For example, you can write

```
var
  Comp: TComponent;
begin
  Comp := FindComponent ('Button1');
  if Assigned (Comp) then
    with Comp as TButton do
      // some code...
```

NOTE Delphi includes also a FindGlobalComponent function, which finds a top-level component, basically a form or data module, that has a given name. To be precise, the FindGlobalComponent function calls one or more installed functions, so in theory you can modify the way the function works. However, as FindGlobalComponent is used by the streaming system, I strongly recommend against installing your own replacement functions. If you want to have a customized way to search for components on other containers, simply write a new function with a custom name.

Removing Form Fields

Every time you add a component to a form, Delphi adds an entry for it, along with some of its properties, to the DFM file. To the Pascal file, Delphi adds the corresponding field in the form class declaration. When the form is created, Delphi loads the DFM file and uses it to re-create all the components and set their properties back. Then it hooks the new object with the form field corresponding to its `Name` property.

For this reason, it is certainly possible to have a component without a name. If your application will not manipulate the component or modify it at run time, you can remove the component name from the Object Inspector. Examples are a static label with fixed text, or a menu item, or even more obviously, menu item separators. By blanking out the name, you'll remove the corresponding element from the form class declaration. This reduces the size of the form object (by only four bytes, the size of the object reference) and it reduces the DFM file by not including a useless string (the component name). Reducing the DFM also implies reducing the final EXE file size, even if only slightly.

WARNING If you blank out component names, just make sure to leave at least one named component of each class used on the form so that the smart linker will link in the required code for the class. If, as an example, you remove from a form all the fields referring to `TLabel` components, the Delphi linker will remove the implementation of the `TLabel` class from the executable file. The effect is that when the system loads the form at run time, it is unable to create an object of an unknown class and issues an error indicating that the class is not available.

You can also keep the component name and manually remove the corresponding field of the form class. Even if the component has no corresponding form field, it is created anyway, although using it (through the `FindComponent` method, for example) will be a little more difficult.

Hiding Form Fields

Many OOP purists complain that Delphi doesn't really follow the encapsulation rules, because all of the components of a form are mapped to public fields and can be accessed from other forms and units. Fields for components, in fact, are listed in the first unnamed section of a class declaration, which has a default visibility of published. However, Delphi does that only as a default to help beginners learn to use the Delphi visual development environment quickly. A programmer can follow a different approach and use properties and methods to operate on forms. The risk, however, is that another programmer of the same team might inadvertently bypass this approach, directly accessing the components if they are left in the published section. The solution, which many programmers don't know about, is to move the components to the private portion of the class declaration.

As an example, I've taken a very simple form with an edit box, a button, and a list box. When the edit box contains text and the user presses the button, the text is added to the list box. When the edit box is empty, the button is disabled. This is the simple code of the HideComp example:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  ListBox1.Items.Add (Edit1.Text);
end;

procedure TForm1.Edit1Change(Sender: TObject);
begin
  Button1.Enabled := Length (Edit1.Text) <> 0;
end;
```

I've listed these methods only to show you that in the code of a form we usually refer to the available components, defining their interactions. For this reason it seems impossible to get rid of the fields corresponding to the component. However, what we can do is hide them, moving them from the default published section to the private section of the form class declaration:

```
TForm1 = class(TForm)
  procedure Button1Click(Sender: TObject);
  procedure Edit1Change(Sender: TObject);
  procedure FormCreate(Sender: TObject);
private
  Button1: TButton;
  Edit1: TEdit;
  ListBox1: TListBox;
end;
```

Now if you run the program you'll get in trouble: The form will load fine, but because the private fields are not initialized, the events above will use `nil` object references. Delphi usually initializes the published fields of the form using the components created from the DFM file. What if we do it ourselves, with the following code?

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  Button1 := FindComponent ('Button1') as TButton;
  Edit1 := FindComponent ('Edit1') as TEdit;
  ListBox1 := FindComponent ('ListBox1') as TListBox;
end;
```

It will *almost* work, but it generates a system error, similar to the one we discussed in the previous section. This time, the private declarations will cause the linker to link in the implementations of those classes, but the problem is that the streaming system needs to know the names of the classes in order to locate the class reference needed to construct the components while loading the DFM file.

The final touch we need is some registration code to tell Delphi at run time about the existence of the component classes we want to use. We should do this before the form is created, so I generally place this code in the initialization section of the unit:

```
initialization
  RegisterClasses ([TButton, TEdit, TListBox]);
```

Now the question is, is this really worth the effort? What we obtain is a higher degree of encapsulation, protecting the components of a form from other forms (and other programmers writing them). I have to say that replicating these steps for each and every form can be tedious, so I ended up writing a wizard to generate this code for me on the fly. The wizard is far from perfect, as it doesn't handle changes automatically, but it is usable. You can find it on my Web site, www.marcocantu.com, under the CanTools section. My simple wizard apart, for a large project built according to the principles of object-oriented programming, I recommend you consider this or a similar technique.

The Customizable Tag Property

The Tag property is a strange one, because it has no effect at all. It is merely an extra memory location, present in each component class, where you can store custom values. The kind of information stored and the way it is used are completely up to you.

It is often useful to have an extra memory location to attach information to a component without needing to define your component class. Technically, the Tag property stores a long integer so that, for example, you can store the entry number of an array or list that corresponds to an object. Using typecasting, you can store in the Tag property a pointer, an object, or anything else that is four bytes wide. This allows a programmer to associate virtually anything with a component using its tag. We'll see how to use this property in several examples in future chapters, including the ODMenu examples in Chapter 5.

Events

Now that I've introduced the TComponent class, there is one more element of Delphi we have to introduce. Delphi components, in fact, are programmed using "PME," properties, methods, and events. If methods and properties should be clear by now, events have not been fully introduced yet. The reason is that events don't imply a new language feature but are simply a standard coding technique. An event, in fact, is technically a property, with the only difference being that it refers to a method (a method pointer type, to be precise) instead of other types of data.

Events in Delphi

When a user does something with a component, such as clicking it, the component generates an event. Other events are generated by the system, in response to a method call or a change to one of that component's properties (or even a different component's). For example, if you set the focus on a component, the component currently having the focus loses it, triggering the corresponding event.

Technically, most Delphi events are triggered when a corresponding operating system message is received, although the events do not match the messages on a one-to-one basis. Delphi events tend to be higher-level than operating system messages, and Delphi provides a number of extra inter-component messages.

From a theoretical point of view, an event is the result of a request sent to a component or control, which can respond to the message. Following this approach, to handle the click event of a button, we would need to subclass the `TButton` class and add the new event handler code inside the new class.

In practice, creating a new class for every component you want to use is too complex to be a reasonable solution. In Delphi, the event handler of a component usually is a method of the form that holds the component, not of the component itself. In other words, the component relies on its owner, the form, to handle its events. This technique is called *delegation*, and it is fundamental to the Delphi component-based model. This way, you don't have to modify the `TButton` class, unless you want to define a new type of component, but simply customize its owner to modify the behavior of the button.

Method Pointers

Events rely on a specific feature of the Object Pascal language: *method pointers*. A method pointer type is like a procedural type, but one that refers to a method. Technically, a method pointer type is a procedural type that has an implicit `Self` parameter. In other words, a variable of a procedural type stores the address of a function to call, provided it has a given set of parameters. A method pointer variable stores two addresses: the address of the method code and the address of an object instance (data). The address of the object instance will show up as `Self` inside the method body when the method code is called using this method pointer.

NOTE This explains the definition of Delphi's generic `TMethod` type, a record with a `Code` field and a `Data` field.

The declaration of a method pointer type is similar to that of a procedural type, except that it has the keywords of object at the end of the declaration:

```
type
  IntProceduralType = procedure (Num: Integer);
  IntMethodPointerType = procedure (Num: Integer) of object;
```

When you have declared a method pointer, such as the one above, you can declare a variable of this type and assign to it a compatible method—a method that has the same parameters—of another object.

When you add an OnClick event handler for a button, Delphi does exactly that. The button has a method pointer type property, named OnClick, and you can directly or indirectly assign to it a method of another object, such as a form. When a user clicks the button, this method is executed, even if you have defined it inside another class.

What follows is a sketch of the code actually used by Delphi to define the event handler of a button component and the related method of a form:

```
type
  TNotifyEvent = procedure (Sender: TObject) of object;

  MyButton = class
    OnClick: TNotifyEvent;
  end;

  TForm1 = class (TForm)
    procedure Button1Click (Sender: TObject);
    Button1: MyButton;
  end;

var
  Form1: TForm1;
```

Now inside a procedure, you can write

```
MyButton.OnClick := Form1.Button1Click;
```

The only real difference between this code fragment and the code of VCL is that OnClick is a property name, and the actual data it refers to is called FOnClick. An event that shows up in the Events page of the Object Inspector, in fact, is nothing more than a property of a method pointer type. This means, for example, that you can dynamically modify the event handler attached to a component at design time or even build a new component at run time and assign an event handler to it.

Events Are Properties

Another important concept I've already mentioned is that events are properties. This means that to handle an event of a component, you assign a method to the corresponding event property. When you double-click an event in the Object Inspector, a new method is added to the owner form and assigned to the proper event property of the component.

This is why it is possible for several events to share the same event handler or change an event handler at run time. To use this feature, you don't need much knowledge of the language. In fact, when you select an event in the Object Inspector, you can press the arrow button on the right of the event name to see a drop-down list of "compatible" methods—a list of methods having the same method pointer type. Using the Object Inspector, it is easy to select the same method for the same event of different components or for different, compatible events of the same component.

As we've added some properties to the `TDate` class in Chapter 3, we can add one event. The event is going to be very simple. It will be called `OnChange`, and it can be used to warn the user of the component that the value of the date has changed. To define an event, we simply define a property corresponding to it, and we add some data to store the actual method pointer the event refers to. These are the new definitions added to the class, available in the DateEvt example:

```
type
  TDate = class
  private
    FOnChange: TNotifyEvent;
    ...
  protected
    procedure DoChange; dynamic;
    ...
  public
    property OnChange: TNotifyEvent
      read FonChange write FOnChange;
    ...
  end;
```

The property definition is actually very simple. A user of this class can assign a new value to the property and, hence, to the `FOnChange` private field. The class doesn't assign a value to this `FOnChange` field; it is the user of the component who does the assignment. The `TDate` class simply calls the method stored in the `FOnChange` field when the value of the date changes. Of course, the call takes place only if the event property has been assigned. The `DoChange` method (declared as a dynamic method as it is traditional with event firing methods) makes the test and the method call:

```
procedure TDate.DoChange;
begin
  if Assigned (FOnChange) then
    FOnChange (Self);
end;
```

The DoChange method in turn is called every time one of the values changes, as in the following method:

```
procedure TDate.SetValue (y, m, d: Integer);
begin
  fDate := EncodeDate (y, m, d);
  // fire the event
  DoChange;
```

Now if we look at the program that uses this class, we can simplify its code considerably. First, we add a new custom method to the form class:

```
type
  TDateForm = class(TForm)
    ...
    procedure DateChange(Sender: TObject);
```

The code of this method simply updates the label with the current value of the Text property of the TDate object:

```
procedure TDateForm.DateChange;
begin
  LabelDate.Caption := TheDay.Text;
end;
```

This event handler is then installed in the FormCreate method:

```
procedure TDateForm.FormCreate(Sender: TObject);
begin
  TheDay := TDate.Init (2001, 7, 4);
  LabelDate.Caption := TheDay.Text;
  // assign the event handler for future changes
  TheDay.OnChange := DateChange;
end;
```

Well, this seems like a lot of work. Was I lying when I told you that the event handler would save us some coding? No. Now, after we've added some code, we can completely forget about updating the label when we change some of the data of the object. Here, as an example, is the handler of the OnClick event of one of the buttons:

```
procedure TDateForm.BtnIncreaseClick(Sender: TObject);
begin
  TheDay.Increase;
end;
```

The same simplified code is present in many other event handlers. Once we have installed the event handler, we don't have to remember to update the label continually. That eliminates a significant potential source of errors in the program. Also note that we had to write some code at the beginning because this is not a component installed in Delphi but simply a class. With a component, you simply select the event handler in the Object Inspector and write a single line of code to update the label. That's all.

NOTE This is meant to be just a short introduction to defining events. A basic understanding of these features is important for every Delphi programmer. If your aim is to write new components, with complex events, you'll find a lot more information on all these topics in Chapter 11.

Lists and Container Classes

It is often important to handle groups of components or objects. Besides using standard arrays and dynamic arrays, there are a few classes of VCL that represent lists of other objects. These classes can be divided into three groups: simple lists, collections, and containers. The last group was introduced in Delphi 5 and has been further expanded in Delphi 6.

Lists and String Lists

Lists are represented by the generic list of objects, `TList`, and by the two lists of strings, `TStrings` and `TStringList`:

- `TList` defines a list of pointers, which can be used to store objects of any class. A `TList` is more flexible than a dynamic array, because it is expanded automatically, simply by adding new items to it. The advantage of dynamic arrays over a `TList`, instead, is that dynamic arrays allow you to indicate a specific type for contained objects and perform the proper compile-time type checking.
- `TStrings` is an abstract class to represent all forms of string lists, regardless of their storage implementations. This class defines an abstract list of strings. For this reason, `TStrings` objects are used only as properties of components capable of storing the strings themselves, such as a list box.
- `TStringList`, a subclass of `TStrings`, defines a list of strings with their own storage. You can use this class to define a list of strings in a program.

`TStringList` and `TStrings` objects have both a list of strings and a list of objects associated with the strings. This opens up a number of different uses for these classes. For example, you can use them for dictionaries of associated objects or to store bitmaps or other elements to be used in a list box.

The two classes of lists of strings also have ready-to-use methods to store or load their contents to or from a text file, SaveToFile and LoadFromFile. To loop through a list, you can use a simple for statement based on its index, as if the list were an array. All these lists have a number of methods and properties. You can operate on lists using the array notation ("[" and "]") both to read and to change elements. There is a Count property, as well as typical access methods, such as Add, Insert, Delete, Remove, and search methods (for example, IndexOf). In Delphi 6, the TList class has an Assign method that, besides copying the source data, can perform set operations on the two lists, including *and*, *or*, and *xor*.

To fill a string list with items and later check whether one is present, you can write code like this:

```
var
  sl: TStringList;
  idx: Integer;
begin
  sl := TStringList.Create;
  try
    sl.Add ('one');
    sl.Add ('two');
    sl.Add ('three');
    // later
    idx := sl.IndexOf ('two');
    if idx >= 0 then
      ShowMessage ('String found');
  finally
    sl.Free;
  end;
end;
```

Using Lists of Objects

We can write an example focusing on the use of the generic TList class. When you need a list of any kind of data, you can generally declare a TList object, fill it with the data, and then access the data while casting it to the proper type. The ListDemo example demonstrates just this. It also shows the pitfalls of this approach. Its form has a private variable, holding a list of dates:

```
private
  ListDate: TList;
```

This list object is created when the form itself is created:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  Randomize;
  ListDate := TList.Create;
end;
```

A button of the form adds a random date to the list (of course, I've included in the project the unit containing the date component built in the previous chapter):

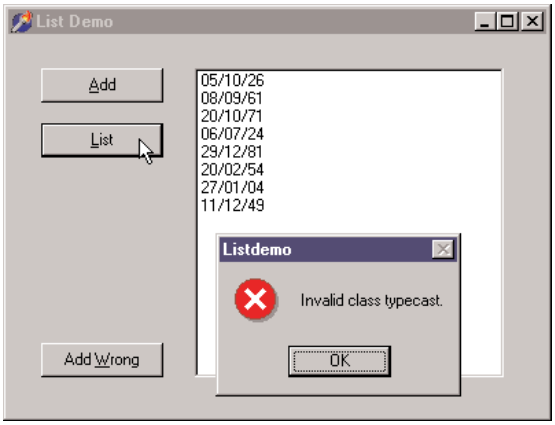
```
procedure TForm1.ButtonAddClick(Sender: TObject);
begin
  ListDate.Add (TDate.Create (1900 + Random (200), 1 + Random (12),
    1 + Random (30)));
end;
```

When you extract the items from the list, you have to cast them back to the proper type, as in the following method, which is connected to the List button (you can see its effect in Figure 5.4):

```
procedure TForm1.ButtonListDateClick(Sender: TObject);
var
  I: Integer;
begin
  ListBox1.Clear;
  for I := 0 to ListDate.Count - 1 do
    Listbox1.Items.Add ((TObject(ListDate [I]) as TDate).Text);
end;
```

FIGURE 5.4:

The list of dates shown by the ListDemo example



05/10/26
08/09/61
20/10/71
06/07/24
29/12/81
20/02/54
27/01/04
11/12/49

Invalid class typecast.

At the end of the code above, before we can do an as downcast, we first need to hard-cast the pointer returned by the TList into a TObject reference. This kind of expression can result in an invalid typecast exception, or it can generate a memory error when the pointer is not a reference to an object.

To demonstrate that things can indeed go wrong, I've added one more button, which adds a TButton object to the list:

```
procedure TForm1.ButtonWrongClick(Sender: TObject);
begin
  // add a button to the list
  ListDate.Add (Sender);
end;
```

If you click this button and then update one of the lists, you'll get an error. Finally, remember that when you destroy a list of objects, you should remember to destroy all of the objects of the list first. The ListDemo program does this in the FormDestroy method of the form:

```
procedure TForm1.FormDestroy(Sender: TObject);
var
  I: Integer;
begin
  for I := 0 to ListDate.Count - 1 do
    TObject(ListDate [I]).Free;
  ListDate.Free;
end;
```

Collections

The second group, collections, contains only two classes, TCollection and TCollectionItem. TCollection defines a homogeneous list of objects, which are owned by the collection class. The objects in the collection must be descendants of the TCollectionItem class. If you need a collection storing specific objects, you have to create both a subclass of TCollection and a matching subclass of TCollectionItem.

Collections are used to specify values of properties of components. It is very unusual to work with collections for storing your own objects, so I won't discuss them here.

Container Classes

Delphi 5 introduced a new series of container classes, defined in the Contnrs unit. Delphi 6 extends these classes by adding hashed associative lists, as discussed in the following section. The container classes extend the TList classes by adding the idea of ownership and by defining specific extraction rules (mimicking stacks and queues) or sorting capabilities.

The basic difference between TList and the new TObjectList class, for example, is that the latter is defined as a list of TObject objects, not a list of pointers. Even more important, however, is the fact that if the object list has the OwnsObjects property set to True, it automatically deletes an object when it is replaced by another one and deletes each object when the list itself is destroyed. Here's a list of all the new container classes:

- The `TObjectList` class I've already described represents a list of objects, eventually owned by the list itself.
- The inherited class `TComponentList` represents a list of components, with full support for destruction notification (an important safety feature when two components are connected using their properties; that is, when a component is the value of a property of another component).
- The `TClassList` class is a list of class references. It inherits from `TList` and requires no destruction.
- The classes `TStack` and `TObjectStack` represent lists of pointers and objects, from which you can only extract elements starting from the last one you've inserted. A stack follows the LIFO order (Last In, First Out). The typical methods of a stack are Push for insertion, Pop for extraction, and Peek to preview the first item without removing it. You can still use all the methods of the base class, `TList`.
- The classes `TQueue` and `TObjectQueue` represent lists of pointers and objects, from which you always remove the *first* item you've inserted (FIFO: first in, first out). The methods of these classes are the same as those of the stack classes but behave differently.

WARNING Unlike the `TObjectList`, the `TObjectStack` and the `TObjectQueue` do not own the inserted objects and will not destroy those objects left in the data structure when it is destroyed. You can simply `Pop` all the items, destroy them once you're finished using them, and then destroy the container.

To demonstrate the use of these classes, I've modified the earlier ListDate example into the new Contain example on the CD. First, I changed the type of the `ListDate` variable to `TObjectList`. In the `FormCreate` method, I've modified the list creation to the following code, which activates the list ownership:

```
ListDate := TObjectList.Create (True);
```

At this point, we can simplify the destruction code, as applying `Free` to the list will automatically free the dates it holds.

I've also added to the program a stack and a queue object, filling each of them with numbers. One of the form's two buttons displays a list of the numbers in each container, and the other removes the last item (displayed in a message box):

```
procedure TForm1.btnQueueClick(Sender: TObject);
var
  I: Integer;
```

```
begin
  ListBox1.Clear;
  for I := 0 to Stack.Count - 1 do begin
    ListBox1.Items.Add (IntToStr (Integer (Queue.Peek)));
    Queue.Push(Queue.Pop);
  end;
  ShowMessage ('Removed: ' + IntToStr (Integer (Stack.Pop)));
end;
```

By pressing the two buttons, you can see that calling Pop for each container returns the last item. The difference is that the TQueue class inserts elements at the beginning, and the TStack class inserts them at the end.

Hashed Associative Lists

After whetting our appetite in Delphi 5, Borland has pushed the idea of container classes a little further in Delphi 6, introducing a new set of lists, particularly TBucketList and TObjectBucketList. These two lists are associative, which means they have a key and an actual entry. The key is used to identify the items and search for them. To add an item, you call the Add method, with two parameters, the key and the actual data. When you use the Find method, you pass the key and retrieve the data. The same effect is achieved by using the Data array property, passing the key as parameter.

These lists are also based on a hash system. The lists create an internal array of items, called buckets, each having a sub-list of actual elements of the list. As you add an item, its key value is used to compute the *hash* value, which determines the bucket to add the item to. When searching the item, the hash is computed again, and the list immediately grabs the sublist containing the item, searching for it there. This makes for very fast insertion and searches, but only if the hash algorithm distributes the items evenly among the various buckets and if there are enough different entries in the array. In fact, when many elements can be in the same bucket, searching gets slower.

For this reason, as you create the TObjectBucketList you can specify the number of entries for the list, using the parameter of the constructor, choosing a value between 2 and 256. The value of the bucket is determined by taking the first byte of the pointer (or number) passed as key and doing an and operation with a number corresponding to the entries.

NOTE I don't find this algorithm very convincing for a hash system, but replacing it with your own implies only overriding the BucketFor virtual function and eventually changing the number of entries in the array, by setting a different value for the BucketCount property.

Another interesting feature, not available for lists, is the ForEach method, which allows you to execute a given function on each item contained in the list. You pass to the ForEach method a pointer to data of your own and a procedure, which receives four parameters, including your custom pointer, each key and object of the list, and a Boolean parameter you can set to False to stop the execution. In other words, these are the two signatures:

```
type
  TBucketProc = procedure(AInfo, AItem, AData: Pointer;
    out AContinue: Boolean);

function TCustomBucketList.ForEach(AProc: TBucketProc;
  AInfo: Pointer): Boolean;
```

NOTE Besides these containers, Delphi includes also a THashedStringList class, which inherits from TStringList. This class has no direct relationship with the hashed lists and is even defined in a different unit,IniFiles The hashed string list has two associated hash tables (of type TStringHash), which are completely refreshed every time the content of the string list changes. So this class is useful only for reading a large set of fixed strings, not for handling a list of strings changing often over time. On the other hand, the TStringHash support class seems to be quite useful in general cases, and has a good algorithm for computing the hash value of a string.

Type-Safe Containers and Lists

Containers and lists have a problem: They are not type-safe, as I've shown in both examples by adding a button object to a list of dates. To ensure that the data in a list is homogenous, you can check the type of the data you extract before you insert it, but as an extra safety measure you might also want to check the type of the data while extracting it. However, adding run-time type checking slows down a program and is risky—a programmer might fail to check the type in some cases.

To solve both problems, you can create specific list classes for given data types and fashion the code from the existing TList or TObjectList classes (or another container class). There are two approaches to accomplish this:

- Derive a new class from the list class and customize the Add method and the access methods, which relate to the Items property. This is also the approach used by Borland for the container classes, which all derive from TList.

NOTE Delphi container classes use static overrides to perform simple type conveniences (parameters and function results of the desired type). Static overrides are not the same as polymorphism; someone using a container class via a TList variable will not be calling the container's specialized functions. Static override is a simple and effective technique, but it has one very important restriction: The methods in the descendent should not do anything beyond simple type-casting, because you aren't guaranteed that the descendent methods will be called. The list might be accessed and manipulated using the ancestor methods as much as by the descendent methods, so their actual operations must be identical. The only difference is the type used in the descendent methods, which allows you to avoid extra typecasting.

- Create a brand-new class that contains a TList object, and map the methods of the new class to the internal list using proper type checking. This approach defines a wrapper class, a class that "wraps" around an existing one to provide a different or limited access to its methods (in our case, to perform a type conversion).

I've implemented both solutions in the DateList example, which defines lists of TDate objects. In the code that follows, you'll find the declaration of the two classes, the inheritance-based TDateListI class and the wrapper class TDateListW.

```
type
// inheritance-based
TDateListI = class (TObjectList)
protected
  procedure SetObject (Index: Integer; Item: TDate);
  function GetObject (Index: Integer): TDate;
public
  function Add (Obj: TDate): Integer;
  procedure Insert (Index: Integer; Obj: TDate);
  property Objects [Index: Integer]: TDate
    read GetObject write SetObject; default;
end;

// wrapper based
TDateListW = class(TObject)
private
  FList: TObjectList;
  function GetObject (Index: Integer): TDate;
    procedure SetObject (Index: Integer; Obj: TDate);
  function GetCount: Integer;
public
  constructor Create;
  destructor Destroy; override;
  function Add (Obj: TDate): Integer;
  function Remove (Obj: TDate): Integer;
  function IndexOf (Obj: TDate): Integer;
  property Count: Integer read GetCount;
  property Objects [Index: Integer]: TDate
    read GetObject write SetObject; default;
end;
```

Obviously, the first class is simpler to write—it has fewer methods, and they simply call the inherited ones. The good thing is that a TDateListI object can be passed to parameters expecting a TList. The problem is that the code that manipulates an instance of this list via a generic TList variable will not be calling the specialized methods, because they are not virtual and might end up adding to the list objects of other data types.

Instead, if you decide not to use inheritance, you end up writing a lot of code, because you need to reproduce each and every one of the original `TList` methods, simply calling the methods of the internal `FList` object. The drawback is that the `TDateListW` class is not type compatible with `TList`, which limits its usefulness. It can't be passed as parameter to methods expecting a `TList`.

Both of these approaches provide good type checking. After you've created an instance of one of these list classes, you can add only objects of the appropriate type, and the objects you extract will naturally be of the correct type. This is demonstrated by the DateList example. This program has a few buttons, a combo box to let a user choose which of the lists to show, and a list box to show the actual values of the list. The program stretches the lists by trying to add a button to the list of `TDate` objects. To add an object of a different type to the `TDateListI` list, we can simply convert the list to its base class, `TList`. This might accidentally happen if you pass the list as a parameter to a method that expects a base class object. In contrast, for the `TDateListW` list to fail we must explicitly cast the object to `TDate` before inserting it, something a programmer should never do:

```
procedure TForm1.ButtonAddButtonClick(Sender: TObject);
begin
  ListW.Add (TDate(TButton.Create (nil)));
  TList(ListI).Add (TButton.Create (nil));
  UpdateList;
end;
```

The `UpdateList` call triggers an exception, displayed directly in the list box, because I've used an `as` typecast in the custom list classes. A wise programmer should never write the above code. To summarize, writing a custom list for a specific type makes a program much more robust. Writing a wrapper list instead of one that's based on inheritance tends to be a little safer, although it requires more coding.

NOTE Instead of rewriting wrapper-style list classes for different types, you can use my List Template Wizard, available on my Web site, **`www.marcocantu.com`**.

Streaming

Another core area of the Delphi class library is its support for streaming, which includes file management, memory, sockets, and other sources of information arranged in a sequence. The idea of streaming is that you move along the data while reading it, much like the traditional `read` and `write` functions used by the Pascal language (and discussed in Chapter 12 of *Essential Pascal*, available on the companion CD).

The *TStream* Class

The VCL defines the abstract TStream class and several subclasses. The parent class, TStream, has just a few properties, and you'll never create an instance of it, but it has an interesting list of methods you'll generally use when working with derived stream classes.

The TStream class defines two properties, Size and Position. All stream objects have a specific size (which generally grows if you write something after the end of the stream), and you must specify a position within the stream where you want to either read or write information.

Reading and writing bytes depends on the actual stream class you are using, but in both cases you don't need to know much more than the size of the stream and your relative position in the stream to read or write data. In fact, that's one of the advantages of using streams. The basic interface remains the same whether you're manipulating a disk file, a binary large object (BLOB) field, or a long sequence of bytes in memory.

In addition to the Size and Position properties, the TStream class also defines several important methods, most of which are virtual and abstract. (In other words, the TStream class doesn't define what these methods do; therefore, derived classes are responsible for implementing them.) Some of these methods are important only in the context of reading or writing components within a stream (for instance, ReadComponent and WriteComponent), but some are useful in other contexts, too. In Listing 5.2, you can find the declaration of the TStream class, extracted from the Classes unit.

Listing 5.2: The public portion of the definition of the *TStream* class

```
TStream = class(TObject)
public
  // read and write a buffer
  function Read(var Buffer; Count: Longint): Longint; virtual; abstract;
  function Write(const Buffer; Count: Longint): Longint; virtual; abstract;
  procedure ReadBuffer(var Buffer; Count: Longint);
  procedure WriteBuffer(const Buffer; Count: Longint);

  // move to a specific position
  function Seek(Offset: Longint; Origin: Word): Longint; overload; virtual;
  function Seek(const Offset: Int64; Origin: TSeekOrigin): Int64;
    overload; virtual;

  // copy the stream
  function CopyFrom(Source: TStream; Count: Int64): Int64;

  // read or write a component
  function ReadComponent(Instance: TComponent): TComponent;
  function ReadComponentRes(Instance: TComponent): TComponent;
  procedure WriteComponent(Instance: TComponent);
  procedure WriteComponentRes(const ResName: string; Instance: TComponent);
```

```
    procedure WriteDescendent(Instance, Ancestor: TComponent);
    procedure WriteDescendentRes(
      const ResName: string; Instance, Ancestor: TComponent);
    procedure WriteResourceHeader(const ResName: string; out FixupInfo: Integer);
    procedure FixupResourceHeader(FixupInfo: Integer);
    procedure ReadResHeader;

    // properties
    property Position: Int64 read GetPosition write SetPosition;
    property Size: Int64 read GetSize write SetSize64;
  end;
```

The basic use of a string involves calling the ReadBuffer and WriteBuffer methods, which are very powerful but not terribly easy to use. The first parameter, in fact, is an untyped buffer in which you can pass the variable to save from or load to. For example, you can save into a file a number (in binary format) and a string, with this code:

```
var
  stream: TStream;
  n: integer;
  str: string;
begin
  n := 10;
  str := 'test string';
  stream := TFileStream.Create ('c:\tmp\test', fmCreate);
  stream.WriteBuffer (n, sizeOf(integer));
  stream.WriteBuffer (str[1], Length (str));
  stream.Free;
```

A totally alternative approach is to let specific components save or load data to and from streams. Many VCL classes define a LoadFromStream or a SaveToStream method, including TStrings, TStringList, TBlobField, TMemoField, TIcon, and TBitmap.

Specific Stream Classes

Creating a TStream instance makes no sense, because this class is abstract and provides no direct support for saving data. Instead, you can use one of the derived classes to load data from or store it to an actual file, a BLOB field, a socket, or a memory block. Use TFileStream when you want to work with a file, passing the filename and some file access options to the Create method. Use TMemoryStream to manipulate a stream in memory and not an actual file.

Several units define TStream-derived classes. In the Classes unit are the following classes:

- THandleStream defines a stream that manipulates a disk file represented by a Windows file handle.

- TFileStream defines a stream that manipulates a disk file (a file that exists on a local or network disk) represented by a filename. It inherits from THandleStream.
- TCustomMemoryStream is the base class for streams stored in memory but is not used directly.
- TMemoryStream defines a stream that manipulates a sequence of bytes in memory. It inherits from TCustomMemoryStream.
- TStringStream provides a simple way for associating a stream to a string in memory, so that you can access the string with the TStream interface and also copy the string to and from another stream.
- TResourceStream defines a stream that manipulates a sequence of bytes in memory, and provides read-only access to resource data linked into the executable file of an application (an example of these resource data are the DFM files). It inherits from TCustomMemoryStream.

Stream classes defined in other units include

- TBlobStream defines a stream that provides simple access to database BLOB fields. There are similar BLOB streams for other database access technologies rather than the BDE.
- TOleStream defines a stream for reading and writing information over the interface for streaming provided by an OLE object.
- TWinSocketStream provides streaming support for a socket connection.

Using File Streams

Creating and using a file stream can be as simple as creating a variable of a type that descends from TStream and calling components methods to load content from the file:

```
var
  S: TFileStream;
begin
  if OpenDialog1.Execute then
  begin
    S := TFileStream.Create (OpenDialog1.FileName, fmOpenRead);
    try
      Memo1.Lines.LoadFromStream (S);
    finally
      S.Free;
    end;
  end;
end;
```

As you can see in this code, the Create method for file streams has two parameters: the name of the file and a flag indicating the requested access mode. In this case, we want to read the file, so we used the fmOpenRead flag (other available flags are documented in the Delphi help).

NOTE Of the different modes, the most important are fmShareDenyWrite, which you'll use when you're simply reading data from a shared file, and fmShareExclusive, which you'll use when you're writing data to a shared file.

A big advantage of streams over other file access techniques is that they're very interchangeable, so you can work with memory streams and then save them to a file, or you can perform the opposite operations. This might be a way to improve the speed of a file-intensive program. Here is a snippet of code, a file-copying function, to give you another idea of how you can use streams:

```
procedure CopyFile (SourceName, TargetName: String);
var
  Stream1, Stream2: TFileStream;
begin
  Stream1 := TFileStream.Create (SourceName, fmOpenRead);
  try
    Stream2 := TFileStream.Create (TargetName, fmOpenWrite or fmCreate);
    try
      Stream2.CopyFrom (Stream1, Stream1.Size);
    finally
      Stream2.Free;
    end
  finally
    Stream1.Free;
  end
end;
```

Another important use of streams is to handle database BLOB fields or other large fields directly. In fact, you can export such data to a stream or read it from one by simply calling the SaveToStream and LoadFromStream methods of the TBlobField class.

The *TReader* and *TWriter* Classes

By themselves, the stream classes of VCL don't provide much support for reading or writing data. In fact, stream classes don't implement much beyond simply reading and writing blocks of data. If you want to load or save specific data types in a stream (and don't want to perform a great deal of typecasting), you can use the TReader and TWriter classes, which derive from the generic TFiler class.

Basically, the TReader and TWriter classes exist to simplify loading and saving stream data according to its type, and not just as a sequence of bytes. To do this, TWriter embeds special signatures into the stream that specify the type for each object's data. Conversely, the TReader class reads these signatures from the stream, creates the appropriate objects, and then initializes those objects using the subsequent data from the stream.

For example, I could have written out a number and a string to a stream by writing:

```
var
  stream: TStream;
  n: integer;
  str: string;
  w: TWriter;
begin
  n := 10;
  str := 'test string';
  stream := TFileStream.Create ('c:\tmp\test.txt', fmCreate);
  w := TWriter.Create (stream, 1024);
  w.WriteInteger (n);
  w.WriteString (str);
  w.Free;
  stream.Free;
```

This time the actual file will include also the extra signature characters, so that I can read back this file only by using a TReader object. For this reason, using the TReader and TWriter is generally confined to components streaming and is seldom applied in general file management.

Streams and Persistency

In Delphi, streams play a considerable role for persistency. For this reason, many methods of TStream relate to saving and loading a component and its subcomponents. For example, you can store a form in a stream by writing

```
stream.WriteComponent(Form1);
```

If you examine the structure of a Delphi DFM file, you'll discover that it's really just a resource file that contains a custom format resource. Inside this resource, you'll find the component information for the form or data module and for each of the components it contains. As you would expect, the stream classes provide two methods to read and write this custom resource data for components: WriteComponentRes to store the data, and ReadComponentRes to load it.

For your experiment in memory (not involving actual DFM files), though, using WriteComponent is generally better suited. After you create a memory stream and save the current form to it, the problem is how to display it. This can be accomplished by transforming the binary representation of forms to a textual representation. Even though the Delphi

IDE, since version 5, can save DFM files in text format, the representation used internally for the compiled code is invariably a binary format.

The form conversion can be accomplished by the IDE, generally with the View as Text command of the form designer, and in other ways. There is also a command-line utility, `CONVERT.EXE`, found in the Delphi `Bin` directory. Within your own code, the standard way to obtain a conversion is to call the specific methods of VCL. There are four functions for converting to and from the internal object format obtained by the `WriteComponent` method:

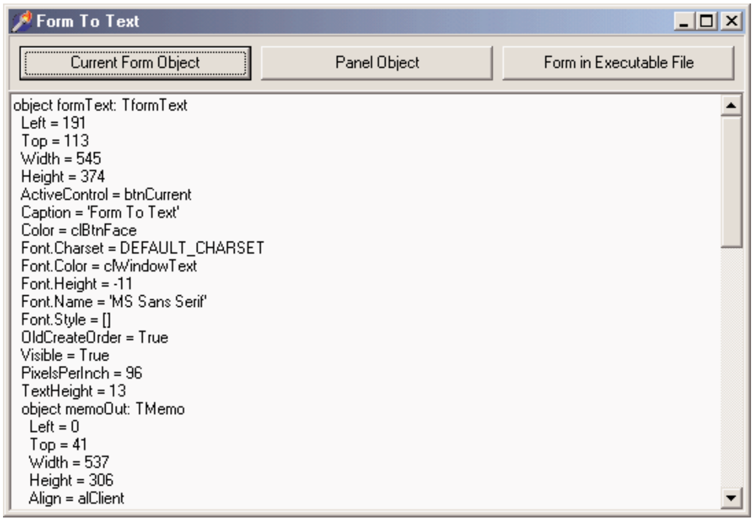
```
procedure ObjectBinaryToText(Input, Output: TStream); overload;
procedure ObjectBinaryToText(Input, Output: TStream;
  var OriginalFormat: TStreamOriginalFormat); overload;
procedure ObjectTextToBinary(Input, Output: TStream); overload;
procedure ObjectTextToBinary(Input, Output: TStream;
  var OriginalFormat: TStreamOriginalFormat); overload;
```

Four different functions, with the same parameters and names containing the name *Resource* instead of *Binary* (as in `ObjectResourceToText`), convert the resource format obtained by `WriteComponentRes`. A final method, `TestStreamFormat`, indicates whether a DFM is storing a binary or textual representation.

In the FormToText program, I've used the `ObjectBinaryToText` method to copy the binary definition of a form into another stream, and then I've displayed the resulting stream in a memo, as you can see in Figure 5.5. This is the code of the two methods involved:

FIGURE 5.5:

The textual description of a form component, displayed inside itself by the FormToText example



```
object formText: TformText
  Left = 191
  Top = 113
  Width = 545
  Height = 374
  ActiveControl = btnCurrent
  Caption = 'Form To Text'
  Color = clBtnFace
  Font.Charset = DEFAULT_CHARSET
  Font.Color = clWindowText
  Font.Height = -11
  Font.Name = 'MS Sans Serif'
  Font.Style = []
  OldCreateOrder = True
  Visible = True
  PixelsPerInch = 96
  TextHeight = 13
  object memoOut: TMemo
    Left = 0
    Top = 41
    Width = 537
    Height = 306
    Align = alClient
```

```
procedure TformText.btnCurrentClick(Sender: TObject);
var
  MemStr: TStream;
begin
  MemStr := TMemoryStream.Create;
  try
    MemStr.WriteComponent (Self);
    ConvertAndShow (MemStr);
  finally
    MemStr.Free
  end;
end;

procedure TformText.ConvertAndShow (aStream: TStream);
var
  ConvStream: TStream;
begin
  aStream.Position := 0;
  ConvStream := TMemoryStream.Create;
  try
    ObjectBinaryToText (aStream, ConvStream);
    ConvStream.Position := 0;
    MemoOut.Lines.LoadFromStream (ConvStream);
  finally
    ConvStream.Free
  end;
end;
```

Notice that by repeatedly clicking the Current Form Object button you'll get more and more text, and the text of the memo is included in the stream. After a few times, the entire operation will get extremely slow, so that the program seems to be hung up. In this code, we start to see some of the flexibility of using streams—we can write a generic procedure we can use to convert any stream.

NOTE It's important to stress that after you've written data to a stream, you must explicitly seek back to the beginning (or set the `Position` property to 0) before you can use the stream further, unless you want to append data to the stream, of course.

Another button, labeled Panel Object, shows the textual representation of a specific component, the panel, passing the component to the `WriteComponent` method. The third button, Form in Executable File, does a different operation. Instead of streaming an existing object in memory, it loads in a TResourceStream object the design-time representation of the form—that is, its DFM file—from the corresponding resource embedded in the executable file:

```
procedure TformText.btnResourceClick(Sender: TObject);
var
  ResStr: TResourceStream;
begin
  ResStr := TResourceStream.Create(hInstance, 'TFORMTEXT', RT_RCDATA);
  try
    ConvertAndShow (ResStr);
  finally
    ResStr.Free
  end;
end;
```

By clicking the buttons in sequence (or modifying the form of the program) you can compare the form saved in the DFM file to the current run-time object.

Writing a Custom Stream Class

Besides using the existing stream classes, Delphi programmers can write their own stream classes, and use them in place of the existing ones. To accomplish this, you need only specify how a generic block of raw data is saved and loaded, and VCL will be able to use your new class wherever you call for it. You may not need to create a brand-new stream class for working with a new type of media, but only need to customize an existing stream. In that case, all you have to do is write the proper read and write methods.

As an example, I created a class to encode and decode a generic file stream. Although this example is limited by its use of a totally dumb encoding mechanism, it fully integrates with VCL and works properly. The new stream class simply declares the two core reading and writing methods and has a property that stores a key.

```
type
  TEncodedStream = class (TFileStream)
  private
    FKey: Char;
  public
    constructor Create(const FileName: string; Mode: Word);
    function Read(var Buffer; Count: Longint): Longint; override;
    function Write(const Buffer; Count: Longint): Longint; override;
    property Key: Char read FKey write FKey;
  end;
```

Continued on next page

The value of the key is simply added to each of the bytes saved to a file, and subtracted when the data is read. Here is the complete code of the Write and Read methods, which uses pointers quite heavily:

```
constructor TEncodedStream.Create( const FileName: string; Mode: Word);
begin
  inherited Create (FileName, Mode);
  FKey := 'A'; // default
end;

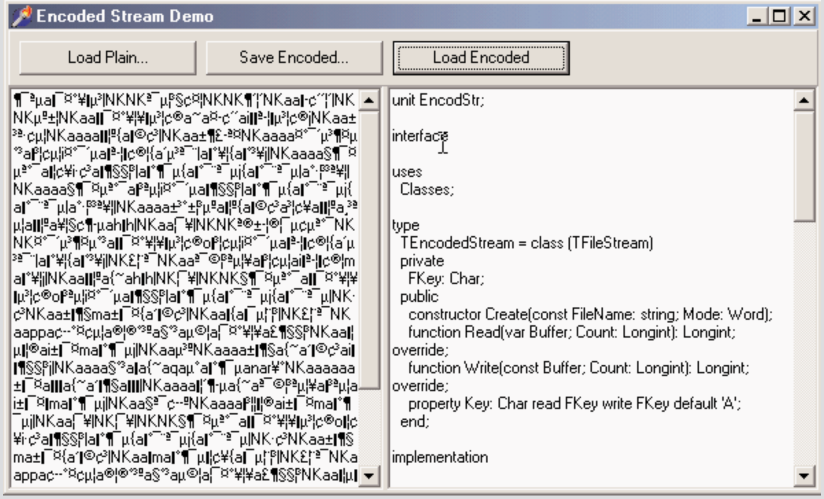
function TEncodedStream.Write(const Buffer; Count: Longint): Longint;
var
  pBuf, pEnc: PChar;
  I, EncVal: Integer;
begin
  // allocate memory for the encoded buffer
  GetMem (pEnc, Count);
  try
    // use the buffer as an array of characters
    pBuf := PChar (@Buffer);
    // for every character of the buffer
    for I := 0 to Count - 1 do
    begin
      // encode the value and store it
      EncVal := ( Ord (pBuf[I]) + Ord(Key) ) mod 256;
      pEnc [I] := Chr (EncVal);
    end;
    // write the encoded buffer to the file
    Result := inherited Write (pEnc^, Count);
  finally
    FreeMem (pEnc, Count);
  end;
end;

function TEncodedStream.Read(var Buffer; Count: Longint): Longint;
var
  pBuf, pEnc: PChar;
  I, CountRead, EncVal: Integer;
begin
  // allocate memory for the encoded buffer
  GetMem (pEnc, Count);
  try
```

Continued on next page

```
    // read the encoded buffer from the file
    CountRead := inherited Read (pEnc^, Count);
    // use the output buffer as a string
    pBuf := PChar (@Buffer);
    // for every character actually read
    for I := 0 to CountRead - 1 do
    begin
      // decode the value and store it
      EncVal := ( Ord (pEnc[I]) - Ord(Key) ) mod 256;
      pBuf [I] := Chr (EncVal);
    end;
  finally
    FreeMem (pEnc, Count);
  end;
  // return the number of characters read
  Result := CountRead;
end;
```

The comments in this rather complex code should help you understand the details. Now that we have an encoded stream, we can try to use it in a demo program, which is called EncDemo. The form of this program has two memo components and three buttons, as you can see in the graphic below. The first button loads a plain text file in the first memo; the second button saves the text of this first memo in an encoded file; and the last button reloads the encoded file into the second memo, decoding it. In this example, after encoding the file, I've reloaded it in the first memo as a plain text file on the left, which of course is unreadable.



```
unit EncodStr;

interface

uses
  Classes;

type
  TEncodedStream = class (TFileStream)
  private
    FKey: Char;
  public
    constructor Create(const FileName: string; Mode: Word);
    function Read(var Buffer; Count: Longint): Longint;
override;
    function Write(const Buffer; Count: Longint): Longint;
override;
    property Key: Char read FKey write FKey default 'A';
  end;

implementation
```

Continued on next page

Since we have the encoded stream class available, the code of this program is very similar to that of any other program using streams. For example, here is the method used to save the encoded file (you can compare its code to that of earlier examples based on streams):

```
procedure TFormEncode.BtnSaveEncodedClick(Sender: TObject);
var
  EncStr: TEncodedStream;
begin
  if SaveDialog1.Execute then
  begin
    EncStr := TEncodedStream.Create(SaveDialog1.Filename, fmCreate);
    try
      Memo1.Lines.SaveToStream (EncStr);
    finally
      EncStr.Free;
    end;
  end;
end;
```

Summarizing the Core VCL and BaseCLX Units

We've spent most of the space of this chapter discussing the classes of a single unit of the library, Classes. This unit is certainly important, but it is not the only core unit of the library (although there aren't many others). In this section, I'm providing an overview of these units and their content.

The Classes Unit

The Classes unit is at the heart of both VCL and CLX libraries, and though it sees many internal changes from the last version of Delphi, there is little new for the average users. (Most changes are related to modified IDE integration and are meant for expert component writers.)

Here is a list of what you can find in the Classes unit, a unit that every Delphi programmer should spend some time with:

- Many enumerated types, the standard method pointer types (including `TNotifyEvent`), and many exception classes.

- Core library classes, including TPersistent and TComponent but also TBasicAction and TBasicActionLink.
- List classes, including TList, TThreadList (a thread-safe version of the list), TInterfaceList (a list of interfaces, used internally), TCollection, TCollectionItem, TOwnedCollection (which is simply a collection with an owner), TStrings, and TStringList.
- All the stream classes I discussed in the previous section but won't list here again. There are also the TFiler, TReader, and TWriter classes and a TParser class used internally for DFM parsing.
- Utility classes, such as TBits for binary manipulation and a few utility routines (for example, point and rectangle constructors, and string list manipulation routines such as LineStart and ExtractStrings). There are also many registration classes, to notify the system of the existence of components, classes, special utility functions you can replace, and much more.
- The TDataModule class, a simple object container alternative to a form. Data modules can contain only nonvisual components and are generally used in database and Web applications.

NOTE In past versions of Delphi, the TDataModule class was defined in the Forms unit; now it has been moved to the Classes unit. This was done to eliminate the code overhead of the GUI classes from non-visual applications (for example, Web server modules) and to better separate non-portable Windows code from OS-independent classes, such as TDataModule. Other changes relate to the data modules, for example, to allow the creation of Web applications with multiple data modules, something not possible in Delphi 5.

- New interface-related classes, such as TInterfacedPersistent, aimed at providing further support for interfaces. This particular class allows Delphi code to hold onto a reference to a TPersistent object or any descendent implementing interfaces, and is a core element of the new support for interfaced objects in the Object Inspector (see Chapter 11 for an example).
- The new TRecall class, used to maintain a temporary copy of an object, particularly useful for graphical-based resources.
- The new TClassFinder class used for finding a registered class instead of the FindClass method.
- The TThread class, which provides the core to operating system–independent support for multithreaded applications.

Other Core Units

Other units that are part of the RTL package are not directly used by typical Delphi programmers as often as Classes. Here is a list:

- The TypInfo unit includes support for Accessing RTTI information for published properties, as we've seen in the section "Accessing Properties by Name."
- The SyncObjs unit contains a few generic classes for thread synchronization.

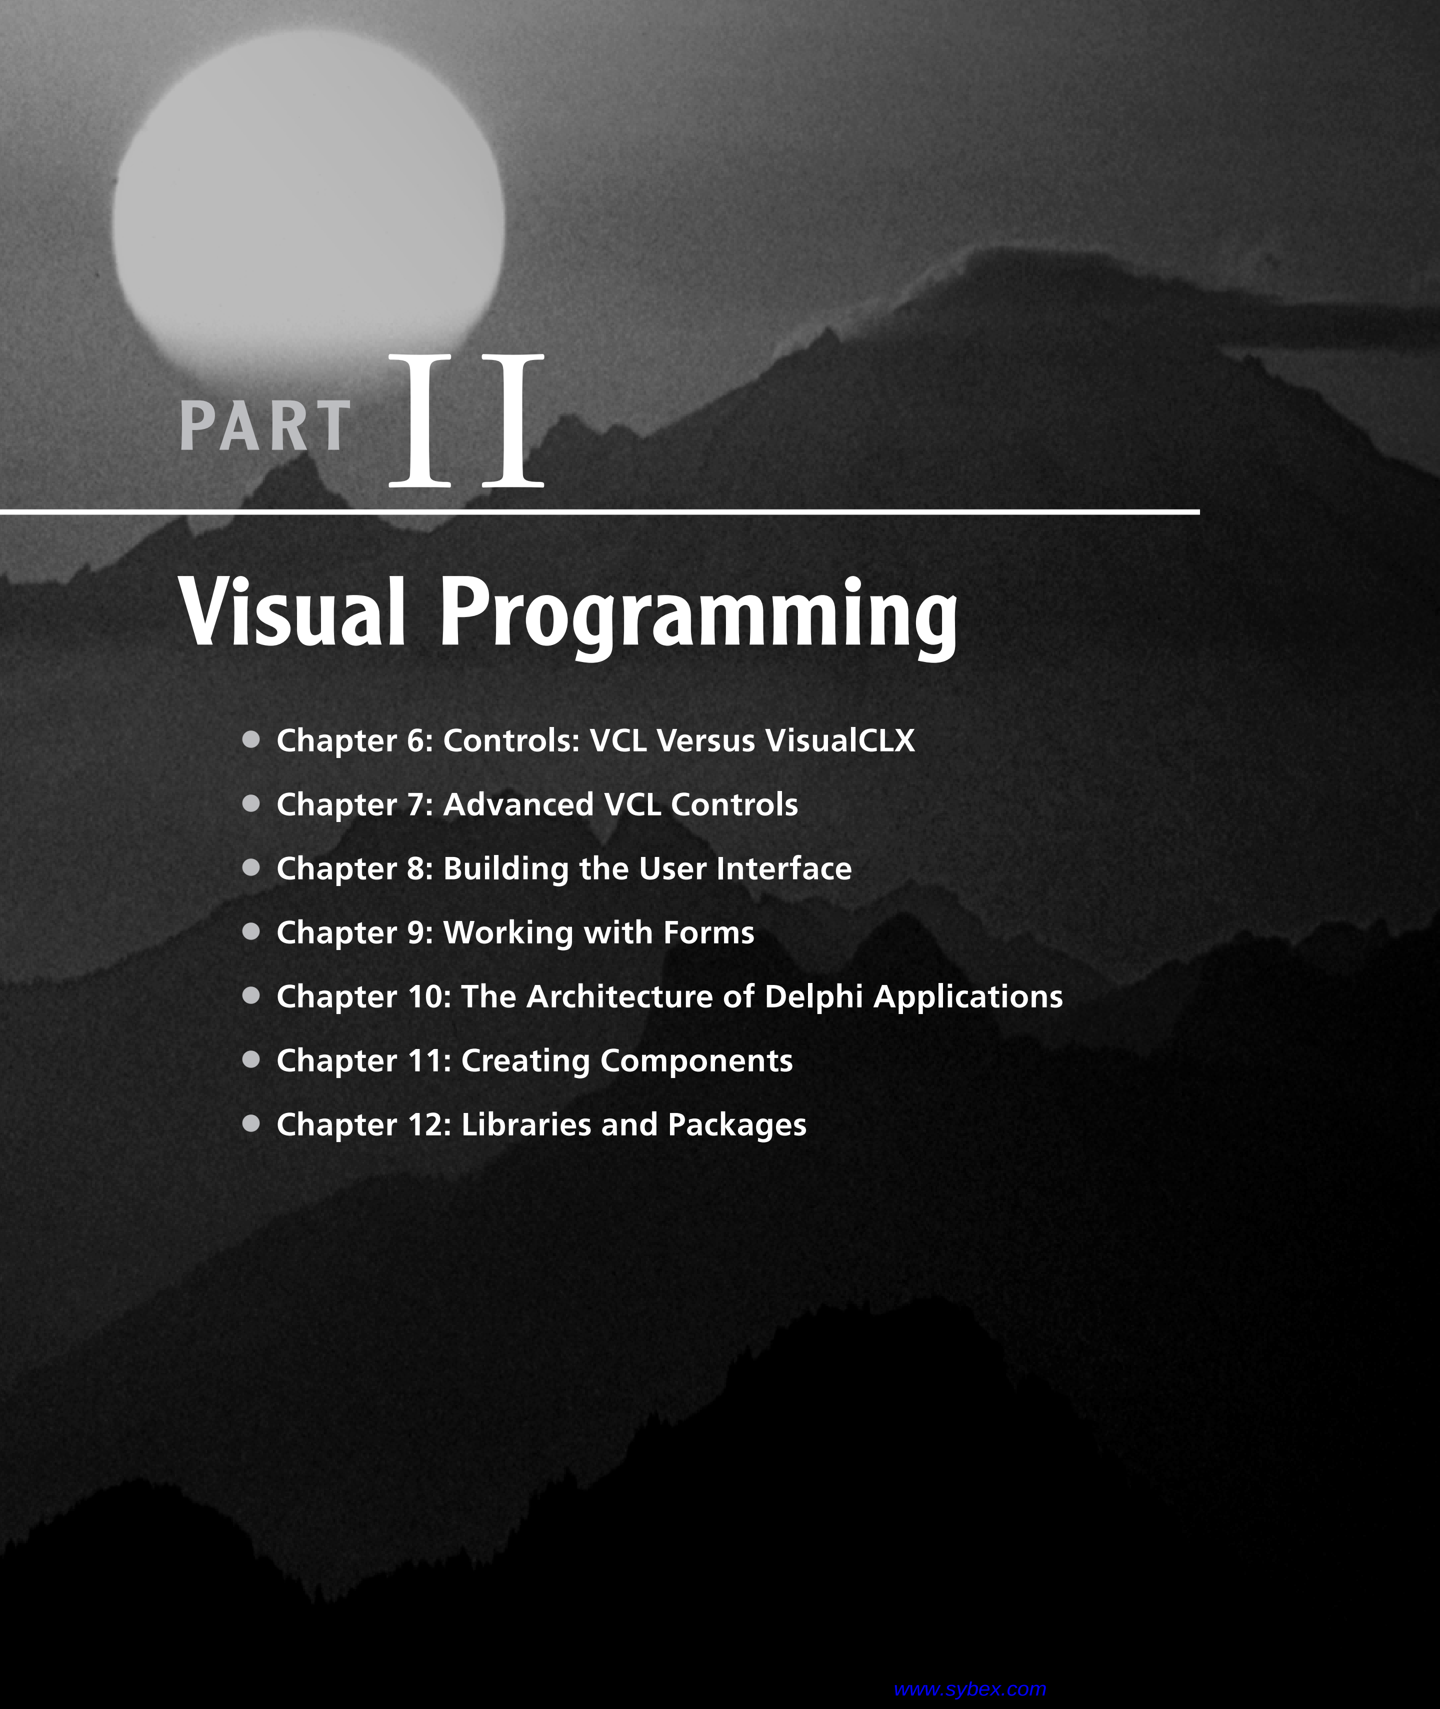
Of course, the RTL package also includes the units with functions and procedures discussed in the preceding chapter, such as Math, SysUtils, Variants, VarUtils, StrUtils, DateUtils, and so on.

What's Next?

As we have seen in this chapter, the Delphi class library has a few root classes that play a considerable role and that you should learn to leverage to the maximum possible extent. Some programmers tend to become expert on the components they use every day, and this is important, but without understanding the core classes (and ideas such as ownership and streaming), you'll have a tough time grasping the full power of Delphi.

Of course, in this book, we also need to discuss visual and database classes, which I will do in the next chapter. Now that we've seen all the base elements of Delphi (language, RTL, core classes), we are ready to discuss the development of real applications with this tool.

Part II of the book, which starts with the next chapter, is fully devoted to examples of the use of the various components, particularly visual components with the development of the user interface. We'll start with the advanced use of traditional controls and menus, discuss the actions architecture, cover the `TForm` class, and then examine toolbars, status bars, dialog boxes, and MDI applications in later chapters. Then we'll move to the development of database applications in Part III of the book.



PART II

Visual Programming

CHAPTER 6

Controls: VCL Versus VisualCLX

- VCL versus VisualCLX
- TControl, TWinControl, and TWidgetControl
- An overview of the standard components
- Basic and advanced menu construction
- Modifying the system menu
- Graphics in menus and list boxes
- OwnerDraw and styles

Now that you've been introduced to the Delphi environment and have seen an overview of the Object Pascal language and the base elements of component library, we are ready to delve into the second part of the book: the use of components and the development of the user interface of applications. This is really what Delphi is about. Visual programming using components is the key feature of this development environment.

Delphi comes with a large number of ready-to-use components. I won't describe every component in detail, examining each of its properties and methods; if you need this information, you can find it in the Help system. The aim of Part II of this book is to show you how to use some of the advanced features offered by the Delphi predefined components to build applications and to discuss specific programming techniques.

I'll start with a comparison of the VCL and VisualCLX libraries available in Delphi 6 and a coverage of the core classes (particularly `TControl`). Then I'll try to list all the various visual components you have, because choosing the right basic controls is often a way to get into a project faster.

VCL versus VisualCLX

As we've seen in the last chapter, Delphi 6 introduces the new CLX library alongside the traditional VCL library. There are certainly many differences, even in the use of the RTL and code library classes, between developing programs specifically for Windows or with a cross-platform attitude, but the user interface portion is where differences are most striking.

The visual portion of VCL is a wrapper of the Window API. It includes wrappers of the native Windows controls (like buttons and edit boxes), of the common controls (like tree views and list views), plus a bunch of native Delphi controls bound to the Windows concept of a window. There is also a `TCanvas` class that wraps the basic graphic calls, so you can easily paint on the surface of a window.

VisualCLX, the visual portion of CLX, is a wrapper of the Qt (pronounced "cute") library. It includes wrappers of the native Qt widgets, which range from basic to advanced controls, very similar to Windows' own standard and common controls. It includes also painting support using another, similar, `TCanvas` class. Qt is a C++ class library, developed by Trolltech (`www.trolltech.com`), a Norwegian company with a strong relationship with Borland.

On Linux, Qt is one of the de facto standard user-interface libraries and is the basis of the KDE desktop environment. On Windows, Qt provides an alternative to the use of the native APIs. In fact, unlike VCL, which provides a wrapper to the native controls, Qt provides an alternate implementation to those controls. This allows programs to be truly portable, as there are no hidden differences created by the operating system (and that the operating system vendor can introduce behind the scenes). It also allows us to avoid an extra layer; CLX on top of Qt on top of Windows native controls suggests three layers, but in fact there are two layers in each solution (CLX controls on top of Qt, VCL controls on top of Windows).

NOTE Distributing Qt applications on Windows implies the distribution of the Qt library itself (something you can generally take for granted on the Linux platform). Distributing the Qt libraries with a professional application (as opposed to an open source project) generally implies paying a license to Trolltech. If you use Delphi or Kylix to build Qt applications, however, Borland has already paid the license to Trolltech for you. However, you must use the CLX classes wrapping Qt: If you use the Qt classes directly, you apparently still owe the license to Qt, even when using Delphi or Kylix.

Technically, there are huge differences behind the scenes between a native Windows application built with VCL and a portable Qt program developed with VisualCLX. Suffice to say that at the low level, Windows uses API function calls and messages to communicate with controls, while Qt uses class methods and direct method callbacks and has no internal messages. Technically, the Qt classes offer a high-level object-oriented architecture, while the Windows API is still bound to its C legacy and a message-based system dated 1985 (when Windows was released). VCL offers an object-oriented abstraction on top of a low-level API, while VisualCLX remaps an already high-level interface into a more *familiar* class library.

NOTE To be honest, Microsoft has apparently reached the point of starting to abandon the traditional low-level Windows API for a native high-level class library, part of the dotNet architecture. Of course, this change won't happen overnight, but new high-level user-interface technologies might be introduced only in dotNet. Actually, dotNet consists of multiple technologies, including a virtual machine or runtime interpreter, a low-level nonvisual RTL, and a class framework for visual stuff (partially overlapping with VCL. If having a new visual class library on top of the Windows API might be of little use to programmers already using a modern class library (like VCL) other areas of dotNet would be of interest to Delphi programmers. So far, Borland has released no official statement regarding possible support for the dotNet byte code and virtual machine, or other areas of the future Microsoft operating system offering.

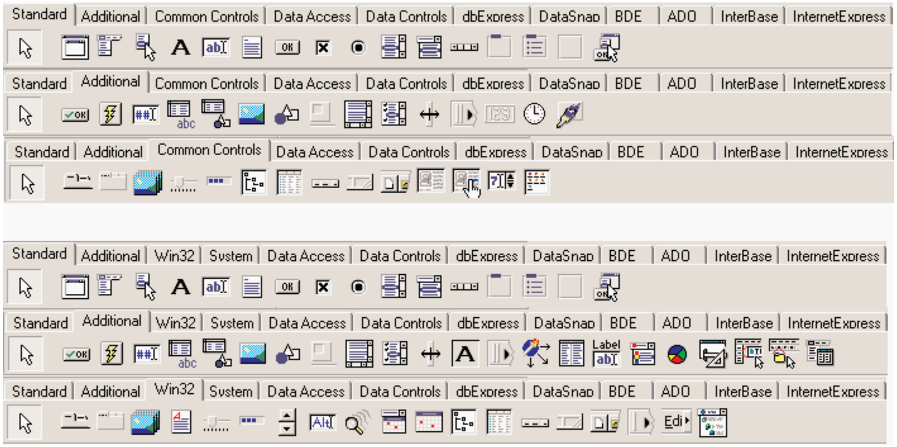
Having a familiar class library on top of a totally new platform is the advantage for Delphi programmers of using VisualCLX on Linux. This implies that the two class libraries, CLX and VCL, are very similar for their users, even if they are very different internally, as I mentioned. From the outside, a button is an object of the `TButton` class for both libraries, and it has more or less the same set of methods, properties, and events. In many occasions, you can recompile your existing programs for the new class library in a matter of minutes, if they don't map directly to low-level APIs.

Delphi 6 Dual Libraries Support

Delphi 6 has full support for both libraries at design time and at run time. As you start developing a new application, you can use the File ➢ New Application command to create a new VCL-based program and File ➢ New CLX Application for a new CLX-based program. After giving one of these two commands, Delphi's IDE will create a VCL or CLX design-time form and update the Component Palette so that it displays only the visual components compatible with the type of application you've selected (see Figure 6.1 for a comparison). In fact, you cannot place a VCL button into a CLX form, and you cannot even mix forms of the libraries within a single executable file. In other words, the user interface of every application must be built using exclusively one of the two libraries, which (aside from the technical implications) actually makes a lot of sense to me.

FIGURE 6.1:

A comparison of the first three pages of the Component Palette for a CXL-based application (above) and a VCL-based application (below)



Standard | Additional | Common Controls | Data Access | Data Controls | dbExpress | DataSnap | BDE | ADO | InterBase | InternetExpress
Standard | Additional | Common Controls | Data Access | Data Controls | dbExpress | DataSnap | BDE | ADO | InterBase | InternetExpress
Standard | Additional | Common Controls | Data Access | Data Controls | dbExpress | DataSnap | BDE | ADO | InterBase | InternetExpress
Standard | Additional | Win32 | System | Data Access | Data Controls | dbExpress | DataSnap | BDE | ADO | InterBase | InternetExpress
Standard | Additional | Win32 | System | Data Access | Data Controls | dbExpress | DataSnap | BDE | ADO | InterBase | InternetExpress
Standard | Additional | Win32 | System | Data Access | Data Controls | dbExpress | DataSnap | BDE | ADO | InterBase | InternetExpress

If you haven't already done so, I suggest you to try experimenting with the creation of a CLX application, looking at the available controls and trying to use them. You'll find very few differences in the use of the components, and if you have been using Delphi for some time, you'll probably be immediately adept with CLX.

Same Classes, Different Units

One of the cornerstones of the source-code compatibility between CLX and VCL code is that fact that similar classes in the two libraries have exactly the same class name. Each library has a class called `TButton` representing a push button; the methods and properties are so similar, this code will work with both libraries:

```
with TButton.Create (Self) do
begin
  SetBounds (20, 20, 80, 35);
```

```
    Caption := 'New';
    Parent := Self;
  end;
```

The two TButton classes have the same name, and this is possible because they are saved in two different units, called StdCtrls and QStdCtrls. Of course, you cannot have the two components available at design time in the palette, as the Delphi IDE can register only components with unique names. The entire VisualCLX library is defined by units corresponding to the VCL units, but with the letter *Q* as a prefix—so there is a QForms unit, a QDialogs unit, a QGraphics unit, and so on. There are also a few peculiar ones, such as the QStyle unit, that have no correspondence in VCL.

Notice that there are no compile settings or other hidden techniques to distinguish between the two libraries; what matters is the set of units referenced in the code. Remember that these references must be consistent, as you cannot mix visual controls of the two libraries in a single form and not even in a single program.

DFM and XFM

As you create a form at design time, this is saved to a form definition file. Traditional VCL applications use the DFM extension, which stands for Delphi form module. CLX applications use the XFM extension, which stands for cross-platform (i.e., *X*) form modules. The actual format of DFM or XFM files, which can be based on a textual or binary representation, is identical. A form module is the result of streaming the form and its components, and the two libraries share the streaming code, so they produce a fairly similar effect.

So the reason for having two different extensions doesn't lie in internal compiler tricks or incompatible formats. It is merely an indication to programmers and to the IDE of the type of components you should expect to find within that definition (as this indication is *not* included in the file itself).

If you want to convert a DFM file into an XFM file, you can simply rename the file. However, expect to find some differences in the properties, events, and available components, so that reopening the form definition for a different library will probably cause quite a few warnings.

TIP

Apparently Delphi's IDE chooses the active library only by looking at the extension of the form module, ignoring the references in the `uses` statements. For this reason, do change the extension if you plan using CLX. On Kylix, a different extension is pretty useless, because any form is opened in the IDE as a CLX form, regardless of the extension. On Linux, there is only the Qt-based CLX library, which is both the cross-platform *and* the native library.

As an example, I've built two simple identical applications, LibComp and QLibComp (available on this book's CD-ROM), with only a few components and a single event handler. Listing 6.1 presents the textual form definitions for two applications, built using the same steps in the Delphi 6 IDE, after choosing a CLX or VCL application. I've marked out differences in bold; as you can see, there are very few, most relating to the form and its font. The `OldCreateOrder` is a legacy property, used for compatibility with Delphi 3 and older code; standard colors have different names; and CLX saves the scrollbars' ranges.

Listing 6.1: An XFM file (left) and an equivalent DFM file (right)

```
object Form1: TForm1              object Form1: TForm1
  Left = 192                        Left = 192
  Top = 107                         Top = 107
  Width = 350                       Width = 350
  Height = 210                      Height = 210
  Caption = 'QLibComp'              Caption = 'LibComp'
  Color = clBackground              Color = clBtnFace
  VertScrollBar.Range = 161         Font.Charset = DEFAULT_CHARSET
  HorzScrollBar.Range = 297         Font.Color = clWindowText
                                    Font.Height = -11
                                    Font.Name = 'MS Sans Serif'
                                    Font.Style = []
  TextHeight = 13                   TextHeight = 13
  TextWidth = 6                     OldCreateOrder = False
  PixelsPerInch = 96                PixelsPerInch = 96
  object Button1: TButton           object Button1: TButton
    Left = 56                         Left = 56
    Top = 64                          Top = 64
    Width = 75                        Width = 75
    Height = 25                       Height = 25
    Caption = 'Add'                   Caption = 'Add'
    TabOrder = 0                      TabOrder = 0
    OnClick = Button1Click            OnClick = Button1Click
  end                               end
  object Edit1: TEdit                object Edit1: TEdit
    Left = 40                         Left = 40
    Top = 32                          Top = 32
    Width = 105                       Width = 105
    Height = 21                       Height = 21
    TabOrder = 1                      TabOrder = 1
    Text = 'my name'                  Text = 'my name'
  end                               end
  object ListBox1: TListBox         object ListBox1: TListBox
    Left = 176                        Left = 176
    Top = 32                          Top = 32
    Width = 121                       Width = 121
    Height = 129                      Height = 129
    Rows = 3                          ItemHeight = 13
    Items.Strings = (                 Items.Strings = (
   'marco'
   'john'
   'helen')
  TabOrder = 2
 end
end
```

```
   'marco'
   'john'
   'helen')
  TabOrder = 2
 end
end
```

uses Statements

By looking at the source code of the two examples, the differences are even less relevant, as they simply relate to the uses statements. The form of the CLX application has the following initial code:

```
unit QLibCompForm;
interface
uses
  SysUtils, Types, Classes, QGraphics, QControls, QForms, QDialogs, QStdCtrls;
```

The form of the VCL program has the traditional uses statement:

```
unit LibCompForm;
interface
uses
  Windows, Messages, SysUtils, Variants, Classes, Graphics, Controls, Forms,
  Dialogs, StdCtrls;
```

The code of the class and of the only event handler is absolutely identical. Of course, the classic compiler directive {$R *.dfm} is replaced by {$R *.xfm} in the CLX version of the program.

Disabling the Dual Library Help Support

In Delphi 6, when you press the F1 key in the editor asking for help on a routine, class, or method of the Delphi library, you'll usually get a choice between the VCL and CLX declarations of the same feature. You'll need to make a choice to proceed to the related help page, which can be quite annoying after a while (especially as the two pages are often identical).

If you don't care about CLX and are planning to use only VCL (or vice versa), you can disable this alternative by choosing the Help ➢ Customize command, removing everything with *CLX* in the name from Contents, Index, and Link, and saving the project. Then restart the Delphi IDE, and the Help engine won't bother asking you about CLX any more. Of course, don't forget to add those help files again in case you decide to start using CLX.

Choosing a Visual Library

Because you have two different user interface libraries available in Delphi 6, you'll have to choose one for each *visual* application. You must evaluate multiple criteria to come to the proper decision, which isn't always easy.

The first criterion is portability. If running your program on Windows and on Linux, with the same user interface, is a major concern to you, using CLX will probably make your life simpler and let you keep a single source code file with very limited IFDEFs. The same applies if you consider Linux to be (or possibly become) your key platform. Instead, if most of your users are on Windows and you just want to extend your offering with a Linux version, you might want to keep a dual VCL/CLX system. This probably implies two different sets of source code files, or too many for IFDEFs.

In fact, another criterion is the native look-and-feel. By using CLX on Windows, some of the controls will behave slightly differently than users will expect—at least expert users. For a simple user interface (edits, buttons, grids), this probably won't matter much, but if you have many tree view and list view controls, the differences will be quite clear. On the other hand, with CLX you'll be able to let your users select a look-and-feel of their choice, different from the basic Windows look, and use it consistently across platforms.

Using native controls implies also that as soon as you get a new version of the Windows operating system, your application will (probably) adapt to it. This is good for the user, but might cause you a lot of headaches in case of incompatibilities. Differences in the Microsoft common controls library over the last few years have been a major source of frustration for Windows programmers in general, including Delphi programmers.

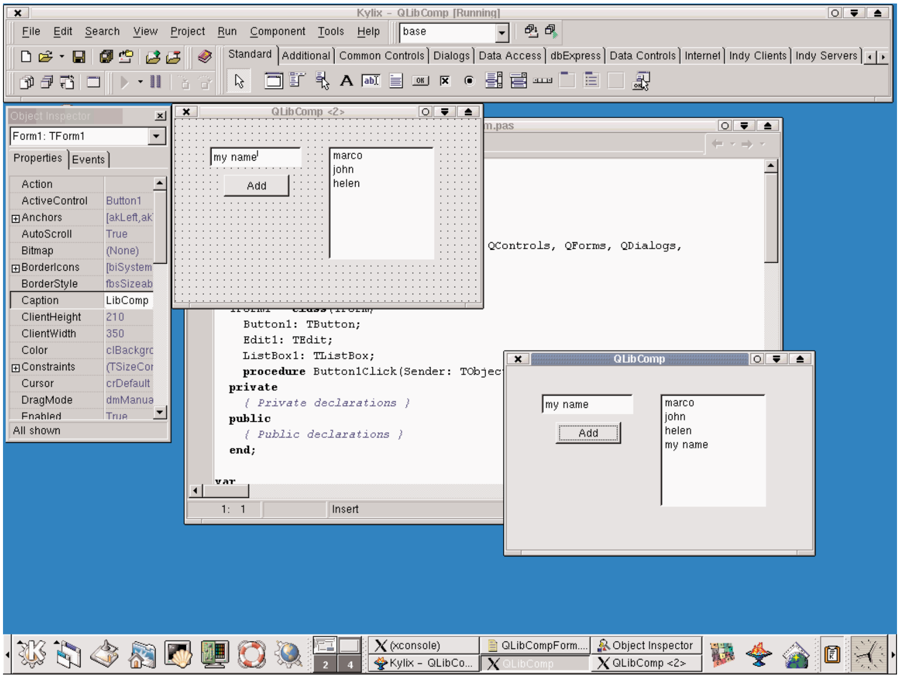
Another criterion is the deployment: If you use CLX, you'll have to ship your Windows program with the Qt libraries, which are not commonly available on Windows systems.

Finally, I've done a little testing, and it seems that the speed of VCL and CLX applications is similar. I've tried creating a thousand components, showing them on screen, and the speed differences are few, with a slight advantage for the VCL-based solution. You can try them out with the LibSpeed and QLibSpeed applications on the companion CD.

Running It on Linux

So the real issue of choosing the library resolves to the importance of Linux for you and your users. What is very important to notice is that, if you create a CLX application, you'll be able to recompile it unchanged (with the exact source code) with Kylix producing a native Linux application.

As an example, I've recompiled the QLibComp example introduced earlier, and you can see it running in Figure 6.2, where you can also see the Kylix IDE in action on a KDE 2 SuSE system.



Action	
ActiveControl	Button1
⊞Anchors	[akLeft,ak
AutoScroll	True
Bitmap	(None)
⊞BorderIcons	[biSystem
BorderStyle	fbsSizeab
Caption	LibComp
ClientHeight	210
ClientWidth	350
Color	clBackgrc
⊞Constraints	(TSizeCor
Cursor	crDefault
DragMode	dmManua
Enabled	True

```
QControls, QForms, QDialogs,

    Button1: TButton;
    Edit1: TEdit;
    ListBox1: TListBox;
    procedure Button1Click(Sender: TObjec
  private
    { Private declarations }
  public
    { Public declarations }
  end;

var
```

FIGURE 6.2: An application written with CLX can be directly recompiled under Linux with Kylix (displayed in the background).

Conditional Compilation for Libraries

If you want to keep a single source code file but compile with VCL on Windows and CXL on Linux, you can use platform-specific symbols (such as `$IFDEF LINUX`) to distinguish the two situations in case of conditional compilation. But what if you want to be able to compile a portion of code for both libraries on Windows?

You can either define a symbol of your own, and use conditional compilation, or (at times) test for the presence of identifiers that exist only in VCL or CLX only, as in:

```
{$IF Declared(QForms)}
  ...CLX-specific code
{$IFEND}
```

Converting Existing Applications

Besides starting with new CLX applications, you might want to convert some of your existing VCL applications to the new class library. There are a series of operations you have to do, without any specific help from the Delphi IDE:

- You'll have to rename the DFM file as XFM and update all of the `{$R *.DFM}` statements as `{$R *.XFM}`.
- You'll have to update all of the `uses` statements of your program (in the units and project files) to refer to the CLX units instead of the VCL units. Notice that by missing even a few, you'll bump into trouble when running your application.

TIP To prevent a CLX application from compiling if it contains references to VCL units, you can move the VCL units to a different directory under `lib` and avoid including this folder in your search path. This way, eventual leftover references to VCL units will cause a "Unit not found" error.

Table 6.1 is a comparison of the names of the visual VCL and CLX units, excluding the database portion and some rarely referenced units:

TABLE 6.1: Names of Equivalent VCL and CLX Units

VCL	CLX
ActnList	QActnList
Buttons	QButtons
Clipbrd	QClipbrd
ComCtrls	QComCtrls
Consts	QConsts
Controls	QControls
Dialogs	QDialogs
ExtCtrls	QExtCtrls
Forms	QForms
Graphics	QGraphics
Grids	QGrids
ImgList	QImgList
Menus	QMenus
Printers	QPrinters
Search	QSearch
StdCtrls	QStdCtrls

You might also convert references to Windows and Messages into references to the Qt unit. Some Windows data structures are now also available in the Types unit (see Chapter 4, “The Run-Time Library,” for details), so you might have to add it to your CLX programs. Notice, however, that the QTypes unit is not the CLX version of VCL’s Types unit; these two units are totally unrelated.

WARNING Watch out for your `uses` statements! If you happen to compile a project that includes a CLX form, but fail to update the project unit, leaving a reference to the VCL Forms unit there, your program will run but stop immediately. The reason is that no VCL form was created, so the program terminated right away. In other cases, trying to create a CLX form within a VCL application will cause run-time errors. Finally, the Delphi IDE might inappropriately add references to `uses` statements of the wrong library, so you end up with a single `uses` statement referring to the same unit for both, but only the second of the two will be effective. This rarely prevents the program from compiling, but you won’t be able to run it.

The VclToClx Helper Tool

As a helper in converting some of my own programs, I’ve written a simple unit-replacement tool, called VclToClx and available with its complete source code in the `Tools` folder of the book CD and on my Web site.

The program converts unit names, based on a configuration file, and fixes the DFM issue, by renaming the DFM files to XFM and fixing the references in the source code. The program is quite naive, as it doesn’t really parse the source code, but simply looks for the occurrences of the unit names followed by a comma or semicolon, as happens in a `uses` statement. It also requires that the unit name is preceded by a space, but of course you can modify the program to look for a comma. Don’t skip this extra test; otherwise the Forms unit will be turned to QForms, but the QForms unit will be converted again to QQForms!

TControl and Derived Classes

In the preceding chapter, I discussed the base classes of the Delphi library, focusing particularly on the `TComponent` class. One of the most important subclasses of `TComponent` is `TControl`, which corresponds to visual components. This base class is available both in CLX and VCL and defines general concepts, such as the position and the size of the control, the parent control hosting it, and more. For an actual implementation, though, you have to refer to its two subclasses. In VCL these are TWinControl and TGraphicControl; in CLX they are TWidgetControl and TGraphicControl. Here are their key features:

- *Window-based controls* (also called *windowed controls*) are visual components based on an operating-system window. A `TWinControl` in VCL has a window handle, a number referring to an internal Windows structure. A `TWidgetControl` in CLX has a Qt handle, a reference to the internal Qt object. From a user perspective, windowed controls can receive the input focus, and some of them can contain other controls. This is the biggest group of components in the Delphi library. We can further divide windowed controls in two groups: wrappers of native controls of Windows or Qt, and custom controls, which generally inherit from `TCustomControl`.

- *Graphical controls* (also called *nonwindowed controls*) are visual components that are not based on an operating-system window. Therefore, they have no handle, cannot receive the focus, and cannot contain other controls. These controls inherit from `TGraphicControl` and are painted by their parent form, which sends them mouse-related and other events. Examples of nonwindowed controls are the Label and SpeedButton components. There are just a few controls in this group, which were critical to minimizing the use of system resources in the early days of Delphi (on 16-bit Windows). Using graphical controls to save Windows resources is still quite useful on Win9*x*/Me, which has pushed the system limits higher but hasn't fully gotten rid of them (unlike Windows NT/2000).

A Short History of Windows Controls

You might have asked yourself where the idea of using components for Windows programming came from. The answer is simple: Windows itself has some components, usually called controls. A *control* is technically a predefined window that has a specific behavior and some styles and is capable of responding to specific messages. These controls were the first step in the direction of component development. The second step was probably Visual Basic controls, and the third step is Delphi components. (Actually, Microsoft's third step was its ActiveX technology, which is now followed by the dotNet framework, which is more or less at the level of the VCL controls.)

Windows 3.1 had six kinds of predefined controls, which were generally used in dialog boxes. Still used in Win32, they are buttons (push buttons, check boxes, and radio buttons), static labels, edit fields, list boxes, combo boxes, and scroll bars. Windows 95 added new predefined components, such as the list view, the status bar, the spin button, the progress bar, the tab control, and many others. Win32 developers can use the standard common controls provided by the system, and Delphi developers have the further advantage of having corresponding easy-to-use components.

As we have seen, Qt offers to CLX comparable basic and common controls, and even if there are internal differences, the Delphi libraries exposing those controls provide wrappers that can minimize those differences. VCL, in fact, literally wraps Windows predefined controls in some of its basic components. A Delphi wrapper class—for example, `TEdit`—simply surfaces the capabilities of the underlying Windows control, making it easier to use. However, Delphi adds nothing to the capabilities of this control. In Windows 95/98, an edit or memo control has a physical limit of 32 KB of text, and this limit is retained by the Delphi component.

Continued on next page

Why hasn't Borland overcome this limit? Why can't we change the color of a button? Simply because by replacing a Windows control with a custom version, we would lose the close connection with the operating system. Suppose Microsoft improves some of the controls in the next version of Windows. If we use our own version of the component, the application we build won't have the new features. By using controls that are based on the operating-system capabilities, instead, our programs have the opportunity to migrate through different versions of the OS and retain all the features provided by the specific version. This doesn't apply to the use of Qt, of course, but you have the advantage of being able to have an identical application based on the same source code running on Linux.

Note that wrapping an existing Windows or Qt control is an effective way of reusing code and also helps reduce the size of your compiled program. Implementing yet another button control from scratch requires custom code in your application, while a wrapper around the OS-supplied button control requires less code and makes use of system code shared by many applications.

Parent and Controls

The `Parent` property of a control indicates which other control is responsible for displaying it. When you drop a component into a form in the Form Designer, the form will become both parent and owner of the new control. But if you drop the component inside a Panel, ScrollBox, or any other *container* component, this will become its parent, while the form will still be the owner of the control.

When you create the control at run time, you'll need to set the owner (using the `Create` constructor parameter); but you must also set the `Parent` property, or the control won't be visible.

Like the `Owner` property, the `Parent` property has an inverse. The `Controls` array, in fact, lists all of the controls parented by the current one, numbered from `0` to `ControlsCount - 1`. You can scan this property to operate on all of the controls hosted by another one, eventually using a recursive method that operates on the controls parented by each subcontrol.

Properties Related to Control Size and Position

Some of the properties introduced by `TControl` and common to all controls are those related to size and position. The position of a control is determined by its `Left` and `Top` properties, its size by the `Height` and `Width` properties. Technically, all components have a position, because when you reopen an existing form at design time, you want to be able to see the icons for the nonvisual components in exactly the position where you've placed them. This position is visible in the form file.

TIP As you change any of the positional or size properties, you end up calling the single SetBounds method. So any time you need to change two or more of these properties at once, calling SetBounds directly will speed up the program. Another method, BoundsRect, returns the rectangle bounding of the control and corresponds to accessing those four properties.

An important feature of the position of a component is that, like any other coordinate, it always relates to the client area of its parent component (indicated by its Parent property). For a form, the client area is the surface included within its borders (excluding the borders themselves). It would have been messy to work in screen coordinates, although there are some ready-to-use methods that convert the coordinates between the form and the screen and vice versa.

Note, however, that the coordinates of a control are always relative to the parent control, such as a form or another *container* component. If you place a panel in a form, and a button in a panel, the coordinates of the button relate to the panel and not to the form containing the panel. In fact, in this case, the parent component of the button is the panel.

Activation and Visibility Properties

There are two basic properties you can use to let the user activate or hide a component. The simpler is the Enabled property. When a component is disabled (when Enabled is set to False), usually some visual hint indicates this state to the user. At design time, the "disabled" property does not always have an effect, but at run time, disabled components are generally grayed.

For a more radical approach, you can completely hide a component, either by using the corresponding Hide method or by setting its Visible property to False. Be aware, however, that reading the status of the Visible property does not tell you whether the control is actually visible. In fact, if the container of a control is hidden, even if the control is set to Visible, you cannot see it. For this reason, there is another property, Showing, which is a run-time and read-only property. You can read the value of Showing to know whether the control is really visible to the user; that is, if it is visible, its parent control is also visible, the parent control of the parent control is also visible, and so on.

Fonts

Two properties often used to customize the user interface of a component are Color and Font. Several properties are related to the color. The Color property itself usually refers to the background color of the component. Also, there is a Color property for fonts and many other graphic elements. Many components also have a ParentColor and a ParentFont property, indicating whether the control should use the same font and color as its parent component, which is usually the form. You can use these properties to change the font of each control on a form by setting only the Font property of the form itself.

When you set a font, either by entering values for the attributes of the property in the Object Inspector or by using the standard font selection dialog box, you can choose one of the fonts installed in the system. The fact that Delphi allows you to use all the fonts installed on your system has both advantages and drawbacks. The main advantage is that if you have a number of nice fonts installed, your program can use any of them. The drawback is that if you distribute your application, these fonts might not be available on your users' computers.

If your program uses a font that your user doesn't have, Windows will select some other font to use in its place. A program's carefully formatted output can be ruined by the font substitution. For this reason, you should probably rely only on standard Windows fonts (such as MS Sans Serif, System, Arial, Times New Roman, and so on).

Colors

There are various ways to set the value of a color. The type of this property is `TColor`. For properties of this type, you can choose a value from a series of predefined name constants or enter a value directly. The constants for colors include clBlue, clSilver, clWhite, clGreen, clRed, and many others.

TIP Delphi 6 adds four new standard colors: clMoneyGreen, clSkyBlue, clCream, and clMedGray.

As a better alternative, you can use one of the colors used by the system to denote the status of given elements. These sets of colors are different in VCL and CLX. VCL includes predefined Windows colors such as the background of a window (clWindow), the color of the text of a highlighted menu (clHightlightText), the active caption (clActiveCaption), and the ubiquitous button face color (clBtnFace).

CLX includes a different and incompatible set of system colors, including clBackground, which is the standard color of a form; clBase, used by edit boxes and other visual controls; clActiveForeground, the foreground color for active controls; and clDisabledBase, the background color for disabled text controls. All the color constants mentioned here are listed in VCL and CLX Help files under the "TColor type" topic.

Another option is to specify a `TColor` as a number (a 4-byte hexadecimal value) instead of using a predefined value. If you use this approach, you should know that the low three bytes of this number represent RGB color intensities for blue, green, and red, respectively. For example, the value $00FF0000 corresponds to a pure blue color, the value $0000FF00 to green, the value $000000FF to red, the value $00000000 to black, and the value $00FFFFFF to white. By specifying intermediate values, you can obtain any of 16 million possible colors.

Instead of specifying these hexadecimal values directly, you should use the Windows `RGB` function, which has three parameters, all ranging from 0 to 255. The first indicates the amount of red, the second the amount of green, and the last the amount of blue. Using the `RGB` function makes programs generally more readable than using a single hexadecimal constant. Actually, RGB is *almost* a Windows API function. It is defined by the Windows-related units and not by Delphi units, but a similar function does not exist in the Windows API. In C, there is a macro that has the same name and effect, so this is a welcome addition to the Pascal interface to Windows. RGB is not available on CLX, so I've written my own version as:

```
function RGB (red, green, blue: Byte): Cardinal;
begin
  Result := blue + green * 256 + red * 256 * 256;
end;
```

The highest-order byte of the TColor type is used to indicate which palette should be searched for the closest matching color, but palettes are too advanced a topic to discuss here. (Sophisticated imaging programs also use this byte to carry transparency information for each display element on the screen.) Regarding palettes and color matching, note that Windows sometimes replaces an arbitrary color with the closest available solid color, at least in video modes that use a palette. This is always the case with fonts, lines, and so on. At other times, Windows uses a dithering technique to mimic the requested color by drawing a tight pattern of pixels with the available colors. In 16-color (VGA) adapters and at higher resolutions, you often end up seeing strange patterns of pixels of different colors and not the color you had in mind.

The *TWinControl* Class (VCL)

In Windows, most elements of the user interface are windows. From a user standpoint, a window is a portion of the screen surrounded by a border, having a caption and usually a system menu. But technically speaking, a window is an entry in an internal system table, often corresponding to an element visible on the screen that has some associated code. Most of these windows have the role of controls; others are temporarily created by the system (for example, to show a pull-down menu). Still other windows are created by the application but remain hidden from the user and are used only as a way to receive a message (for example, nonblocking sockets use windows to communicate with the system).

The common denominator of all windows is that they are known by the Windows system and refer to a function for their behavior; each time something happens in the system, a notification message is sent to the proper window, which responds by executing some code. Each window of the system, in fact, has an associated function (generally called its *window procedure*), which handles the various messages the window is interested in.

In Delphi, any TWinControl class can override the WndProc method or define a new value for the WindowProc property. Interesting Windows messages, however, can be better tracked by providing specific message handlers. Even better, VCL converts these lower-level messages into events. In short, Delphi allows us to work at a high level, making application development easier, but still allows us to go low-level when this is required.

Notice also that creating a WinControl doesn't automatically create its corresponding Window handle. Delphi, in fact, uses a lazy initialization technique, so that the low control is only created when this is required, generally as soon as a method accesses the `Handle` property. The get method for this property the first time calls `HandleNeeded`, which eventually calls `CreateHandle`… and so on reaching `CreateWnd`, `CreateParams`, and `CreateWindowHandle` (the sequence is rather complex, and I don't think it is necessary to know it in detail). At the opposite end, you can keep an existing (perhaps invisible) control in memory but destroy its window handle, to save system resources.

The *TWidgetControl* Class (CLX)

In CLX, every `TWidgetControl` has an internal Qt object, referenced using the `Handle` property. This property has the same name as the corresponding Windows property, but it is totally different behind the scenes.

The Qt object is generally owned by the `TWidgetControl`, which automatically frees the object when it is destroyed. The class also uses delayed construction, as you can see in the `InitWidget` method, similar to `CreateWindow`. However it is also possible to create a widget around an existing Qt object: in this case, the widget won't own the Qt object and won't destroy it. The behavior is indicated by the `OwnHandle` property.

Actually each VisualCLX component has two associated C++ objects, the Qt `Handle` and the Qt `Hook`, which is the object receiving the system events. With the current Qt design, this has to be a C++ object, which acts as an intermediary to the event handlers of the Object Pascal control. The `HookEvents` method associates the hook object to the CLX control.

Differently from Windows, Qt defines two different types of events:

- *Events* are the translation of input or system events (such as key press, mouse move, and paint).
- *Signals* are internal component events (corresponding to VCL internal or abstract operations, such as `OnClick` and `OnChange`)

NOTE In CLX there is a seldom-used `EventHandler` method, which corresponds more or less to the `WndProc` method of VCL.

Opening the Component Tool Box

So you want to write a Delphi application. You open a new Delphi project and find yourself faced with a large number of components. The problem is that for every operation, there are multiple alternatives. For example, you can show a list of values using a list box, a combo box, a radio group, a string grid, a list view, or even a tree view if there is a hierarchical order. Which should you use? That's difficult to say. There are many considerations, depending on what you want your application to do. For this reason, I've provided a highly condensed summary of alternative options for a few common tasks.

NOTE For some of the controls described in the following sections, Delphi also includes a data-aware version, usually indicated by the *DB* prefix. As you'll see in Chapter 13, "Delphi's Database Architecture," the DB version of a control typically serves a role similar to that of its "standard" equivalent; but the properties and the ways you use it are often quite different. For example, in an Edit control you use the `Text` property, while in a DBEdit component you access the `Value` of the related field object.

The Text Input Components

Although a form or component can handle keyboard input directly, using the `OnKeyPress` event, this isn't a common operation. Windows provides ready-to-use controls you can use to get string input and even build a simple text editor. Delphi has several slightly different components in this area.

The Edit Component

The Edit component allows the user to enter a single line of text. You can also display a single line of text with a Label or a StaticText control, but these components are generally used only for fixed text or program-generated output, not for input. In CLX, there is also a native LCD digit control you can use to display numbers.

The Edit component uses the `Text` property, whereas many other controls use the `Caption` property to refer to the text they display. The only condition you can impose on user input is the number of characters to accept. If you want to accept only specific characters, you can handle the `OnKeyPress` event of the edit box. For example, we can write a method that tests whether the character is a number or the Backspace key (which has a numerical value of 8). If it's not, we change the value of the key to the null character (`#0`), so that it won't be processed by the edit control and will produce a warning beep:

```
procedure TForm1.Edit1KeyPress(
  Sender: TObject; var Key: Char);
begin
  // check if the key is a number or backspace
  if not (Key in ['0'..'9', #8]) then
  begin
    Key := #0;
    Beep;
  end;
end;
```

NOTE A minor difference of CLX is that the Edit control has no Undo mechanism built in. Another is that the `PasswordChar` property is *replaced* by the `EchoMode` property. You don't determine the character to display, but whether to echo the entered text or display an asterisk instead.

The New LabeledEdit Control

Delphi 6 adds a very nice control, called LabeledEdit, which is an Edit control with a label attached to it. The Label appears as a property of the compound control, which inherits from `TCustomEdit`.

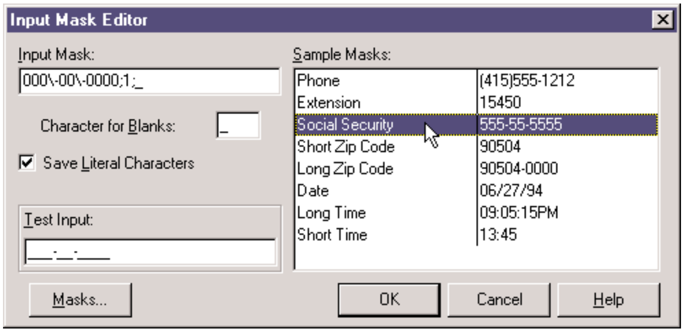
I have to say this component is very handy, because it allows you to reduce the number of components on your forms, move them around more easily, and have a more standard layout for labels, particularly when they are placed above the edit box. The `EditLabel` property is connected with the subcomponent, which has the usual properties and events. Two more properties, `LabelPosition` and `LabelSpacing`, allow you to configure the relative positions of the two controls.

NOTE This component has been added to the ExtCtrls unit to demonstrate the use of subcomponents in the Object Inspector, which is a new feature of Delphi 6. I'll discuss the development of these components in Chapter 11, "Creating Components." Notice also that this component, along with all of the other new Delphi 6 components, is not (yet) available on CLX and on the first release of Kylix. However, we can expect all non–Windows-specific additions to VCL, including subcomponents in general and the LabeledEdit control in particular, to be available in the next release of Kylix.

The MaskEdit Component

To customize the input of an edit box further, you can use the MaskEdit component, which has an `EditMask` property. This is a string indicating for each character whether it should be uppercase, lowercase, or a number, and other similar conditions. You can see the editor of the `EditMask` property in Figure 6.3.

FIGURE 6.3: The MaskEdit component's EditMask property editor



Input Mask: 000\-00\-0000;1;_

Character for Blanks: _

☑ Save Literal Characters

Test Input: ___-__-____

Sample Masks:

Phone	(415)555-1212
Extension	15450
Social Security	555-55-5555
Short Zip Code	90504
Long Zip Code	90504-0000
Date	06/27/94
Long Time	09:05:15PM
Short Time	13:45

TIP You can display any property's editor by selecting the property in the Object Inspector and clicking the ellipsis (…) button.

The Input Mask editor allows you to enter a mask, but it also asks you to indicate a character to be used as a placeholder for the input and to decide whether to save the *literals* present in the mask, together with the final string. For example, you can choose to display the parentheses around the area code of a phone number only as an input hint or to save them with the string holding the resulting number. These two entries in the Input Mask editor correspond to the last two fields of the mask (separated by semicolons).

TIP Clicking the Masks button of the Mask Editor lets you choose predefined input masks for different countries.

The Memo and RichEdit Components

Both of the controls discussed so far allow a single line of input. The Memo component, by contrast, can host several lines of text but (on the Win95/98 platforms) still retains the 16-bit Windows text limit (32 KB) and allows only a single font for the entire text. You can work on the text of the memo line by line (using the `Lines` string list) or access the entire text at once (using the `Text` property).

If you want to host a large amount of text or change fonts and paragraph alignments, in VCL you should use the RichEdit control, a Win32 common control based on the RTF document format. You can find an example of a complete editor based on the RichEdit component among the sample programs that ship with Delphi. (The example is named RichEdit, too.)

The RichEdit component has a `DefAttributes` property indicating the default styles and a `SelAttributes` property indicating the style of the current selection. These two properties are not of the `TFont` type, but they are compatible with fonts, so we can use the `Assign` method to copy the value, as in the following code fragment:

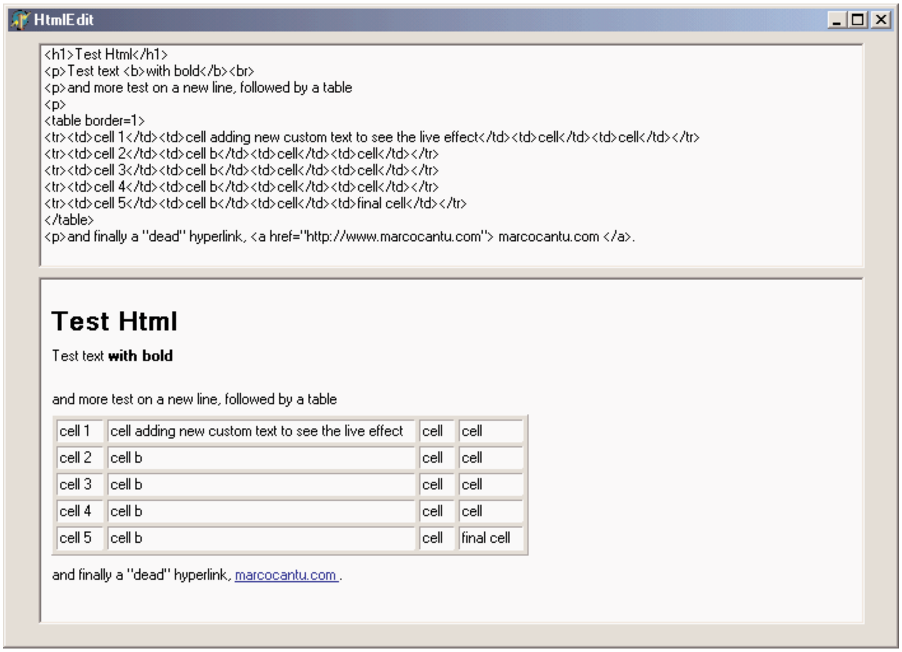
```
procedure TForm1.Button1Click(Sender: TObject);
begin
  if RichEdit1.SelLength > 0 then
  begin
    FontDialog1.Font.Assign (RichEdit1.DefAttributes);
    if FontDialog1.Execute then
      RichEdit1.SelAttributes.Assign (FontDialog1.Font);
  end;
end;
```

The TextViewer CLX Control

Among all of the common controls, CLX and Qt lack a RichEdit control. However, they provide a full-blown HTML viewer, which is very powerful for displaying formatted text but not for typing it. This HTML viewer is embedded in two different controls, the single-page TextViewer control or the TextBrowser control with active links.

As a simple demo, I've added a memo and a text viewer to a CLX form and connected them so that everything you type on the memo is immediately displayed in the viewer. I've called the example HtmlEdit not because this is a real HTML editor, but because this is the simplest way I know of to build an HTML preview inside a program. The form of the program is visible at run time in Figure 6.4, while typing some text inside a cell of the table.

FIGURE 6.4: The HtmlEdit example at run time: when you add new HTML text to the memo, you get an immediate preview.



```
<h1>Test Html</h1>
<p>Test text <b>with bold</b><br>
<p>and more test on a new line, followed by a table
<p>
<table border=1>
<tr><td>cell 1</td><td>cell adding new custom text to see the live effect</td><td>cell</td><td>cell</td></tr>
<tr><td>cell 2</td><td>cell b</td><td>cell</td><td>cell</td></tr>
<tr><td>cell 3</td><td>cell b</td><td>cell</td><td>cell</td></tr>
<tr><td>cell 4</td><td>cell b</td><td>cell</td><td>cell</td></tr>
<tr><td>cell 5</td><td>cell b</td><td>cell</td><td>final cell</td></tr>
</table>
<p>and finally a "dead" hyperlink, <a href="http://www.marcocantu.com"> marcocantu.com </a>.
```

Test Html

Test text **with bold**

and more test on a new line, followed by a table

cell 1	cell adding new custom text to see the live effect	cell	cell
cell 2	cell b	cell	cell
cell 3	cell b	cell	cell
cell 4	cell b	cell	cell
cell 5	cell b	cell	final cell

and finally a "dead" hyperlink, marcocantu.com .

TIP I originally built this example with Kylix on Linux. To port it to Windows and Delphi 6, all I had to do was to copy the files and recompile.

Selecting Options

There are two standard Windows controls that allow the user to choose different options, as well as controls for grouping sets of options.

The CheckBox and RadioButton Components

The first standard option-selecting control is the *check box*, which corresponds to an option that can be selected regardless of the status of other check boxes. Setting the `AllowGrayed` property of the check box allows you to display three different states (selected, not selected, and grayed), which alternate as a user clicks the check box.

The second type of control is the *radio button*, which corresponds to an exclusive selection. Two radio buttons on the same form or inside the same radio group container cannot be selected at the same time, and one of them should always be selected (as programmer, you are responsible for selecting one of the radio buttons at design time).

The GroupBox Components

To host several groups of radio buttons, you can use a GroupBox control to hold them together, both functionally and visually. To build a group box with radio buttons, simply place the GroupBox component on a form and then add the radio buttons to the group box.

You can handle the radio buttons individually, but it's easier to navigate through the array of controls owned by the group box, as discussed in the previous chapter. Here is a small code excerpt used to get the text of the selected radio button of a group:

```
var
  I: Integer;
  Text: string;
begin
  for I := 0 to GroupBox1.ControlCount - 1 do
    if (GroupBox1.Controls[I] as TRadioButton).Checked then
      Text := (GroupBox1.Controls[I] as TRadioButton).Caption;
```

The RadioGroup Component

Delphi has a similar component that can be used specifically for radio buttons: the RadioGroup component. A RadioGroup is a group box with some radio button *clones* painted inside it. The term *clone* in this context refers to the fact that the RadioGroup component is a single control, a single window, with elements similar to radio buttons painted on its surface.

Using the radio group is generally easier than using the group box, since the various items are part of a list, as in a list box. This is how you can get the text of the selected item:

```
Text := RadioGroup1.Items [RadioGroup1.ItemIndex];
```

Technically, a RadioGroup uses fewer resources and less memory, and it should be faster to create and paint. Also, the RadioGroup component can automatically align its radio buttons in one or more columns (as indicated by the `Columns` property), and you can easily add new choices at run time, by adding strings to the `Items` string list. By contrast, adding new radio buttons to a group box would be quite complex.

Lists

When you have many selections, radio buttons are not appropriate. The usual number of radio buttons is no more than five or six, to avoid cluttering the user interface; when you have more choices, you can use a list box or one of the other controls that display lists of items and allow the selection of one of them.

The ListBox Component

The selection of an item in a list box uses the `Items` and `ItemIndex` properties as in the code shown above for the RadioGroup control. If you need access to the text of selected list box items often, you can write a small wrapper function like this:

```
function SelText (List: TListBox): string;
var
  nItem: Integer;
begin
  nItem := List.ItemIndex;
  if nItem >= 0 then
    Result := List.Items [nItem]
  else
    Result := '';
end;
```

Another important feature is that by using the ListBox component, you can choose between allowing only a single selection, as in a group of radio buttons, and allowing multiple selections, as in a group of check boxes. You make this choice by specifying the value of the `MultiSelect` property. There are two kinds of multiple selections in Windows and in Delphi list boxes: *multiple selection* and *extended selection*. In the first case, a user selects multiple items simply by clicking them, while in the second case the user can use the Shift and Ctrl keys to select multiple consecutive or nonconsecutive items, respectively. This second choice is determined by the `ExtendedSelect` property.

For a multiple-selection list box, a program can retrieve information about the number of selected items by using the `SelCount` property, and it can determine which items are selected by examining the `Selected` array. This array of Boolean values has the same number of entries as the list box. For example, to concatenate all the selected items into a string, you can scan the `Selected` array as follows:

```
var
  SelItems: string;
  nItem: Integer;
begin
  SelItems := '';
  for nItem := 0 to ListBox1.Items.Count - 1 do
    if ListBox1.Selected [nItem] then
      SelItems := SelItems + ListBox1.Items[nItem] + ' ';
```

In CLX the ListBox can be configured to use a fixed number of columns and rows, using the `Columns`, `Row`, `ColumnLayout` and `RowLayout` properties. Of these, the VCL ListBox has only the `Columns` property.

The ComboBox Component

List boxes take up a lot of screen space, and they offer a fixed selection—that is, a user can choose only among the items in the list box and cannot enter any choice that the programmer did not specifically foresee.

You can solve both problems by using a ComboBox control, which combines an edit box and a drop-down list. The behavior of a ComboBox component changes a lot depending on the value of its `Style` property:

- The csDropDown style defines a typical combo box, which allows direct editing and displays a list box on request.
- The csDropDownList style defines a combo box that does not allow editing (but uses the keystrokes to select an item).
- The csSimple style defines a combo box that always displays the list box below it.

Note also that accessing the text of the selected value of a ComboBox is easier than doing the same operation for a list box, since you can simply use the `Text` property. A useful and common trick for combo boxes is to add a new element to the list when a user enters some text and presses the Enter key. The following method first tests whether the user has pressed that key, by looking for the character with the numeric (ASCII) value of 13. It then tests to make sure the text of the combo box is not empty and is not already in the list—if its position in the list is less than zero. Here is the code:

```
procedure TForm1.ComboBox1KeyPress(
  Sender: TObject; var Key: Char);
begin
  // if the user presses the Enter key
  if Key = Chr (13) then
    with ComboBox3 do
      if (Text <> '') and (Items.IndexOf (Text) < 0) then
        Items.Add (Text);
end;
```

NOTE In CLX, the combo box can automatically add the text typed into the edit to the drop-down list, when the user presses the Enter key. Also, some events fire at different times than in VCL.

Delphi 6 includes two new events for the combo box. The `OnCloseUp` event corresponds to the closing of the drop-down list and complements the preexisting `OnDropDown` event. The `OnSelect` event fires only when the user selects something in the drop-down list, as opposed to typing in the edit portion.

Another very nice addition is the `AutoComplete` property. When it is set, the ComboBox component (and the ListBox, as well) automatically locates the string nearest to the one the user is entering, suggesting the final part of the text. The core of this feature, available also in CLX, is implemented in the `TCustomListBox.KeyPress` method.

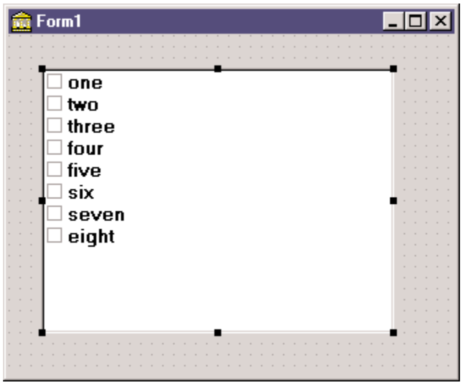
The CheckListBox Component

Another extension of the list box control is represented by the CheckListBox component, a list box with each item preceded by a check box (as you can see in Figure 6.5). A user can select a single item of the list, but can also click the check boxes to toggle their status. This makes the CheckListBox a very good component for multiple selections or for highlighting the status of a series of independent items (as in a series of check boxes).

To check the current status of each item, you can use the `Checked` and the `State` array properties (use the latter if the check boxes can be grayed). Delphi 5 introduced the `ItemEnabled` array property, which you can use to enable or disable each item of the list. We'll use the CheckListBox in the DragList example, later in this chapter.

FIGURE 6.5:

The user interface of the CheckListBox control, basically a list of check boxes



TIP

Most of the list-based controls share a common and important feature. Each item of the list has an associated 32-bit value, usually indicated by the TObject type. This value can be used as a tag for each list item, and it's very useful for storing additional information along with each item. This approach is connected to a specific feature of the native Windows list box control, which offers four bytes of extra storage for each list box item. We'll use this feature in the ODList example later on in this chapter.

New Combo Boxes: ComboBoxEx and ColorBox

The ComboBoxEx (where *ex* stands for extended) is the wrapper of a new Win32 common controls, which extends the traditional combo box by allowing images to appear next to the items in the list. You attach an image list to the combo, and then select an image index for each item to display. The effect of this change is that the simple Items string list is replaced by a more complex collection, the ItemsEx property.

The ColorBox control is a new version of the combo box specifically aimed at selecting colors. You can use its Style property for choosing which groups of colors you want to see in the list (standard color, extended colors, system colors, and so on).

The ListView and TreeView Components

If you want an even more sophisticated list, you can use the ListView common control, which will make the user interface of your application look very modern. This component is slightly more complex to use, as described at the beginning of the next chapter, "Advanced VCL Controls." Other alternatives for listing values are the TreeView common control, which shows items in a hierarchical output, and the StringGrid control, which shows multiple elements for each line. The string grid control is described in the "Graphics in Delphi" bonus chapter, available on the companion CD.

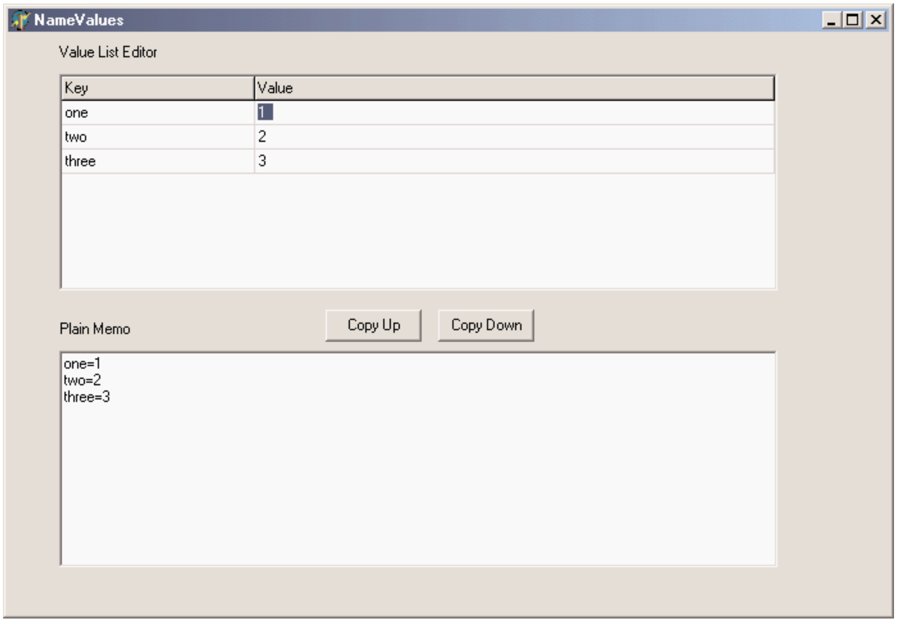
If you use the common controls in your application, users will already know how to interact with them, and they will regard the user interface of your program as up to date. TreeView and ListView are the two key components of Windows Explorer, and you can assume that many users will be familiar with them, even more than with the traditional Windows controls. CLX adds also an IconView control, which parallels part of the features of the VCL ListView.

The New ValueListEditor Component

Delphi applications often use the name/value structure natively offered by string lists, which I discussed in the last chapter. Delphi 6 introduces a version of the StringGrid component specifically geared towards this type of string lists. The ValueListEditor has two columns where you can display and let the user edit the contents of a string list with name/value pairs, as you can see in Figure 6.6. This string list is indicated in the Strings property of the control.

FIGURE 6.6:

The NameValues example has the new ValueListEditor component, which shows the name/value or key/value pairs of a string list, visible also in a plain memo.



Key	Value
one	1
two	2
three	3

```
one=1
two=2
three=3
```

The power of this control lies in the fact you can customize the editing options for each position of the grid or for each key value, using the run-time-only `ItemProps` array property. For each item, you can indicate:

- Whether it is read-only
- The maximum number of characters of the string
- An edit mask (eventually requested in the `OnGetEditMask` event)
- The items of a drop-down pick list (eventually requested in the `OnGetPickList` event)
- The display of a button for showing an editing dialog (in the `OnEditButtonClick` event)

Needless to say, this behavior resembles what is available generally for string grids and the DBGrid control, but also the behavior of the Object Inspector.

The `ItemProps` property has to be set up at run time, by creating an object of the `TItemProp` class and assigning it to an index or a key of the string list. To have a default editor for each line, you can assign the same item property object multiple times. In the example, this shared editor sets an edit mask for up to three numbers:

```
procedure TForm1.FormCreate(Sender: TObject);
var
  I: Integer;
```

```
begin
  SharedItemProp := TItemProp.Create (ValueListEditor1);
  SharedItemProp.EditMask := '999;0; ';

  Memo1.Lines := ValueListEditor1.Strings;
  for I := 0 to ValueListEditor1.Strings.Count - 1 do
    ValueListEditor1.ItemProps [I] := SharedItemProp;
end;
```

Similar code has to be repeated in case the number of lines changes—for example, by adding new elements in the memo and copying them up to the value list:

```
procedure TForm1.ValueListEditor1StringsChange(Sender: TObject);
var
  I: Integer;
begin
  for I := 0 to ValueListEditor1.Strings.Count - 1 do
    if not Assigned (ValueListEditor1.ItemProps [I]) then
      ValueListEditor1.ItemProps [I] := SharedItemProp;
end;
```

NOTE Apparently reassigning the same editor twice causes some trouble, so I've assigned the editor only to the lines not having already one.

Another property, KeyOptions, allows you to let the user also edit the keys (the names), add new entries, delete existing ones, and allow for duplicated names in the first portion of the string. Oddly enough, you cannot add new keys unless you also activate the edit options, which makes it hard to let the user add extra entries while preserving the names of the basic ones.

Ranges

Finally, there are a few components you can use to select values in a range. Ranges can be used for numeric input and for selecting an element in a list.

The ScrollBar Component

The stand-alone ScrollBar control is the original component of this group, but it is seldom used by itself. Scroll bars are usually associated with other components, such as list boxes and memo fields, or are associated directly with forms. In all these cases, the scroll bar can be considered part of the surface of the other components. For example, a form with a scroll bar is actually a form that has an area resembling a scroll bar painted on its border, a feature governed by a specific Windows style of the form window. By *resembling*, I mean that it is not technically a separate window of the ScrollBar component type. These "fake" scroll bars are usually controlled in Delphi using specific properties of the form and the other components hosting them.

The TrackBar and ProgressBar Components

Direct use of the ScrollBar component is quite rare, especially with the TrackBar component introduced with Windows 95, which is used to let a user select a value in a range. Among Win32 common controls is the companion ProgressBar control, which allows the program to output a value in a range, showing the progress of a lengthy operation.

The UpDown Component

Another related control is the UpDown component, which is usually connected to an edit box so that the user can either type a number in it or increase and decrease the number using the two small arrow buttons. To connect the two controls, you set the `Associate` property of the UpDown component. Nothing prevents you from using the UpDown component as a standalone control, displaying the current value in a label or in some other way.

NOTE In CLX there is no UpDown control, but a SpinEdit that bundles an Edit with the UpDown in a single control.

The PageScroller Component

The Win32 PageScroller control is a container allowing you to scroll the internal control. For example, if you place a toolbar in the page scroller and the toolbar is larger than the available area, the PageScroller will display two small arrows on the side. Clicking these arrows will scroll the internal area. This component can be used as a scrollbar, but it also partially replaces the ScrollBox control.

The ScrollBox Component

The ScrollBox control represents a region of a form that can scroll independently from the rest of the surface. For this reason, the ScrollBox has two scrollbars used to move the embedded components. You can easily place other components inside a ScrollBox, as you do with a panel. In fact, a ScrollBox is basically a panel with scroll bars to move its internal surface, an interface element used in many Windows applications. When you have a form with many controls and a toolbar or status bar, you might use a ScrollBox to cover the central area of the form, leaving its toolbars and status bars outside of the scrolling region. By relying on the scrollbars of the form, in fact, you might allow the user to move the toolbar or status bar out of view, a very odd situation.

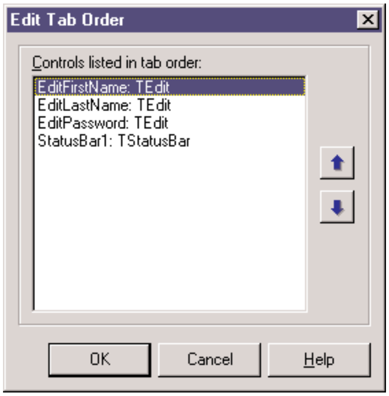
Handling the Input Focus

Using the `TabStop` and `TabOrder` properties available in most controls, you can specify the order in which controls will receive the input focus when the user presses the Tab key.

Instead of setting the tab order property of each component of a form manually, you can use the shortcut menu of the Form Designer to activate the Edit Tab Order dialog box, as shown in Figure 6.7.

FIGURE 6.7:

The Edit Tab Order dialog box



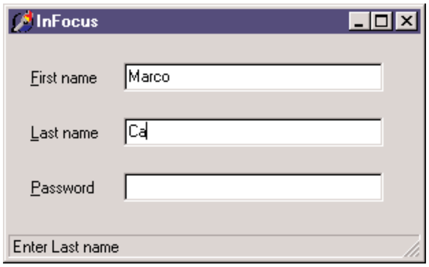
Controls listed in tab order:

EditFirstName: TEdit
EditLastName: TEdit
EditPassword: TEdit
StatusBar1: TStatusBar

Besides these basics settings, it is important to know that each time a component receives or loses the input focus, it receives a corresponding `OnEnter` or `OnExit` event. This allows you to fine-tune and customize the order of the user operations. Some of these techniques are demonstrated by the InFocus example, which creates a fairly typical password-login window. Its form has three edit boxes with labels indicating their meaning, as shown in Figure 6.8. At the bottom of the window is a status area with prompts guiding the user. Each item needs to be entered in sequence.

FIGURE 6.8:

The InFocus example at run time



First name: Marco
Last name: Ca
Password:
Enter Last name

For the output of the status information, I've used the StatusBar component, with a single output area (obtained by setting its `SimplePanel` property to `True`). Here is a summary of the properties for this example. Notice the `&` character in the labels, indicating a shortcut key, and the connection of these labels with corresponding edit boxes (using the FocusControl property):

```
object FocusForm: TFocusForm
  ActiveControl = EditFirstName
  Caption = 'InFocus'
  object Label1: TLabel
    Caption = '&First name'
    FocusControl = EditFirstName
  end
  object EditFirstName: TEdit
    OnEnter = GlobalEnter
    OnExit = EditFirstNameExit
  end
  object Label2: TLabel
    Caption = '&Last name'
    FocusControl = EditLastName
  end
  object EditLastName: TEdit
    OnEnter = GlobalEnter
  end
  object Label3: TLabel
    Caption = '&Password'
    FocusControl = EditPassword
  end
  object EditPassword: TEdit
    PasswordChar = '*'
    OnEnter = GlobalEnter
  end
  object StatusBar1: TStatusBar
    SimplePanel = True
  end
end
```

The program is very simple and does only two operations. The first is to identify, in the status bar, the edit control that has the focus. It does this by handling the controls' OnEnter event, possibly using a single generic event handler to avoid repetitive code. In the example, instead of storing some extra information for each edit box, I've checked each control of the form to determine which label is connected to the current edit box (indicated by the Sender parameter):

```
procedure TFocusForm.GlobalEnter(Sender: TObject);
var
  I: Integer;
begin
  for I := 0 to ControlCount - 1 do
    // if the control is a label
    if (Controls [I] is TLabel) and
      // and the label is connected to the current edit box
      (TLabel(Controls[I]).FocusControl = Sender) then
    // copy the text, leaving off the initial & character
    StatusBar1.SimpleText := 'Enter ' +
      Copy (TLabel(Controls[I]).Caption, 2, 1000);
end;
```

The second event handler of the form relates to the `OnExit` event of the first edit box. If the control is left empty, it refuses to release the input focus and sets it back before showing a message to the user. The methods also look for a given input value, automatically filling the second edit box and moving the focus directly to the third one:

```
procedure TFocusForm.EditFirstNameExit(Sender: TObject);
begin
  if EditFirstName.Text = '' then
  begin
    // don't let the user get out
    EditFirstName.SetFocus;
    MessageDlg ('First name is required', mtError, [mbOK], 0);
  end
  else if EditFirstName.Text = 'Admin' then
  begin
    // fill the second edit and jump to the third
    EditLastName.Text := 'Admin';
    EditPassword.SetFocus;
  end;
end;
```

TIP The CLX version of this example has exactly the same code and is available as the QInFocus program. The same happens for most of the other examples of this chapter. Notice that some of the examples are quite complex, but I rarely had to touch the code at all.

Working with Menus

Working with menus and menu items is generally quite simple. This section offers only some very brief notes and a few more advanced examples. The first thing to keep in mind about menu items is that they can serve different purposes:

Commands are menu items used to execute an action.

State-setters are menu items used to toggle an option on and off, to change the state of a particular element. These commands usually have a check mark on the left to indicate they are active. In Delphi 6 you can automatically obtain this behavior using the handy AutoCheck property.

Radio items have a round check mark and are grouped to represent alternative selections, like radio buttons. To obtain radio menu items, simply set the RadioItem property to True and set the GroupIndex property for the alternative menu items to the same value.

Dialog menu items cause a dialog box to appear and are usually indicated by an ellipsis (three dots) after the text.

As you enter new elements in the Menu Designer, Delphi creates a new component for each menu item and lists it in the Object Inspector (although nothing is added to the form). To name each component, Delphi uses the caption you enter and appends a number (so that *Open* becomes Open1). Because Delphi removes spaces and other special characters in the caption when it creates the name, and the menu item separators are set up using a hyphen as caption, these items would have an empty name. For this reason Delphi adds the letter *N* to the name, appending the number and generating items called N1, N2, and so on.

WARNING Do not use the Break property, which is used to lay out a pull-down menu on multiple columns. The mbMenuBarBreak value indicates that this item will be displayed in a second or subsequent line; the mbMenuBreak value that this item will be added to a second or subsequent column of the pull-down.

Accelerator Keys

Since Delphi 5, you don't need to enter the & character in the Caption of a menu item; it provides an automatic accelerator key if you omit one. Delphi's automatic accelerator-key system can also figure out if you have entered conflicting accelerator keys and fix them on-the-fly. This doesn't mean you should stop adding custom accelerator keys with the & character, because the automatic system simply uses the first available letter, and it doesn't follow the default standards. You might also find better mnemonic keys than those chosen by the automatic system.

This feature is controlled by the AutoHotkeys property, which is available in the main menu component and in each of the pull-down menus and menu items. In the main menu, this property defaults to maAutomatic, while in the pull-downs and menu items it defaults to maParent, so that the value you set for the main menu component will be used automatically by all the subitems, unless they have a specific value of maAutomatic or maManual.

The engine behind this system is the RethinkHotkeys method of the TMenuItem class, and the companion InternalRethinkHotkeys. There is also a RethinkLines method, which checks whether a pull-down has two consecutive separators or begins or ends with a separator. In all these cases, the separator is automatically removed.

One of the reasons Delphi includes this feature is the Integrated Translation Environment (ITE). When you need to translate the menu of an application, it is convenient if you don't have to deal with the accelerator keys, or at least if you don't have to worry about whether two items on the same menu conflict. Having a system that can automatically resolve similar problems is definitely an advantage. Another motivation was Delphi's IDE itself. With all the dynamically loaded packages that install menu items in the IDE main menu or in pop-up menus, and with different packages loaded in different versions of the product, it's next to impossible to get nonconflicting accelerator-key selections in each menu. That is why this mechanism isn't a wizard that does static analysis of your menus at design time; it was created to deal with the real problem of managing menus created dynamically at run time.

WARNING This feature is certainly very handy, but because it is active by default, it can break existing code. I had to modify two of this chapter's program examples, between the Delphi 4 and Delphi 5 edition of the book, just to avoid run-time errors caused by this change. The problem is that I use the caption in the code, and the extra *&* broke my code. The change was quite simple, though: All I had to do was to set the `AutoHotkeys` property of the main menu component to maManual.

Pop-Up Menus and the *OnContextPopup* Event

Besides the MainMenu component, you can use the similar PopupMenu component. This is typically displayed when the user right-clicks a component that uses the given pop-up menu as the value for its `PopupMenu` property.

However, besides connecting the pop-up menu to a component with the corresponding property, you can call its `Popup` method, which requires the position of the pop-up in screen coordinates. The proper values can be obtained by converting a local point to a screen point with the `ClientToScreen` method of the local component, in this code fragment a label:

```
procedure TForm1.Label3MouseDown(Sender: TObject;
  Button: TMouseButton; Shift: TShiftState; X, Y: Integer);
var
  ScreenPoint: TPoint;
begin
  // if some condition applies...
  if Button = mbRight then
  begin
    ScreenPoint := Label3.ClientToScreen (Point (X, Y));
    PopupMenu1.Popup (ScreenPoint.X, ScreenPoint.Y)
  end;
end;
```

An alternative approach is the use of the OnContextMenu event. This event, introduced in Delphi 5, fires when a user right-clicks a component—exactly what we've traced above with the test if Button = mbRight. The advantage is that the same event is also fired in response to a Shift+F10 key combination, as well as by any other user-input methods defined by Windows Accessibility options or hardware (including the shortcut-menu key of some Windows-compatible keyboards). We can use this event to fire a pop-up menu with little code:

```
procedure TFormPopup.Label1ContextPopup(Sender: TObject;
  MousePos: TPoint; var Handled: Boolean);
var
  ScreenPoint: TPoint;
begin
  // add dynamic items
  PopupMenu2.Items.Add (NewLine);
  PopupMenu2.Items.Add (NewItem (TimeToStr (Now), 0, False, True, nil, 0, ''));
  // show popup
  ScreenPoint := ClientToScreen (MousePos);
  PopupMenu2.Popup (ScreenPoint.X, ScreenPoint.Y);
  Handled := True;
  // remove dynamic items
  PopupMenu2.Items [4].Free;
  PopupMenu2.Items [3].Free;
end;
```

This example adds some dynamic behavior to the shortcut menu, adding a temporary item indicating when the pop-up menu is displayed. This is not particularly useful, but I've done it to highlight that if you need to display a plain pop-up menu, you can easily use the PopupMenu property of the control in question or one of its parent controls. Handling the OnContextMenu event makes sense only when you want to do some extra processing.

The Handled parameter is preinitialized to False, so that if you do nothing in the event handler, the normal pop-up menu processing will occur. If you do something in your event handler to replace the normal pop-up menu processing (such as popping up a dialog or a customized menu, as in this case), you should set Handled to True and the system will stop processing the message. Setting Handled to True should be fairly rare, as you'll generally handle the OnContextPopup to dynamically create or customize the pop-up menu, but then you can let the default handler actually show the menu.

The handler of an OnContextPopup event isn't limited to displaying a pop-up menu. It can do any other operation, such as directly display a dialog box. Here is an example of a right-click operation used to change the color of the control:

```
procedure TFormPopup.Label2ContextPopup(Sender: TObject;
  MousePos: TPoint; var Handled: Boolean);
begin
```

```
    ColorDialog1.Color := Label2.Color;
    if ColorDialog1.Execute then
      Label2.Color := ColorDialog1.Color;
    Handled := True;
  end;
```

All the code snippets of this section are available in the simple CustPop example for VCL and QCustPop for CLX, on the book's companion CD.

Creating Menu Items Dynamically

Besides defining the structure of a menu with the Menu Designer and modifying the status of the items using the Checked, Visible, and Caption properties, you can create an entire menu or portions of one at run time. This makes sense, for example, when you have many repetitive items, or when the menu items depend on some system configuration or user permissions.

The basic idea is that each object of the TMenuItem class—which Delphi uses for both menu items and pull-down menus—contains a list of menu items. Each of these items has the same structure, in a kind of recursive way. A pull-down menu has a list of submenus, and each submenu has a list of submenus, each with its own list of submenus, and so on. The properties you can use to explore the structure of an existing menu are Items, which contains the actual list of menu items, and Count, which contains the number of subitems. Adding new menu items or entire pull-down menus to an existing menu is fairly easy, particularly if you can write a single event handler for all of them.

This is demonstrated by the DynaMenu example (and its QDynaMenu counterpart), which also illustrates the use of menu check marks, radio items, and many other features of menus that aren't described in detail in the text. As soon as you start this program, it creates a new pull-down with menu items used to change the font size of a big label hosted by the form. Instead of creating a bunch of menu items with captions indicating sizes ranging from 8 to 48, you can let the program do this repetitive work for you.

The new pull-down menu should be inserted in the Items property of the MainMenu1 component. You can calculate the position by asking the MainMenu component for the previous pull-down menu:

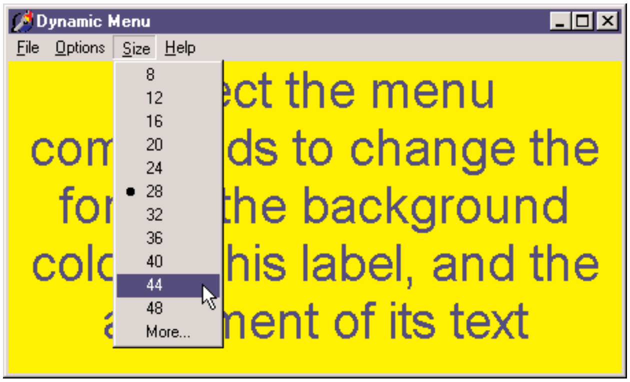
```
procedure TFormColorText.FormCreate(Sender: TObject);
var
  PullDown, Item: TMenuItem;
  Position, I: Integer;
begin
  // create the new pull-down menu
  PullDown := TMenuItem.Create (Self);
  PullDown.AutoHotkeys := maManual;
  PullDown.Caption := '&Size';
  PullDown.OnClick := SizeClick;
  // compute the position and add it
```

```
    Position := MainMenu1.Items.IndexOf (Options1);
    MainMenu1.Items.Insert (Position + 1, PullDown);
    // create menu items for various sizes
    I := 8;
    while I <= 48 do
    begin
      // create the new item
      Item := TMenuItem.Create (Self);
      Item.Caption := IntToStr (I);
      // make it a radio item
      Item.GroupIndex := 1;
      Item.RadioItem := True;
      // handle click and insert
      Item.OnClick := SizeItemClick;
      PullDown.Insert (PullDown.Count, Item);
      I := I + 4;
    end;
    // add extra item at the end
    Item := TMenuItem.Create (Self);
    Item.Caption := 'More...';
    // make it a radio item
    Item.GroupIndex := 1;
    Item.RadioItem := True;
    // handle it by showing the font selection dialog
    Item.OnClick := Font1Click;
    PullDown.Insert (PullDown.Count, Item);
  end;
```

As you can see in the preceding code, the menu items are created in a `while` loop, setting the radio item style and calling the `Insert` method with the number of items as a parameter to add each item at the end of the pull-down. At the end, the program adds one extra item, which is used to set a different size than those listed. The `OnClick` event of this last menu item is handled by the `Font1Click` method (also connected to a specific menu item), which displays the font selection dialog box. You can see the dynamic menu in Figure 6.9.

FIGURE 6.9:

The Size pull-down menu of the DynaMenu example is created at run time, along with all of its menu items.



ect the menu
com ds to change the
for the background
colc his label, and the
a ment of its text

WARNING Because the program uses the Caption of the new items dynamically, we should either disable the AutoHotkeys property of the main menu component, or disable this feature for the pull-down menu we are going to add (and thus automatically disable it for the menu items). This is what I've done in the code above by setting the AutoHotkeys property of the dynamically created pull-down component to maManual. An alternative approach is to let the menu display the automatic captions and then call the new StripHotkeys function before converting the caption to a number. There is also a new GetHotkey function, which returns the *active* character of the caption.

The handler for the OnClick event of these dynamically created menu items uses the caption of the Sender menu item to set the size of the font:

```
procedure TFormColorText.SizeItemClick(Sender: TObject);
begin
  with Sender as TMenuItem do
    Label1.Font.Size := StrToInt (Caption);
end;
```

This code doesn't set the proper radio-item mark next to the selected item, because the user can select a new size also by changing the font. The proper radio item is checked in the OnClick event handler of the entire pull-down menu, which is connected just after the pull-down is created and activated just before showing the pull-down. The code scans the items of the pull-down menu (the Sender object) and checks whether the caption matches the current Size of the font. If no match is found, the program checks the last menu item, to indicate that a different size is active:

```
procedure TFormColorText.SizeClick (Sender: TObject);
var
  I: Integer;
  Found: Boolean;
begin
  Found := False;
  with Sender as TMenuItem do
  begin
    // look for a match, skipping the last item
    for I := 0 to Count - 2 do
      if StrToInt (Items [I].Caption) = Label1.Font.Size then
      begin
        Items [I].Checked := True;
        Found := True;
        System.Break; // skip the rest of the loop
      end;
    if not Found then
      Items [Count - 1].Checked := True;
  end;
end;
```

When you want to create a menu or a menu item dynamically, you can use the corresponding components, as I've done in the DynaMenu and QDynaMenu examples. As an alternative, you can also use some global functions available in the Menus unit: `NewMenu`, `NewPopupMenu`, `NewSubMenu`, `NewItem`, and `NewLine`.

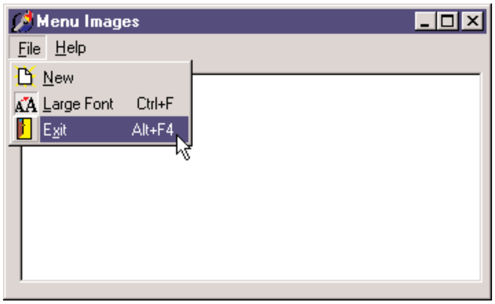
Using Menu Images

In Delphi it is very easy to improve a program's user interface by adding images to menu items. This is becoming common in Windows applications, and it's very nice that Borland has added all the required support, making the development of graphical menu items trivial.

All you have to do is add an image list control to the form, add a series of bitmaps to the image list, connect the image list to the menu using its `Images` property, and set the proper `ImageIndex` property for the menu items. You can see the effect of these simple operations in Figure 6.10. (You can also associate a bitmap with the menu item directly, using the `Bitmap` property.)

FIGURE 6.10:

The simple graphical menu of the MenuImg example



TIP The definition of images for menus is quite flexible, as it allows you to associate an image list with any specific pull-down menu (and even a specific menu item) using the `SubMenuImages` property. Having a specific and smaller image list for each pull-down menu, instead of one single huge image list for the entire menu, allows for more run-time customization of an application.

To create the image list, double-click the component, activating the corresponding editor (shown in Figure 6.11), then import existing bitmap or icon files. You can actually prepare a single large bitmap and let the image editor divide it according to the `Height` and `Width` properties of the ImageList component, which refer to the size of the individual bitmaps in the list.

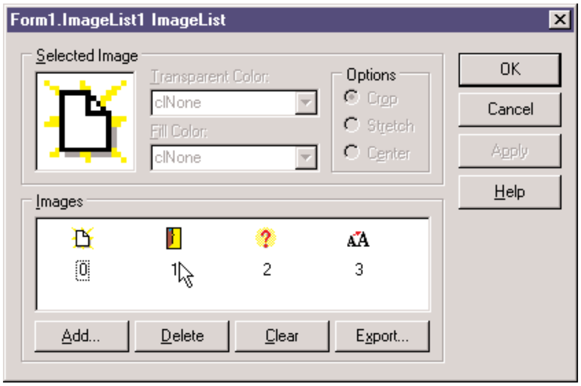


FIGURE 6.11:

The Image List editor, with the bitmaps of the MenuImg example

TIP

As an alternative, you can use the series of images that ship with Delphi and are stored by default in the `\Program Files\Common Files\Borland Shared\Images\Buttons` directory. Each bitmap contains both an "enabled" and a "disabled" image. As you import them, the Image List editor will ask you whether to split them in two, a suggestion you should accept. This operation adds to the image list a normal image and a disabled one, which is not generally used (as it can be built automatically when needed). For this reason I generally delete the disabled part of the bitmap from the image list.

The program's code is very simple. The only element I want to emphasize is that if you set the `Checked` property of a menu item with an image instead of displaying a check mark, the item paints its image as "sunken" or "recessed." You can see this in the Large Font menu of the MenuImg example in Figure 6.10. Here is the code for that menu item selection:

```
procedure TForm1.LargeFont1Click(Sender: TObject);
begin
  if Memo1.Font.Size = 8 then
    Memo1.Font.Size := 12
  else
    Memo1.Font.Size := 8;
  // changes the image style near the item
  LargeFont1.Checked := not LargeFont1.Checked;
end;
```

WARNING

To make the CLX version of the program, QMenuImg, display the bitmaps properly, I had to reimport them. Simply converting the Image List component data didn't work.

Customizing the System Menu

In some circumstances, it is interesting to add menu commands to the system menu itself, instead of (or besides) having a menu bar. This might be useful for secondary windows, toolboxes, windows requiring a large area on the screen, and "quick-and-dirty" applications. Adding a single menu item to the system menu is straightforward:

```
AppendMenu (GetSystemMenu (Handle, FALSE), MF_SEPARATOR, 0, '');
AppendMenu (GetSystemMenu (Handle, FALSE), MF_STRING, idSysAbout, '&About...');
```

This code fragment (extracted from the `OnCreate` event handler of the SysMenu example) adds a separator and a new item to the system menu item. The `GetSystemMenu` API function, which requires as a parameter the handle of the form, returns a handle to the system menu. The `AppendMenu` API function is a general-purpose function you can use to add menu items or complete pull-down menus to any menu (the menu bar, the system menu, or an existing pull-down menu). When adding a menu item, you have to specify its text and a numeric identifier. In the example I've defined this identifier as:

```
const idSysAbout = 100;
```

Adding a menu item to the system menu is easy, but how can we handle its selection? Selecting a normal menu generates the `wm_Command` Windows message. This is handled internally by Delphi, which activates the `OnClick` event of the corresponding menu item component. The selection of system menu commands, instead, generates a `wm_SysCommand` message, which is passed by Delphi to the default handler. Windows usually needs to do something in response to a system menu command.

We can intercept this command and check to see whether the command identifier (passed in the `CmdType` field of the `TWmSysCommand` parameter) of the menu item is idSysAbout. Since there isn't a corresponding event in Delphi, we have to define a new message-response method for the form class:

```
public
  procedure WMSysCommand (var Msg: TMessage);
    message wm_SysCommand;
```

The code of this procedure is not very complex. We just need to check whether the command is our own and call the default handler:

```
procedure TForm1.WMSysCommand (var Msg: TWMSysCommand);
begin
  if Msg.CmdType = idSysAbout then
    ShowMessage ('Mastering Delphi: SysMenu example');
  inherited;
end;
```

To build a more complex system menu, instead of adding and handling each menu item as we have just done, we can follow a different approach. Just add a MainMenu component to the form, create its structure (any structure will do), and write the proper event handlers. Then reset the value of the Menu property of the form, removing the menu bar.

Now we can add some code to the SysMenu example to add each of the items from the hidden menu to the system menu. This operation takes place when the button of the form is clicked. The corresponding handler uses generic code that doesn't depend on the structure of the menu we are appending to the system menu:

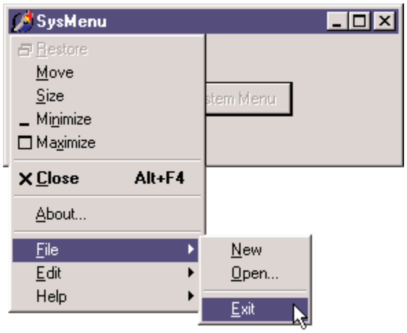
```
procedure TForm1.Button1Click(Sender: TObject);
var
  I: Integer;
begin
  // add a separator
  AppendMenu (GetSystemMenu (Handle, FALSE), MF_SEPARATOR, 0, '');
  // add the main menu to the system menu
  with MainMenu1 do
    for I := 0 to Items.Count - 1 do
      AppendMenu (GetSystemMenu (Self.Handle, FALSE),
        mf_Popup, Items[I].Handle, PChar (Items[I].Caption));
  // disable the button
  Button1.Enabled := False;
end;
```

TIP This code uses the expression Self.Handle to access the handle of the form. This is required because we are currently working on the MainMenu1 component, as specified by the with statement.

The menu flag used in this case, mf_Popup, indicates that we are adding a pull-down menu. In this function call, the fourth parameter is interpreted as the handle of the pull-down menu we are adding (in the previous example, we passed the identifier of the menu, instead). Since we are adding to the system menu items with submenus, the final structure of the system menu will have two levels, as you can see in Figure 6.12.

FIGURE 6.12:

The second-level system menu items of the SysMenu example are the result of copying a complete main menu to the system menu.



WARNING The Windows API uses the terms *pop-up menu* and *pull-down menu* interchangeably. This is really odd, because most of us use the terms to mean different things. Pop-up menus are shortcut menus, and pull-down menus are the secondary menus of the menu bar. Apparently, Microsoft uses the terms in this way because the two elements are implemented with the same kind of internal windows; the fact that they are two distinct user-interface elements is probably something that was later conceptually built over a single basic internal structure.

Once you have added the menu items to the system menu, you need to handle them. Of course, you can check for each menu item in the WMSysCommand method, or you can try building a smarter approach. Since in Delphi it is easier to write a handler for the OnClick event of each item, we can look for the item corresponding to the given identifier in the menu structure. Delphi helps us by providing a FindItem method.

When (and if) we have found a main menu item that corresponds to the item selected in the system menu, we can call its Click method (which invokes the OnClick handler). Here is the code I've added to the WMSysCommand method:

```
var
  Item: TMenuItem;
begin
  ...
  Item := MainMenu1.FindItem (Msg.CmdType, fkCommand);
  if Item <> nil then
    Item.Click;
```

In this code, the CmdType field of the message structure that is passed to the WMSysCommand procedure holds the command of the menu item being called.

You can also use a simple if or case statement to handle one of the system menu's predefined menu items that have special codes for this identifier, such as sc_Close, sc_Minimize, sc_Maximize, and so on. For more information, you can see the description of the wm_SysCommand message in the Windows API Help file.

This application works but has one glitch. If you click the right mouse button over the Taskbar icon representing the application, you get a plain system menu (actually different from the default one). The reason is that this system menu belongs to a different window, the window of the Application global object. I'll discuss the Application object, and update this example to make it work with the Taskbar button, in Chapter 9, "Working with Forms."

NOTE Because this program uses low-level Windows features (API calls and messages), it is not possible to compile it with CLX, so there is no Qt version of this example.

Owner-Draw Controls and Styles

Let's return briefly to menu graphics. Besides using an ImageList to add glyphs to the menu items, you can turn a menu into a completely graphical element, using the owner-draw technique. The same technique also works for other controls, such as list boxes. In Windows, the system is usually responsible for painting buttons, list boxes, edit boxes, menu items, and similar elements. Basically, these controls know how to paint themselves. As an alternative, however, the system allows the owner of these controls, generally a form, to paint them. This technique, available for buttons, list boxes, combo boxes, and menu items, is called *owner-draw*.

In VCL, the situation is slightly more complex. The components can take care of painting themselves in this case (as in the `TBitBtn` class for bitmap buttons) and possibly activate corresponding events. The system sends the request for painting to the owner (usually the form), and the form forwards the event back to the proper control, firing its event handlers.

In CLX, some of the controls, such as ListBoxes and ComboBoxes, surface events very similar to Windows owner-draw, but menus lack them. The native approach of Qt is to use styles to determine the graphical behavior of all of the controls in the system, of a specific application, or of a given control. I'll introduce styles shortly, later in this section.

NOTE Most of the Win32 common controls have support for the owner-draw technique, generally called *custom drawing*. You can fully customize the appearance of a ListView, TreeView, TabControl, PageControl, HeaderControl, StatusBar, and ToolBar. The ToolBar, ListView, and TreeView controls also support *advanced* custom drawing, a more fine-tuned drawing capability introduced by Microsoft in the latest versions of the Win32 common controls library. The downside to owner-draw is that when the Windows user interface style changes in the future (and it always does), your owner-draw controls that fit in perfectly with the current user interface styles will look outdated and out of place. Since you are creating a custom user interface, you'll need to keep it updated yourself. By contrast, if you use the standard output of the controls, your applications will automatically adapt to a new version of such controls.

Owner-Draw Menu Items

VCL makes the development of graphical menu items quite simple compared to the traditional approach of the Windows API: You set the `OwnerDraw` property of a menu item component to True and handle its `OnMeasureItem` and `OnDrawItem` events. This same feature is not available on CLX.

In the `OnMeasureItem` event, you can determine the size of the menu items. This event handler is activated once for each menu item when the pull-down menu is displayed and has two reference parameters you can set:

```
procedure ColorMeasureItem (Sender: TObject; ACanvas: TCanvas;
  var Width, Height: Integer);
```

The other parameter, ACanvas, is typically used to determine the height of the current font.

In the OnDrawItem event, you paint the actual image. This event handler is activated every time the item has to be repainted. This happens when Windows first displays the items and each time the status changes; for example, when the mouse moves over an item, it should become highlighted. In fact, to paint the menu items, we have to consider all the possibilities, including drawing the highlighted items with specific colors, drawing the check mark if required, and so on. Luckily enough, the Delphi event passes to the handler the Canvas where it should paint, the output rectangle, and the status of the item (selected or not):

```
procedure ColorDrawItem(Sender: TObject; ACanvas: TCanvas; ARect: TRect;
  Selected: Boolean);
```

In the ODMenu example, I'll handle the highlighted color, but skip other advanced aspects (such as the check marks). I've set the OwnerDraw property of the menu and written handlers for some of the menu items. To write a single handler for each event of the three color-related menu items, I've set their Tag property to the value of the actual color in the OnCreate event handler of the form. This makes the handler of the actual OnClick event of the items quite straightforward:

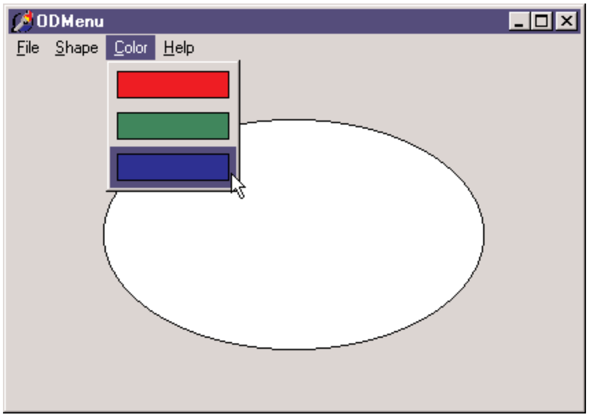
```
procedure TForm1.ColorClick(Sender: TObject);
begin
  ShapeDemo.Brush.Color := (Sender as TComponent).Tag
end;
```

The handler of the OnMeasureItem event doesn't depend on the actual items, but uses fixed values (different from the handler of the other pull-down). The most important portion of the code is in the handlers of the OnDrawItem events. For the color, we use the value of the tag to paint a rectangle of the given color, as you can see in Figure 6.13. Before doing this, however, we have to fill the background of the menu items (the rectangular area passed as a parameter) with the standard color for the menu (clMenu) or the selected menu items (clHighlight):

```
procedure TForm1.ColorDrawItem(Sender: TObject; ACanvas: TCanvas;
  ARect: TRect; Selected: Boolean);
begin
  // set the background color and draw it
  if Selected then
    ACanvas.Brush.Color := clHighlight
  else
    ACanvas.Brush.Color := clMenu;
  ACanvas.FillRect (ARect);
  // show the color
  ACanvas.Brush.Color := (Sender as TComponent).Tag;
  InflateRect (ARect, -5, -5);
  ACanvas.Rectangle (ARect.Left, ARect.Top, ARect.Right, ARect.Bottom);
end;
```

FIGURE 6.13:

The owner-draw menu of the ODMenu example



The three handlers for this event of the Shape pull-down menu items are all different, although they use similar code:

```
procedure TForm1.Ellipse1DrawItem(Sender: TObject; ACanvas: TCanvas;
  ARect: TRect; Selected: Boolean);
begin
  // set the background color and draw it
  if Selected then
    ACanvas.Brush.Color := clHighlight
  else
    ACanvas.Brush.Color := clMenu;
  ACanvas.FillRect (ARect);
  // draw the ellipse
  ACanvas.Brush.Color := clWhite;
  InflateRect (ARect, -5, -5);
  ACanvas.Ellipse (ARect.Left, ARect.Top, ARect.Right, ARect.Bottom);
end;
```

NOTE To accommodate the increasing number of states in the Windows 2000 user interface style, since version 5, Delphi has included the `OnAdvancedDrawItem` event for menus.

A ListBox of Colors

As we have just seen for menus, list boxes have an owner-draw capability, which means a program can paint the items of a list box. The same support is provided for combo boxes and is also available on CLX. To create an owner-draw list box, we set its `Style` property to lbOwnerDrawFixed or lbOwnerDrawVariable. The first value indicates that we are going to set the height of the items of the list box by specifying the `ItemHeight` property and that this will be the height of each and every item. The second owner-draw style indicates a list box with items of different heights; in this case, the component will trigger the `OnMeasureItem` event for each item, to ask the program for their heights.

In the ODList example (and its QODList version), I'll stick with the first, simpler, approach. The example stores color information along with the items of the list box and then draws the items in colors (instead of using a single color for the whole list).

The DFM or XFM file of every form, including this one, has a `TextHeight` attribute, which indicates the number of pixels required to display text. This is the value we should use for the `ItemHeight` property of the list box. An alternative solution is to compute this value at run time, so that if we later change the font at design time, we don't have to remember to set the height of the items accordingly.

NOTE I've just described `TextHeight` as an *attribute* of the form, not a property. And in fact it isn't a property but a local value of the form. If it is not a property, you might ask, how does Delphi save it in the `DFM` file? Well, the answer is that Delphi's streaming mechanism is based on properties plus special *property clones* created by the `DefineProperties` method.

Since `TextHeight` is *not* a property, although it is listed in the form description, we cannot access it directly. Studying the VCL source code, I found that this value is computed by calling a private method of the form: `GetTextHeight`. Since it is private, we cannot call this function. What we can do is duplicate its code (which is actually quite simple) in the `FormCreate` method of the form, after selecting the font of the list box:

```
Canvas.Font := ListBox1.Font;
ListBox1.ItemHeight := Canvas.TextHeight('0');
```

The next thing we have to do is add some items to the list box. Since this is a list box of colors, we want to add color names to the `Items` of the list box and the corresponding color values to the `Objects` data storage related to each item of the list. Instead of adding the two values separately, I've written a procedure to add new items to the list:

```
procedure TODListForm.AddColors (Colors: array of TColor);
var
  I: Integer;
begin
  for I := Low (Colors) to High (Colors) do
    ListBox1.Items.AddObject (ColorToString (Colors[I]), TObject(Colors[I]));
end;
```

This method uses an open-array parameter, an array of an undetermined number of elements of the same type. For each item passed as a parameter, we add the name of the color to the list, and we add its value to the related data, by calling the `AddObject` method. To obtain the string corresponding to the color, we call the Delphi `ColorToString` function. This returns a string containing either the corresponding color constant, if any, or the hexadecimal value of the color. The color data is added to the list box after casting its value to the TObject data type (a four-byte reference), as required by the AddObject method.

TIP Besides ColorToString, which converts a color value into the corresponding string with the identifier or the hexadecimal value, there is also a Delphi function to convert a properly formatted string into a color, StringToColor.

In the ODList example, this method is called in the OnCreate event handler of the form (after previously setting the height of the items):

```
AddColors ([clRed, clBlue, clYellow, clGreen, clFuchsia, clLime, clPurple,
  clGray, RGB (213, 23, 123), RGB (0, 0, 0), clAqua, clNavy, clOlive, clTeal]);
```

To compile the CLX version of this code, I've added to it the RGB function described earlier in the section "Colors." The code used to draw the items is not particularly complex. We simply retrieve the color associated with the item, set it as the color of the font, and then draw the text:

```
procedure TODListForm.ListBox1DrawItem(Control: TWinControl; Index: Integer;
  Rect: TRect; State: TOwnerDrawState);
begin
  with Control as TListbox do
  begin
    // erase
    Canvas.FillRect(Rect);
    // draw item
    Canvas.Font.Color := TColor (Items.Objects [Index]);
    Canvas.TextOut(Rect.Left, Rect.Top, Listbox1.Items[Index]);
   end;
end;
```

The system already sets the proper background color, so the selected item is displayed properly even without any extra code on our part. You can see an example of the output of this program at startup in Figure 6.14.

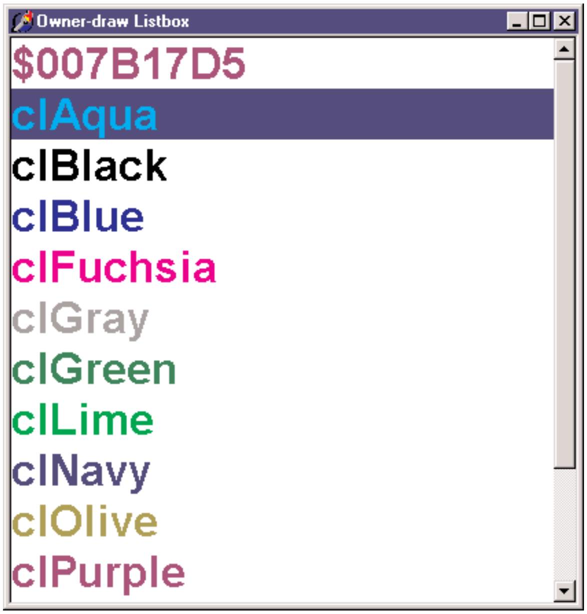
The example also allows you to add new items, by double-clicking the list box:

```
procedure TODListForm.ListBox1DblClick(Sender: TObject);
begin
  if ColorDialog1.Execute then
    AddColors ([ColorDialog1.Color]);
end;
```

If you try using this capability, you'll notice that some colors you add are turned into color names (one of the Delphi color constants) while others are converted into hexadecimal numbers.

FIGURE 6.14:

The output of the ODList example, with a colored owner-draw list box



CLX Styles

In Windows, the system has full control of the user interface of the controls, unless the program takes over using owner-draw or other advanced techniques. In Qt (and in Linux in general), the user chooses the user interface style of the controls. A system will generally offer a few basic styles, such as the Windows look-and-feel, the Motif one, and others. A user can add also install new styles in the system and make them available to applications.

NOTE The styles I'm discussing here refer to the user interface of the controls, not of the forms and their borders. This is generally configurable on Linux systems but is technically a separate element of the user interface.

Because this technique is embedded in Qt, it is also available on the Windows version of the library, and CLX makes it available to Delphi developers. The `Application` global object of CLX has a `Style` property, which can be used to set a custom style or a default one, indicated by the `DefaultStyle` subproperty. For example, you can select a Motif look-and-feel with this code:

```
Application.Style.DefaultStyle := dsMotif;
```

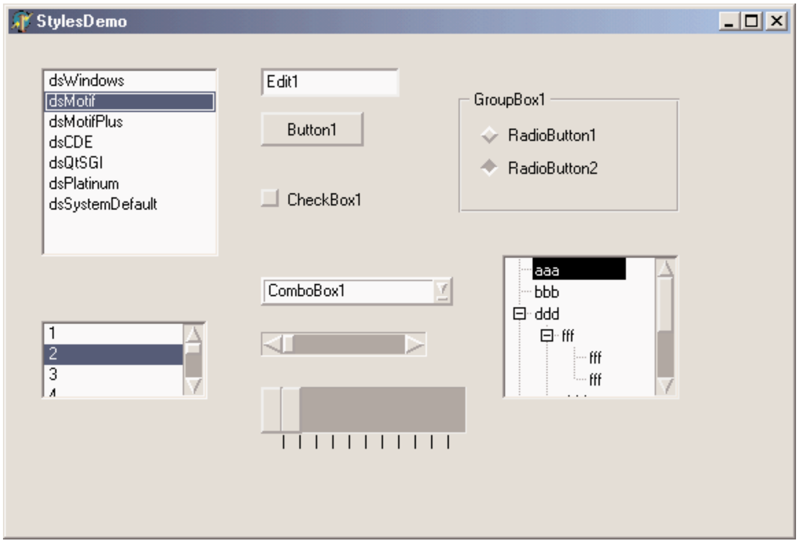
In the StylesDemo program, I've added, among various sample controls, a list box with the names of the default styles, as indicated in the TDefaultStyle enumeration, and this code for its OnDblClick event:

```
procedure TForm1.ListBox1DblClick(Sender: TObject);
begin
  Application.Style.DefaultStyle := TDefaultStyle (ListBox1.ItemIndex);
end;
```

The effect is that, by double-clicking the list box, you can change the current application style and immediately see its effect on screen, as demonstrated in Figure 6.15.

FIGURE 6.15:

The StylesDemo program, a Windows application currently with an unusual Motif layout



What's Next?

In this chapter, we have explored the foundations of the libraries available in Delphi for building user interfaces, the native-Windows VCL and the Qt-based CLX. We've discussed the TControl class, its properties, and its most important derived classes.

Then we've started to explore some of the basic components available in Delphi, looking at both libraries. These components correspond to the standard Windows controls and some of the common controls, and they are extremely common in applications. You've also seen how to create main menus and pop-up menus and how to add extra graphics to some of these controls.

The next step, however, is to explore in depth the elements of a complete user interface, discussing other common controls, multipage forms, action lists, and the new Delphi 6 Action Manager, to end up discussing technical details of forms. All of these topics will be covered in the next three chapters.

CHAPTER 7

Advanced VCL Controls

- ListView and TreeView controls
- Multipage forms
- Pages and tabs
- Form-splitting techniques
- Control anchors
- A ToolBar and a StatusBar for the RichEdit control
- Customizing hints

In the preceding chapter, I discussed the core concepts of the TControl class and its derived classes in the VCL and VisualCLX libraries. After that, I provided a sort of rapid tour of the key controls you can use to build a user interface, including editing components, lists, range selectors, and more.

This chapter provides more details on some of these components (such as the ListView and TreeView) and then discusses other controls used to define the overall design of a form, such as the PageControl, TabControl, and Splitter. The chapter also presents examples of splitting forms and resizing controls dynamically. These topics are not particularly complex, but it is worth examining their key concepts briefly.

After these components, I'll introduce toolbars and status bars, including the customization of hints and other slightly more advanced features. This will give us all the foundation material for the following chapter, which covers actions and the new action manager architecture of Delphi 6.

ListView and TreeView Controls

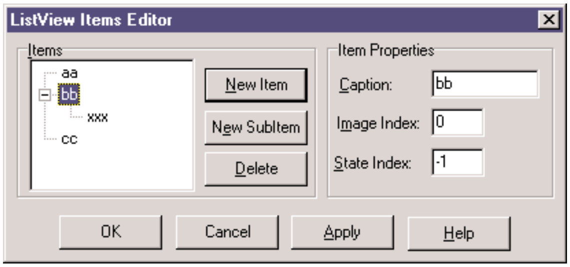
In Chapter 6, I introduced all the various visual controls you can use to display lists of values. The standard list box and combo box components are still very common, but they are often replaced by the more powerful ListView and TreeView controls. Again, these two controls are part of the Win32 common controls, stored in the ComCtl32.DLL library. Similar controls are available in Qt and VisualCLX.

A Graphical Reference List

When you use a ListView component, you can provide bitmaps both indicating the status of the element (for example, the selected item) and describing the contents of the item in a graphical way.

How do we connect the images to a list or tree? We need to refer to the ImageList component we've already used for the images of the menu. A ListView can actually have three image lists: one for the large icons (the LargeImages property), one for the small icons (the SmallImages property), and one used for the state of the items (the StateImages property). In the RefList example on the companion CD, I've set the first two properties using two different ImageList components.

Each of the items of the ListView has an ImageIndex, which refers to its image in the list. For this to work properly, the elements in the two image lists should follow the same order. When you have a fixed image list, you can add items to it using Delphi's ListView Item Editor, which is connected to the Items property. In this editor, you can define items and so-called subitems. The subitems are displayed only in the detailed view (when you set the vsReport value of the `ViewStyle` property) and are connected with the titles set in the `Columns` property.



Caption: bb
Image Index: 0
State Index: -1

In my RefList example (a simple list of references to books, magazines, CD-ROMs, and Web sites), the items are stored to a file, since users of the program can edit the contents of the list, which are automatically saved as the program exits. This way, edits made by the user become persistent. Saving and loading the contents of a ListView is not trivial, since the `TListItems` type doesn't have an automatic mechanism to save the data. As an alternative simple approach, I've copied the data to and from a string list, using a custom format. The string list can then be saved to a file and reloaded with a single command.

The file format is simple, as you can see in the following saving code. For each item of the list, the program saves the caption on one line, the image index on another line (prefixed by the `@` character), and the subitems on the following lines, indented with a tab character:

```
procedure TForm1.FormDestroy(Sender: TObject);
var
  I, J: Integer;
  List: TStringList;
begin
  // store the items
  List := TStringList.Create;
  try
    for I := 0 to ListView1.Items.Count - 1 do
    begin
      // save the caption
      List.Add (ListView1.Items[I].Caption);
      // save the index
      List.Add ('@' + IntToStr (ListView1.Items[I].ImageIndex));
      // save the subitems (indented)
      for J := 0 to ListView1.Items[I].SubItems.Count - 1 do
        List.Add (#9 + ListView1.Items[I].SubItems [J]);
    end;
    List.SaveToFile (ExtractFilePath (Application.ExeName) + 'Items.txt');
  finally
```

```
    List.Free;
  end;
end;
```

The items are then reloaded in the FormCreate method:

```
procedure TForm1.FormCreate(Sender: TObject);
var
  List: TStringList;
  NewItem: TListItem;
  I: Integer;
begin
  // stops warning message
  NewItem := nil;
  // load the items
  ListView1.Items.Clear;
  List := TStringList.Create;
  try
    List.LoadFromFile (
      ExtractFilePath (Application.ExeName) + 'Items.txt');
    for I := 0 to List.Count - 1 do
      if List [I][1] = #9 then
        NewItem.SubItems.Add (Trim (List [I]))
      else if List [I][1] = '@' then
        NewItem.ImageIndex := StrToIntDef (List [I][2], 0)
      else
      begin
        // a new item
        NewItem := ListView1.Items.Add;
        NewItem.Caption := List [I];
      end;
  finally
    List.Free;
  end;
end;
```

The program has a menu you can use to choose one of the different views supported by the ListView control, and to add check boxes to the items, as in a CheckListBox. You can see some of the various combinations of these styles in Figure 7.1.

FIGURE 7.1:

Different examples of the output of a ListView component of the RefList program, obtained by changing the `ViewStyle` property and adding the check boxes

Another important feature, which is common in the detailed or report view of the control, is to let a user sort the items on one of the columns. To accomplish this requires three operations. The first is to set the `SortType` property of the ListView to stBoth or stData. In this way, the ListView will operate the sorting not based on the captions, but by calling the `OnCompare` event for each two items it has to sort. Since we want to do the sorting on each of the columns of the detailed view, we also handle the `OnColumnClick` event (which takes place when the user clicks the column titles in the detailed view, but only if the `ShowColumnHeaders` property is set to True). Each time a column is clicked, the program saves the number of that column in the `nSortCol` private field of the form class:

```
procedure TForm1.ListView1ColumnClick(Sender: TObject;
  Column: TListColumn);
begin
  nSortCol := Column.Index;
  ListView1.AlphaSort;
end;
```

Then, in the third step, the sorting code uses either the caption or one of the subitems according to the current sort column:

```
procedure TForm1.ListView1Compare(Sender: TObject;
  Item1, Item2: TListItem;
  Data: Integer; var Compare: Integer);
begin
  if nSortCol = 0 then
    Compare := CompareStr (Item1.Caption, Item2.Caption)
  else
    Compare := CompareStr (Item1.SubItems [nSortCol - 1],
      Item2.SubItems [nSortCol - 1]);
end;
```

The final features I've added to the program relate to mouse operations. When the user left-clicks an item, the RefList program shows a description of the selected item. Right-clicking the selected item sets it in edit mode, and a user can change it (keep in mind that the changes will automatically be saved when the program terminates). Here is the code for both operations, in the OnMouseDown event handler of the ListView control:

```
procedure TForm1.ListView1MouseDown(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
var
  strDescr: string;
  I: Integer;
begin
  // if there is a selected item
  if ListView1.Selected <> nil then
    if Button = mbLeft then
    begin
      // create and show a description
      strDescr := ListView1.Columns [0].Caption + #9 +
        ListView1.Selected.Caption + #13;
      for I := 1 to ListView1.Selected.SubItems.Count do
        strDescr := strDescr + ListView1.Columns [I].Caption + #9 +
          ListView1.Selected.SubItems [I-1] + #13;
      ShowMessage (strDescr);
    end
    else if Button = mbRight then
      // edit the caption
      ListView1.Selected.EditCaption;
end;
```

Although it is not feature-complete, this example shows some of the potential of the ListView control. I've also activated the "hot-tracking" feature, which lets the list view highlight and underline the item under the mouse. The relevant properties of the ListView can be seen in its textual description:

```
object ListView1: TListView
  Align = alClient
  Columns = <
    item
      Caption = 'Reference'
      Width = 230
    end
    item
      Caption = 'Author'
      Width = 180
    end
    item
      Caption = 'Country'
      Width = 80
    end>
  Font.Height = -13
  Font.Name = 'MS Sans Serif'
  Font.Style = [fsBold]
  FullDrag = True
  HideSelection = False
  HotTrack = True
  HotTrackStyles = [htHandPoint, htUnderlineHot]
  SortType = stBoth
  ViewStyle = vsList
  OnColumnClick = ListView1ColumnClick
  OnCompare = ListView1Compare
  OnMouseDown = ListView1MouseDown
end
```

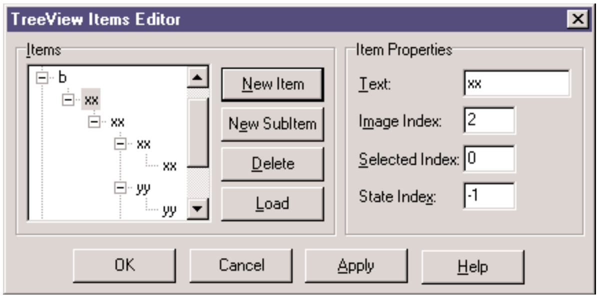
This program is actually quite interesting, and I'll further extend it in Chapter 9, adding a dialog box to it.

To build its CLX version, QRefList, I had to use only one of the image lists, and disable the small images and large images menus, as a ListView is limited to the list and report view styles. Large and small icons are available in a different control, called IconView.

A Tree of Data

Now that we've seen an example based on the ListView, we can examine the TreeView control. The TreeView has a user interface that is flexible and powerful (with support for editing and dragging elements). It is also standard, because it is the user interface of the Windows Explorer. There are properties and various ways to customize the bitmap of each line or of each type of line.

To define the structure of the nodes of the TreeView at design time, you can use the TreeView `Items` property editor. In this case, however, I've decided to load it in the TreeView data at startup, in a way similar to the last example.



Text: xx
Image Index: 2
Selected Index: 0
State Index: -1

The `Items` property of the TreeView component has many member functions you can use to alter the hierarchy of strings. For example, we can build a two-level tree with the following lines:

```
var
  Node: TTreeNode;
begin
  Node := TreeView1.Items.Add (nil, 'First level');
  TreeView1.Items.AddChild (Node, 'Second level');
```

Using these two methods (`Add` and `AddChild`), we can build a complex structure at run time. But how do we load the information? Again, you can use a StringList at run time, load a text file with the information, and parse it.

However, since the TreeView control has a `LoadFromFile` method, the DragTree and QDragTree examples use the following simpler code:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  TreeView1.LoadFromFile (ExtractFilePath (Application.ExeName) +
    'TreeText.txt');
end;
```

The `LoadFromFile` method loads the data in a string list and checks the level of each item by looking at the number of tab characters. (If you are curious, see the `TTreeStrings.GetBufStart` method, which you can find in the ComCtrls unit in the VCL source code included in Delphi.) By the way, the data I've prepared for the TreeView is the organizational chart of a multinational company.

Besides loading the data, the program saves it when it terminates, making the changes persistent. It also has a few menu items to customize the font of the TreeView control and change some other simple settings. The specific feature I've implemented in this example is support for dragging items and entire subtrees. I've set the DragMode property of the component to dmAutomatic and written the event handlers for the OnDragOver and OnDragDrop events.

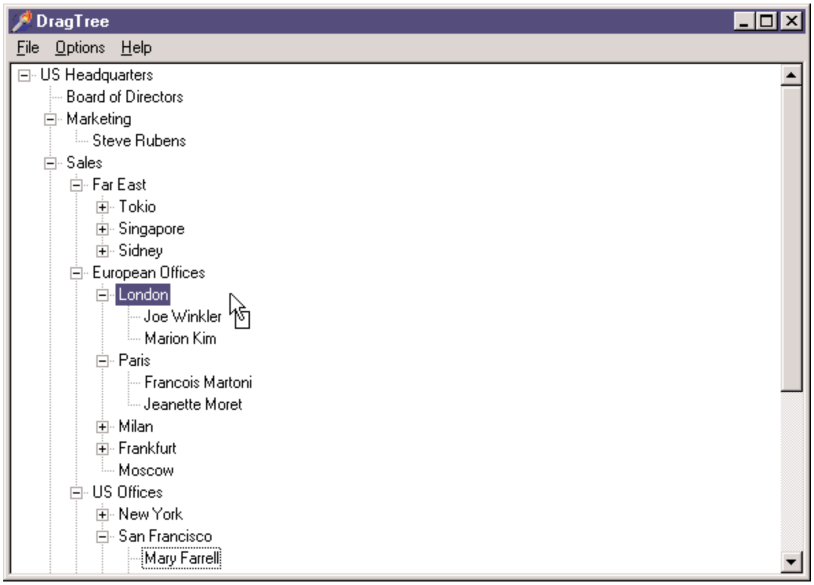
In the first of the two handlers, the program makes sure the user is not trying to drag an item over a child item (which would be moved along with the item, leading to an infinite recursion):

```
procedure TForm1.TreeView1DragOver(Sender, Source: TObject;
  X, Y: Integer; State: TDragState; var Accept: Boolean);
var
  TargetNode, SourceNode: TTreeNode;
begin
  TargetNode := TreeView1.GetNodeAt (X, Y);
  // accept dragging from itself
  if (Source = Sender) and (TargetNode <> nil) then
  begin
    Accept := True;
    // determines source and target
    SourceNode := TreeView1.Selected;
    // look up the target parent chain
    while (TargetNode.Parent <> nil) and (TargetNode <> SourceNode) do
      TargetNode := TargetNode.Parent;
    // if source is found
    if TargetNode = SourceNode then
      // do not allow dragging over a child
      Accept := False;
  end
  else
    Accept := False;
end;
```

The effect of this code is that (except for the particular case we need to disallow) a user can drag an item of the TreeView over another one, as shown in Figure 7.2. Writing the actual code for moving the items is simple, because the TreeView control provides the support for this operation, through the MoveTo method of the TTreeNode class.

FIGURE 7.2:

The DragTree example during a dragging operation



```
procedure TForm1.TreeView1DragDrop(Sender, Source: TObject; X, Y: Integer);
var
  TargetNode, SourceNode: TTreeNode;
begin
  TargetNode := TreeView1.GetNodeAt (X, Y);
  if TargetNode <> nil then
  begin
    SourceNode := TreeView1.Selected;
    SourceNode.MoveTo (TargetNode, naAddChildFirst);
    TargetNode.Expand (False);
    TreeView1.Selected := TargetNode;
  end;
end;
```

NOTE Among the demos shipping with Delphi is an interesting one showing a custom-draw TreeView control. The example is in the `CustomDraw` subdirectory.

Custom Tree Nodes

Delphi 6 adds a few new features to the TreeView controls, including multiple selection (see the `MultiSelect` and `MultiSelectStyle` properties and the `Selections` array), improved sorting, and several new events.

Another improved area relates to the creation of custom tree node items, which is useful to add extra custom information to each node and possibly create nodes of different classes. To support this technique, there is a new AddNode method for the TTreeItems class and a new specific event, OnCreateNodesClass. In the handler of this event, you return the class of the object to be created, which must inherit from TTreeNode.

As this is a very common technique, I've built an example to discuss it in detail. The CustomNodes example on the CD doesn't focus on a real-world case, but it shows a rather complex situation, in which there are two different custom tree node classes, derived one from the other. The base class adds an ExtraCode property, mapped to virtual methods, and the subclass overrides one of these methods. For the base class the GetExtraCode function simply returns the value, while for the derived class the value is multiplied to the parent node value. Here are the classes and this second method:

```
type
  TMyNode = class (TTreeNode)
  private
    FExtraCode: Integer;
  protected
    procedure SetExtraCode(const Value: Integer); virtual;
    function GetExtraCode: Integer; virtual;
  public
    property ExtraCode: Integer read GetExtraCode write SetExtraCode;
  end;

  TMySubNode = class (TMyNode)
  protected
    function GetExtraCode: Integer; override;
  end;

function TMySubNode.GetExtraCode: Integer;
begin
  Result := fExtraCode * (Parent as TMyNode).ExtraCode;
end;
```

With these custom tree node classes available, the program creates a tree of items, using the first type for the first-level nodes and the second class for the other nodes. As we have only one OnCreateNodeClass event handler, it uses the class reference stored in a private field of the form (CurrentNodeClass of type TTreeNodeClass):

```
procedure TForm1.TreeView1CreateNodeClass(Sender: TCustomTreeView;
  var NodeClass: TTreeNodeClass);
begin
  NodeClass := CurrentNodeClass;
end;
```

The program sets this class reference before creating nodes of each type—for example, with code like

```
var
  MyNode: TMyNode;
begin
  CurrentNodeClass := TMyNode;
  MyNode := TreeView1.Items.AddChild (nil, 'item' + IntToStr (nValue))
    as TMyNode;
  MyNode.ExtraCode := nValue;
```

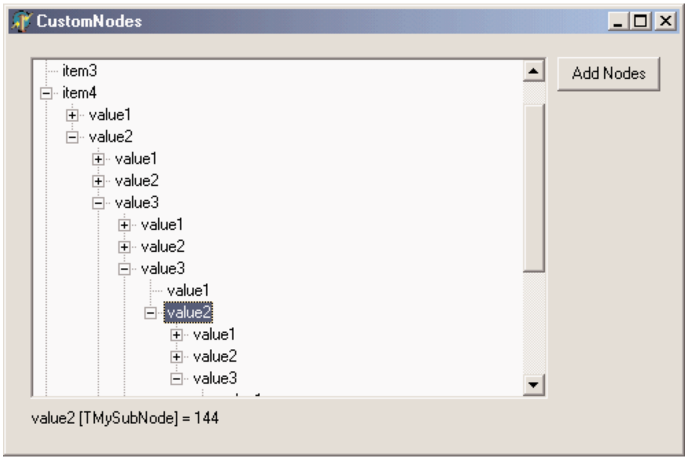
Once the entire tree has been created, as the user selects an item, you can cast its type to TMyNode and access to the extra properties (but also methods and data):

```
procedure TForm1.TreeView1Click(Sender: TObject);
var
  MyNode: TMyNode;
begin
  MyNode := TreeView1.Selected as TMyNode;
  Label1.Caption := MyNode.Text + ' [' + MyNode.ClassName + '] = ' +
    IntToStr (MyNode.ExtraCode);
end;
```

This is the code used by the CustomNodes example to display the description of the selected node into a label, as you can see in Figure 7.3. Note that when you select an item down into the tree, its value is multiplied for that of each of the parent nodes. Though there are certainly easier ways to obtain this effect, having a tree view with item objects created from different classes of a hierarchy provides an object-oriented structure upon which you can base some very complex code.

FIGURE 7.3:

The CustomNodes example has a tree view with node objects based on different custom classes, thanks to the new OnCreateNodesClass event.



value2 [TMySubNode] = 144

Multiple-Page Forms

When you have a lot of information and controls to display in a dialog box or a form, you can use multiple pages. The metaphor is that of a notebook: Using tabs, a user can select one of the possible pages.

There are two controls you can use to build a multiple-page application in Delphi:

- You can use the PageControl component, which has tabs on one of the sides and multiple pages (similar to panels) covering the rest of its surface. As there is one page per tab, you can simply place components on each page to obtain the proper effect both at design time and at run time.
- You can use the TabControl, which has only the tab portion but offers no pages to host the information. In this case, you'll want to use one or more components to mimic the *page change* operation.

A third related class, the `TabSheet`, represents a single page of the PageControl. This is not a stand-alone component and is not available on the Component Palette. You create a `TabSheet` at design time by using the local menu of the PageControl or at run time by using methods of the same control.

NOTE Delphi still includes the Notebook, TabSet, and TabbedNotebook components introduced in early versions. Use these components only if you need to create a 16-bit version of an application. For any other purpose, the PageControl and TabControl components, which encapsulate Win32 common controls, provide a more modern user interface. Actually, in 32-bit versions of Delphi, the TabbedNotebook component was reimplemented using the Win32 PageControl internally, to reduce the code size and update the look.

PageControls and TabSheets

As usual, instead of duplicating the Help system's list of properties and methods of the PageControl component, I've built an example that stretches its capabilities and allows you to change its behavior at run time. The example, called Pages, has a PageControl with three pages. The structure of the PageControl and of the other key components is listed here:

```
object Form1: TForm1
  BorderIcons = [biSystemMenu, biMinimize]
  BorderStyle = bsSingle
  Caption = 'Pages Test'
  OnCreate = FormCreate
  object PageControl1: TPageControl
    ActivePage = TabSheet1
    Align = alClient
```

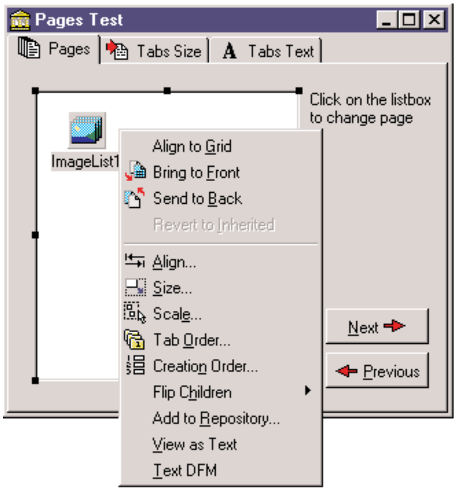
```
      HotTrack = True
      Images = ImageList1
      MultiLine = True
      object TabSheet1: TTabSheet
        Caption = 'Pages'
        object Label3: TLabel
        object ListBox1: TListBox
      end
      object TabSheet2: TTabSheet
        Caption = 'Tabs Size'
        ImageIndex = 1
        object Label1: TLabel
        // other controls
      end
      object TabSheet3: TTabSheet
        Caption = 'Tabs Text'
        ImageIndex = 2
        object Memo1: TMemo
          Anchors = [akLeft, akTop, akRight, akBottom]
          OnChange = Memo1Change
        end
        object BitBtnChange: TBitBtn
          Anchors = [akTop, akRight]
          Caption = '&Change'
        end
      end
    end
    object BitBtnPrevious: TBitBtn
      Anchors = [akRight, akBottom]
      Caption = '&Previous'
      OnClick = BitBtnPreviousClick
    end
    object BitBtnNext: TBitBtn
      Anchors = [akRight, akBottom]
      Caption = '&Next'
      OnClick = BitBtnNextClick
    end
    object ImageList1: TImageList
      Bitmap = {...}
    end
  end
```

Notice that the tabs are connected to the bitmaps provided by an ImageList control and that some controls use the `Anchors` property to remain at a fixed distance from the right or bottom borders of the form. Even if the form doesn't support resizing (this would have been far too complex to set up with so many controls), the positions can change when the tabs are displayed on multiple lines (simply increase the length of the captions) or on the left side of the form.

Each TabSheet object has its own `Caption`, which is displayed as the sheet's tab. At design time, you can use the local menu to create new pages and to move between pages. You can see the local menu of the PageControl component in Figure 7.4, together with the first page. This page holds a list box and a small caption, and it shares two buttons with the other pages.

FIGURE 7.4:

The first sheet of the PageControl of the Pages example, with its local menu



If you place a component on a page, it is available only in that page. How can you have the same component (in this case, two bitmap buttons) in each of the pages, without duplicating it? Simply place the component on the form, outside of the PageControl (or before aligning it to the client area) and then move it in front of the pages, calling the Bring To Front command of the form's local menu. The two buttons I've placed in each page can be used to move back and forth between the pages and are an alternative to using the tabs. Here is the code associated with one of them:

```
procedure TForm1.BitBtnNextClick(Sender: TObject);
begin
  PageControl1.SelectNextPage (True);
end;
```

The other button calls the same procedure, passing False as its parameter to select the previous page. Notice that there is no need to check whether we are on the first or last page, because the `SelectNextPage` method considers the last page to be the one before the first and will move you directly between those two pages.

Now we can focus on the first page again. It has a list box, which at run time will hold the names of the tabs. If a user clicks an item of this list box, the current page changes. This is the third method available to change pages (after the tabs and the Next and Previous buttons). The list box is filled in the `FormCreate` method, which is associated with the `OnCreate` event of the form and copies the caption of each page (the `Page` property stores a list of TabSheet objects):

```
for I := 0 to PageControl1.PageCount - 1 do
  ListBox1.Items.Add (PageControl1.Pages.Caption);
```

When you click a list item, you can select the corresponding page:

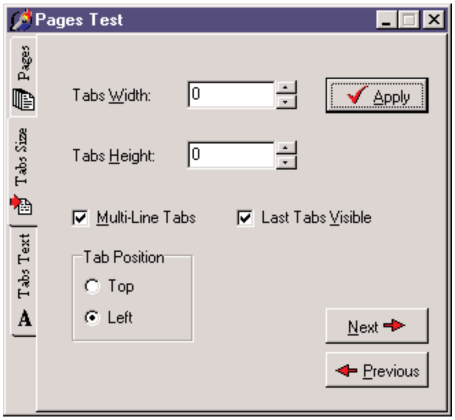
```
procedure TForm1.ListBox1Click(Sender: TObject);
begin
  PageControl1.ActivePage := PageControl1.Pages [ListBox1.ItemIndex];
end;
```

The second page hosts two edit boxes (connected with two UpDown components), two check boxes, and two radio buttons, as you can see in Figure 7.5. The user can input a number (or choose it by clicking the up or down buttons with the mouse or pressing the Up or Down arrow key while the corresponding edit box has the focus), check the boxes and the radio buttons, and then click the Apply button to make the changes:

```
procedure TForm1.BitBtnApplyClick(Sender: TObject);
begin
  // set tab width, height, and lines
  PageControl1.TabWidth := StrToInt (EditWidth.Text);
  PageControl1.TabHeight := StrToInt (EditHeight.Text);
  PageControl1.MultiLine := CheckBoxMultiLine.Checked;
  // show or hide the last tab
  TabSheet3.TabVisible := CheckBoxVisible.Checked;
  // set the tab position
  if RadioButton1.Checked then
    PageControl1.TabPosition := tpTop
  else
    PageControl1.TabPosition := tpLeft;
end;
```

FIGURE 7.5:

The second page of the example can be used to size and position the tabs. Here you can see the tabs on the left of the page control.



Pages Test

Tabs Width: 0

Tabs Height: 0

☑ Multi-Line Tabs ☑ Last Tabs Visible

Tab Position
○ Top
● Left

With this code, we can change the width and height of each tab (remember that 0 means the size is computed automatically from the space taken by each string). We can choose to have either multiple lines of tabs or two small arrows to scroll the tab area, and move them to the left side. The control also allows tabs to be placed on the bottom or on the right, but our program doesn't allow that, because it would make the placement of the other controls quite complex.

You can also hide the last tab on the PageControl, which corresponds to the TabSheet3 component. If you hide one of the tabs by setting its TabVisible property to False, you cannot reach that tab by clicking on the Next and Previous buttons, which are based on the SelectNextPage method. Instead, you should use the FindNextPage function, as shown below in this new version of the Next button's OnClick event handler:

```
procedure TForm1.BitBtnNextClick(Sender: TObject);
begin
  PageControl1.ActivePage := PageControl1.FindNextPage (
    PageControl1.ActivePage, True, False);
end;
```

The last page has a memo component, again with the names of the pages (added in the FormCreate method). You can edit the names of the pages and click the Change button to change the text of the tabs, but only if the number of strings matches the number of tabs:

```
procedure TForm1.BitBtnChangeClick(Sender: TObject);
var
  I: Integer;
begin
  if Memo1.Lines.Count <> PageControl1.PageCount then
    MessageDlg ('One line per tab, please', mtError, [mbOK], 0)
  else
    for I := 0 to PageControl1.PageCount -1 do
      PageControl1.Pages [I].Caption := Memo1.Lines [I];
  BitBtnChange.Enabled := False;
end;
```

Finally the last button, Add Page, allows you to add a new tab sheet to the page control, although the program doesn't add any components to it. The (empty) tab sheet object is created using the page control as its owner, but it won't work unless you also set the PageControl property. Before doing this, however, you should make the new tab sheet visible. Here is the code:

```
procedure TForm1.BitBtnAddClick(Sender: TObject);
var
  strCaption: string;
  NewTabSheet: TTabSheet;
begin
  strCaption := 'New Tab';
  if InputQuery ('New Tab', 'Tab Caption', strCaption) then
  begin
    // add a new empty page to the control
    NewTabSheet := TTabSheet.Create (PageControl1);
    NewTabSheet.Visible := True;
    NewTabSheet.Caption := strCaption;
    NewTabSheet.PageControl := PageControl1;
    PageControl1.ActivePage := NewTabSheet;
    // add it to both lists
    Memo1.Lines.Add (strCaption);
    ListBox1.Items.Add (strCaption);
  end;
end;
```

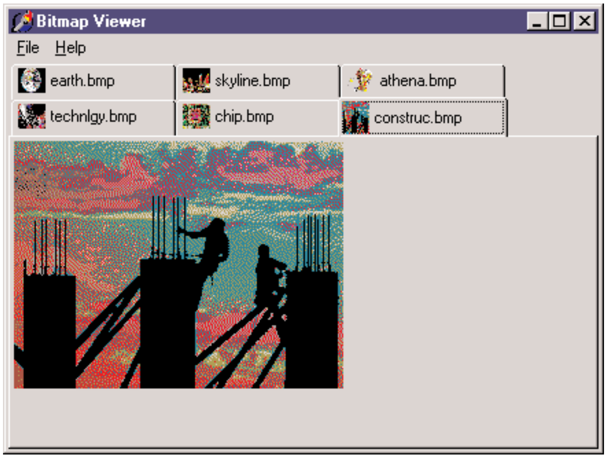
TIP Whenever you write a form based on a PageControl, remember that the first page displayed at run time is the page you were in before the code was compiled. This means that if you are working on the third page and then compile and run the program, it will start with that page. A common way to solve this problem is to add a line of code in the `FormCreate` method to set the PageControl or notebook to the first page. This way, the current page at design time doesn't determine the initial page at run time.

An Image Viewer with Owner-Draw Tabs

The use of the TabControl and of a dynamic approach, as described in the last example, can also be applied in more general (and simpler) cases. Every time you need multiple pages that all have the same type of content, instead of replicating the controls in each page, you can use a TabControl and change its contents when a new tab is selected.

This is what I'll do in the multiple-page bitmap viewer example, called BmpViewer. The image that appears in the TabControl of this form, aligned to the whole client area, depends on the selection in the tab above it (as you can see in Figure 7.6).

FIGURE 7.6: The interface of the bitmap viewer in the BmpViewer example. Notice the owner-draw tabs.



At the beginning, the TabControl is empty. After selecting File ➢ Open, the user can choose various files in the File Open dialog box, and the array of strings with the names of the files (the `Files` property of the `OpenDialog1` component) is added to the tabs (the `Tabs` property of `TabControl1`):

```
procedure TFormBmpViewer.Open1Click(Sender: TObject);
begin
  if OpenDialog1.Execute then
  begin
    TabControl1.Tabs.AddStrings (OpenDialog1.Files);
    TabControl1.TabIndex := 0;
    TabControl1Change (TabControl1);
  end;
end;
```

After we display the new tabs, we have to update the image so that it matches the first tab. To accomplish this, the program calls the method connected with the `OnChange` event of the TabControl, which loads the file corresponding to the current tab in the image component:

```
procedure TFormBmpViewer.TabControl1Change(Sender: TObject);
begin
  Image1.Picture.LoadFromFile (TabControl1.Tabs [TabControl1.TabIndex]);
end;
```

This example works, unless you select a file that doesn't contain a bitmap. The program will warn the user with a standard exception, ignore the file, and continue its execution.

The program also allows pasting the bitmap on the clipboard (without actually copying it, though) and copying the current bitmap to it. Clipboard support is available in Delphi via the global `Clipboard` object defined in the ClipBrd unit. For copying or pasting bitmaps, you can use the `Assign` method of the `TClipboard` and `TBitmap` classes. When you select the Edit ➢ Paste command of the example, a new tab named Clipboard is added to the tab set (unless it is already present). Then the number of the new tab is used to change the active tab:

```
procedure TFormBmpViewer.Paste1Click(Sender: TObject);
var
  TabNum: Integer;
begin
  // try to locate the page
  TabNum := TabControl1.Tabs.IndexOf ('Clipboard');
  if TabNum < 0 then
    // create a new page for the Clipboard
    TabNum := TabControl1.Tabs.Add ('Clipboard');
  // go to the Clipboard page and force repaint
  TabControl1.TabIndex := TabNum;
  TabControl1Change (Self);
end;
```

The Edit ➢ Copy operation, instead, is as simple as copying the bitmap currently in the image control:

```
Clipboard.Assign (Image1.Picture.Graphic);
```

To account for the possible presence of the Clipboard tab, the code of the TabControl1Change method becomes:

```
procedure TFormBmpViewer.TabControl1Change(Sender: TObject);
var
  TabText: string;
begin
  Image1.Visible := True;
  TabText := TabControl1.Tabs [TabControl1.TabIndex];
  if TabText <> 'Clipboard' then
    // load the file indicated in the tab
    Image1.Picture.LoadFromFile (TabText)
  else
    {if the tab is 'Clipboard' and a bitmap
    is available in the clipboard}
    if Clipboard.HasFormat (cf_Bitmap) then
      Image1.Picture.Assign (Clipboard)
    else
    begin
      // else remove the clipboard tab
      TabControl1.Tabs.Delete (TabControl1.TabIndex);
      if TabControl1.Tabs.Count = 0 then
        Image1.Visible := False;
    end;
```

This program pastes the bitmap from the Clipboard each time you change the tab. The program stores only one image at a time, and it has no way to store the Clipboard bitmap. However, if the Clipboard content changes and the bitmap format is no longer available, the Clipboard tab is automatically deleted (as you can see in the listing above). If no more tabs are left, the Image component is hidden.

An image can also be removed using either of two menu commands: Cut or Delete. Cut removes the tab after making a copy of the bitmap to the Clipboard. In practice, the Cut1Click method does nothing besides calling the Copy1Click and Delete1Click methods. The Copy1Click method is responsible for copying the current image to the Clipboard, Delete1Click simply removes the current tab. Here is their code:

```
procedure TFormBmpViewer.Copy1Click(Sender: TObject);
begin
  Clipboard.Assign (Image1.Picture.Graphic);
end;
```

```
procedure TFormBmpViewer.Delete1Click(Sender: TObject);
begin
  with TabControl1 do
  begin
    if TabIndex >= 0 then
      Tabs.Delete (TabIndex);
    if Tabs.Count = 0 then
      Image1.Visible := False;
  end;
end;
```

One of the special features of the example is that the TabControl has the OwnerDraw property set to True. This means that the control won't paint the tabs (which will be empty at design time) but will have the application do this, by calling the OnDrawTab event. In its code, the program displays the text vertically centered, using the DrawText API function. The text displayed is not the entire file path but only the filename. Then, if the text is not *None*, the program reads the bitmap the tab refers to and paints a small version of it in the tab itself. To accomplish this, the program uses the TabBmp object, which is of type TBitmap and is created and destroyed along with the form. The program also uses the BmpSide constant to position the bitmap and the text properly:

```
procedure TFormBmpViewer.TabControl1DrawTab(Control: TCustomTabControl;
  TabIndex: Integer; const Rect: TRect; Active: Boolean);
var
 TabText: string;
 OutRect: TRect;
begin
  TabText := TabControl1.Tabs [TabIndex];
  OutRect := Rect;
  InflateRect (OutRect, -3, -3);
  OutRect.Left := OutRect.Left + BmpSide + 3;
  DrawText (Control.Canvas.Handle, PChar (ExtractFileName (TabText)),
    Length (ExtractFileName (TabText)), OutRect,
    dt_Left or dt_SingleLine or dt_VCenter);
  if TabText = 'Clipboard' then
    if Clipboard.HasFormat (cf_Bitmap) then
      TabBmp.Assign (Clipboard)
    else
      TabBmp.FreeImage
  else
    TabBmp.LoadFromFile (TabText);
  OutRect.Left := OutRect.Left - BmpSide - 3;
  OutRect.Right := OutRect.Left + BmpSide;
  Control.Canvas.StretchDraw (OutRect, TabBmp);
end;
```

The program has also support for printing the current bitmap, after showing a page preview form in which the user can select the proper scaling. This extra portion of the program I built for earlier editions of the book is not discussed in detail, but I've left the code in the program so that you can have a look at its code anyway.

The User Interface of a Wizard

Just as you can use a TabControl without pages, you can also take the opposite approach and use a PageControl without tabs. What I want to focus on now is the development of the user interface of a wizard. In a wizard, you are directing the user through a sequence of steps, one screen at a time, and at each step you typically want to offer the choice of proceeding to the next step or going back to correct input entered in a previous step. So instead of tabs that can be selected in any order, wizards typically offer Next and Back buttons to navigate. This won't be a complex example; its purpose is just to give you a few guidelines. The example is called WizardUI.

The starting point is to create a series of pages in a PageControl and set the `TabVisible` property of each TabSheet to False (while keeping the `Visible` property set to True). Unlike past versions, since Delphi 5 you can also hide the tabs at design time. In this case, you'll need to use the shortcut menu of the page control or the combo box of the Object Inspector to move to another page, instead of the tabs. But why don't you want to see the tabs at design time? You can place controls on the pages and then place extra controls in front of the pages (as I've done in the example), without seeing their relative positions change at run time. You might also want to remove the useless captions of the tabs, which take up space in memory and in the resources of the application.

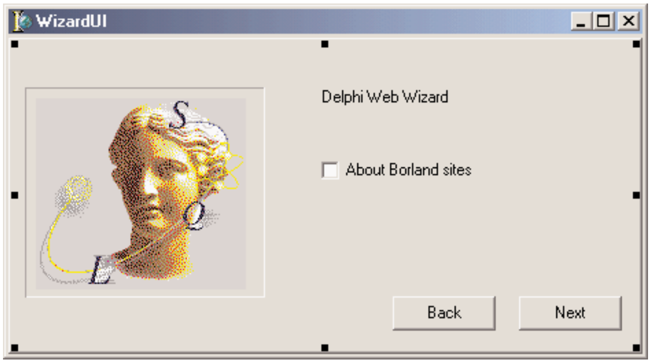
In the first page, I've placed on one side an image and a bevel control and on the other side some text, a check box, and two buttons. Actually, the Next button is inside the page, while the Back button is over it (and is shared by all the pages). You can see this first page at design time in Figure 7.7. The following pages look similar, with a label, check boxes, and buttons on the right side and nothing on the left.

When you click the Next button on the first page, the program looks at the status of the check box and decides which page is the following one. I could have written the code like this:

```
procedure TForm1.btnNext1Click(Sender: TObject);
begin
  BtnBack.Enabled := True;
  if CheckInprise.Checked then
    PageControl1.ActivePage := TabSheet2
  else
    PageControl1.ActivePage := TabSheet3;
  // move image and bevel
  Bevel1.Parent := PageControl1.ActivePage;
  Image1.Parent := PageControl1.ActivePage;
end;
```

FIGURE 7.7:

The first page of the WizardUI example at design time



After enabling the common Back button, the program changes the active page and finally moves the graphical portion to the new page. Because this code has to be repeated for each button, I've placed it in a method after adding a couple of extra features. This is the actual code:

```
procedure TForm1.btnNext1Click(Sender: TObject);
begin
  if CheckInprise.Checked then
    MoveTo (TabSheet2)
  else
    MoveTo (TabSheet3);
end;

procedure TForm1.MoveTo(TabSheet: TTabSheet);
begin
  // add the last page to the list
  BackPages.Add (PageControl1.ActivePage);
  BtnBack.Enabled := True;
  // change page
  PageControl1.ActivePage := TabSheet;
  // move image and bevel
  Bevel1.Parent := PageControl1.ActivePage;
  Image1.Parent := PageControl1.ActivePage;
end;
```

Besides the code I've already explained, the MoveTo method adds the last page (the one before the page change) to a list of visited pages, which behaves like a stack. In fact, the BackPages object of the TList class is created as the program starts and the last page is always added to the end. When the user clicks the Back button, which is not dependent on the page, the program extracts the last page from the list, deletes its entry, and moves to that page:

```
procedure TForm1.btnBackClick(Sender: TObject);
var
```

```
    LastPage: TTabSheet;
  begin
    // get the last page and jump to it
    LastPage := TTabSheet (BackPages [BackPages.Count - 1]);
    PageControl1.ActivePage := LastPage;
    // delete the last page from the list
    BackPages.Delete (BackPages.Count - 1);
    // eventually disable the back button
    BtnBack.Enabled := not (BackPages.Count = 0);
    // move image and bevel
    Bevel1.Parent := PageControl1.ActivePage;
    Image1.Parent := PageControl1.ActivePage;
  end;
```

With this code, the user can move back several pages until the list is empty, at which point we disable the Back button. The complication we need to deal with is that while moving from a particular page, we know which pages are its "next" and "previous," but we don't know which page we came from, because there can be multiple paths to reach a page. Only by keeping track of the movements with a list can we reliably go back.

The rest of the code of the program, which simply shows some Web site addresses, is very simple. The good news is that you can reuse the navigational structure of this example in your own programs and modify only the graphical portion and the content of the pages. Actually, as most of the labels of the programs show HTTP addresses, a user can click those labels to open the default browser showing that page. This is accomplished by extracting the HTTP address from the label and calling the ShellExecute function.

```
  procedure TForm1.LabelLinkClick(Sender: TObject);
  var
    Caption, StrUrl: string;
  begin
    Caption := (Sender as TLabel).Caption;
    StrUrl := Copy (Caption, Pos ('http://', Caption), 1000);
    ShellExecute (Handle, 'open', PChar (StrUrl), '', '', sw_Show);
  end;
```

The method above is hooked to the OnClick event of many labels of the form, which have been turned into *links* by setting its Cursor to a hand. This is one of the labels:

```
  object Label2: TLabel
    Cursor = crHandPoint
    Caption = 'Main site: http://www.borland.com'
    OnClick = LabelLinkClick
  end
```

Form-Splitting Techniques

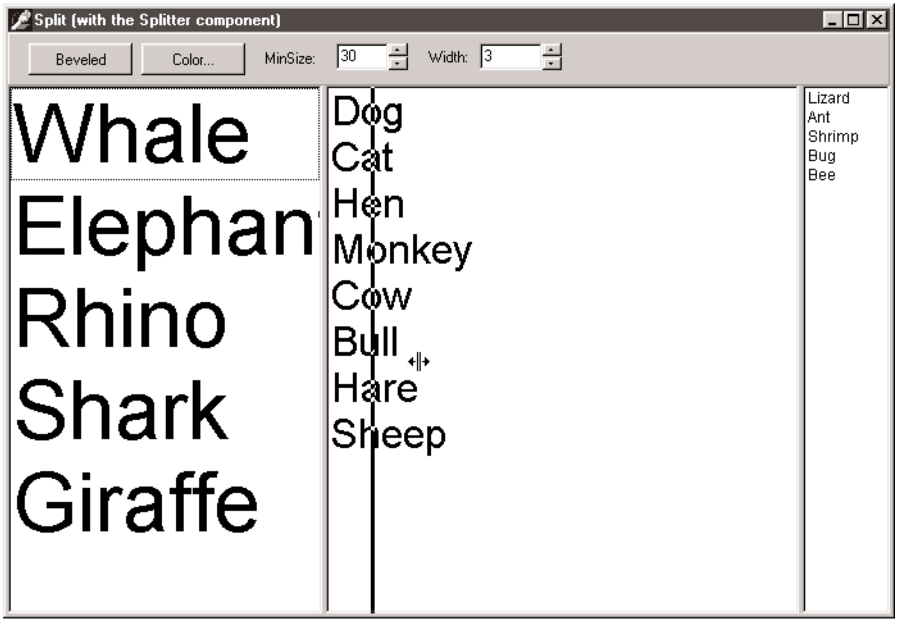
There are several ways to implement form-splitting techniques in Delphi, but the simplest approach is to use the Splitter component, found in the Additional page of the Component Palette. To make it more effective, the splitter can be used in combination with the `Constraints` property of the controls it relates to. As we'll see in the Split1 example, this allows us to define maximum and minimum positions of the splitter and of the form.

To build this example, simply place a ListBox component in a form; then add a Splitter component, a second ListBox, another Splitter, and finally a third ListBox component. The form also has a simple toolbar based on a panel.

By simply placing these two splitter components, you give your form the complete functionality of moving and sizing the controls it hosts at run time. The `Width`, `Beveled`, and `Color` properties of the splitter components determine their appearance, and in the Split1 example you can use the toolbar controls to change them. Another relevant property is `MinSize`, which determines the minimum size of the components of the form. During the splitting operation (see Figure 7.8), a line marks the final position of the splitter, but you cannot drag this line beyond a certain limit. The behavior of the Split1 program is not to let controls become too small. An alternative technique is to set the new `AutoSnap` property of the splitter to True. This property will make the splitter hide the control when its size goes below the `MinSize` limit.

FIGURE 7.8:

The splitter component of the Split1 example determines the minimum size for each control on the form, even those not adjacent to the splitter itself.



I suggest you try using the Split1 program, so that you'll fully understand how the splitter affects its adjacent controls and the other controls of the form. Even if we set the MinSize property, a user of this program can reduce the size of its entire form to a minimum, hiding some of the list boxes. If you test the Split2 version of the example, instead, you'll get better behavior. In Split2, I've set some Constraints for the ListBox controls—for example,

```
object ListBox1: TListBox
  Constraints.MaxHeight = 400
  Constraints.MinHeight = 200
  Constraints.MinWidth = 150
```

The size constraints are applied only as you actually resize the controls, so to make this program work in a satisfactory way, you have to set the ResizeStyle property of the two splitters to rsUpdate. This value indicates that the position of the controls is updated for every movement of the splitter, not only at the end of the operation. If you select the rsLine or the new rsPattern values, instead, the splitter simply draws a line in the required position, checking the MinSize property but not the constraints of the controls.

TIP

When you set the Splitter component's AutoSnap property to True, the splitter will completely hide the neighboring control when the size of that control is below the minimum set for it in the Splitter component.

Horizontal Splitting

The Splitter component can also be used for horizontal splitting, instead of the default vertical splitting. However, this approach is a little more complicated. Basically you can place a component on a form, align it to the top, and then place the splitter on the form. By default, it will be left aligned. Choose the alTop value for the Align property, and then resize the component manually, by changing the Height property in the Object Inspector (or by resizing the component).

You can see a form with a horizontal splitter in the SplitH example. This program has two memo components you can open a file into, and it has a splitter dividing them, defined as:

```
object Splitter1: TSplitter
  Cursor = crVSplit
  Align = alTop
  OnMoved = Splitter1Moved
end
```

When you double-click a memo, the program loads a text file into it (notice the structure of the with statement):

```
procedure TForm1.MemoDblClick(Sender: TObject);
begin
```

```
    with Sender as TMemo, OpenDialog1 do
      if Execute then
        Lines.LoadFromFile (FileName);
  end;
```

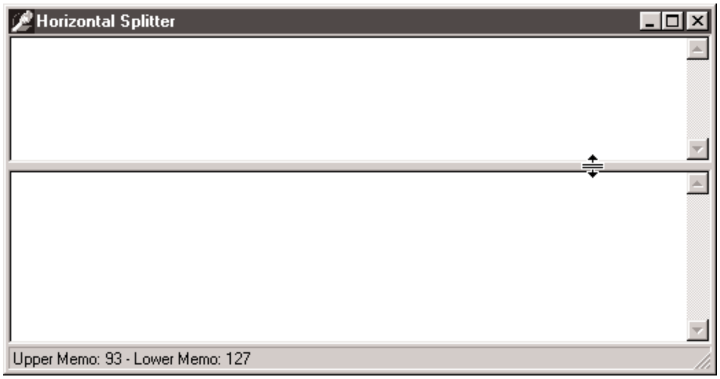
The program features a status bar, which keeps track of the current height of the two memo components. It handles the `OnMoved` event of the splitter (the only event of this component) to update the text of the status bar. The same code is executed whenever the form is resized:

```
procedure TForm1.Splitter1Moved(Sender: TObject);
begin
  StatusBar1.Panels[0].Text := Format ('Upper Memo: %d - Lower Memo: %d',
    [MemoUp.Height, MemoDown.Height]);
end;
```

You can see the effect of this code by looking at Figure 7.9, or by running the SplitH example.

FIGURE 7.9:

The status bar of the SplitH example indicates the position of the horizontal splitter component.



Upper Memo: 93 - Lower Memo: 127

Splitting with a Header

An alternative to using splitters is to use the standard HeaderControl component. If you place this control on a form, it will be automatically aligned with the top of the form. Then you can add the three list boxes to the rest of the client area of the form. The first list box can be aligned on the left, but this time you cannot align the second and third list box as well. The problem is that the sections of the header can be dragged outside the visible surface of the form. If the list boxes use automatic alignment, they cannot move outside the visible surface of the form, as the program requires.

The solution is to define the sections of the header, using the specific editor of the `Sections` property. This property editor allows you to access the various subobjects of the collection, changing various settings. You can set the caption and alignment of the text; the current, minimum, and maximum size of the header; and so on. Setting the limit values is a powerful tool, and it replaces the MinSize property of the splitter or the constraints of the list boxes we've used in past examples. You can see the output of this program, named HdrSplit, in Figure 7.10.

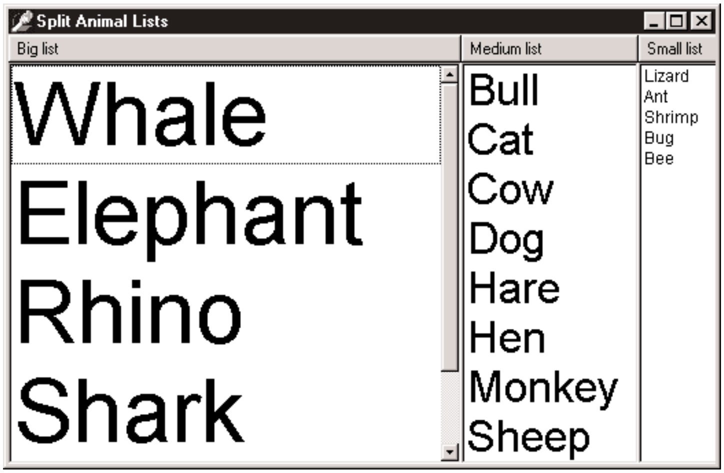


FIGURE 7.10: The output of the HdrSplit example

We need to handle two events: OnSectionResize and OnSectionClick. The first handler simply resizes the list box connected with the modified section (determined by associating numbers with the ImageIndex property of each section and using it to determine the name of the list box control):

```
procedure TForm1.HeaderControl1SectionResize(
  HeaderControl: THeaderControl; Section: THeaderSection);
var
  List: TListBox;
begin
  List := FindComponent ('ListBox' + IntToStr (Section.ImageIndex))
    as TListBox;
  List.Width := Section.Width;
end;
```

Along with this event, we need to handle the resizing of the form, using it to synchronize the list boxes with the sections, which are all resized by default:

```
procedure TForm1.FormResize(Sender: TObject);
var
  I: Integer;
  List: TListBox;
begin
  for I := 0 to 2 do
  begin
    List := FindComponent ('ListBox' + IntToStr (
      HeaderControl1.Sections[I].ImageIndex)) as TListBox;
    List.Left := HeaderControl1.Sections[I].Left;
    List.Width := HeaderControl1.Sections[I].Width;
  end;
end;
```

After setting the height of the list boxes, this method simply calls the previous one, passing parameters that we won't use in this example. The second method of the HeaderControl, called in response to a click on one of the sections, is used to sort the contents of the corresponding list box:

```
procedure TForm1.HeaderControl1SectionClick(
  HeaderControl: THeaderControl; Section: THeaderSection);
var
  List: TListBox;
begin
  List := FindComponent ('ListBox' + IntToStr (Section.ImageIndex))
    as TListBox;
  List.Sorted := not List.Sorted;
end;
```

Of course, this code doesn't provide the common behavior of sorting the elements when you click the header and then sorting them in the reverse order if you click again. To implement this, you should write your own sorting algorithm.

Finally, the HdrSplit example uses a new feature for the header control. It sets the `DragReorder` property to enable dragging operations to reorder the header sections. When this operation is performed, the control fires the `OnSectionDrag` event, where you can exchange the positions of the list boxes. This event fires before the sections are actually moved, so I have to use the coordinates of the other section:

```
procedure TForm1.HeaderControl1SectionDrag(Sender: TObject; FromSection,
  ToSection: THeaderSection; var AllowDrag: Boolean);
var
  List: TListBox;
begin
  List := FindComponent ('ListBox' + IntToStr (FromSection.ImageIndex))
    as TListBox;
  List.Left := ToSection.Left;
  List.Width := ToSection.Width;

  List := FindComponent ('ListBox' + IntToStr (ToSection.ImageIndex))
    as TListBox;
  List.Left := FromSection.Left;
  List.Width :=fromSection.Width
end;
```

Control Anchors

In this chapter, I've described how you can use alignment and splitters to create nice, flexible user interfaces, that adapt to the current size of the form, giving users maximum freedom. Delphi also supports right and bottom anchors. Before this feature was introduced in Delphi 4, every control placed on a form had coordinates relative to the top and bottom, unless it was aligned to the bottom or right sides. Aligning is good for some controls but not all of them, particularly buttons.

By using anchors, you can make the position of a control relative to any side of the form. For example, to have a button anchored to the bottom-right corner of the form, place the button in the required position and set its `Anchors` property to `[akRight, akBottom]`. When the form size changes, the distance of the button from the anchored sides is kept fixed. In other words, if you set these two anchors and remove the two defaults, the button will remain in the bottom-right corner.

On the other hand, if you place a large component such as a Memo or a ListBox in the middle of a form, you can set its `Anchors` property to include all four sides. This way the control will behave as an aligned control, growing and shrinking with the size of the form, but there will be some margin between it and the form sides.

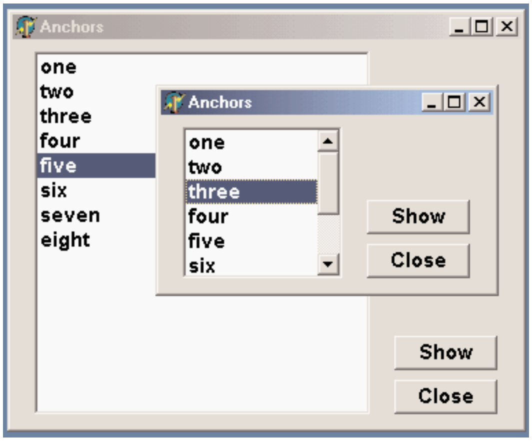
TIP Anchors, like constraints, work both at design time and at run time, so you should set them up as early as possible, to benefit from this feature while you're designing the form as well as at run time.

As an example of both approaches, you can try out the Anchors application, which has two buttons on the bottom-right corner and a list box in the middle. As shown in Figure 7.11, the controls automatically move and stretch as the form size changes. To make this form work properly, you must also set its `Constraints` property; otherwise, as the form becomes too small the controls can overlap or disappear.

TIP If you remove all of the anchors, or two opposite ones (for example, left and right), the resize operations will cause the control to float. The control keeps its current size, and the system adds or removes the same number of pixels on each side of it. This can be defined as a centered anchor, because if the component is initially in the middle of the form it will keep that position. In any case, if you want a centered control, you should generally use both opposite anchors, so that if the user makes the form larger, the control size will grow as well. In the case just presented, in fact, making the form larger leaves a small control in its center.

FIGURE 7.11:

The controls of the Anchors example move and stretch automatically as the user changes the size of the form. No code is needed to move the controls, only a proper use of the `Anchors` property.



The ToolBar Control

In early versions of Delphi, toolbars had to be created using panels and speed buttons. Starting with version 3, Delphi introduced a specific ToolBar component, which encapsulates the corresponding Win32 common control or the corresponding Qt widget in VisualCLX. This component provides a toolbar, with its own buttons, and it has many advanced capabilities. To use this component, you place it on a form and then use the component editor (the shortcut menu activated by a right mouse button click) to create a few buttons and separators.

Building a Toolbar with a Panel

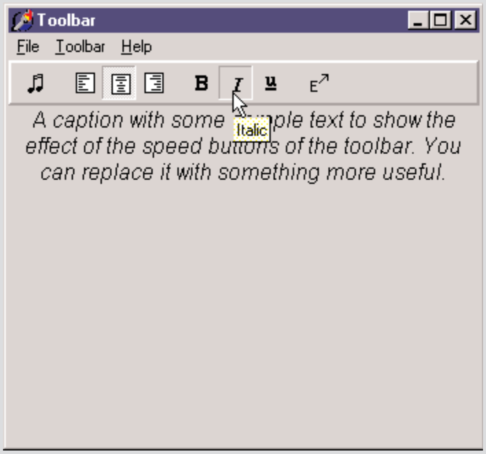
Before the toolbar control was available in Delphi, the standard approach for building a toolbar was to use a panel aligned to the top of the form and place SpeedButton components inside it. A *speed button* is a lightweight graphical control (consuming no Windows resources); it cannot receive the input focus, it has no tab order, and it is faster to create and paint than a bitmap button.

Speed buttons can behave like push buttons, check boxes, or radio buttons, and they can have different bitmaps depending on their status. To make a group of speed buttons work like radio buttons, just place some speed buttons on the panel, select all of them, and give the same value to each one's `GroupIndex` property. All the buttons having the same `GroupIndex` become mutually exclusive selections. One of these buttons should always be selected, so remember to set the `Down` property to True for one of them at design time or as soon as the program starts.

Continued on next page

By setting the `AllowAllUp` property, you can create a group of mutually exclusive buttons, each of which can be *up*—that is, a group from which the user can select one option or leave them all unselected. As a special case, you can make a speed button work as a check box, simply by defining a group (the `GroupIndex` property) that has only one button and that allows it to be deselected (the `AllowAllUp` property).

Finally, you can set the `Flat` property of all the SpeedButton components to True, obtaining a more modern user interface. If you are interested in this approach, you can look at the PanelBar example, illustrated here:



A caption with some sample text to show the effect of the speed buttons of the toolbar. You can replace it with something more useful.

The use of SpeedButton controls is becoming less common. Besides the fact that the ToolBar control is very handy and definitely more standard, speed buttons have two big problems. First, each of them requires a specific bitmap and cannot use one from an image list (unless you write some complex code). Second, speed buttons don't work very well with actions, because some properties, such as the Down state, do not map directly.

The toolbar is populated with objects of the `TToolButton` class. These objects have a fundamental property, `Style`, which determines their behavior:

- The tbsButton style indicates a standard push button.
- The tbsCheck style indicates a button with the behavior of a check box, or that of a radio button if the button is `Grouped` with the others in its block (determined by the presence of separators).

- The tbsDropDown style indicates a drop-down button, a sort of combo box. The drop-down portion can be easily implemented in Delphi by connecting a PopupMenu control to the `DropdownMenu` property of the control.
- The tbsSeparator and tbsDivider styles indicate separators with no or different vertical lines (depending on the `Flat` property of the toolbar).

To create a graphic toolbar, you can add an ImageList component to the form, load some bitmaps into it, and then connect the ImageList with the `Images` property of the toolbar. By default, the images will be assigned to the buttons in the order they appear, but you can change this quite easily by setting the `ImageIndex` property of each toolbar button. You can prepare further ImageLists for special conditions of the buttons and assign them to the `DisabledImages` and `HotImages` properties of the toolbar. The first group is used for the disabled buttons; the second for the button currently under the mouse.

NOTE In a nontrivial application, you would generally create toolbars using an ActionList or the new Action Manager architecture, both discussed in the next chapter. In this case, you'll attach very little behavior to the toolbar buttons, as their properties and events will be managed by the action components.

The RichBar Example

As an example of the use of a toolbar, I've built the RichBar application, which has a RichEdit component you can operate by using the toolbar. The program has buttons for loading and saving files, for copy and paste operations, and to change some of the attributes of the current font.

I don't want to cover the details of the features of the RichEdit control, which are many, nor discuss the details of this application, which has quite a lot of code. All I want to do is to focus on features specific to the ToolBar used by the example and visible in Figure 7.12. This toolbar has buttons, separators, and even a drop-down menu and two combo boxes discussed in the next section.

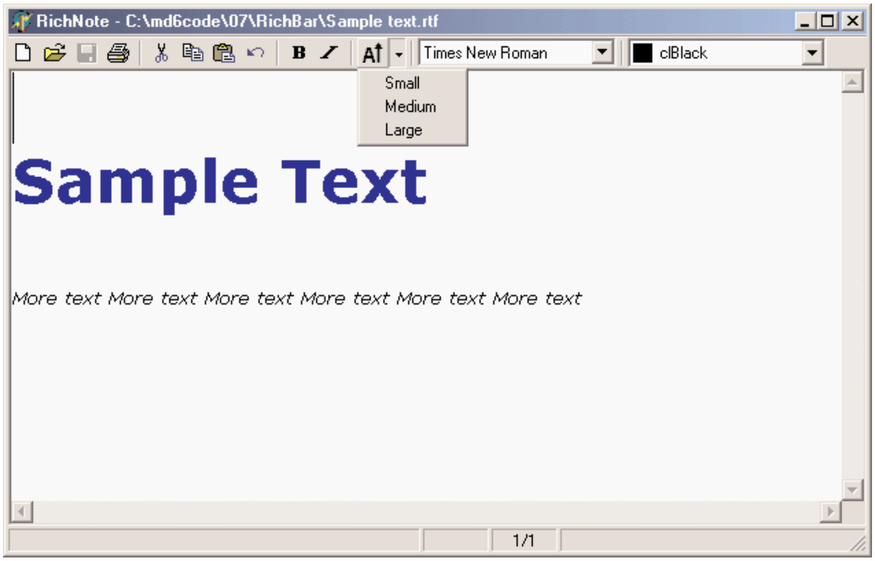
The various buttons implement features, one of them being a complete scheme for opening and saving the text files, including the ability to ask the user to save any modified file before opening a new one, to avoid losing any changes. The file-handling portion of the program is quite complex, but it is worth exploring, as many file-based applications will use similar code. I've made more details available in the bonus chapter "The RichBar Example" on the companion CD.

Besides file operations, the program supports copy and paste operations and font management. The copy and paste operations don't require an actual interaction with the clipboard, as the component can handle them with simple commands, such as:

```
RichEdit.CutToClipboard;
RichEdit.CopyToClipboard;
RichEdit.PasteFromClipboard;
RichEdit.Undo;
```

FIGURE 7.12:

The toolbar of the RichBar example. Notice the drop-down menu.



RichNote - C:\md6code\07\RichBar\Sample text.rtf
Times New Roman
clBlack
Small
Medium
Large
Sample Text
More text More text More text More text More text More text
1/1

It is a little more advanced to know when these operations (and the corresponding buttons) should be enabled. We can enable Copy and Cut buttons when some text is selected, in the OnSelectionChange event of the RichEdit control:

```
procedure TFormRichNote.RichEditSelectionChange(Sender: TObject);
begin
  tbtnCut.Enabled := RichEdit.SelLength > 0;
  tbtnCopy.Enabled := tbtnCut.Enabled;
end;
```

The Copy operation, instead, cannot be determined by an action of the user, as it depends on the content of the Clipboard, influenced also by other applications. One approach is to use a timer and check the clipboard content from time to time. A better approach is to use the OnIdle event of the Application object (or the ApplicationEvents component). As the

RichEdit supports multiple clipboard formats, the code cannot simply look at those, but should ask the component itself, using a low-level feature not surfaced by the Delphi control:

```
procedure TFormRichNote.ApplicationEvents1Idle(Sender: TObject;
  var Done: Boolean);
begin
  // update toolbar buttons
  tbtnPaste.Enabled := SendMessage (RichEdit.Handle, em_CanPaste, 0, 0) <> 0;
end;
```

Basic font management is given by the Bold and Italic buttons, which have similar code. The Bold button toggles the relative attribute from the selected text (or changes the style at the current edit position):

```
procedure TFormRichNote.BoldExecute(Sender: TObject);
begin
  with RichEdit.SelAttributes do
    if fsBold in Style then
      Style := Style - [fsBold]
    else
      Style := Style + [fsBold];
end;
```

Again, the current status of the button is determined by the current selection, so we'll need to add the following line to the `RichEditSelectionChange` method:

```
tbtnBold.Down := fsBold in RichEdit.SelAttributes.Style;
```

A Menu and a Combo Box in a Toolbar

Besides a series of buttons, the RichBar example has a drop-down menu and a couple of combo boxes, a feature shared by many common applications. The drop-down button allows selection of the font size, while the combo boxes allow rapid selection of the font family and the font color. This second combo is actually built using a ColorBox control.

The Size button is connected to a PopupMenu component (called `SizeMenu`) using the `DropdownMenu` property. A user can press the button, firing its `OnClick` event as usual, or select the drop-down arrow, open the pop-up menu (see again Figure 7.12), and choose one of its options. This case has three possible font sizes, per the menu definition:

```
object SizeMenu: TPopupMenu
  object Small1: TMenuItem
    Tag = 10
    Caption = 'Small'
    OnClick = SetFontSize
  end
  object Medium1: TMenuItem
    Tag = 16
```

```
      Caption = 'Medium'
      OnClick = SetFontSize
    end
    object Large1: TMenuItem
      Tag = 32
      Caption = 'Large'
      OnClick = SetFontSize
    end
  end
```

Each menu item has a tag indicating the actual size of the font, activated by a shared event handler:

```
procedure TFormRichNote.SetFontSize(Sender: TObject);
begin
  RichEdit.SelAttributes.Size := (Sender as TMenuItem).Tag;
end;
```

As the ToolBar control is a full-featured control container, you can directly take an edit box, a combo box, and other controls and place them inside the toolbar. The combo box in the toolbar is initialized in the `FormCreate` method, which extracts the screen fonts available in the system:

```
ComboFont.Items := Screen.Fonts;
ComboFont.ItemIndex := ComboFont.Items.IndexOf (RichEdit.Font.Name)
```

The combo box initially displays the name of the default font used in the RichEdit control, which is set at design time. This value is recomputed each time the current selection changes, using the font of the selected text, along with the current color for the ColorBox:

```
procedure TFormRichNote.RichEditSelectionChange(Sender: TObject);
begin
  ComboFont.ItemIndex :=
    ComboFont.Items.IndexOf (RichEdit.SelAttributes.Name);
  ColorBox1.Selected := RichEdit.SelAttributes.Color;
end;
```

When a new font is selected from the combo box, the reverse action takes place. The text of the current combo box item is assigned as the name of the font for any text selected in the RichEdit control:

```
RichEdit.SelAttributes.Name := ComboFont.Text;
```

The selection of a color in the ColorBox activates similar code.

Toolbar Hints

Another common element in toolbars is the *fly-by hint*, also called *balloon help*—some text that briefly describes the button currently under the cursor. This text is usually displayed in a yellow box after the mouse cursor has remained steady over a button for a set amount of time. To add hints to an application's toolbar, simply set its ShowHints property to True and enter some text for the Hint property of each button (more on hints text in the next section, "A Simple Status Bar").

If you want to have more control on how hints are displayed, you can use some of the properties and events of the Application object. This global object has, among others, the following properties:

Property	Defines
HintColor	The background color of the hint window
HintPause	How long the cursor should remain on a component before hints are displayed
HintHidePause	How long the hint will be displayed
HintShortPause	How long the system should wait to display a hint if another hint has just been displayed

A program, for example, might allow a user to customize the hint background color by selecting a specific with the following code:

```
ColorDialog.Color := Application.HintColor;
if ColorDialog.Execute then
  Application.HintColor := ColorDialog.Color;
```

NOTE As an alternative, you can change the hint color by handling the OnShowHint property of the Application object. This handler can change the color of the hint just for specific controls. The OnShowHint event is used in the CustHint example described later in this chapter.

A Simple Status Bar

Building a status bar is even simpler than building a toolbar. Delphi includes a specific StatusBar component, based on the corresponding Windows common control (a similar control is available also in VisualCLX). This component can be used almost as a panel when its SimplePanel property is set to True. In this case, you can use the SimpleText property to output some text. The real advantage of this component, however, is that it allows you to define a number of subpanels just by activating the editor of its Panels property. (You can also display this property editor by double-clicking the status bar control.) Each subpanel has its own graphical attributes, which you can customize using the editor. Another feature of the status bar component is the "size grip" area added to the lower-right corner of the bar, which is useful for resizing the form itself. This is a typical element of the Windows user interface, and you can control it with the SizeGrip property.

There are various uses for a status bar. The most common is to display information about the menu item currently selected by the user. Besides this, a status bar often displays other information about the status of a program: the position of the cursor in a graphical application, the current line of text in a word processor, the status of the lock keys, the time and date, and so on. To show information on a panel, you simply use its `Text` property, generally using an expression like this:

```
StatusBar1.Panels[1].Text := 'message';
```

In the RichBar example, I've built a status bar with three panels, for command hints, the status of the Caps Lock key, and the current editing position. The StatusBar component of the example actually has four panels; we need to define the fourth in order to delimit the area of the third panel. The last panel, in fact, is always large enough to cover the remaining surface of the status bar.

TIP Again, for more detail on the RichBar program, see the bonus chapter "The RichBar Example" on the companion CD.

The panels are not independent components, so you cannot access them by name, only by position as in the preceding code snippet. A good solution to improve the readability of a program is to define a constant for each panel you want to use, and then use these constants when referring to the panels. This is my sample code:

```
const
  sbpMessage = 0;
  sbpCaps = 1;
  sbpPosition = 2;
```

In the first panel of the status bar, I want to display the hint message of the toolbar button. The program obtains this effect by handling the application's `OnHint` event, again using the ApplicationEvents component, and copying the current value of the application's `Hint` property to the status bar:

```
procedure TFormRichNote.ApplicationEvents1Hint (Sender: TObject);
begin
  StatusBar1.Panels[sbpMessage].Text := Application.Hint;
end;
```

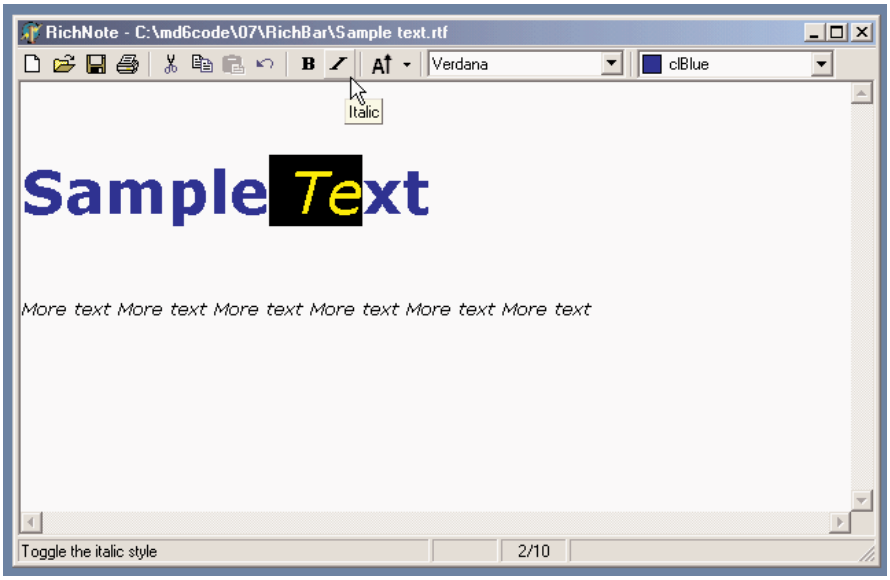
By default, this code displays in the status bar the same text of the fly-by hints. Actually, we can use the `Hint` property to specify different strings for the two cases, by writing a string divided into two portions by a separator, the pipe (`|`) character. For example, you might enter the following as the value of the `Hint` property:

```
'New|Create a new document'
```

The first portion of the string, *New*, is used by fly-by hints, and the second portion, *Create a new document*, by the status bar. You can see an example in Figure 7.13.

FIGURE 7.13:

The StatusBar of the RichBar example displays a more detailed description than the fly-by hint.



RichNote - C:\md6code\07\RichBar\Sample text.rtf

Sample Text

More text More text More text More text More text More text

Toggle the italic style

2/10

TIP

When the hint for a control is made up of two strings, you can use the `GetShortHint` and `GetLongHint` methods to extract the first (short) and second (long) substrings from the string you pass as a parameter, which is usually the value of the `Hint` property.

The second panel displays the status of the Caps Lock key, obtained by calling the `GetKeyState` API function, which returns a state number. If the low-order bit of this number is set (that is, if the number is odd), then the key is pressed. When do we check this state? I've decided to do this when the application is idle, so that this test is executed every time a key is pressed, but also as soon as a message reaches the window (in case the user changes this setting while working with another program). I've added to the `ApplicationEvents1Idle` handler a call to the custom `CheckCapslock` method, implemented as follows:

```
procedure TFormRichNote.CheckCapslock;
begin
  if Odd (GetKeyState (VK_CAPITAL)) then
    StatusBar1.Panels[sbpCaps].Text := 'CAPS'
  else
    StatusBar1.Panels[sbpCaps].Text := '';
end;
```

Finally, the program uses the third panel to display the current cursor position (measured in lines and characters per line) every time the selection changes. Because the `CaretPos` values are zero-based (that is, the upper-left corner is line 0, character 0), I've decided to add one to each value, to make them more reasonable for a casual user:

```
procedure TFormRichNote.RichEditSelectionChange(Sender: TObject);
begin
  ...
  // update the position in the status bar
  StatusBar.Panels[sbpPosition].Text := Format ('%d/%d',
    [RichEdit.CaretPos.Y + 1, RichEdit.CaretPos.X + 1]);
end;
```

Customizing the Hints

Just as we have added hints to an application's toolbar, we can add hints to forms or to the components of a form. For a large control, the hint will show up near the mouse cursor. In some cases, it is important to know that a program can freely customize how hints are displayed.

The simplest thing you can do is, change the value of the properties of the Application object as I mentioned at the end of the last section. To obtain more control over hints, you can customize them even further by assigning a method to the application's OnShowHint event. You need to either hook them up manually or—better—add an ApplicationEvents component to the form and handle its OnShowHint event.

The method you have to define has some interesting parameters, such as a string with the text of the hint, a Boolean flag for its activation, and a THintInfo structure with further information, including the control, the hint position, and its color. Each of the parameters is passed by reference, so you have a chance to change them and also modify the values of the THintInfo structure; for example, you can change the position of the hint window before it is displayed.

This is what I've done in the CustHint example, which shows the hint of the label at the center of its area. Here is what you can write to show the hint for the big label in the center of its surface:

```
procedure TForm1.ShowHint (var HintStr: string; var CanShow: Boolean;
  var HintInfo: THintInfo);
begin
  with HintInfo do
    if HintControl = Label1 then
      HintPos := HintControl.ClientToScreen (Point (
        HintControl.Width div 2, HintControl.Height div 2));
end;
```

The code has to retrieve the center of the generic control (the HintInfo.HintControl) and then convert its coordinates to screen coordinates, applying the ClientToScreen method to the control itself. We can further update the CustHint example in a different way. The RadioGroup control in the form has three radio buttons. However, these are not stand-alone components, but simply radio button clones painted on the surface of the radio group. What if we want to add a hint for each of them?

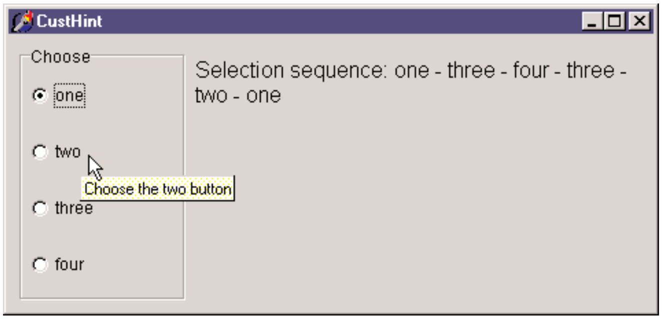
The CursorRect field of the THintInfo record can be used for this purpose. It indicates the area of the component that the cursor can move over without disabling the hint. When the cursor moves outside this area, Delphi hides the hint window. If we specify a different text for the hint and a different area for each of the radio buttons, we can in practice provide three different hints. Because computing the actual position of each radio button isn't easy, I've simply divided the surface of the radio group into as many equal parts as there are radio buttons. The text of the radio button (not the selected item, but the item under the cursor) is then added to the text of the hint:

```
procedure TForm1.ShowHint (var HintStr: string;
  var CanShow: Boolean; var HintInfo: THintInfo);
var
  RadioItem, RadioHeight: Integer;
  RadioRect: TRect;
begin
  with HintInfo do
    if HintControl = Label1 ... // as before
    else
    if HintControl = RadioGroup1 then
    begin
      RadioHeight := (RadioGroup1.Height) div RadioGroup1.Items.Count;
      RadioItem := CursorPos.Y div RadioHeight;
      HintStr := 'Choose the ' + RadioGroup1.Items [RadioItem] + ' button';
      RadioRect := RadioGroup1.ClientRect;
      RadioRect.Top := RadioRect.Top + RadioHeight * RadioItem;
      RadioRect.Bottom := RadioRect.Top + RadioHeight;
      // assign the hints rect and pos
      CursorRect := RadioRect;
    end;
end;
```

The final part of the code builds the rectangle for the hint, starting with the rectangle corresponding to the client area of the component and moving its Top and Bottom values to the proper section of the RadioGroup1 component. The resulting effect is that each radio button of the radio group appears to have a specific hint, as shown in Figure 7.14.

FIGURE 7.14:

The RadioGroup control of the CustHint example shows a different hint, depending on which radio button the mouse is over.



Selection sequence: one - three - four - three - two - one

What's Next?

In this chapter I've discussed the use of some Delphi common controls, including the ListView, TreeView, PageControl, TabControl, ToolBar, StatusBar, and RichEdit. For each of these controls, I've built one example, trying to discuss it in the context of an actual application, even if most of the programs have been quite simple. I've also covered the Splitter component and various form-splitting techniques, the anchors for control positioning, and the customization of hints.

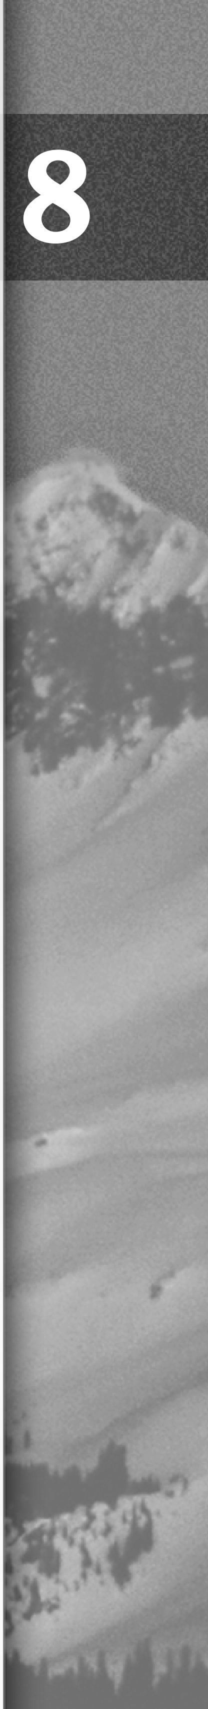
What is still missing is the development of an application with a complete user interface, including a menu and one or more toolbars. The reason I haven't covered this topic in the current chapter is that Delphi 6 adds quite a lot to VCL in this respect, including a complete architecture for letting the end users configure menus and toolbars based on a number of predefined actions. As this topic and related ones, such as docking toolbars, are complex, I've devoted the entire next chapter to them.

After this step, we'll move to the development of applications with multiple forms, including advanced dialog boxes, MDI, visual form inheritance, and the use of frames. All these topics are covered in Chapters 9 and 10.

CHAPTER 8

Building the User Interface

- Actions and ActionList
- Predefined actions in Delphi 6
- The ControlBar and CoolBar components
- Docking toolbars and other controls
- The Action Manager architecture



Modern Windows applications usually have multiple ways of giving a command, including menu items, toolbar buttons, shortcut menus, and so on. To separate the actual commands a user can give from their multiple representations in the user interface, Delphi has the idea of actions. In Delphi 6 this architecture has been largely extended to make the construction of the user interface on top of actions totally visual. You can now also easily let the user of your programs customize this interface, as happens in many professional programs.

This chapter focuses on actions, action lists and action managers, and the related components. It also covers a few related topics, such as toolbar container controls and toolbar docking, and docking in general.

The ActionList Component

Delphi's event architecture is very open: You can write a single event handler and connect it to the `OnClick` events of a toolbar button and a menu. You can also connect the same event handler to different buttons or menu items, as the event handler can use the `Sender` parameter to refer to the object that fired the event. It's a little more difficult to synchronize the status of toolbar buttons and menu items. If you have a menu item and a toolbar button that both toggle the same option, every time the option is toggled, you must both add the check mark to the menu item and change the status of the button to show it pressed.

To overcome this problem, Delphi 4 introduced an event-handling architecture based on actions. An *action* (or command) both indicates the operation to do when a menu item or button is clicked and determines the status of all the elements connected to the action. The connection of the action with the user interface of the linked controls is very important and should not be underestimated, because it is where you can get the real advantages of this architecture.

NOTE If you have ever written code using the MFC class library of Visual C++, you'll recognize that a Delphi action maps to both a command and a `CCommandUpdateUI` object. The Delphi architecture is more flexible, though, because it can be extended by subclassing the action classes.

There are many players in this event-handling architecture. The central role is certainly played by the action objects. An action object has a name, like any other component, and other properties that will be applied to the linked controls (called action clients). These properties include the `Caption`, the graphical representation (`ImageIndex`), the status (`Checked`, `Enabled`, and `Visible`), and the user feedback (`Hint` and `HelpContext`). There is also the `ShortCut` and a list of `SecondaryShortCuts`, the `AutoCheck` property for two-state actions, the help support, and a `Category` property used to arrange actions in logical groups.

The base class for an all action object is TBasicAction, which introduces the abstract core behavior of an action, without any specific binding or correction (not even to menu items or controls). The derived TContainedAction class introduces properties and methods that enable actions to appear in an action list or action manager. The further-derived TCustomAction class introduces support for the properties and methods of menu items and controls that are linked to action objects. Finally, there is the derived ready-to-use TAction class.

Each action object is connected to one or more client objects through an ActionLink object. Multiple controls, possibly of different types, can share the same action object, as indicated by their Action property. Technically, the ActionLink objects maintain a bidirectional connection between the client object and the action. The ActionLink object is required because the connection works in both directions. An operation on the object (such as a click) is forwarded to the action object and results in a call to its OnExecute event; an update to the status of the action object is reflected in the connected client controls. In other words, one or more client controls can create an ActionLink, which registers itself with the action object.

You should not set the properties of the client controls you connect with an action, because the action will override the property values of the client controls. For this reason, you should generally write the actions first and then create the menu items and buttons you want to connect with them. Note also that when an action has no OnExecute handler, the client control is automatically disabled (or grayed), unless the DisableIfNoHandler property is set to False.

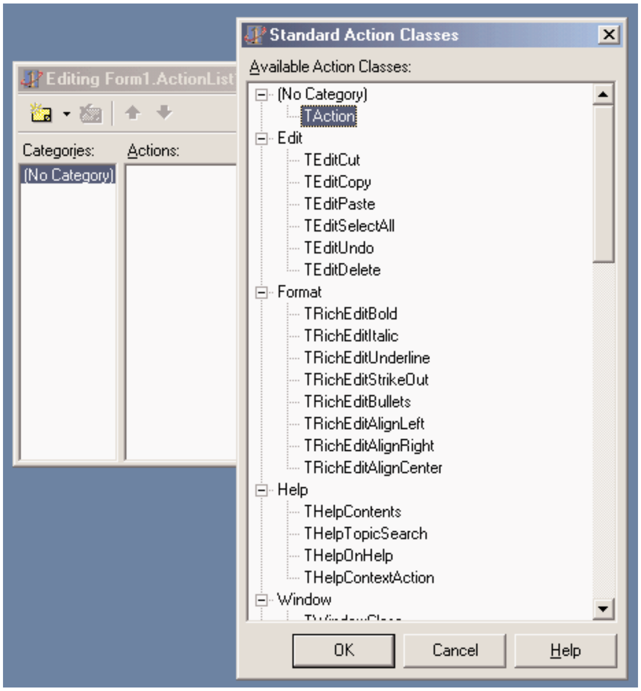
The client controls connected to actions are usually menu items and various types of buttons (push buttons, check boxes, radio buttons, speed buttons, toolbar buttons, and the like), but nothing prevents you from creating new components that hook into this architecture. Component writers can even define new actions, as we'll do in Chapter 11, and new link action objects.

Besides a client control, some actions can also have a target component. Some predefined actions hook to a specific target component (for examples, see the coverage of the DataSet components in the Chapter 13 section "Looking for Records in a Table"). Other actions automatically look for a target component in the form that supports the given action, starting with the active control.

Finally, the action objects are held by an ActionList component, the only class of the basic architecture that shows up on the Component Palette. The action list receives the execute actions that aren't handled by the specific action objects, firing the OnExecuteAction. If even the action list doesn't handle the action, Delphi calls the OnExecuteAction event of the Application object. The ActionList component has a special editor you can use to create several actions, as you can see in Figure 8.1.

FIGURE 8.1:

The ActionList component editor, with a list of predefined actions you can use



In the editor, actions are displayed in groups, as indicated by their `Category` property. By simply setting this property to a brand-new value, you instruct the editor to introduce a new category. These categories are basically logical groups, although in some cases a group of actions can work only on a specific type of target component. You might want to define a category for every pull-down menu or group them in some other logical way.

Predefined Actions in Delphi 6

With the action list editor, you can create a brand new action or choose one of the existing actions registered in the system. These are listed in a secondary dialog box, as shown in Figure 8.1. There are many predefined actions, which can be divided into logical groups:

File actions include open, save as, open with, run, print setup, and exit.

Edit actions are illustrated in the next example. They include cut, copy, paste, select all, undo, and delete.

RichEdit actions complement the edit actions for RichEdit controls and include bold, italic, underline, strikeout, bullets, and various alignment actions.

MDI window actions will be demonstrated in Chapter 10, as we examine the Multiple Document Interface approach. They include all the most common MDI operations: arrange, cascade, close, tile (horizontally or vertically), and minimize all.

Dataset actions relate to database tables and queries and will be discussed in Chapter 13. There are many dataset actions, representing all the main operations you can perform on a dataset.

Help actions allow you to activate the contents page or index of the Help file attached to the application.

Search actions include find, find first, find next, and replace.

Tab and Page control actions include previous page and next page navigation.

Dialog actions activate color, font, open, save, and print dialogs.

List actions include clear, copy, move, delete, and select all. These actions let you interact with a list control. Another group of actions, including static list, virtual list, and some support classes, allow the definition of lists that can be connected to a user interface. More on this topic is in the section "Using List Actions" toward the end of this chapter.

Web actions include browse URL, download URL, and send mail actions.

Tools actions include only the dialog to customize the action bars.

NOTE You can also define new custom actions and register them in Delphi's IDE, as we'll see in Chapter 11.

Besides handling the `OnExecute` event of the action and changing the status of the action to affect the user interface of the client controls, an action can also handle the `OnUpdate` event, which is activated when the application is idle. This gives you the opportunity to check the status of the application or the system and change the user interface of the controls accordingly. For example, the standard PasteEdit action enables the client controls only when there is some text in the Clipboard.

Actions in Practice

Now that you understand the main ideas behind this very important Delphi feature, let's try out an example from the companion CD. The program is called Actions and demonstrates a number of features of the action architecture. I began building it by placing a new ActionList component in its form and adding the three standard edit actions and a few custom ones. The form also has a panel with some speed buttons, a main menu, and a Memo control (the automatic target of the edit actions). Listing 8.1 is the list of the actions, extracted from the DFM file.

Listing 8.1: The actions of the Actions example

```
object ActionList1: TActionList
  Images = ImageList1
  object ActionCopy: TEditCopy
    Category = 'Edit'
    Caption = '&Copy'
    ShortCut = <Ctrl+C>
  end
  object ActionCut: TEditCut
    Category = 'Edit'
    Caption = 'Cu&t'
    ShortCut = <Ctrl+X>
  end
  object ActionPaste: TEditPaste
    Category = 'Edit'
    Caption = '&Paste'
    ShortCut = <Ctrl+V>
  end
  object ActionNew: TAction
    Category = 'File'
    Caption = '&New'
    ShortCut = <Ctrl+N>
    OnExecute = ActionNewExecute
  end
  object ActionExit: TAction
    Category = 'File'
    Caption = 'E&xit'
    ShortCut = <Alt+F4>
    OnExecute = ActionExitExecute
  end
  object NoAction: TAction
    Category = 'Test'
    Caption = '&No Action'
  end
  object ActionCount: TAction
    Category = 'Test'
    Caption = '&Count Chars'
    OnExecute = ActionCountExecute
    OnUpdate = ActionCountUpdate
  end
  object ActionBold: TAction
    Category = 'Edit'
    Caption = '&Bold'
    ShortCut = <Ctrl+B>
    OnExecute = ActionBoldExecute
  end
  object ActionEnable: TAction
    Category = 'Test'
    Caption = '&Enable NoAction'
```

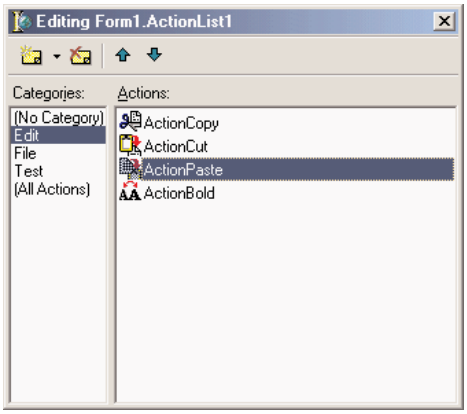
```
      OnExecute = ActionEnableExecute
    end
    object ActionSender: TAction
      Category = 'Test'
      Caption = 'Test &Sender'
      OnExecute = ActionSenderExecute
    end
  end
```

NOTE The shortcut keys are stored in the DFM files using virtual key numbers, which also include values for the Ctrl and Alt keys. In this and other listings throughout the book, I've replaced the numbers with the literal values, enclosing them in angle brackets.

All of these actions are connected to the items of a MainMenu component and some of them also to the buttons of a Toolbar control. Notice that the images selected in the ActionList control affect the actions in the editor only, as you can see in Figure 8.2. For the images of the ImageList to show up also in the menu items and in the toolbar buttons, you must also select the image list in the MainMenu and in the Toolbar components.

FIGURE 8.2:

The ActionList editor of the Actions example



The three predefined actions for the Edit menu don't have associated handlers, but these special objects have internal code to perform the related action on the active edit or memo control. These actions also enable and disable themselves, depending on the content of the Clipboard and on the existence of selected text in the active edit control. Most other actions have custom code, except for the `NoAction` object. Having no code, the menu item and the button connected with this command are disabled, even if the `Enabled` property of the action is set to True.

I’ve added to the example, and to the Test menu, another action that enables the menu item connected to the NoAction object:

```
procedure TForm1.ActionEnableExecute(Sender: TObject);
begin
  NoAction.DisableIfNoHandler := False;
  NoAction.Enabled := True;
  ActionEnable.Enabled := False;
end;
```

Simply setting Enabled to True will produce the effect for only a very short time, unless you set the DisableIfNoHandler property, as discussed in the previous section. Once this operation is done, I disable the current action, since there is no need to issue the same command again.

This is different from an action you can toggle, such as the Edit ➢ Bold menu item and the corresponding speed button. Here is the code of the Bold action:

```
procedure TForm1.ActionBoldExecute(Sender: TObject);
begin
  with Memo1.Font do
    if fsBold in Style then
      Style := Style - [fsBold]
    else
      Style := Style + [fsBold];
  // toggle status
  ActionBold.Checked := not ActionBold.Checked;
end;
```

The ActionCount object has very simple code, but it demonstrates an OnUpdate handler; when the memo control is empty, it is automatically disabled. We could have obtained the same effect by handling the OnChange event of the memo control itself, but in general it might not always be possible or easy to determine the status of a control simply by handling one of its events. Here is the code of the two handlers of this action:

```
procedure TForm1.ActionCountExecute(Sender: TObject);
begin
  ShowMessage ('Characters: ' + IntToStr (Length (Memo1.Text)));
end;

procedure TForm1.ActionCountUpdate(Sender: TObject);
begin
  ActionCount.Enabled := Memo1.Text <> '';
end;
```

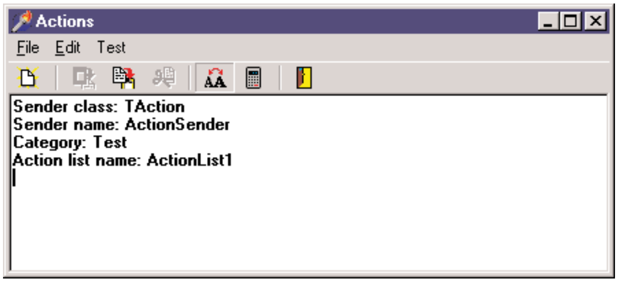
Finally, I’ve added a special action to test the sender object of the action event handler and get some other system information. Besides showing the object class and name, I’ve added code that accesses the action list object. I've done this mainly to show that you can access this information and how to do it:

```
procedure TForm1.ActionSenderExecute(Sender: TObject);
begin
  Memo1.Lines.Add ('Sender class: ' + Sender.ClassName);
  Memo1.Lines.Add ('Sender name: ' + (Sender as TComponent).Name);
  Memo1.Lines.Add ('Category: ' + (Sender as TAction).Category);
  Memo1.Lines.Add (
    'Action list name: ' + (Sender as TAction).ActionList.Name);
  end;
```

You can see the output of this code in Figure 8.3, along with the user interface of the example. Notice that the Sender is not the menu item you've selected, even if the event handler is connected to it. The Sender object, which fires the event, is the action, which intercepts the user operation.

FIGURE 8.3:

The Actions example, with a detailed description of the Sender of an Action object's OnExecute event



```
Sender class: TAction
Sender name: ActionSender
Category: Test
Action list name: ActionList1
```

Finally, keep in mind that you can also write handlers for the events of the ActionList object itself, which play the role of global handlers for all the actions of the list, and for the Application global object, which fires for all the actions of the application. Before calling the action's OnExecute event, in fact, Delphi activates the OnExecute event of the ActionList and the OnActionExecute event of the Application global object. These events can have a look at the action, eventually execute some shared code, and then stop the execution (using the Handled parameter) or let it reach the next level.

If no event handler is assigned to respond to the action, either at the action list, application, or action level, then the application tries to identify a target object to which the action can apply itself.

NOTE When an action is executed, it searches for a control to play the role of the action target, by looking at the active control, the active form, and other controls on the form. For example, edit actions refer to the currently active control (if they inherit from TCustomEdit), while dataset controls look for the dataset connected with the data source of the data-aware control having the input focus. Other actions follow different approaches to find a target component, but the overall idea is shared by most standard actions.

The Toolbar and the ActionList of an Editor

In the previous chapter, I built the RichBar example to demonstrate the development of an editor with a toolbar and a status bar. Of course, I should have also added a menu bar to the form, but this would have created quite a few troubles in synchronizing the status of the toolbar buttons with those of the menu items. A very good solution to this problem is to use actions, which is what I've done in the MdEdit example, discussed in this section and available on the CD.

The application is based on an ActionList component, which includes actions for file handling and Clipboard support, with code similar to the RichBar version. The Font type and color selection is still based on combo boxes, so this doesn't involve action—same for the drop-down menu of the Size button. The menu, however, has a few extra commands, including one for character counting and one for changing the background color. These are based on actions, and the same happens for the three new paragraph justification buttons (and menu commands).

One of the key differences in this new version is that the code never refers to the status of the toolbar buttons, but eventually modifies the status of the actions. In other cases I've used the actions `OnUpdate` events. For example, the `RichEditSelectionChange` method doesn't update the status of the bold button, which is connected to an action with the following `OnUpdate` handler:

```
procedure TFormRichNote.acBoldUpdate(Sender: TObject);
begin
  acBold.Checked := fsBold in RichEdit.SelAttributes.Style;
end;
```

Similar `OnUpdate` event handlers are available for most actions, including the counting operations (available only if there is some text in the RichEdit control), the Save operation (available if the text has been modified), and the Cut and Copy operations (available only if some text is selected):

```
procedure TFormRichNote.acCountcharsUpdate(Sender: TObject);
begin
  acCountChars.Enabled := RichEdit.GetTextLen > 0;
end;

procedure TFormRichNote.acSaveUpdate(Sender: TObject);
begin
  acSave.Enabled := Modified;
end;

procedure TFormRichNote.acCutUpdate(Sender: TObject);
begin
  acCut.Enabled := RichEdit.SelLength > 0;
  acCopy.Enabled := acCut.Enabled;
end;
```

In the older example, the status of the Paste button was updated in the OnIdle event of the Application object. Now that we use actions we can convert it into yet another OnUpdate handler (see the preceding chapter for details on this code):

```
procedure TFormRichNote.acPasteUpdate(Sender: TObject);
begin
  acPaste.Enabled := SendMessage (RichEdit.Handle, em_CanPaste, 0, 0) <> 0;
end;
```

Finally, the program has an addition compared to the last version: the three paragraph-alignment buttons. These toolbar buttons and the related menu items should work like radio buttons, being mutually exclusive with one of the three options always selected. For this reason the actions have the GroupIndex set to 1, the corresponding menu items have the RadioItem property set to True, and the three toolbar buttons have their Grouped property set to True and the AllowAllUp property set to False. (They are also visually enclosed between two separators.)

This is required so that the program can set the Checked property for the action corresponding to the current style, which avoids unchecking the other two actions directly. This code is part of the OnUpdate event of the action list, as it applies to multiple actions:

```
procedure TFormRichNote.ActionListUpdate(Action: TBasicAction;
  var Handled: Boolean);
begin
  // check the proper paragraph alignment
  case RichEdit.Paragraph.Alignment of
    taLeftJustify: acLeftAligned.Checked := True;
    taRightJustify: acRightAligned.Checked := True;
    taCenter: acCentered.Checked := True;
  end;
  // checks the caps lock status
  CheckCapslock;
end;
```

Finally, when one of these buttons is selected, the shared event handler uses the value of the Tag, set to the corresponding value of the TAlignment enumeration, to determine the proper alignment:

```
procedure TFormRichNote.ChangeAlignment(Sender: TObject);
begin
  RichEdit.Paragraph.Alignment := TAlignment ((Sender as TAction).Tag);
end;
```

Toolbar Containers

Most modern applications have multiple toolbars, generally hosted by a specific container. Microsoft Internet Explorer, the various standard business applications, and the Delphi IDE all use this general approach. However, they each implement this differently. Delphi has two ready-to-use toolbar containers, the CoolBar and the ControlBar components. They have differences in their user interface, but the biggest one is that the CoolBar is a Win32 common control, part of the operating system, while the ControlBar is a VCL-based component.

Both components can host toolbar controls as well as some extra elements such as combo boxes and other controls. Actually, a toolbar can also replace the menu of an application, as we'll see later on.

We'll investigate the two components in the next two sections, but I want to emphasize here (without getting too far ahead of myself) that I generally favor the use of the ControlBar. It is based on VCL (and not subject to upgrade along with each minor release of Microsoft Internet Explorer), and its user interface is nicer and more similar to that of common office applications.

A Really Cool Toolbar

The CoolBar component is basically a collection of `TCoolBand` objects that you can activate by selecting the Band Editor item of the CoolBar shortcut menu, the `Bands` property, or the Object TreeView. You can customize the CoolBar component in many ways: You can set a bitmap for its background, add some bands to the `Bands` collection, and then assign to each band an existing component or component container. You can use any window-based control (not graphic controls), but only some of them will show up properly. If you want to have a bitmap on the background of the CoolBar, for example, you need to use partially transparent controls.

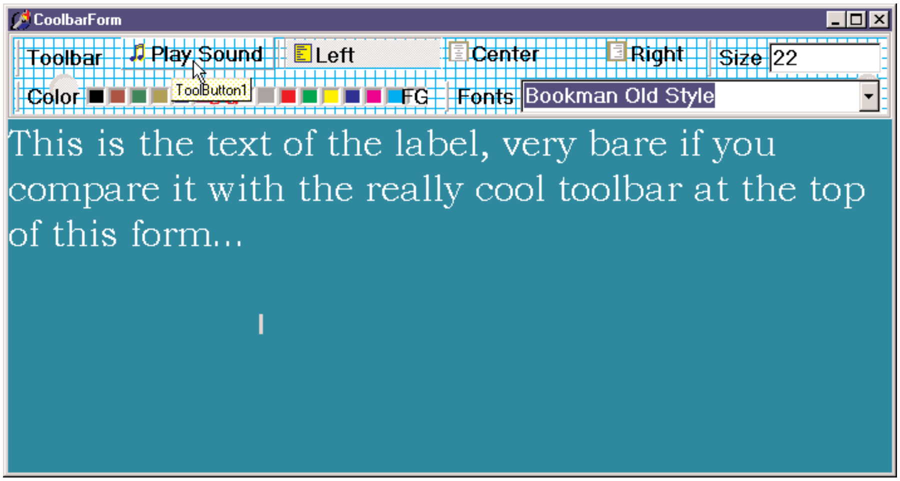
The typical component used in a CoolBar is the Toolbar (which can be made completely transparent), but combo boxes, edit boxes, and animation controls are also quite common. This is often inspired by the user interface of Internet Explorer, the first Microsoft application featuring the CoolBar component.

You can place one band on each line or all of them on the same line. Each would use a part of the available surface, and it would be automatically enlarged when the user clicks on its title. It is easier to use this new component than to explain it. Try it yourself or follow the description below, in which we build a new version of our continuing toolbar example based on a CoolBar control. You can see the form displayed by this application at run time in Figure 8.4.

The CoolBar example has a `TCoolBar` component with four bands, two for each of the two lines. The first band includes a subset of the toolbar of the previous example, this time adding an ImageList for the highlighted images. The second has an edit box used to set the font of the text; the third has a ColorGrid component, used to choose the font color and that of the background. The last band has a ComboBox control with the available fonts.

FIGURE 8.4:

The form of the CoolBar example at run time



This is the text of the label, very bare if you compare it with the really cool toolbar at the top of this form...

The user interface of the CoolBar component is really very nice, and Microsoft is increasingly using it in its applications. However, the Windows CoolBar control has had many different and incompatible versions, as Microsoft has released different versions of the common control library with different versions of the Internet Explorer. Some of these versions "broke" existing programs built with Delphi.

NOTE

It is interesting to note that Microsoft applications generally don't use the common control libraries. Word and Excel use their own internal versions of the common controls, and VB uses an OCX, not the common controls directly. Part of the reason that Borland had so much trouble with the common controls is that it uses them more (and in more ways) than even Microsoft does.

For this reason, Borland introduced (in Delphi 4) a toolbar container called the ControlBar. A control bar hosts several controls, as a CoolBar does, and offers a similar user interface that lets a user drag items and reorganize the toolbar at run time. A good example of the use of the ControlBar control is Delphi's own toolbar, but Microsoft applications use a very similar user interface.

The ControlBar

The ControlBar is a control container, and you build it just by placing other controls inside it, as you do with a panel (there is no list of `Bands` in it). Every control placed in the bar gets its own dragging area (a small panel with two vertical lines, on the left of the control), as you can see in Figure 8.5. For this reason, you should generally avoid placing specific buttons inside the ControlBar, but rather add containers with buttons inside them. Rather than using a panel, you should generally use one ToolBar control for every section of the ControlBar.

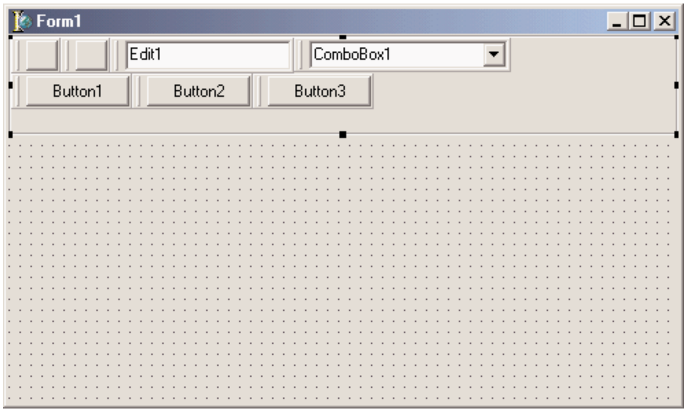


FIGURE 8.5: The ControlBar is a container that allows a user to drag all the elements, using the special drag bar on the side. Notice that each button gets a separate drag bar, something you'll generally try to avoid.

The MdEdit2 example is another version of the demo we've developed throughout the last and this chapter. I've basically grouped the buttons into three toolbars (instead of a single one) and left the two combo boxes as stand-alone controls. All these components are inside a ControlBar, so that a user can arrange them at runtime, as you can see in Figure 8.6.

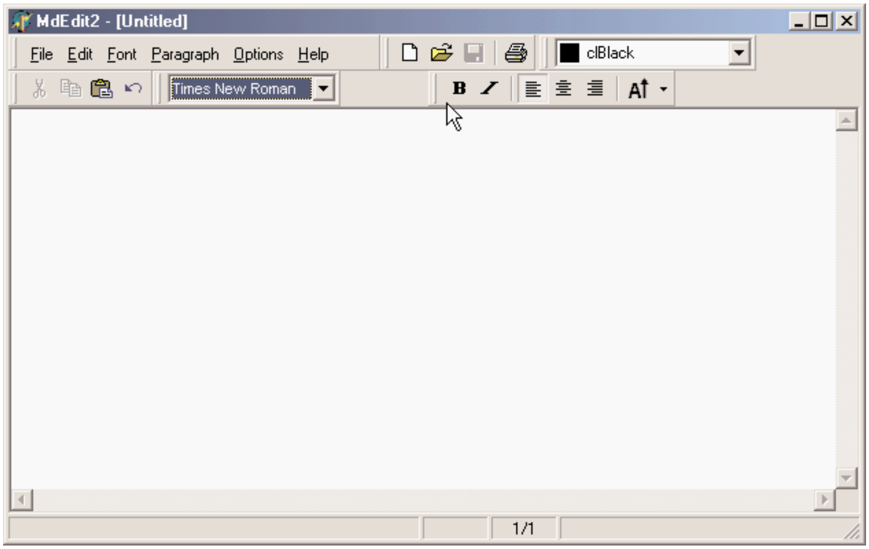

FIGURE 8.6: The MdEdit2 example at run time, while a user is rearranging the toolbars in the control bar

The following snippet of the DFM listing of the MdEdit2 example shows how the various toolbars and controls are embedded in the ControlBar component:

```
object ControlBar1: TControlBar
  Align = alTop
  AutoSize = True
  ShowHint = True
  PopupMenu = BarMenu
  object ToolBarFile: TToolBar
    Flat = True
    Images = Images
    Wrapable = False
    object ToolButton1: TToolButton
      Action = acNew
    end
    // more buttons...
  end
  object ToolBarEdit: TToolBar...
  object ToolBarFont: TToolBar...
  object ToolBarMenu: TToolBar
    AutoSize = True
    Flat = True
    Menu = MainMenu
  end
  object ComboFont: TComboBox
    Hint = 'Font Family'
    Style = csDropDownList
    OnClick = ComboFontClick
  end
  object ColorBox1: TColorBox...
end
```

To obtain the standard effect, you have to disable the edges of the toolbar controls and set their style to flat. Sizing all the controls alike, so that you obtain one or two rows of elements of the same height, is not as easy as it might seem at first. Some controls have automatic sizing or various constraints. In particular, to make the combo box the same height as the toolbars, you have to tweak the type and size of its font. Resizing the control itself has no effect.

The ControlBar also has a shortcut menu that allows you to show or hide each of the controls currently inside it. Instead of writing code specific to this example, I've implemented a more generic (and reusable) solution. The shortcut menu, called `BarMenu`, is empty at design time and is populated when the program starts:

```
procedure TFormRichNote.FormCreate(Sender: TObject);
var
  I: Integer;
  mItem: TMenuItem;
```

```
begin
  ...
  // populate the control bar menu
  for I := 0 to ControlBar.ControlCount - 1 do
  begin
    mItem := TMenuItem.Create (Self);
    mItem.Caption := ControlBar.Controls [I].Name;
    mItem.Tag := Integer (ControlBar.Controls [I]);
    mItem.OnClick := BarMenuClick;
    BarMenu.Items.Add (mItem);
  end;
```

The BarMenuClick procedure is a single event handler that is used by all of the items of the menu and uses the Tag property of the Sender menu item to refer to the element of the ControlBar associated with the item in the FormCreate method:

```
procedure TFormRichNote.BarMenuClick(Sender: TObject);
var
  aCtrl: TControl;
begin
  aCtrl := TControl ((Sender as TComponent).Tag);
  aCtrl.Visible := not aCtrl.Visible;
end;
```

Finally, the OnPopup event of the menu is used to refresh the check mark of the menu items:

```
procedure TFormRichNote.BarMenuPopup(Sender: TObject);
var
  I: Integer;
begin
  // update the menu checkmarks
  for I := 0 to BarMenu.Items.Count - 1 do
    BarMenu.Items [I].Checked := TControl (BarMenu.Items [I].Tag).Visible;
end;
```

A Menu in a Control Bar

If you look at the user interface of the MdEdit2 application, in Figure 8.6, you'll notice that the menu of the form actually shows up inside a toolbar, hosted by the control bar, and below the application caption. In prior versions of Delphi, this required writing some custom code. In Delphi 6, instead, all you have to do is to set the Menu property of the toolbar. You must also remove the main menu from the Menu property of the form, to avoid having two menus.

Delphi's Docking Support

Another feature added in Delphi 4 was support for *dockable* toolbars and controls. In other words, you can create a toolbar and move it to any of the sides of a form, or even move it freely on the screen, undocking it. However, setting up a program properly to obtain this effect is not as easy as it sounds.

First of all, Delphi's docking support is connected with container controls, not with forms. A panel, a ControlBar, and other containers (technically, any control derived from `TWinControl`) can be set up as dock targets by enabling their `DockSite` property. You can also set the `AutoSize` property of these containers, so that they'll show up only if they actually hold a control.

To be able to drag a control (an object of any `TControl`-derived class) into the dock site, simply set its `DragKind` property to dkDock and its `DragMode` property to dmAutomatic. This way, the control can be dragged away from its current position into a new docking container. To undock a component and move it to a special form, you can set its `FloatingDockSiteClass` property to `TCustomDockForm` (to use a predefined stand-alone form with a small caption).

All the docking and undocking operations can be tracked by using special events of the component being dragged (`OnStartDock` and `OnEndDock`) and the component that will receive the docked control (`OnDragOver` and `OnDragDrop`). These docking events are very similar to the dragging events available in earlier versions of Delphi.

There are also commands you can use to accomplish docking operations in code and to explore the status of a docking container. Every control can be moved to a different location using the `Dock`, `ManualDock`, and `ManualFloat` methods. A container has a `DockClientCount` property, indicating the number of docked controls, and a `DockClients` property, with the array of these controls.

Moreover, if the dock container has the `UseDockManager` property set to True, you'll be able to use the `DockManager` property, which implements the `IDockManager` interface. This interface has many features you can use to customize the behavior of a dock container, even including support for streaming its status.

As you can see from this brief description, docking support in Delphi is based on a large number of properties, events, methods and objects (such as dock zones and dock trees)—more features than we have room to explore in detail. The next example introduces the main features you'll generally need.

NOTE Docking support in not currently available in VisualCLX on either platform.

Docking Toolbars in ControlBars

In the MdEdit2 example, already discussed, I've included docking support. The program has a second ControlBar at the bottom of the form, which accepts dragging one of the toolbars in the ControlBar at the top. Since both toolbar containers have the AutoSize property set to True, they are automatically removed when the host contains no controls. I've also set to True the AutoDrag and AutoDock properties of both ControlBars.

Actually, I had to place the bottom ControlBar inside a panel, together with the RichEdit control. Without this trick, the ControlBar, when activated and automatically resized, kept moving below the status bar, which I don't think is the correct behavior. Because, in the example, the ControlBar is the only control of the panel aligned to the bottom, there is no possible confusion.

To let users drag the toolbars out of the original container, all you have to do is, once again (as stated previously), set their DragKind property to dkDock and their DragMode property to dmAutomatic. The only two exceptions are the menu toolbar, which I decided to keep close to the typical position of a menu bar, and the ColorBox control, as unlike the combo box this component doesn't expose the DragMode and DragKind properties. (Actually, in the FormCreate method of the example, you'll find code you can use to activate docking for the component, based on the "protected hack" discussed in Chapter 3.) The Fonts combo box can be dragged, but I don't want to let a user dock it in the lower control bar. To implement this constraint, I've used the control bar's OnDockOver event handler, by accepting the docking operation only for toolbars:

```
procedure TFormRichNote.ControlBarLowerDockOver(Sender: TObject;
  Source: TDragDockObject; X, Y: Integer; State: TDragState;
  var Accept: Boolean);
begin
  Accept := Source.Control is TToolbar;
end;
```

When you move one of the toolbars outside of any container, Delphi automatically creates a floating form; you might be tempted to set it back by closing the floating form. This doesn't work, as the floating form is removed along with the toolbar it contains. However, you can use the shortcut menu of the topmost ControlBar, attached also to the other ControlBar, to show this hidden toolbar.

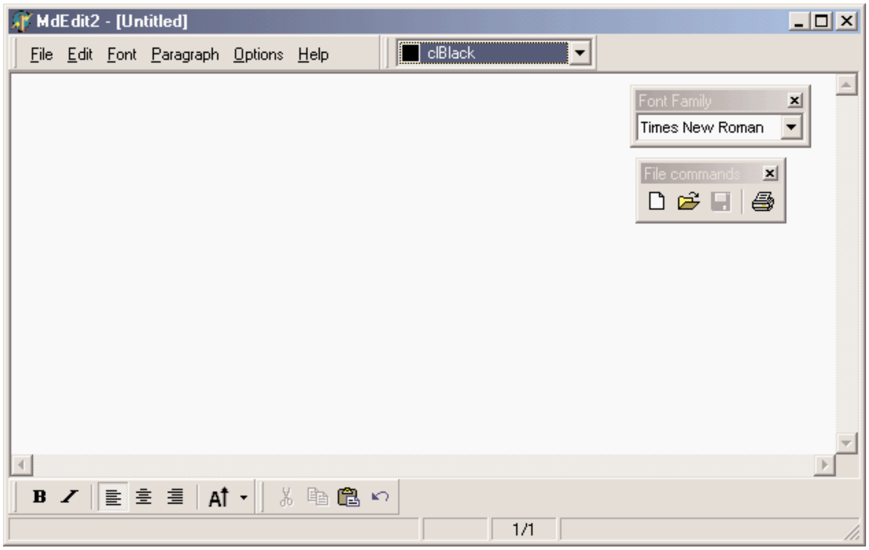
The floating form created by Delphi to host undocked controls has a thin caption, the so-called *toolbar caption*, which by default has no text. For this reason, I've added some code to the OnEndDock event of each dockable control, to set the caption of the newly created form into which the control is docked. To avoid a custom data structure for this information, I've used the text of the Hint property of these controls, which is basically not used, to provide a suitable caption:

```
procedure TFormRichNote.EndDock(Sender, Target: TObject; X, Y: Integer);
begin
  if Target is TCustomForm then
    TCustomForm(Target).Caption := GetShortHint((Sender as TControl).Hint);
end;
```

You can see an example of this effect in the MdEdit2 program in Figure 8.7. Another extension of the example, one which I haven't done, could be the addition of dock areas on the two sides of the form. The only extra effort this requires would be a routine to turn the toolbars vertically, instead of horizontally. This basically implies switching the Left and Top properties of each button, after disabling the automatic sizing.

FIGURE 8.7:

The MdEdit2 example allows you to dock the toolbars (but not the menu) at the top or bottom of the form or to leave them floating.



Controlling Docking Operations

Delphi provides many events and methods that give you a lot of control over docking operations, including a dock manager. To explore some of these features, try out the DockTest example, a test bed for docking operations. The program assigns the FloatingDockSiteClass property of a Memo component to TForm2, so that you can design specific features and add them to the floating frame that will host the control when it is floating, instead of using an instance of the default TCustomDockForm class.

Another feature of the program is that it handles the OnDockOver and OnDockDrop events of a dock host panel to display messages to the user, such as the number of controls currently docked:

```
procedure TForm1.Panel1DockDrop(Sender: TObject; Source: TDragDockObject;
  X, Y: Integer);
begin
  Caption := 'Docked: ' + IntToStr (Panel1.DockClientCount);
end;
```

In the same way, the program also handles the main form's docking events. Another control, a list box, has a shortcut menu you can invoke to perform docking and undocking operations in code, without the usual mouse dragging:

```
procedure TForm1.DocktoPanel1Click(Sender: TObject);
begin
  // dock to the panel
  ListBox1.ManualDock (Panel1, Panel1, alBottom);
end;

procedure TForm1.DocktoForm1Click(Sender: TObject);
begin
  // dock to the current form
  ListBox1.Dock (Self, Rect (200, 100, 100, 100));
end;

procedure TForm1.Floating1Click(Sender: TObject);
begin
  // toggle the floating status
  if ListBox1.Floating then
    ListBox1.ManualDock (Panel1, Panel1, alBottom)
  else
    ListBox1.ManualFloat (Rect (100, 100, 200, 300));
  Floating1.Checked := ListBox1.Floating;
end;
```

The final feature of the example is probably the most interesting one: Every time the program closes, it saves the current docking status of the panel, using the dock manager support. When the program is reopened, it reapplies the docking information, restoring the previous configuration of the windows. The program does this only with the panel, so the other floating windows will be displayed in their original positions. Here is the code for saving and loading:

```
procedure TForm1.FormDestroy(Sender: TObject);
var
  FileStr: TFileStream;
begin
```

```
    if Panel1.DockClientCount > 0 then
    begin
      FileStr := TFileStream.Create (DockFileName, fmCreate or fmOpenWrite);
      try
        Panel1.DockManager.SaveToStream (FileStr);
      finally
        FileStr.Free;
      end;
    end
    else
      // remove the file
      DeleteFile (DockFileName);
  end;

  procedure TForm1.FormCreate(Sender: TObject);
  var
    FileStr: TFileStream;
  begin
    // reload the settings
    DockFileName := ExtractFilePath (Application.Exename) + 'dock.dck';
    if FileExists (DockFileName) then
    begin
      FileStr := TFileStream.Create (DockFileName, fmOpenRead);
      try
        Panel1.DockManager.LoadFromStream (FileStr);
      finally
        FileStr.Free;
      end;
    end;
    Panel1.DockManager.ResetBounds (True);
  end;
```

There are more features one might theoretically add to a docking program, but to add those you should remove other features, as some of them might conflict. For example, automatic alignments don't work terribly well with the docking manager's code for restoring. I suggest you take this program and explore its behavior, extending it to support the type of user interface you prefer.

NOTE Remember that although docking panels make an application look nice, some users get confused by the fact that their toolbars might disappear or be in a different position than they are used to. Don't overuse the docking features, or some of your inexperienced users may get lost.

Docking to a PageControl

Another interesting feature of page controls is the specific support for docking. As you dock a new control over a PageControl, a new page is automatically added to host it, as you can easily see in the Delphi environment. To accomplish this, you simply set the PageControl as a dock host and activate docking for the client controls. This works best when you have secondary forms you want to host. Moreover, if you want to be able to move the entire PageControl into a floating window and then dock it back, you'll need a docking panel in the main form.

This is exactly what I've done in the DockPage example, which has a main form with the following settings:

```
object Form1: TForm1
  Caption = 'Docking Pages'
  object Panel1: TPanel
    Align = alLeft
    DockSite = True
    OnMouseDown = Panel1MouseDown
    object PageControl1: TPageControl
      ActivePage = TabSheet1
      Align = alClient
      DockSite = True
      DragKind = dkDock
      object TabSheet1: TTabSheet
        Caption = 'List'
        object ListBox1: TListBox
          Align = alClient
        end
      end
    end
  end
  object Splitter1: TSplitter
    Cursor = crHSplit
  end
  object Memo1: TMemo
    Align = alClient
  end
end
```

Notice that the Panel has the `UseDockManager` property set to True and that the PageControl invariably hosts a page with a list box, as when you remove all of the pages, the code used for automatic sizing of dock containers might cause you some trouble. Now the program has two other forms, with similar settings (although they host different controls):

```
object Form2: TForm2
  Caption = 'Small Editor'
  DragKind = dkDock
  DragMode = dmAutomatic
  object Memo1: TMemo
    Align = alClient
  end
end
```

You can drag these forms onto the page control to add new pages to it, with captions corresponding with the form titles. You can also undock each of these controls and even the entire PageControl. To do this, the program doesn't enable automatic dragging, which would make it impossible to switch pages anymore. Instead, the feature is activated when the user clicks on the area of the PageControl that has no tabs—that is, on the underlying panel:

```
procedure TForm1.Panel1MouseDown(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  PageControl1.BeginDrag (False, 10);
end;
```

You can test this behavior by running the DockPage example, although Figure 8.8 tries to depict it. Notice that when you remove the PageControl from the main form, you can directly dock the other forms to the panel and then split the area with other controls. This is the situation captured by the figure.

FIGURE 8.8:

The main form of the DockPage example after a form has been docked to the page control on the left. Notice that another form uses part of the area of a hosting panel.

The ActionManager Architecture

We have seen that actions and the ActionManager component can play a central role in the development of Delphi applications, since they allow a much better separation of the user interface from the actual code of the application. The user interface, in fact, can now easily change without impacting the code too much. The drawback of this approach is that a programmer has more work to do. To have a new menu item, you need to add the corresponding action first, than move to the menu, add the menu item, and connect it to the action.

To solve this issue, and to provider developers and end users with some advanced features, Delphi 6 introduces a brand new architecture, based on the ActionManager component, which largely extends the role of actions. The ActionManager, in fact, has a collection of actions but also a collection of toolbars and menus tied to them. The development of these toolbars and menus is completely visual: you drag actions from a special component editor of the ActionManager to the toolbars to have the buttons you need. Moreover, you can let the end user of your programs do the same operation, and rearrange their own toolbars and menus starting with the actions you provide them.

In other words, using this architecture allows you to build applications with a modern user interface, customizable by the user. The menu can show only the recently used items (as many Microsoft programs do, nowadays), allows for animation, and more.

This architecture is centered on the ActionManager component, but includes also a few others components found at the end of the Additional page of the palette:

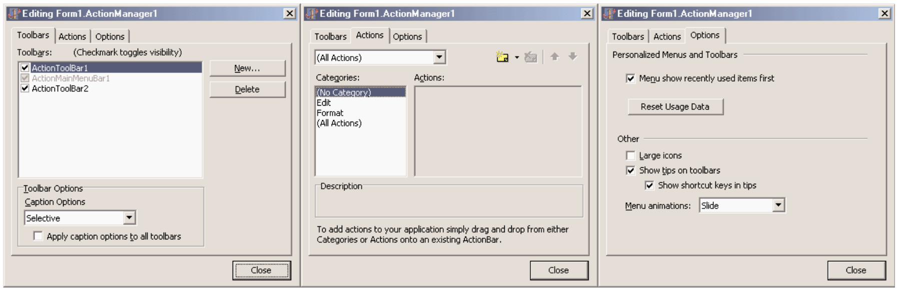
- The ActionManager component is a replacement of the ActionList (but can also use one or more existing ActionLists) adding to the architecture visual containers of actions.
- The ActionMainMenuBar control is a toolbar used to display the menu of an application based on the actions of an ActionManager component.
- The ActionToolBar control is a toolbar used to host buttons based on the actions of an ActionManager component.
- The CustomizeDlg component includes the dialog box you can use to let users customize the user interface of an application based on the ActionManager component.

Building a Simple Demo

As this architecture is mostly a visual architecture, a demo is probably worth more than a general discussion (although a printed book is not the best way to discuss a highly visual series of operations). To create a sample program based on this architecture, first drop an ActionManager component on a form, then double click it to open its component editor, shown in Figure 8.9. Notice that this editor is not modal, so you can keep it open while doing other operations in Delphi. Consider also that this same dialog box is displayed by the CustomizeDlg component, although with some limited features (for example, adding new actions is disabled).

FIGURE 8.9:

The three pages of the ActionManager editor dialog box



Toolbars: (Checkmark toggles visibility)

☑ ActionToolBar1
☑ ActionMainMenuBar1
☑ ActionToolBar2

Caption Options: Selective

□ Apply caption options to all toolbars

(All Actions)

Categories: (No Category) Edit Format (All Actions)

Actions:

To add actions to your application simply drag and drop from either Categories or Actions onto an existing ActionBar.

Personalized Menus and Toolbars

☑ Menu show recently used items first

□ Large icons
☑ Show tips on toolbars
☑ Show shortcut keys in tips

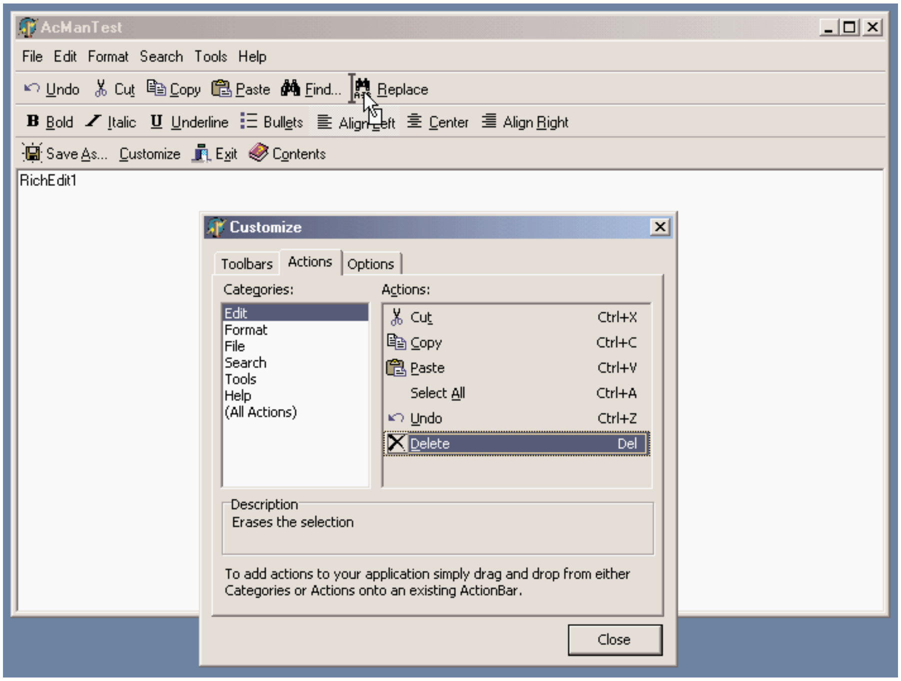
Menu animations: Slide

- The first page of this editor provides a list of visual containers of actions (toolbars or menus). You add new toolbars by clicking the New button. To add new menus, you have to add the corresponding component to the form, then open the `ActionBars` collection of the ActionManager, select an action bar or add a new one, and hook the menu to it using the `ActionBar` property. These are the same steps you could follow to connect a new toolbar to this architecture at run time.
- The second page of the ActionManager editor is very similar to the ActionList editor, providing a way to add new standard or custom action, arrange them in categories, and change their order. The new feature of this page, though, is that fact you can drag a category or a single action from it and drop it onto an action bar control. If you drag a category to a menu, you obtain a pull-down menu with all of the items of the category; if you drag it to a toolbar, each of the actions of the category gets a button on the toolbar. If you drag a single action to a toolbar, you get the corresponding button; if you drag it to the menu, you get a direct menu command, which is something you should generally avoid.
- The last page of the ActionManager editor allows you (and optionally an end user) to activate the display of recently used menu items and to modify some of the visual properties of the toolbars.

The AcManTest program is an example that uses some of the standard actions and a RichEdit control to showcase the use of this architecture (I haven't actually written any custom code to make the actions work better, as I wanted to focus only on the action manager for this example). You can experiment with it at design time or run it, click the Customize button, and see what an end user can do to customize the application (see Figure 8.10).

FIGURE 8.10:

Using the CustomizeDlg component, you can let a user customize the toolbars and the menu of an application, simply by dragging items from the dialog box or moving them around in the actions bars themselves.



Erases the selection

To add actions to your application simply drag and drop from either Categories or Actions onto an existing ActionBar.

Actually, in the program you can prevent the user from doing some operations on actions. Any specific element of the user interface (a `TActionClient` object) has a `ChangedAllowed` property that you can use to disable modify, move, and delete operations. Any action client container (the visual bars) has a property to disable hiding itself (`AllowHiding` by default is set to True). Each ActionBar `Items` collection has a `Customizable` option you can turn off to disable all user changes to the entire bar.

TIP

When I say "ActionBar" I don't mean the visual toolbars containing action items, but the items of the `ActionBars` collection of the ActionManager component, which in turn has an `Items` collection. The best way to understand this structure is to look at the sub-tree displayed by the Object TreeView for an ActionManager component. Each `TActionBar` collection item has an actual `TCustomActionBar` visual component connected, but not the reverse (so, for example, you cannot reach this `Customizable` property if you start by selecting the visual toolbar). Due to the similarity of the two names, it can take a while to understand what the Delphi help actually means.

To make user settings persistent, I've connected a file (called `settings`) to the `FileName` property of the ActionManager component. When you assign this property, you should enter a name of the file you want to use; when you start the program, the file will be created for you by the ActionManager.

The persistency is accomplished by streaming each ActionClientItem connected with the action manager. As these action client items are based on the user settings and maintain state information, a single file collects both user changes to the interface and usage data.

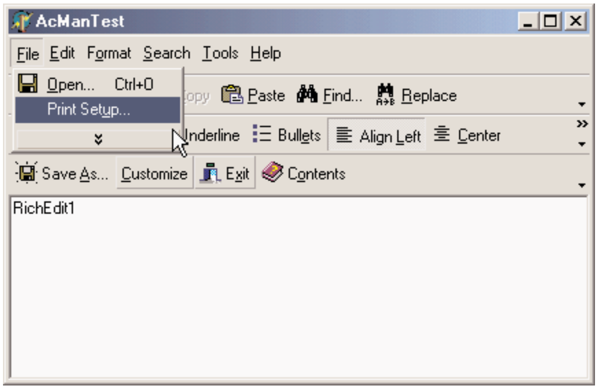
Since Delphi stores user setting and status information in a file you provide, you can make your application support multiple users on a single computer. Simply use a file of settings for each of them and connect it to the action manager as the program starts (using the current user of the computer or after some custom login). Another possibility is to store these settings over the network, so that even when a user moves to a different computer, the current personal settings will move along.

Least-Recently Used Menu Items

Once a file for the user settings is available, the ActionManager will save into it the user preferences and also use it to track the user activity. This is essential to let the system remove menu items which haven't been used for some time, making them available in an extended menu, using the same user interface adopted by Microsoft (see Figure 8.11 for an actual example).

FIGURE 8.11:

The ActionManager disables least recently used menu items that you can still see by selecting the menu extension command.



The ActionManager doesn't simply show the least recently used items: it allows you to customize this behavior in a very precise way. Each action bar has a `SessionCount` property that keeps track of the number of times the application has been executed. Each ActionClientItem has a `LastSession` property and a `UsageCount` property used to track user operations. Notice, by the way, that a user can reset all this dynamic information by using the Reset Usage Data button of the customization dialog.

The system calculates the number of sessions the action has gone unused, by computing the difference between the number of times the application has been executed (SessionCount) and the last session in which the action has been used (LastSession). The value of UsageCount is used to look up in the PrioritySchedule how many sessions the items can go unused before it is removed. In other words, the PrioritySchedule maps each the usage count with a number of *unused* sessions. By modifying the PrioritySchedule, you can determine how fast the items are removed in case they are not used.

You can also prevent this system to be activated for specific actions or groups of actions. The Items property of the ActionBars of the ActionManager has a HideUnused property you can toggle to disable this feature for an entire menu. To make a specific item always visible, regardless of the actual usage, you can also set its UsageCount property to –1. However, the user settings might override this value.

To understand a little better how this system works, I've added a custom action (ActionShowStatus) to the AcManTest example. The action has the following code that saves the current action manager settings to a memory stream, converts it to text, and shows it inside the memo (refer to Chapter 5 for more information about streaming):

```
procedure TForm1.ActionShowStatusExecute(Sender: TObject);
var
  memStr, memStr2: TMemoryStream;
begin
  memStr := TMemoryStream.Create;
  try
    memStr2 := TMemoryStream.Create;
    try
      ActionManager1.SaveToStream(memStr);
      memStr.Position := 0;
      ObjectBinaryToText(memStr, memStr2);
      memStr2.Position := 0;
      RichEdit1.Lines.LoadFromStream(memStr2);
    finally
      memStr2.Free;
    end;
  finally
    memStr.Free;
  end;
end;
```

The output you obtain is the textual version of the settings file automatically updated at each execution of the program. Here a small portion of this file, with the details of one of pull-down menus and plenty of extra comments:

```
item // File pulldown of the main menu action bar
  Items = <
```

```
      item
        Action = Form1.FileOpen1
        LastSession = 19 // was used in the last session
        UsageCount = 4 // was used four times
      end
      item
        Action = Form1.FileSaveAs1 // never used
      end
      item
        Action = Form1.FilePrintSetup1
        LastSession = 7 // used some time ago
        UsageCount = 1 // only once
      end
      item
        Action = Form1.FileRun1 // never used
      end
      item
        Action = Form1.FileExit1 // never used
      end>
    Caption = '&File'
    LastSession = 19
    UsageCount = 5 // the sum of the usage count of the items
  end
```

Porting an Existing Program

If this architecture is nice, you'll probably need to redo most of your applications to take advantage of it. However, if you're already using actions (with the ActionList component), this conversion will be much simpler. In fact, the ActionManager has its own set of actions but can also use actions from another ActionManager or ActionList. The `LinkedActionLists` property of the ActionManager is a collection of other containers of actions (ActionLists or ActionManagers), which can be associated with the current one. Associating all the various groups of action is useful to let a user customize the entire user interface with a single dialog box.

If you hook external actions and open the ActionManager editor, you'll see in the Actions page a combo box listing the current ActionManager plus the other action containers linked to it. You can choose one of these containers to see its set of actions and change their properties. The All Action option of this combo box allows you to work on all of the actions from the various containers at once, but I've noticed that at startup it is selected but not always *effective*. Reselect it to actually see all of the actions.

As an example of porting an existing application, I've extended the program built throughout this chapter, into the MdEdit3 example. This example uses the same action list of the previous version hooked to an ActionManager that has the extra customize property, to let users rearrange the user interface. Differently from the earlier AcManDemo program, the MdEdit3 example uses a ControlBar as a container for the action bars (a menu, three toolbars, and the usual combo boxes) and has full support for dragging them outside of the container as floating bars and dropping them into the lower ControlBar.

To accomplish this, I only had to modify the source code slightly to refer to the new classes for the containers (that is, TCustomActionToolBar instead of TToolBar) in the ControlBar-LowerDockOver method. I also found out that the OnEndDock event of the ActionToolBar component passes as parameter an empty target when the system creates a floating form to host the control, so that I couldn't easily give to this forms a new custom caption (see the EndDock method of the form).

Using List Actions

We'll see more examples of the use of this architecture in the chapters devoted to MDI and database programming. For the moment, I just want to add an extra example showing how to use a rather complex group of standard actions introduced in Delphi 6, the list actions. List actions, in fact, comprise two different groups. Some of them (such as the Move, Copy, Delete, Clear, and Select All) actions are normal actions working on list boxes or other lists. The VirtualListAction and StaticListAction elements, instead, define actions based multiple choices, which are going to be displayed in a toolbar as a combo box.

The ListActions demo highlights both groups of list actions, as its ActionManager has five of them, displayed on two separate toolbars. This is a summary of the actions of the actions manager (I've omitted the action bars portion of the component's DFM file):

```
object ActionManager1: TActionManager
  ActionBars.SessionCount = 1
  ActionBars = <...>
  object StaticListAction1: TStaticListAction
    Caption = 'Numbers'
    Items.CaseSensitive = False
    Items.SortType = stNone
    Items = <
      item
        Caption = 'one'
      end
      item
        Caption = 'two'
      end
      ...>
    OnItemSelected = ListActionItemSelected
  end
  object VirtualListAction1: TVirtualListAction
    Caption = 'Items'
```

```
      OnGetItem = VirtualListAction1GetItem
      OnGetItemCount = VirtualListAction1GetItemCount
      OnItemSelected = ListActionItemSelected
    end
    object ListControlCopySelection1: TListControlCopySelection
      Caption = 'Copy'
      Destination = ListBox2
      ListControl = ListBox1
    end
    object ListControlDeleteSelection1: TListControlDeleteSelection
      Caption = 'Delete'
    end
    object ListControlMoveSelection2: TListControlMoveSelection
      Caption = 'Move'
      Destination = ListBox2
      ListControl = ListBox1
    end
  end
```

The program has also two list boxes in its form, used as action targets. The Copy and Move actions are tied to these two list boxes by their `ListControl` and `Destination` properties. The Delete action, instead, automatically works with the list box having the input focus.

The StaticListAction defines a series of alternative items, in its `Items` collection. This is not a plain string list, as any item has also an `ImageIndex`, which allows turning the combo box in graphical selection. You can, of course, add more items to this list programmatically. However, in case of a highly dynamic list, you can also use the VirtualListAction. This component doesn't define a list of items but has two events you can use to provide strings and images for the list. The `OnGetItemCount` event allows you to indicate the number of items to display; the `OnGetItem` event is then called for each specific item.

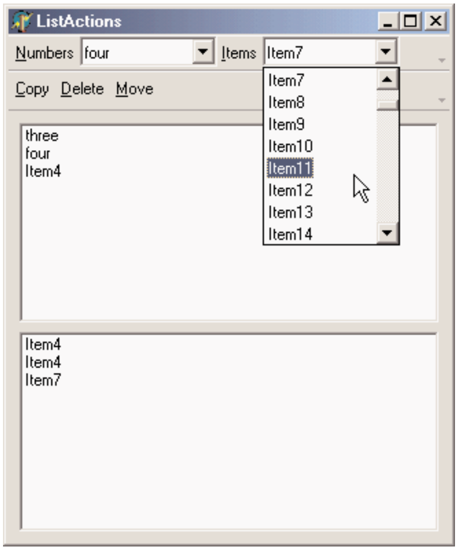
In the ListActions demo, the VirtualListAction has the following event handlers for its definition, producing the list you can see in the active combo box of Figure 8.12:

```
procedure TForm1.VirtualListAction1GetItemCount(Sender: TCustomListAction;
  var Count: Integer);
begin
  Count := 100;
end;

procedure TForm1.VirtualListAction1GetItem(Sender: TCustomListAction;
  const Index: Integer; var Value: String;
  var ImageIndex: Integer; var Data: Pointer);
begin
  Value := 'Item' + IntToStr (Index);
end;
```

FIGURE 8.12:

The ListActions application has a toolbar hosting a static list and a virtual one.



NOTE I thought that the virtual action items were actually requested only when needed to display them, making this actually a virtual list. Instead, all the items are created right away, as you can prove by enabling the commented code of the `VirtualListAction1GetItem` method (not in the listing above), which adds to each item the time its string is requested.

Both the static and the virtual list have an `OnItemSelected` event. In the shared event handler, I've written the following code, to add the current item to the first list box of the form:

```
procedure TForm1.ListActionItemSelected(Sender: TCustomListAction;
  Control: TControl);
begin
  ListBox1.Items.Add ((Control as TCustomActionCombo).SelText);
end;
```

In this case, the sender is the custom action list, but the `ItemIndex` property of this list is not updated with the selected item. However, accessing the visual control that displays the list, we can obtain the value of the selected item.

What's Next?

In this chapter, I've introduced the use of actions, the actions list, and action manager architectures. As you've seen, this is an extremely powerful architecture to separate the user interface from the actual code of your applications, which uses and refers to the actions and not the menu items or toolbar button related to them. The Delphi 6 extension of this architecture allows users of your programs to have a lot of control, and makes your applications resemble high-end programs without much effort on your part. The same architecture is also very handy to let you design the user interface of your program, regardless of whether you give this ability to users.

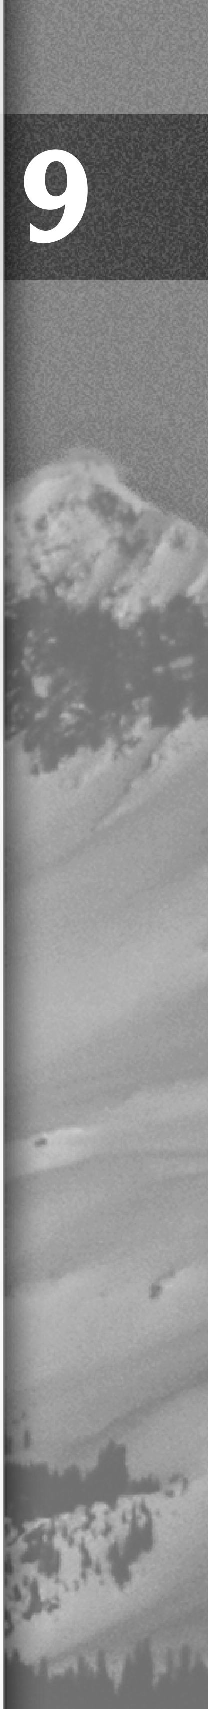
I've also covered other user-interface techniques, such as docking toolbars and other controls. You can consider this chapter the first step toward building professional applications. We will take other steps in the following chapters; but you already know enough to make your programs similar to some best-selling Windows applications, which may be very important for your clients.

Now that the elements of the main form of our programs are properly set up, we can consider adding secondary forms and dialog boxes. This is the topic of the next chapter, along with a general introduction to forms. The following chapter will then cover the overall structure of a Delphi application.

CHAPTER 9

Working with Forms

- Form styles, border styles, and border icons
- Mouse and keyboard input
- Painting and special effects
- Positioning, scaling, and scrolling forms
- Creating and closing forms
- Modal and modeless dialog boxes and forms
- Creating secondary forms dynamically
- Predefined dialog boxes
- Building a splash screen



If you've read the previous chapters, you should now be able to use Delphi's visual components to create the user interface of your applications. So let's turn our attention to another central element of development in Delphi: forms. We have used forms since the initial chapters, but I've never described in detail what you can do with a form, which properties you can use, or which methods of the TForm class are particularly interesting.

This chapter looks at some of the properties and styles of forms and at sizing and positioning them. I'll also introduce applications with multiple forms, the use of dialog boxes (custom and predefined ones), frames, and visual form inheritance. I'll also devote some time to input on a form, both from the keyboard and the mouse.

The *TForm* Class

Forms in Delphi are defined by the TForm class, included in the Forms unit of VCL. Of course, there is now a second definition of forms inside VisualCLX. Although I'll mainly refer to the VCL class in this chapter, I'll also try to highlight differences with the cross-platform version provided in CLX.

The TForm class is part of the windowed-controls hierarchy, which starts with the TWinControl (or TWidgetControl) class. Actually, TForm inherits from the *almost complete* TCustomForm, which in turn inherits from TScrollingWinControl (or TScrollingWidget). Having all of the features of their many base classes, forms have a long series of methods, properties, and events. For this reason, I won't try to list them here, but I'd rather present some interesting techniques related to forms throughout this chapter. I'll start by presenting a technique for *not* defining the form of a program at design time, using the TForm class directly, and then explore a few interesting properties of the form class.

Throughout the chapter, I'll point out a few differences between VCL forms and CLX forms. I've actually built a CLX version for most of the examples of this chapter, so you can immediately start experimenting with forms and dialog boxes in CLX, as well as VCL. As in past chapters, the CLX version of each example is prefixed by the letter *Q*.

Using Plain Forms

Generally, Delphi developers tend to create forms at design time, which implies deriving a new class from the base one, and build the content of the form visually. This is certainly a reasonable standard practice, but it is not compulsory to create a descendant of the TForm class to show a form, particularly if it is a simple one.

Consider this case: you have to show a rather long message (based on a string) to a user, and you don't want to use the simple predefined message box, as it will show up too large and not provide scroll bars. You can create a form with a memo component in it, and display the string inside it. Nothing prevents you from creating this form in the standard visual way, but you might consider doing this in code, particularly if you need a large degree of flexibility.

The DynaForm and QDynaForm examples (both on the companion CD), which are somewhat extreme, have no form defined at design time but include a unit with this function:

```
procedure ShowStringForm (str: string);
var
  form: TForm;
begin
  Application.CreateForm (TForm, form);
  form.caption := 'DynaForm';
  form.Position := poScreenCenter;
  with TMemo.Create (form) do
  begin
    Parent := form;
    Align := alClient;
    Scrollbars := ssVertical;
    ReadOnly := True;
    Color := form.Color;
    BorderStyle := bsNone;
    WordWrap := True;
    Text := str;
  end;
  form.Show;
end;
```

Besides the fact I had to create the form using the `Application` global object, a feature required by Delphi applications and discussed in the next chapter, this code simply does dynamically what you generally do with the form designer. Writing this code is undoubtedly more tedious, but it allows also a greater deal of flexibility, because any parameter can depend on external settings.

The `ShowStringForm` function above is not executed by an event of another form, as there are no traditional forms in this program. Instead, I've modified the project's source code to the following:

```
program DynaForm;

uses
  Forms,
  DynaMemo in 'DynaMemo.pas';

{$R *.RES}

var
```

```
  str: string;

begin
  str := '';
  Randomize;
  while Length (str) < 2000 do
    str := str + Char (32 + Random (94));
  ShowStringForm (str);

  Application.Run;
end.
```

The effect of running the DynaForm program is a strange-looking form filled with random characters (as you can see in Figure 9.1), not terribly useful in itself but for the idea it underscores.

FIGURE 9.1:

The dynamic form generated by the DynaForm example is completely created at run time, with no design-time support.

TIP

An indirect advantage of this approach, compared to the use of DFM files for design-time forms, is that it would be much more difficult for an external programmer to grab information about the structure of the application. In Chapter 5 we saw that you can extract the DFM from the current Delphi executable file, but the same can be easily accomplished for any executable file compiled with Delphi for which you don't have the source code. If it is really important for you to keep to yourself a specific set of components you are using (maybe those in a specific form), and the default values of their properties, writing the extra code might be worth the effort.

The Form Style

The `FormStyle` property allows you to choose between a normal form (fsNormal) and the windows that make up a Multiple Document Interface (MDI) application. In this case, you'll use the fsMDIForm style for the MDI parent window—that is, the frame window of the MDI application—and the fsMDIChild style for the MDI child window. To know more about the development of an MDI application, look at Chapter 10.

A fourth option is the fsStayOnTop style, which determines whether the form has to always remain on top of all other windows, except for any that also happen to be "stay-on-top" windows.

To create a top-most form (a form whose window is always on top), you need only set the `FormStyle` property, as indicated above. This property has two different effects, depending on the kind of form you apply it to:

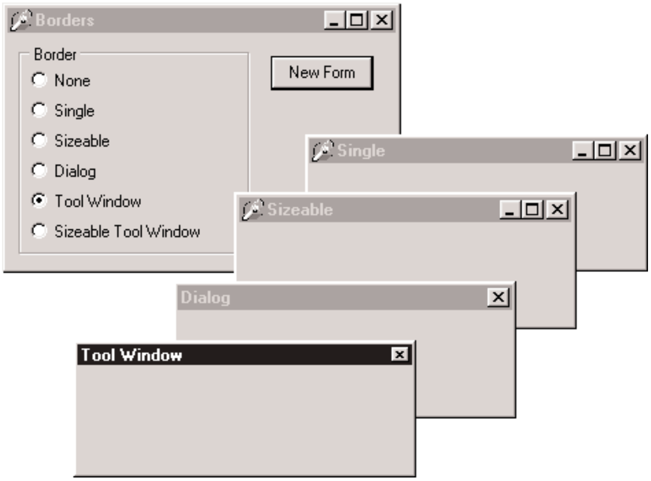
- The main form of an application will remain in front of every other application (unless other applications have the same top-most style, too). At times, this generates a rather ugly visual effect, so this makes sense only for special-purpose alert programs.
- A secondary form will remain in front of any other form of the application it belongs to. The windows of other applications are not affected, though. This is often used for floating toolbars and other forms that should stay in front of the main window.

The Border Style

Another important property of a form is its `BorderStyle`. This property refers to a visual element of the form, but it has a much more profound influence on the *behavior* of the window, as you can see in Figure 9.2.

FIGURE 9.2:

Sample forms with the various border styles, created by the Borders example



At design time, the form is always shown using the default value of the `BorderStyle` property, bsSizeable. This corresponds to a Windows style known as *thick frame*. When a main window has a thick frame around it, a user can resize it by dragging its border. This is made clear by the special *resize* cursors (with the shape of a double-pointer arrow) displayed when the user moves the mouse onto this thick window border.

A second important choice for this property is bsDialog. If you select it, the form uses as its border the typical dialog-box frame—a thick frame that doesn't allow resizing. In addition to this graphical element, note that if you select the bsDialog value, the form becomes a dialog box. This involves several changes. For example, the items on its system menu are different, and the form will ignore some of the elements of the `BorderIcons` set property.

WARNING Setting the `BorderStyle` property at design time produces no visible effect. In fact, several component properties do not take effect at design time, because they would prevent you from working on the component while developing the program. For example, how could you resize the form with the mouse if it were turned into a dialog box? When you run the application, though, the form will have the border you requested.

There are four more values we can assign to the `BorderStyle` property. The style bsSingle can be used to create a main window that's not resizable. Many games and applications based on windows with controls (such as data-entry forms) use this value, simply because resizing these forms makes no sense. Enlarging a form to see an empty area or reducing its size to make some components less visible often doesn't help a program's user (although Delphi's automatic scroll bars partially solve the last problem). The value bsNone is used only in very special situations and inside other forms. You'll never see an application with a main window that has no border or caption (except maybe as an example in a programming book to show you that it makes no sense).

The last two values, bsToolWindow and bsSizeToolWin, are related to the specific Win32 extended style `ws_ex_ToolWindow`. This style turns the window into a floating toolbox, with a small title font and close button. This style should not be used for the main window of an application.

To test the effect and behavior of the different values of the `BorderStyle` property, I've written a simple program called Borders, available also as QBorders in the CLX version. You've already seen its output, in Figure 9.2. However, I suggest you run this example and experiment with it for a while to understand all the differences in the forms.

WARNING In CLX, the enumeration for the `BorderStyle` property uses slightly different values, prefixed by the letters *fbs* (form border style). So we have fbsSingle, fbsDialog, and so on.

The main form of this program contains only a radio group and a button. There is also a secondary form, with no components and the `Position` property set to poDefaultPosOnly. This affects the initial position of the secondary form we'll create by clicking the button. (I'll discuss the `Position` property later in this chapter.)

The code of the program is very simple. When you click the button, a new form is dynamically created, depending on the selected item of the radio group:

```
procedure TForm1.BtnNewFormClick(Sender: TObject);
var
  NewForm: TForm2;
begin
  NewForm := TForm2.Create (Application);
  NewForm.BorderStyle := TFormBorderStyle (BorderRadioGroup.ItemIndex);
  NewForm.Caption := BorderRadioGroup.Items[BorderRadioGroup.ItemIndex];
  NewForm.Show;
end;
```

This code actually uses a trick: it casts the number of the selected item into the TFormBorderStyle enumeration. This works because I've given the radio buttons the same order as the values of this enumeration:

```
type
  TFormBorderStyle = (bsNone, bsSingle, bsSizeable, bsDialog, bsTolWindow,
    bsSizeToolWin);
```

The BtnNewFormClick method then copies the text of the radio button to the caption of the secondary form. This program refers to TForm2, the secondary form defined in a secondary unit of the program, saved as SECOND.PAS. For this reason, to compile the example, you must add the following lines to the implementation section of the unit of the main form:

```
uses
  Second;
```

TIP Whenever you need to refer to another unit of a program, place the corresponding uses statement in the implementation portion instead of the interface portion if possible. This speeds up the compilation process, results in cleaner code (because the units you include are separate from those included by Delphi), and prevents circular unit compilation errors. To accomplish this, you can also use the File ➢ Use Unit menu command.

The Border Icons

Another important element of a form is the presence of icons on its border. By default, a window has a small icon connected to the system menu, a Minimize button, a Maximize button, and a Close button on the far right. You can set different options using the BorderIcons property, a set with four possible values: biSystemMenu, biMinimize, biMaximize, and biHelp.

NOTE The biHelp border icon enables the "What's this?" Help. When this style is included and the biMinimize and biMaximize styles are excluded, a question mark appears in the form's title bar. If you click this question mark and then click a component inside the form (but not the form itself!), Delphi activates the Help about that object inside a pop-up window. This is demonstrated by the BIcons example, which has a simple Help file with a page connected to the `HelpContext` property of the button in the middle of the form.

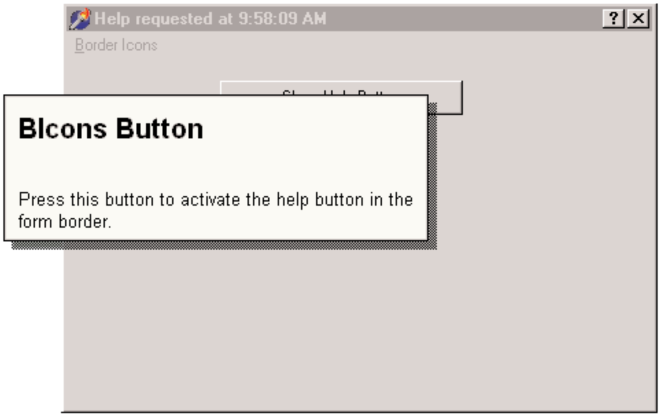
The BIcons example demonstrates the behavior of a form with different border icons and shows how to change this property at run time. The form of this example is very simple: It has only a menu, with a pull-down containing four menu items, one for each of the possible elements of the set of border icons. I've written a single method, connected with the four commands, that reads the check marks on the menu items to determine the value of the `BorderIcons` property. This code is therefore also a good exercise in working with sets:

```
procedure TForm1.SetIcons(Sender: TObject);
var
  BorIco: TBorderIcons;
begin
  (Sender as TMenuItem).Checked := not (Sender as TMenuItem).Checked;
  if SystemMenu1.Checked then
    BorIco := [biSystemMenu]
  else
    BorIco := [];
  if MaximizeBox1.Checked then
    Include (BorIco, biMaximize);
  if MinimizeBox1.Checked then
    Include (BorIco, biMinimize);
  if Help1.Checked then
    Include (BorIco, biHelp);
  BorderIcons := BorIco;
end;
```

While running the BIcons example, you can easily set and remove the various visual elements of the form's border. You'll immediately see that some of these elements are closely related: if you remove the system menu, all of the border icons will disappear; if you remove either the Minimize or Maximize button, it will be grayed; if you remove both these buttons, they will disappear. Notice also that in these last two cases, the corresponding items of the system menu are automatically disabled. This is the standard behavior for any Windows application. When the Maximize and Minimize buttons have been disabled, you can activate the Help button. As a shortcut to obtain this effect, you can click the button inside the form. Also, you can click the button after clicking the Help Menu icon to see a Help message, as you can see in Figure 9.3.

FIGURE 9.3:

The BIcons example. By selecting the help border icon and clicking over the button, you get the help displayed in the figure.



Help requested at 9:58:09 AM

BIcons Button

Press this button to activate the help button in the form border.

As an extra feature, the program also displays the time that the Help was invoked in the caption, by handling the `OnHelp` event of the form. This effect is visible in the figure.

WARNING By looking at the QBIcons version, built with CLX, you can clearly notice that a bug in the library prevents you from changing the border icons at run time, while the different design-time settings fully work.

Setting More Window Styles

The border style and border icons are indicated by two different Delphi properties, which can be used to set the initial value of the corresponding user interface elements. We have seen that besides changing the user interface, these properties affect the behavior of a window. It is important to know that in VCL (and obviously not in CLX), these border-related properties and the `FormStyle` property mainly correspond to different settings in the *style* and *extended style* of a window. These two terms reflect two parameters of the `CreateWindowEx` API function Delphi uses to create forms.

It is important to acknowledge this, because Delphi allows you to modify these two parameters freely by overriding the `CreateParams` virtual method:

```
public
  procedure CreateParams (var Params: TCreateParams); override;
```

This is the only way to use some of the peculiar window styles that are not directly available through form properties. For a list of window styles and extended styles, see the API Help under the topics “CreateWindow” and “CreateWindowEx.” You’ll notice that the Win32 API has styles for these functions, including those related to tool windows.

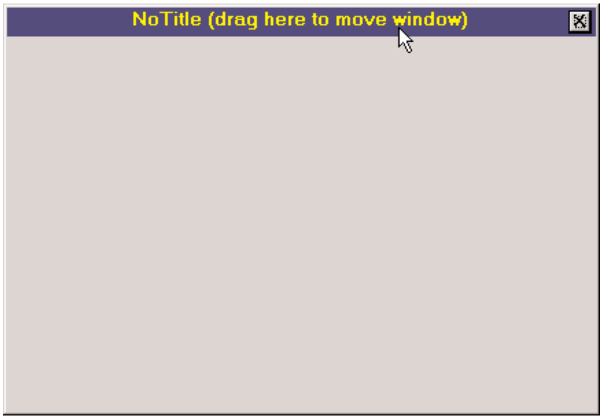
To show how to use this approach, I've written the NoTitle example on the companion CD, which lets you create a program with a custom caption. First we have to remove the standard caption but keep the resizing frame by setting the corresponding styles:

```
procedure TForm1.CreateParams (var Params: TCreateParams);
begin
  inherited CreateParams (Params);
  Params.Style := (Params.Style or ws_Popup) and not ws_Caption;
end;
```

NOTE Besides changing the style and other features of a window when it is created, you can change them at run time, although some of the settings do not take effect. To change most of the creation parameters at run time, you can use the `SetWindowLong` API function, which allows you to change the internal information of a window. The companion `GetWindowLong` function can be used to read the current status. Two more functions, `GetClassLong` and `SetClassLong`, can be used to read and modify class styles (the information of the `WindowClass` structure of `TCreateParams`). You'll seldom need to use these low-level Windows API functions in Delphi, unless you write advanced components.

To remove the caption, we need to change the overlapped style to a pop-up style; otherwise, the caption will simply stick. Now how do we add a custom caption? I've placed a label aligned to the upper border of the form and a small button on the far end. You can see this effect at run time in Figure 9.4.

FIGURE 9.4: The NoTitle example has no real caption but a fake one made with a label.



To make the fake caption work, we have to tell the system that a mouse operation on this area corresponds to a mouse operation on the caption. This can be done by intercepting the `wm_NCHitTest` Windows message, which is frequently sent to Windows to determine where the mouse currently is. When the hit is in the client area and on the label, we can pretend the mouse is on the caption by setting the proper result:

```
procedure TForm1.HitTest (var Msg: TWmNCHitTest);
  // message wm_NcHitTest
begin
  inherited;
  if (Msg.Result = htClient) and
    (Msg.YPos < Label1.Height + Top + GetSystemMetrics (sm_cyFrame)) then
    Msg.Result := htCaption;
end;
```

The GetSystemMetrics API function used in the listing above is used to query the operating system about the size of the various visual elements. It is important to make this request every time (and not cache the result) because users can customize most of these elements by using the Appearance page of the Desktop options (in Control Panel) and other Windows settings. The small button, instead, has a call to the Close method in its OnClick event handler. The button is kept in its position even when the window is resized by using the [akTop,akRight] value for the Anchors property. The form also has size constraints, so that a user cannot make it too small, as described in the "Form Constraints" section later in this chapter.

Direct Form Input

Having discussed some special capabilities of forms, I'll now move to a very important topic: user input in a form. If you decide to make limited use of components, you might write complex programs as well, receiving input from the mouse and the keyboard. In this chapter, I'll only introduce this topic.

Supervising Keyboard Input

Generally, forms don't handle keyboard input directly. If a user has to type something, your form should include an edit component or one of the other input components. If you want to handle keyboard shortcuts, you can use those connected with menus (possibly using a hidden pop-up menu).

At other times, however, you might want to handle keyboard input in particular ways for a specific purpose. What you can do in these cases is turn on the KeyPreview property of the form. Then, even if you have some input controls, the form's OnKeyPress event will always be activated for any keyboard-input operation. The keyboard input will then reach the destination component, unless you stop it in the form by setting the character value to zero (not the character *0*, but the value 0 of the character set, indicated as #0).

The example I've built to demonstrate this, KPreview, has a form with no special properties (not even `KeyPreview`), a radio group with four options, and some edit boxes, as you can see in Figure 9.5.

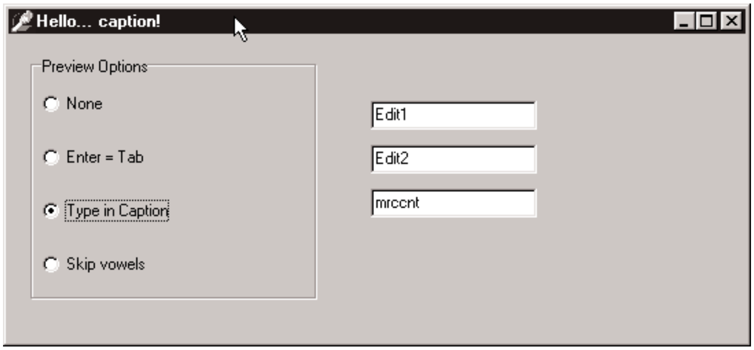


FIGURE 9.5:

The KPreview program allows you to type into the caption of the form (among other things).

By default the program does nothing special, except when the various radio buttons are used to enable the key preview:

```
procedure TForm1.RadioPreviewClick(Sender: TObject);
begin
  KeyPreview := RadioPreview.ItemIndex <> 0;
end;
```

Now we'll start receiving the `OnKeyPress` events, and we can do one of the three actions requested by the three special buttons of the radio group. The action depends on the value of the `ItemIndex` property of the radio group component. This is the reason the event handler is based on a `case` statement:

```
procedure TForm1.FormKeyPress(Sender: TObject; var Key: Char);
begin
  case RadioPreview.ItemIndex of
    ...
```

In the first case, if the value of the `Key` parameter is `#13`, which corresponds to the Enter key, we disable the operation (setting `Key` to zero) and then mimic the activation of the Tab key. There are many ways to accomplish this, but the one I've chosen is quite particular. I send the `CM_DialogKey` message to the form, passing the code for the Tab key (`VK_TAB`):

```
    1: // Enter = Tab
      if Key = #13 then
      begin
        Key := #0;
        Perform (CM_DialogKey, VK_TAB, 0);
      end;
```

NOTE The CM_DialogKey message is an internal, undocumented Delphi message. There are a few of them, actually quite interesting to build advanced components for and for some special coding, but Borland never described those. For more information on this topic, refer to the sidebar "Component Messages and Notifications" in Chapter 11. Notice also that this exact message-based coding style is not available under CLX.

To type in the caption of the form, the program simply adds the character to the current Caption. There are two special cases. When the Backspace key is pressed, the last character of the string is removed (by copying to the Caption all the characters of the current Caption but the last one). When the Enter key is pressed, the program stops the operation, by resetting the ItemIndex property of the radio group control. Here is the code:

```
2: // type in caption
begin
  if Key = #8 then // backspace: remove last char
    Caption := Copy (Caption, 1, Length (Caption) - 1)
  else if Key = #13 then // enter: stop operation
    RadioPreview.ItemIndex := 0
  else // anything else: add character
    Caption := Caption + Key;
  Key := #0;
end;
```

Finally, if the last radio item is selected, the code checks whether the character is a vowel (by testing for its inclusion in a constant "vowel set"). In this case, the character is skipped altogether:

```
3: // skip vowels
  if Key in ['a', 'e', 'i', 'o', 'u', 'A', 'E', 'I', 'O', 'U'] then
    Key := #0;
```

Getting Mouse Input

When a user clicks one of the mouse buttons over a form (or over a component, by the way), Windows sends the application some messages. Delphi defines some events you can use to write code that responds to these messages. The two basic events are OnMouseDown, received when a mouse button is clicked, and OnMouseUp, received when the button is released. Another fundamental system message is related to mouse movement; the event is OnMouseMove. Although it should be easy to understand the meaning of the three messages—down, up, and move—the question that might arise is, how do they relate to the OnClick event we have often used up to now?

We have used the OnClick event for components, but it is also available for the form. Its general meaning is that the left mouse button has been clicked and released on the same window or component. However, between these two actions, the cursor might have been moved outside the area of the window or component, while the left mouse button was held down.

Another difference between the `OnMouseXX` and `OnClick` events is that the latter relates only to the *left* mouse button. Most of the mouse types connected to a Windows PC have two mouse buttons, and some even have three. Usually we refer to these buttons as the left mouse button, generally used for selection; the right mouse button, for local menus; and the middle mouse button, seldom used. Nowadays most new mouse devices have a "button wheel" instead of the middle button. Users typically use the wheel for scrolling (causing an `OnMouseWheel` event), but they can also press it (generating the `OnMouseWheelDown` and `OnMouseWheelUp` events). Mouse wheel events are automatically converted into scrolling events.

Using Windows without a Mouse

A user should always be able to use any Windows application without the mouse. This is not an option; it is a Windows programming rule. Of course, an application might be easier to use with a mouse, but that should never be mandatory. In fact, there are users who for various reasons might not have a mouse connected, such as travelers with a small laptop and no space, workers in industrial environments, and bank clerks with other peripherals around.

There is another reason to support the keyboard: Using the mouse is nice, but it tends to be slower. If you are a skilled touch typist, you won't use the mouse to drag a word of text; you'll use shortcut keys to copy and paste it, without moving your hands from the keyboard.

For all these reasons, you should always set up a proper tab order for a form's components, remember to add keys for buttons and menu items for keyboard selection, use shortcut keys on menu commands, and so on.

The Parameters of the Mouse Events

All of the lower-level mouse events have the same parameters: the usual `Sender` parameter; a `Button` parameter indicating which of the three mouse buttons has been clicked (mbRight, mbLeft, or mbCenter); the `Shift` parameter indicating which of the *mouse-related keys* (Alt, Ctrl, and Shift, plus the three mouse buttons themselves) were pressed when the event occurred; and the `x` and `y` coordinates of the position of the mouse, in *client area* coordinates of the current window.

Using this information, it is very simple to draw a small circle in the position of a left mouse button–down event:

```
procedure TForm1.FormMouseDown(
  Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  if Button = mbLeft then
    Canvas.Ellipse (X-10, Y-10, X+10, Y+10);
end;
```

NOTE To draw on the form, we use a very special property: `Canvas`. A `TCanvas` object has two distinctive features: it holds a collection of drawing tools (such as a pen, a brush, and a font) and it has some drawing methods, which use the current tools. The kind of direct drawing code in this example is not correct, because the on-screen image is not persistent: moving another window over the current one will clear its output. The next example demonstrates the Windows "store-and-draw" approach.

Dragging and Drawing with the Mouse

To demonstrate a few of the mouse techniques discussed so far, I've built a simple example based on a form without any component and called MouseOne in the VCL version and QMouseOne in the CLX version. The first feature of this program is that it displays in the `Caption` of the form the current position of the mouse:

```
procedure TMouseForm.FormMouseMove(Sender: TObject; Shift: TShiftState;
  X, Y: Integer);
begin
  // display the position of the mouse in the caption
  Caption := Format ('Mouse in x=%d, y=%d', [X, Y]);
end;
```

You can use this simple feature of the program to better understand how the mouse works. Make this test: run the program (this simple version or the complete one) and resize the windows on the desktop so that the form of the MouseOne or QMouseOne program is behind another window and inactive but with the title visible. Now move the mouse over the form, and you'll see that the coordinates change. This means that the `OnMouseMove` event is sent to the application even if its window is not active, and it proves what I have already mentioned: Mouse messages are always directed to the window under the mouse. The only exception is the mouse capture operation I'll discuss in this same example.

Besides showing the position in the title of the window, the MouseOne/QMouseOne example can track mouse movements by painting small pixels on the form if the user keeps the Shift key pressed. (Again this direct painting code produces non-persistent output.)

```
procedure TMouseForm.FormMouseMove(Sender: TObject; Shift: TShiftState;
  X, Y: Integer);
begin
  // display the position of the mouse in the caption
  Caption := Format ('Mouse in x=%d, y=%d', [X, Y]);
```

```
    if ssShift in Shift then
      // mark points in yellow
      Canvas.Pixels [X, Y] := clYellow;
  end;
```

TIP The `TCanvas` class of the CLX library doesn't include a `Pixels` array. Instead, you can call the `DrawPoint` method after setting a proper color for the pen, as I've done in the QMouseOne example.

The real feature of this example, however, is the direct mouse-dragging support. Contrary to what you might think, Windows has no system support for dragging, which is implemented in VCL by means of lower-level mouse events and operations. (An example of dragging from one control to another was discussed in the last chapter.) In VCL, forms cannot originate dragging operations, so in this case we are obliged to use the low-level approach. The aim of this example is to draw a rectangle from the initial position of the dragging operation to the final one, giving the users some visual clue of the operation they are doing.

The idea behind dragging is quite simple. The program receives a sequence of button-down, mouse-move, and button-up messages. When the button is clicked, dragging begins, although the real actions take place only when the user moves the mouse (without releasing the mouse button) and when dragging terminates (when the button-up message arrives). The problem with this basic approach is that it is not reliable. A window usually receives mouse events only when the mouse is over its client area; so if the user clicks the mouse button, moves the mouse onto another window, and then releases the button, the second window will receive the button-up message.

There are two solutions to this problem. One (seldom used) is mouse clipping. Using a Windows API function (namely `ClipCursor`), you can force the mouse not to leave a certain area of the screen. When you try to move it outside the specified area, it stumbles against an invisible barrier. The second and more common solution is to capture the mouse. When a window captures the mouse, all the subsequent mouse input is sent to that window. This is the approach we will use for the MouseOne/QMouseOne example.

The code of the example is built around three methods: `FormMouseDown`, `FormMouseMove`, and `FormMouseUp`. Clicking the left mouse button over the form starts the process, setting the `fDragging` Boolean field of the form (which indicates that dragging is in action in the other two methods). The method also uses a `TRect` variable used to keep track of the initial and current position of the dragging. Here is the code:

```
procedure TMouseForm.FormMouseDown(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  if Button = mbLeft then
  begin
    fDragging := True;
    Mouse.Capture := Handle;
    fRect.Left := X;
    fRect.Top := Y;
    fRect.BottomRight := fRect.TopLeft;
    Canvas.DrawFocusRect (fRect);
  end;
end;
```

An important action of this method is the call to the SetCapture API function, obtained by setting the Capture property of the global object Mouse. Now even if a user moves the mouse outside of the client area, the form still receives all mouse-related messages. You can see that for yourself by moving the mouse toward the upper-left corner of the screen; the program shows negative coordinates in the caption.

TIP The global Mouse object allows you to get global information about the mouse, such as its presence, its type, and the current position, as well as set some of its global features. This global object hides a few API functions, making your code simpler and more portable.

When dragging is active and the user moves the mouse, the program draws a dotted rectangle corresponding to the actual position. Actually, the program calls the DrawFocusRect method twice. The first time this method is called, it deletes the current image, thanks to the fact that two consecutive calls to DrawFocusRect simply reset the original situation. After updating the position of the rectangle, the program calls the method a second time:

```
procedure TMouseForm.FormMouseMove(Sender: TObject; Shift: TShiftState;
  X, Y: Integer);
begin
  // display the position of the mouse in the caption
  Caption := Format ('Mouse in x=%d, y=%d', [X, Y]);
  if fDragging then
  begin
    // remove and redraw the dragging rectangle
    Canvas.DrawFocusRect (fRect);
    fRect.Right := X;
    fRect.Bottom := Y;
    Canvas.DrawFocusRect (fRect);
  end
  else
    if ssShift in Shift then
      // mark points in yellow
      Canvas.Pixels [X, Y] := clYellow;
end;
```

When the mouse button is released, the program terminates the dragging operation by resetting the Capture property of the Mouse object, which internally calls the ReleaseCapture API function, and by setting the value of the fDragging field to False:

```
procedure TMouseForm.FormMouseUp(Sender: TObject; Button: TMouseButton;
  Shift: TShiftState; X, Y: Integer);
begin
  if fDragging then
  begin
    Mouse.Capture := 0; // calls ReleaseCapture
    fDragging := False;
    Invalidate;
  end;
end;
```

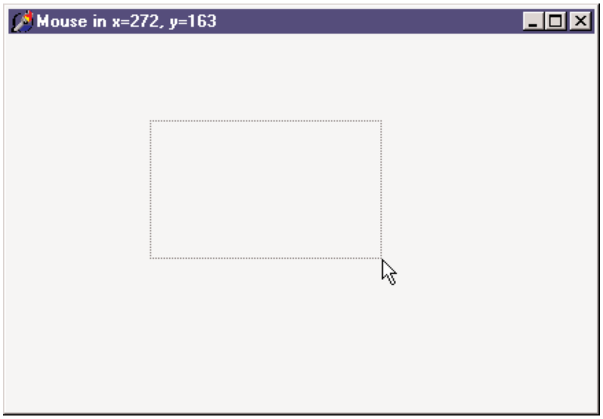
The final call, Invalidate, triggers a painting operation and executes the following OnPaint event handler:

```
procedure TMouseForm.FormPaint(Sender: TObject);
begin
  Canvas.Rectangle (fRect.Left, fRect.Top, fRect.Right, fRect.Bottom);
end;
```

This makes the output of the form persistent, even if you hide it behind another form. Figure 9.6 shows a previous version of the rectangle and a dragging operation in action.

FIGURE 9.6:

The MouseOne example uses a dotted line to indicate, during a dragging operation, the final area of a rectangle.



TIP

Under Qt, there are no Windows handles, but the Capture property of the mouse is still available. You assign to it, however, the object of the component that has to capture the mouse (for example, Self to indicate the form), or set the property to nil to release it. You can see this code in the QMouseOne example.

Painting in Windows

Why do we need to handle the OnPaint event to produce a proper output, and why can't we paint directly over the form canvas? It depends on Windows' default behavior. As you draw on a window, Windows does *not* store the resulting image. When the window is covered, its contents are usually lost.

The reason for this behavior is simple: to save memory. Windows assumes it's "cheaper" in the long run to redraw the screen using code than to dedicate system memory to preserving the display state of a window. It's a classic memory-versus-CPU-cycles trade-off. A color bitmap for a 300×400 image at 256 colors requires about 120 KB. By increasing the color count or the number of pixels, you can easily have full-screen bitmaps of about 1 MB and reach 4 MB of memory for a 1280×1024 resolution at 16 million colors. If storing the bitmap was the default choice, running half a dozen simple applications would require at least 8 MB of memory, if not 16 MB, just for remembering their current output.

In the event that you want to have a consistent output for your applications, there are two techniques you can use. The general solution is to store enough data about the output to be able to reproduce it when the system sends a *painting* requested. An alternative approach is to save the output of the form in a bitmap while you produce it, by placing an Image component over the form and drawing on the canvas of this image component.

The first technique, painting, is the common approach to handling output in Windows, aside from particular graphics-oriented programs that store the form's whole image in a bitmap. The approach used to implement painting has a very descriptive name: *store and paint.* In fact, when the user clicks a mouse button or performs any other operation, we need to store the position and other elements; then, in the painting method, we use this information to actually paint the corresponding image.

The idea of this approach is to let the application repaint its whole surface under any of the possible conditions. If we provide a method to redraw the contents of the form, and if this method is automatically called when a portion of the form has been hidden and needs repainting, we will be able to re-create the output properly.

Since this approach takes two steps, we must be able to execute these two operations in a row, asking the system to repaint the window—without waiting for the system to ask for this. You can use several methods to invoke repainting: Invalidate, Update, Repaint, and Refresh. The first two correspond to the Windows API functions, while the latter two have been introduced by Delphi.

- The Invalidate method informs Windows that the entire surface of the form should be repainted. The most important thing is that Invalidate does *not* enforce a painting operation immediately. Windows simply stores the request and will respond to it only after the current procedure has been completely executed and as soon as there are no other events pending in the system. Windows deliberately delays the painting operation because it is one of the most time-consuming operations. At times, with this delay, it is possible to paint the form only after multiple changes have taken place, avoiding multiple consecutive calls to the (slow) paint method.

- The `Update` method asks Windows to update the contents of the form, repainting it immediately. However, remember that this operation will take place only if there is an *invalid area*. This happens if the `Invalidate` method has just been called or as the result of an operation by the user. If there is no invalid area, a call to `Update` has no effect at all. For this reason, it is common to see a call to `Update` just after a call to `Invalidate`. This is exactly what is done by the two Delphi methods, `Repaint` and `Refresh`.
- The `Repaint` method calls `Invalidate` and `Update` in sequence. As a result, it activates the `OnPaint` event immediately. There is a slightly different version of this method called `Refresh`. For a form the effect is the same; for components it might be slightly different.

When you need to ask the form for a repaint operation, you should generally call `Invalidate`, following the standard Windows approach. This is particularly important when you need to request this operation frequently, because if Windows takes too much time to update the screen, the requests for repainting can be accumulated into a simple repaint action. The `wm_Paint` message in Windows is a sort of low-priority message. To be more precise, if a request for repainting is pending but other messages are waiting, the other messages are handled before the system actually performs the paint action.

On the other hand, if you call `Repaint` several times, the screen must be repainted each time before Windows can process other messages, and because paint operations are computationally intensive, this can actually make your application less responsive. There are times, however, when you want the application to repaint a surface as quickly as possible. In these less-frequent cases, calling `Repaint` is the way to go.

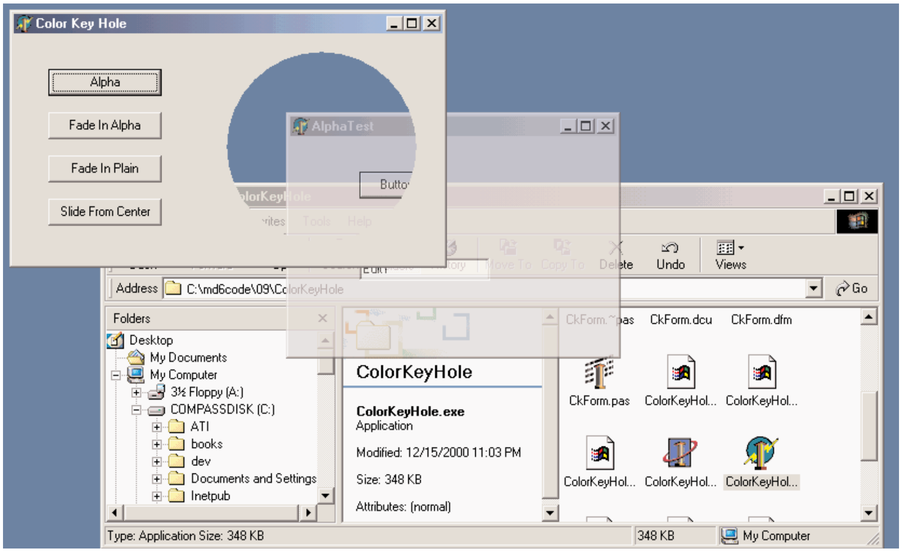
NOTE Another important consideration is that during a paint operation Windows redraws only the so-called *update region*, to speed up the operation. For this reason if you invalidate only a portion of a window, only that area will be repainted. To accomplish this you can use the `InvalidateRect` and `InvalidateRegion` functions. Actually, this feature is a double-edged sword. It is a very powerful technique, which can improve speed and reduce the flickering caused by frequent repaint operations. On the other hand, it can also produce incorrect output. A typical problem is when only some of the areas affected by the user operations are actually modified, while others remain as they were even if the system executes the source code that is supposed to update them. In fact, if a painting operation falls outside the update region, the system ignores it, as if it were outside the visible area of a window.

Unusual Techniques: Alpha Blending, Color Key, and the Animate API

One of the few new features of Delphi 6 related to forms is support for some new Windows APIs regarding the way forms are displayed (not available under Qt/CLX). For a form, *alpha blending* allows you to merge the content of a form with what's behind it on the screen, something you'll rarely need, at least in a business application. The technique is certainly more interesting when applied to bitmap (with the new `AlphaBlend` and `AlphaDIBBlend` API functions) than to a form itself. In any case, by setting the `AlphaBlend` property of a form to True and giving to the `AlphaBlendValue` property a value lower than 255, you'll be able to see, in transparency, what's behind the form. The lower the `AlphaBlendValue`, the more the form will *fade*. You can see an example of alpha blending in Figure 9.7, taken from the CkKeyHole example

FIGURE 9.7:

The output of the CkKeyHole, showing the effect of the new `TransparentColor` and `AlphaBlend` properties, and also the AnimateWindow API.



Address C:\md6code\09\ColorKeyHole

ColorKeyHole

ColorKeyHole.exe
Application

Modified: 12/15/2000 11:03 PM

Size: 348 KB

Attributes: (normal)

Type: Application Size: 348 KB 348 KB

This is not the only new Delphi feature in the area of what I can only call *unusual*. The second is the new `TransparentColor` property, which allows you to indicate a transparent color, which will be replaced by the background, creating a sort of hole in a form. The transparent color is indicated by the `TransparentColorValue` property. Again, you can see an example of this effect in Figure 9.7.

Finally, you can use a native Windows technique, animated display, which is not directly supported by Delphi (beyond the display of hints). For example, instead of calling the Show method of a form, you can write:

```
Form3.Hide;
AnimateWindow (Form3.Handle, 2000, AW_BLEND);
Form3.Show;
```

Notice you have to call the Show method at the end for the form to behave properly. A similar animation effect can also be obtained by changing the AlphaBlendValue in a loop. The AnimateWindow API can also be used to obtain the display of the form starting from the center (with the AW_CENTER flag) or from one of its sides (AW_HOR_POSITIVE, AW_HOR_NEGATIVE, AW_VER_POSITIVE, or AW_VER_NEGATIVE), as is common for slide shows.

This same function can also be applied to windowed controls, obtaining a fade-in effect instead of the usual direct appearance. I keep having serious doubts about the waste of CPU cycles these animations cause, but I have to say that if they are applied properly and in the right program, they can improve the user interface.

Position, Size, Scrolling, and Scaling

Once you have designed a form in Delphi, you run the program, and you expect the form to show up exactly as you prepared it. However, a user of your application might have a different screen resolution or might want to resize the form (if this is possible, depending on the border style), eventually affecting the user interface. We've already discussed (mainly in Chapter 7) some techniques related to controls, such as alignment and anchors. Here I want to specifically address elements related to the form as a whole.

Besides differences in the user system, there are many reasons to change Delphi defaults in this area. For example, you might want to run two copies of the program and avoid having all the forms show up in exactly the same place. I've collected many other related elements, including form scrolling, in this portion of the chapter.

The Form Position

There are a few properties you can use to set the position of a form. The Position property indicates how Delphi determines the initial position of the form. The default poDesigned value indicates that the form will appear where you designed it and where you use the positional (Left and Top) and size (Width and Height) properties of the form.

Some of the other choices (poDefault, poDefaultPosOnly, and poDefaultSizeOnly) depend on a feature of the operating system: using a specific flag, Windows can position and/or size new windows using a cascade layout. In this way, the positional and size properties you set at design time will be ignored, but running the application twice you won't get overlapping windows. The default positions are ignored when the form has a dialog border style.

Finally, with the poScreenCenter value, the form is displayed in the center of the screen, with the size you set at design time. This is a very common setting for dialog boxes and other secondary forms.

Another property that affects the initial size and position of a window is its *state*. You can use the WindowState property at design time to display a maximized or minimized window at startup. This property, in fact, can have only three values: wsNormal, wsMinimized, and wsMaximized. The meaning of this property is intuitive. If you set a minimized window state, at startup the form will be displayed in the Windows Taskbar. For the main form of an application, this property can be automatically set by specifying the corresponding attributes in a shortcut referring to the application.

Of course, you can maximize or minimize a window at run time, too. Simply changing the value of the WindowState property to wsMaximized or to wsNormal produces the expected effect. Setting the property to wsMinimized, however, creates a minimized window that is placed over the Taskbar, not within it. This is not the expected action for a main form, but for a secondary form! The simple solution to this problem is to call the Minimize method of the Application object. There is also a Restore method in the TApplication class that you can use when you need to restore a form, although most often the user will do this operation using the Restore command of the system menu.

The Size of a Form and Its Client Area

At design time, there are two ways to set the size of a form: by setting the value of the Width and Height properties or by dragging its borders. At run time, if the form has a resizable border, the user can resize it (producing the OnResize event, where you can perform custom actions to adapt the user interface to the new size of the form).

However, if you look at a form's properties in source code or in the online Help, you can see that there are two properties referring to its width and two referring to its height. Height and Width refer to the size of the form, including the borders; ClientHeight and ClientWidth refer to the size of the internal area of the form, excluding the borders, caption, scroll bars (if any), and menu bar. The client area of the form is the surface you can use to place components on the form, to create output, and to receive user input.

Since you might be interested in having a certain available area for your components, it often makes more sense to set the client size of a form instead of its global size. This is straightforward, because as you set one of the two client properties, the corresponding form property changes accordingly.

TIP

In Windows, it is also possible to create output and receive input from the nonclient area of the form—that is, its border. Painting on the border and getting input when you click it are complex issues. If you are interested, look in the Help file at the description of such Windows messages as `wm_NCPaint`, `wm_NCCalcSize`, and `wm_NCHitTest` and the series of nonclient messages related to the mouse input, such as `wm_NCLButtonDown`. The difficulty of this approach is in combining your code with the default Windows behavior.

Form Constraints

When you choose a resizable border for a form, users can generally resize the form as they like and also maximize it to full screen. Windows informs you that the form's size has changed with the `wm_Size` message, which generates the `OnResize` event. `OnResize` takes place after the size of the form has already been changed. Modifying the size again in this event (if the user has reduced or enlarged the form too much) would be silly. A preventive approach is better suited to this problem.

Delphi provides a specific property for forms and also for all controls: the `Constraints` property. Simply setting the subproperties of the `Constraints` property to the proper maximum and minimum values creates a form that cannot be resized beyond those limits. Here is an example:

```
object Form1: TForm1
  Constraints.MaxHeight = 300
  Constraints.MaxWidth = 300
  Constraints.MinHeight = 150
  Constraints.MinWidth = 150
end
```

Notice that as you set up the `Constraints` property, it has an immediate effect even at design time, changing the size of the form if it is outside the permitted area.

Delphi also uses the maximum constraints for maximized windows, producing an awkward effect. For this reason, you should generally disable the Maximize button of a window that has a maximum size. There are cases in which maximized windows with a limited size make sense—this is the behavior of Delphi's main window. In case you need to change constraints at run time, you can also consider using two specific events, `OnCanResize` and `OnConstrainedResize`. The first of the two can also be used to disable resizing a form or control in given circumstances.

Scrolling a Form

When you build a simple application, a single form might hold all of the components you need. As the application grows, however, you may need to squeeze in the components, increase the size of the form, or add new forms. If you reduce the space occupied by the components, you might add some capability to resize them at run time, possibly splitting the form into different areas. If you choose to increase the size of the form, you might use scroll bars to let the user move around in a form that is bigger than the screen (or at least bigger than its visible portion on the screen).

Adding a scroll bar to a form is simple. In fact, you don't need to do anything. If you place several components in a big form and then reduce its size, a scroll bar will be added to the form automatically, as long as you haven't changed the value of the AutoScroll property from its default of True.

Along with AutoScroll, forms have two properties, HorzScrollBar and VertScrollBar, which can be used to set several properties of the two TFormScrollBar objects associated with the form. The Visible property indicates whether the scroll bar is present, the Position property determines the initial status of the scroll thumb, and the Increment property determines the effect of clicking one of the arrows at the ends of the scroll bar. The most important property, however, is Range.

The Range property of a scroll bar determines the virtual size of the form, not the actual range of values of the scroll bar. Suppose you need a form that will host several components and will therefore need to be 1000 pixels wide. We can use this value to set the "virtual range" of the form, changing the Range of the horizontal scroll bar.

The Position property of the scroll bar will range from 0 to 1000 minus the current size of the client area. For example, if the client area of the form is 300 pixels wide, you can scroll 700 pixels to see the far end of the form (the thousandth pixel).

A Scroll Testing Example

To demonstrate the specific case I've just discussed, I've built the Scroll1 example, which has a virtual form 1000 pixels wide. To accomplish this, I've set the range of the horizontal scroll bar to 1000:

```
object Form1: TForm1
  Width = 458
  Height = 368
  HorzScrollBar.Range = 1000
  VertScrollBar.Range = 305
  AutoScroll = False
  Caption = 'Scrolling Form'
  OnResize = FormResize
  ...
```

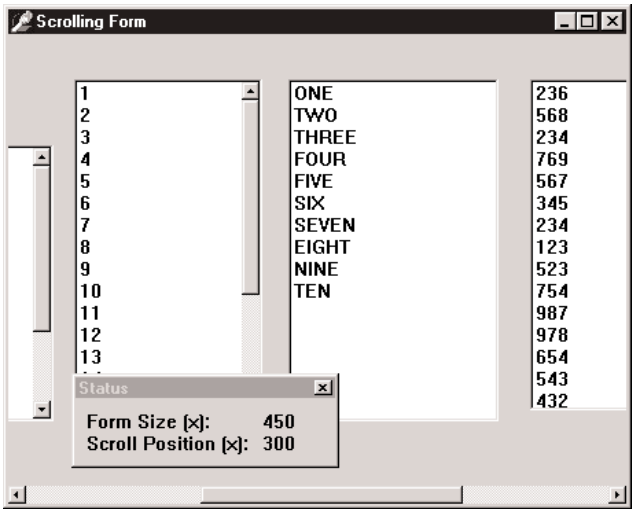
The form of this example has been filled with meaningless list boxes, and I could have obtained the same scroll-bar range by placing the right-most list box so that its position (Left) plus its size (Width) would equal 1000.

The interesting part of the example is the presence of a toolbox window displaying the status of the form and of its horizontal scroll bar. This second form has four labels; two with fixed text and two with the actual output. Besides this, the secondary form (called Status) has a bsToolWindow border style and is a top-most window. You should also set its Visible property to True, to have its window automatically displayed at startup:

```
object Status: TStatus
  BorderIcons = [biSystemMenu]
  BorderStyle = bsToolWindow
  Caption = 'Status'
  FormStyle = fsStayOnTop
  Visible = True
  object Label1: TLabel...
  ...
```

There isn't much code in this program. Its aim is to update the values in the toolbox each time the form is resized or scrolled (as you can see in Figure 9.8). The first part is extremely simple. You can handle the OnResize event of the form and simply copy a couple of values to the two labels. The labels are part of another form, so you need to prefix them with the name of the form instance, Status:

```
procedure TForm1.FormResize(Sender: TObject);
begin
  Status.Label3.Caption := IntToStr(ClientWidth);
  Status.Label4.Caption := IntToStr(HorzScrollBar.Position);
end;
```



```
1     ONE     236
2     TWO     568
3     THREE   234
4     FOUR    769
5     FIVE    567
6     SIX     345
7     SEVEN   234
8     EIGHT   123
9     NINE    523
10    TEN     754
11            987
12            978
13            654
              543
              432
```

Form Size (x): 450
Scroll Position (x): 300

FIGURE 9.8:

The output of the Scroll1 example

If we wanted to change the output each time the user scrolls the contents of the form, we could not use a Delphi event handler, because there isn't an OnScroll event for forms (although there is one for stand-alone ScrollBar components). Omitting this event makes sense, because Delphi forms handle scroll bars automatically in a powerful way. In Windows, by contrast, scroll bars are extremely low-level elements, requiring a lot of coding. Handling the scroll event makes sense only in special cases, such as when you want to keep track precisely of the scrolling operations made by a user.

Here is the code we need to write. First, add a method declaration to the class and associate it with the Windows horizontal scroll message (wm_HScroll):

```
public
  procedure FormScroll (var ScrollData: TWMScroll);
    message wm_HScroll;
```

Then write the code of this procedure, which is almost the same as the code of the FormResize method we've seen before:

```
procedure TForm1.FormScroll (var ScrollData: TWMScroll);
begin
  inherited;
  Status.Label3.Caption := IntToStr(ClientWidth);
  Status.Label4.Caption := IntToStr(HorzScrollBar.Position);
end;
```

It's important to add the call to inherited, which activates the method related to the same message in the base class form. The inherited keyword in Windows message handlers calls the method of the base class we are overriding, which is the one associated with the corresponding Windows message (even if the procedure name is different). Without this call, the form won't have its default scrolling behavior; that is, it won't scroll at all.

NOTE Because in CLX you cannot handle the low-level scroll messages, there seems to be no easy way to create a program similar to Scroll1. This isn't terribly important in real-world applications, as the scrolling system is automatic, and can probably be accomplished by hooking in the CLX library at a lower level.

Automatic Scrolling

The scroll bar's Range property can seem strange until you start to use it consistently. When you think about it a little, you'll start to understand the advantages of the "virtual range" approach. First of all, the scroll bar is automatically removed from the form when the client area of the form is big enough to accommodate the virtual size; and when you reduce the size of the form, the scroll bar is added again.

This feature becomes particularly interesting when the AutoScroll property of the form is set to True. In this case, the extreme positions of the right-most and lower controls are automatically copied into the Range properties of the form's two scroll bars. Automatic scrolling works well in Delphi. In the last example, the virtual size of the form would be set to the right border of the last list box. This was defined with the following attributes:

```
object ListBox6: TListBox
  Left = 832
  Width = 145
end
```

Therefore, the horizontal virtual size of the form would be 977 (the sum of the two preceding values). This number is automatically copied into the Range field of the HorzScrollBar property of the form, unless you change it manually to have a bigger form (as I've done for the Scroll1 example, setting it to 1000 to leave some space between the last list box and the border of the form). You can see this value in the Object Inspector, or make the following test: run the program, size the form as you like, and move the scroll thumb to the right-most position. When you add the size of the form and the position of the thumb, you'll always get 1000, the virtual coordinate of the right-most pixel of the form, whatever the size.

Scrolling and Form Coordinates

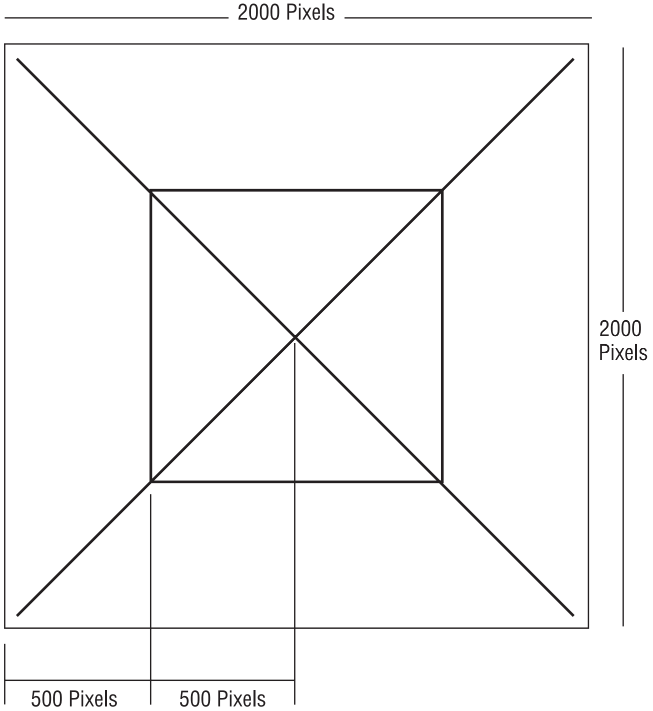
We have just seen that forms can automatically scroll their components. But what happens if you paint directly on the surface of the form? Some problems arise, but their solution is at hand. Suppose that we want to draw some lines on the virtual surface of a form, as shown in Figure 9.9.

Since you probably do not own a monitor capable of displaying 2000 pixels on each axis, you can create a smaller form, add two scroll bars, and set their Range property, as I've done in the Scroll2 example. Here is the textual description of the form:

```
object Form1: TForm1
  HorzScrollBar.Range = 2000
  VertScrollBar.Range = 2000
  ClientHeight = 336
  ClientWidth = 472
  OnPaint = FormPaint
end
```

FIGURE 9.9:

The lines to draw on the virtual surface of the form



If we simply draw the lines using the virtual coordinates of the form, the image won't display properly. In fact, in the `OnPaint` response method, we need to compute the virtual coordinates ourselves. Fortunately, this is easy, since we know that the virtual `X1` and `Y1` coordinates of the upper-left corner of the client area correspond to the current positions of the two scroll bars:

```
procedure TForm1.FormPaint(Sender: TObject);
var
  X1, Y1: Integer;
begin
  X1 := HorzScrollBar.Position;
  Y1 := VertScrollBar.Position;

  // draw a yellow line
  Canvas.Pen.Width := 30;
  Canvas.Pen.Color := clYellow;
  Canvas.MoveTo (30-X1, 30-Y1);
  Canvas.LineTo (1970-X1, 1970-Y1);
// and so on ...
```

As a better alternative, instead of computing the proper coordinate for each output operation, we can call the SetWindowOrgEx API to move the origin of the coordinates of the Canvas itself. This way, our drawing code will directly refer to virtual coordinates but will be displayed properly:

```
procedure TForm2.FormPaint(Sender: TObject);
begin
  SetWindowOrgEx (Canvas.Handle, HorzScrollbar.Position,
    VertScrollbar.Position, nil);

  // draw a yellow line
  Canvas.Pen.Width := 30;
  Canvas.Pen.Color := clYellow;
  Canvas.MoveTo (30, 30);
  Canvas.LineTo (1970, 1970);

  // and so on ...
```

This is the version of the program you'll find in the source code on the CD. Try using the program and commenting out the SetWindowOrgEx call to see what happens if you don't use virtual coordinates: You'll find that the output of the program is not correct—it won't scroll, and the same image will always remain in the same position, regardless of scrolling operations. Notice also that the Qt/CLX version of the program, called QScroll2, doesn't use virtual coordinates but simply subtracts the scroll positions from each of the hard-coded coordinates.

Scaling Forms

When you create a form with multiple components, you can select a fixed size border or let the user resize the form and automatically add scroll bars to reach the components falling outside the visible portion of the form, as we've just seen. This might also happen because a user of your application has a display driver with a much smaller number of pixels than yours.

Instead of simply reducing the form size and scrolling the content, you might want to reduce the size of each of the components at the same time. This automatically happens also if the user has a system font with a different pixel-per-inch ratio than the one you used for development. To address these problems, Delphi has some nice scaling features, but they aren't fully intuitive.

The form's ScaleBy method allows you to scale the form and each of its components. The PixelsPerInch and Scaled properties allow Delphi to resize an application automatically when the application is run with a different system font size, often because of a different screen resolution. In both cases, to make the form scale its window, be sure to also set the

AutoScroll property to False. Otherwise, the contents of the form will be scaled, but the form border itself will not. These two approaches are discussed in the next two sections.

NOTE Form scaling is calculated based on the difference between the font height at run time and the font height at design time. Scaling ensures that edit and other controls are large enough to display their text using the user's font preferences without clipping the text. The form scales as well, as we will see later on, but the main point is to make edit and other controls readable.

Manual Form Scaling

Any time you want to scale a form, including its components, you can use the ScaleBy method, which has two integer parameters, a multiplier and a divisor—it's a fraction. For example, with this statement the size of the current form is reduced to three-quarters of its original size:

```
ScaleBy (3, 4);
```

Generally, it is easier to use percentage values. The same effect can be obtained by using:

```
ScaleBy (75, 100);
```

When you scale a form, all the proportions are maintained, but if you go below or above certain limits, the text strings can alter their proportions slightly. The problem is that in Windows, components can be placed and sized only in whole pixels, while scaling almost always involves multiplying by fractional numbers. So any fractional portion of a component's origin or size will be truncated.

I've built a simple example, Scale or QScale, to show how you can scale a form manually, responding to a request by the user. The form of this application (see Figure 9.10) has two buttons, a label, an edit box, and an UpDown control connected to it (via its Associate property). With this setting, a user can type numbers in the edit box or click the two small arrows to increase or decrease the value (by the amount indicated by the Increment property). To extract the input value, you can use the Text property of the edit box or the Position of the UpDown control.

When you click the Do Scale button, the current input value is used to determine the scaling percentage of the form:

```
procedure TForm1.ScaleButtonClick(Sender: TObject);
begin
  AmountScaled := UpDown1.Position;
  ScaleBy (AmountScaled, 100);
  UpDown1.Height := Edit1.Height;
  ScaleButton.Enabled := False;
  RestoreButton.Enabled := True;
end;
```

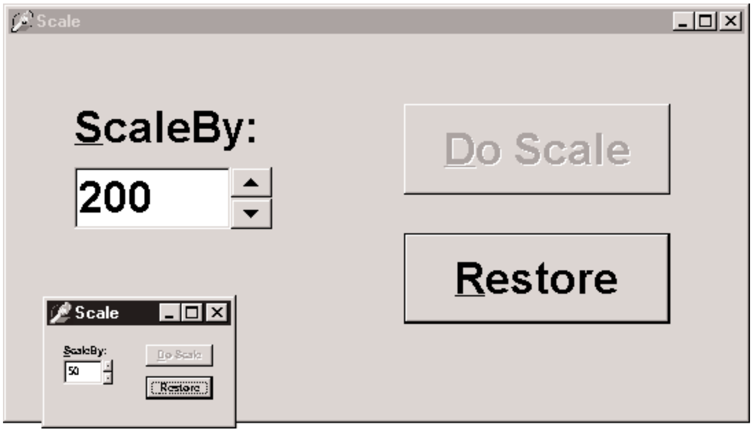


FIGURE 9.10:
The form of the Scale example after a scaling with 50 and 200

This method stores the current input value in the form's `AmountScaled` private field and enables the Restore button, disabling the one that was clicked. Later, when the user clicks the Restore button, the opposite scaling takes place. By having to restore the form before another scaling operation takes place, I avoid an accumulation of round-off errors. I've added also a line to set the `Height` of the UpDown component to the same `Height` as the edit box it is attached to. This prevents small differences between the two, due to scaling problems of the UpDown control.

NOTE If you want to scale the text of the form properly, including the captions of components, the items in list boxes, and so on, you should use TrueType fonts exclusively. The system font (MS Sans Serif) doesn't scale well. The font issue is important because the size of many components depends on the text height of their captions, and if the caption does not scale well, the component might not work properly. For this reason, in the Scale example I've used an Arial font.

Exactly the same scaling technique also works in CLX, as you can see by running the QScale example. The only real difference is that I have to replace the UpDown component (and the related Edit box) with a SpinEdit control, as the former is not available in Qt.

Automatic Form Scaling

Instead of playing with the `ScaleBy` method, you can ask Delphi to do the work for you. When Delphi starts, it asks the system for the display configuration and stores the value in the `PixelsPerInch` property of the `Screen` object, a special global object of VCL, available in any application.

PixelsPerInch sounds like it has something to do with the pixel resolution of the screen, but unfortunately, it doesn't. If you change your screen resolution from 640×480 to 800×600 to 1024×768 or even 1600×1280, you will find that Windows reports the same PixelsPerInch value in all cases, unless you change the system font. What PixelsPerInch really refers to is the screen pixel resolution that the currently installed system font was designed for. When a user changes the system font scale, usually to make menus and other text easier to read, the user will expect all applications to honor those settings. An application that does not reflect user desktop preferences will look out of place and, in extreme cases, may be unusable to visually impaired users who rely on very large fonts and high-contrast color schemes.

The most common PixelPerInch values are 96 (small fonts) and 120 (large fonts), but other values are possible. Newer versions of Windows even allow the user to set the system font size to an arbitrary scale. At design time, the PixelsPerInch value of the screen, which is a read-only property, is copied to every form of the application. Delphi then uses the value of PixelsPerInch, if the Scaled property is set to True, to resize the form when the application starts.

As I've already mentioned, both automatic scaling and the scaling performed by the ScaleBy method operate on components by changing the size of the font. The size of each control, in fact, depends on the font it uses. With automatic scaling, the value of the form's PixelsPerInch property (the design-time value) is compared to the current system value (indicated by the corresponding property of the Screen object), and the result is used to change the font of the components on the form. Actually, to improve the accuracy of this code, the final height of the text is compared to the design-time height of the text, and its size is adjusted if they do not match.

Thanks to Delphi automatic support, the same application running on a system with a different system font size automatically scales itself, without any specific code. The application's edit controls will be the correct size to display their text in the user's preferred font size, and the form will be the correct size to contain those controls. Although automatic scaling has problems in some special cases, if you comply with the following rules, you should get good results:

- Set the Scaled property of forms to True. (This is the default.)
- Use only TrueType fonts.
- Use Windows small fonts (96 dpi) on the computer you use to develop the forms.
- Set the AutoScroll property to False, if you want to scale the form and not just the controls inside it. (AutoScroll defaults to True, so don't forget to do this step.)
- Set the form position either near the upper-left corner or in the center of the screen (with the poScreenCenter value) to avoid having an out-of-screen form. Form position is discussed in the next section.

Creating and Closing Forms

Up to now we have ignored the issue of form creation. We know that when the form is created, we receive the `OnCreate` event and can change or test some of the initial form's properties or fields. The statement responsible for creating the form is in this project's source file:

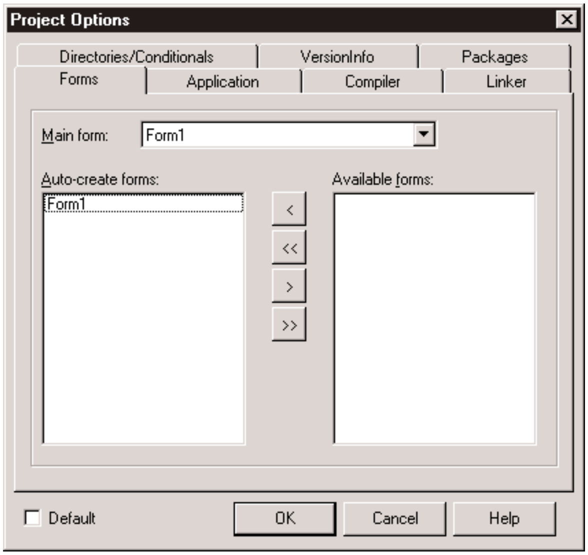
```
begin
  Application.Initialize;
  Application.CreateForm(TForm1, Form1);
  Application.Run;
end.
```

To skip the automatic form creation, you can either modify this code or use the Forms page of the Project Options dialog box (see Figure 9.11). In this dialog box, you can decide whether the form should be automatically created. If you disable the automatic creation, the project's initialization code becomes the following:

```
begin
  Applications.Initialize;
  Application.Run;
end.
```

FIGURE 9.11:

The Forms page of the Delphi Project Options dialog box



Main form: Form1

Auto-create forms: Form1

Available forms:

If you now run this program, nothing happens. It terminates immediately because no main window is created. So what is the effect of the call to the application's `CreateForm` method? It creates a new instance of the form class passed as the first parameter and assigns it to the variable passed as the second parameter.

Something else happens behind the scenes. When CreateForm is called, if there is currently no main form, the current form is assigned to the application's MainForm property. For this reason, the form indicated as Main Form in the dialog box shown in Figure 9.11 corresponds to the first call to the application's CreateForm method (that is, when several forms are created at start-up).

The same holds for closing the application. Closing the main form terminates the application, regardless of the other forms. If you want to perform this operation from the program's code, simply call the Close method of the main form, as we've done several times in past examples.

TIP You can control the automatic creation of secondary forms by using the Auto Create Forms check box on the Preferences page of the Environment Options dialog box.

Form Creation Events

Regardless of the manual or automatic creation of forms, when a form is created, there are many events you can intercept. Form-creation events are fired in the following order:

1. OnCreate indicates that the form is being created.
2. OnShow indicates that the form is being displayed. Besides main forms, this event happens after you set the Visible property of the form to True or call the Show or ShowModal methods. This event is fired again if the form is hidden and then displayed again.
3. OnActivate indicates that the form becomes the active form within the application. This event is fired every time you move from another form of the application to the current one.
4. Other events, including OnResize and OnPaint, indicate operations always done at start-up but then repeated many times.

As you can see in the list above, every event has a specific role apart from form initialization, except for the OnCreate event, which is guaranteed to be called only once as the form is created.

However, there is an alternative approach to adding initialization code to a form: overriding the constructor. This is usually done as follows:

```
constructor TForm1.Create(AOwner: TComponent);
begin
  inherited Create (AOwner);
  // extra initialization code
end;
```

Before the call to the Create method of the base class, the properties of the form are still not loaded and the internal components are not available. For this reason the standard approach is to call the base class constructor first and then do the custom operations.

Old and New Creation Orders

Now the question is whether these custom operations are executed before or after the OnCreate event is fired. The answer depends on the value of the OldCreateOrder property of the form, introduced in Delphi 4 for backward compatibility with earlier versions of Delphi. By default, for a new project, all of the code in the constructor is executed before the OnCreate event handler. In fact, this event handler is not activated by the base class constructor but by its AfterConstruction method, a sort of constructor introduced for compatibility with C++Builder.

To study the creation order and the potential problems, you can examine the CreatOrd program. This program has an OnCreate event handler, which creates a list box control dynamically. The constructor of the form can access this list box or not, depending on the value of the OldCreateOrder property.

Closing a Form

When you close the form using the Close method or by the usual means (Alt+F4, the system menu, or the Close button), the OnCloseQuery event is called. In this event, you can ask the user to confirm the action, particularly if there is unsaved data in the form. Here is a simple scheme of the code you can write:

```
procedure TForm1.FormCloseQuery(Sender: TObject; var CanClose: Boolean);
begin
  if MessageDlg ('Are you sure you want to exit?', mtConfirmation,
      [mbYes, mbNo], 0) = idNo then
    CanClose := False;
end;
```

If OnCloseQuery indicates that the form should still be closed, the OnClose event is called. The third step is to call the OnDestroy event, which is the opposite of the OnCreate event and is generally used to de-allocate objects related to the form and free the corresponding memory.

NOTE To be more precise, the BeforeDestruction method generates an OnDestroy event before the Destroy destructor is called. That is, unless you have set the OldCreateOrder property to True, in which case Delphi uses a different closing sequence.

So what is the use of the intermediate OnClose event? In this method, you have another chance to avoid closing the application, or you can specify alternative “close actions.” The method, in fact, has an Action parameter passed by reference. You can assign the following values to this parameter:

caNone The form is not allowed to close. This corresponds to setting the CanClose parameter of the OnCloseQuery method to False.

caHide The form is not closed, just hidden. This makes sense if there are other forms in the application; otherwise, the program terminates. This is the default for secondary forms, and it’s the reason I had to handle the OnClose event in the previous example to actually close the secondary forms.

caFree The form is closed, freeing its memory, and the application eventually terminates if this was the main form. This is the default action for the main form and the action you should use when you create multiple forms dynamically (if you want to remove the Windows and destroy the corresponding Delphi object as the form closes).

caMinimize The form is not closed but only minimized. This is the default action for MDI child forms.

NOTE When a user shuts down Windows, the OnCloseQuery event is activated, and a program can use it to stop the shut-down process. In this case, the OnClose event is not called even if OnCloseQuery sets the CanClose parameter to True.

Dialog Boxes and Other Secondary Forms

When you write a program, there is really no big difference between a dialog box and another secondary form, aside from the border, the border icons, and similar user-interface elements you can customize.

What users associate with a dialog box is the concept of a *modal window*—a window that takes the focus and must be closed before the user can move back to the main window. This is true for message boxes and usually for dialog boxes, as well. However, you can also have nonmodal—or *modeless*—dialog boxes. So if you think that dialog boxes are just modal forms, you are on the right track, but your description is not precise. In Delphi (as in Windows), you can have modeless dialog boxes and modal forms. We have to consider two different elements:

- The form’s border and its user interface determine whether it looks like a dialog box.
- The use of two different methods (Show or ShowModal) to display the secondary form determines its behavior (modeless or modal).

Adding a Second Form to a Program

To add a second form to an application, you simply click on the New Form button on the Delphi toolbar or use the File ➢ New Form menu command. As an alternative you can select File ➢ New, move to the Forms or Dialogs page, and choose one of the available form templates or form wizards.

If you have two forms in a project, you can use the Select Form or Select Unit button of the Delphi toolbar to navigate through them at design time. You can also choose which form is the main one and which forms should be automatically created at start-up using the Forms page of the Project Options dialog box. This information is reflected in the source code of the project file.

TIP Secondary forms are automatically created in the project source-code file depending on a new Delphi 5 setting, which is the Auto Create Forms check box of the Preferences page of the Environment Options dialog box. Although automatic creation is the simplest and most reliable approach for novice developers and quick-and-dirty projects, I suggest that you disable this check box for any serious development. When your application contains hundreds of forms, you really shouldn't have them all created at application start-up. Create instances of secondary forms when and where you need them, and free them when you're done.

Once you have prepared the secondary form, you can simply set its `Visible` property to True, and both forms will show up as the program starts. In general, the secondary forms of an application are left "invisible" and are then displayed by calling the `Show` method (or setting the `Visible` property at run time). If you use the `Show` function, the second form will be displayed as modeless, so you can move back to the first one while the second is still visible. To close the second form, you might use its system menu or click a button or menu item that calls the `Close` method. As we've just seen, the default close action (see the `OnClose` event) for a secondary form is simply to hide it, so the secondary form is not destroyed when it is closed. It is kept in memory (again, not always the best approach) and is available if you want to show it again.

Creating Secondary Forms at Run Time

Unless you create all the forms when the program starts, you'll need to check whether a form exists and create it if necessary. The simplest case is when you want to create multiple copies of the same form at run time. In the MultiWin/QMultiWin example, I've done this by writing the following code:

```
procedure TForm1.btnMultipleClick(Sender: TObject);
begin
  with TForm3.Create (Application) do
    Show;
end;
```

Every time you click the button, a new copy of the form is created. Notice that I don't use the Form3 global variable, because it doesn't make much sense to assign this variable a new value every time you create a new form object. The important thing, however, is not to refer to the global Form3 object in the code of the form itself or in other portions of the application. The Form3 variable, in fact, will invariably be a pointer to nil. My suggestion, in such a case, is to actually remove it from the unit to avoid any confusion.

TIP

In the code of a form, you should never explicitly refer to the form by using the global variable that Delphi sets up for it. For example, suppose that in the code of TForm3 you refer to Form3.Caption. If you create a second object of the same type (the class TForm3), the expression Form3.Caption will invariably refer to the caption of the form object referenced by the Form3 variable, which might not be the current object executing the code. To avoid this problem, refer to the Caption property in the form's method to indicate the caption of the current form object, and use the Self keyword when you need a specific reference to the object of the current form. To avoid any problem when creating multiple copies of a form, I suggest removing the global form object from the interface portion of the unit declaring the form. This global variable is required only for the automatic form creation.

When you create multiple copies of a form dynamically, remember to destroy each form object as is it closed, by handling the corresponding event:

```
procedure TForm3.FormClose(Sender: TObject; var Action: TCloseAction);
begin
  Action := caFree;
end;
```

Failing to do so will result in a lot of memory consumption, because all the forms you create (both the windows and the Delphi objects) will be kept in memory and simply hidden from view.

Creating Single-Instance Secondary Forms

Now let us focus on the dynamic creation of a form, in a program that accounts for only one copy of the form at a time. Creating a modal form is quite simple, because the dialog box can be destroyed when it is closed, with code like this:

```
procedure TForm1.btnModalClick(Sender: TObject);
var
  Modal: TForm4;
begin
  Modal := TForm4.Create (Application);
  try
    Modal.ShowModal;
  finally
    Modal.Free;
  end;
end;
```

Because the ShowModal call can raise an exception, you should write it in a finally block to make sure the object will be de-allocated. Usually this block also includes code that initializes the dialog box before displaying it and code that extracts the values set by the user before destroying the form. The final values are read-only if the result of the ShowModal function is mrOK, as we'll see in the next example.

The situation is a little more complex when you want to display only one copy of a modeless form. In fact, you have to create the form, if it is not already available, and then show it:

```
procedure TForm1.btnSingleClick(Sender: TObject);
begin
  if not Assigned (Form2) then
    Form2 := TForm2.Create (Application);
  Form2.Show;
end;
```

With this code, the form is created the first time it is required and then is kept in memory, visible on the screen or hidden from view. To avoid using up memory and system resources unnecessarily, you'll want to destroy the secondary form when it is closed. You can do that by writing a handler for the OnClose event:

```
procedure TForm2.FormClose(Sender: TObject; var Action: TCloseAction);
begin
  Action := caFree;
  // important: set pointer to nil!
  Form2 := nil;
end;
```

Notice that after we destroy the form, the global Form2 variable is set to nil. Without this code, closing the form would destroy its object, but the Form2 variable would still refer to the original memory location. At this point, if you try to show the form once more with the btnSingleClick method shown earlier, the if not Assigned test will succeed, as it simply checks whether the Form2 variable is nil. The code fails to create a new object, and the Show method, invoked on a nonexistent object, will result in a system memory error.

As an experiment, you can generate this error by removing the last line of the listing above. As we have seen, the solution is to set the Form2 object to nil when the object is destroyed, so that properly written code will "see" that a new form has to be created before using it. Again, experimenting with the MultiWin/QMultiWin example can prove useful to test various conditions. I haven't illustrated any screens from this example because the forms it displays are quite bare (totally empty except for the main form, which has three buttons).

NOTE Setting the form variable to nil makes sense—and works—if there is to be only one instance of the form present at any given instant. If you want to create multiple copies of a form, you'll have to use other techniques to keep track of them. Also keep in mind that in this case we cannot use the FreeAndNil procedure, because we cannot call Free on Form2. The reason is that we cannot destroy the form before its event handlers have finished executing.

Creating a Dialog Box

I stated earlier in this chapter that a dialog box is not very different from other forms. To build a dialog box instead of a form, you just select the bsDialog value for the `BorderStyle` property. With this simple change, the interface of the form becomes like that of a dialog box, with no system icon, and no Minimize or Maximize boxes. Of course, such a form has the typical thick dialog box border, which is non-resizable.

Once you have built a dialog box form, you can display it as a modal or modeless window using the two usual show methods (`Show` and `ShowModal`). Modal dialog boxes, however, are more common than modeless ones. This is exactly the reverse of forms; modal forms should generally be avoided, because a user won't expect them.

The Dialog Box of the RefList Example

In Chapter 6 we explored the RefList/QRefList program, which used a ListView control to display references to books, magazines, Web sites, and more. In the RefList2 version on the CD (and its QRefLsit2 CLX counterpart), I'll simply add to the basic version of that program a dialog box, used in two different circumstances: adding new items to the list and editing existing items. You can see the form of the dialog box in Figure 9.12 and its textual description in the following listing (detailed because it has many interesting features, so I suggest you read this code with care).

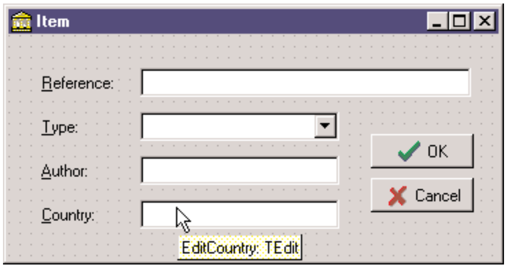


FIGURE 9.12:

The form of the dialog box of the RefList2 example at design time

```
object FormItem: TFormItem
  Caption = 'Item'
  Color = clBtnFace
  Position = poScreenCenter
  object Label1: TLabel
    Caption = '&Reference:'
    FocusControl = EditReference
  end
  object EditReference: TEdit...
  object Label2: TLabel
```

```
    Caption = '&Type:'
    FocusControl = ComboType
  end
  object ComboType: TComboBox
    Style = csDropDownList
    Items.Strings = (
      'Book'
      'CD'
      'Magazine'
      'Mail Address'
      'Web Site')
  end
  object Label3: TLabel
    Caption = '&Author:'
    FocusControl = EditAuthor
  end
  object EditAuthor: TEdit...
  object Label4: TLabel
    Caption = '&Country:'
    FocusControl = EditCountry
  end
  object EditCountry: TEdit...
  object BitBtn1: TBitBtn
    Kind = bkOK
  end
  object BitBtn2: TBitBtn
    Kind = bkCancel
  end
end
```

TIP The items of the combo box in this dialog describe the available images of the image list so that a user can select the type of the item and the system will show the corresponding glyph. An even better option would have been to show those glyphs in a graphical combo box, along with their descriptions.

As I mentioned, this dialog box is used in two different cases. The first takes place as the user selects File ➢ Add Items from the menu:

```
procedure TForm1.AddItems1Click(Sender: TObject);
var
  NewItem: TListItem;
begin
  FormItem.Caption := 'New Item';
  FormItem.Clear;
  if FormItem.ShowModal = mrOK then
  begin
```

```
    NewItem := ListView1.Items.Add;
    NewItem.Caption := FormItem.EditReference.Text;
    NewItem.ImageIndex := FormItem.ComboType.ItemIndex;
    NewItem.SubItems.Add (FormItem.EditAuthor.Text);
    NewItem.SubItems.Add (FormItem.EditCountry.Text);
  end;
end;
```

Besides setting the proper caption of the form, this procedure needs to initialize the dialog box, as we are entering a brand-new value. If the user clicks OK, however, the program adds a new item to the list view and sets all its values. To empty the edit boxes of the dialog, the program calls the custom `Clear` method, which resets the text of each edit box control:

```
procedure TFormItem.Clear;
var
  I: Integer;
begin
  // clear each edit box
  for I := 0 to ControlCount - 1 do
    if Controls [I] is TEdit then
      TEdit (Controls[I]).Text := '';
end;
```

Editing an existing item requires a slightly different approach. First, the current values are moved to the dialog box before it is displayed. Second, if the user clicks OK, the program modifies the current list item instead of creating a new one. Here is the code:

```
procedure TForm1.ListView1DblClick(Sender: TObject);
begin
  if ListView1.Selected <> nil then
  begin
    // dialog initialization
    FormItem.Caption := 'Edit Item';
    FormItem.EditReference.Text := ListView1.Selected.Caption;
    FormItem.ComboType.ItemIndex := ListView1.Selected.ImageIndex;
    FormItem.EditAuthor.Text := ListView1.Selected.SubItems [0];
    FormItem.EditCountry.Text := ListView1.Selected.SubItems [1];

    // show it
    if FormItem.ShowModal = mrOK then
    begin
      // read the new values
      ListView1.Selected.Caption := FormItem.EditReference.Text;
      ListView1.Selected.ImageIndex := FormItem.ComboType.ItemIndex;
      ListView1.Selected.SubItems [0] := FormItem.EditAuthor.Text;
      ListView1.Selected.SubItems [1] := FormItem.EditCountry.Text;
    end;
  end;
end;
```

You can see the effect of this code in Figure 9.13. Notice that the code used to read the value of a new item or modified one is similar. In general, you should try to avoid this type of duplicated code and possibly place the shared code statements in a method added to the dialog box. In this case, the method could receive as parameter a `TListItem` object and copy the proper values into it.

FIGURE 9.13:

The dialog box of the RefList2 example used in edit mode

Type: Book

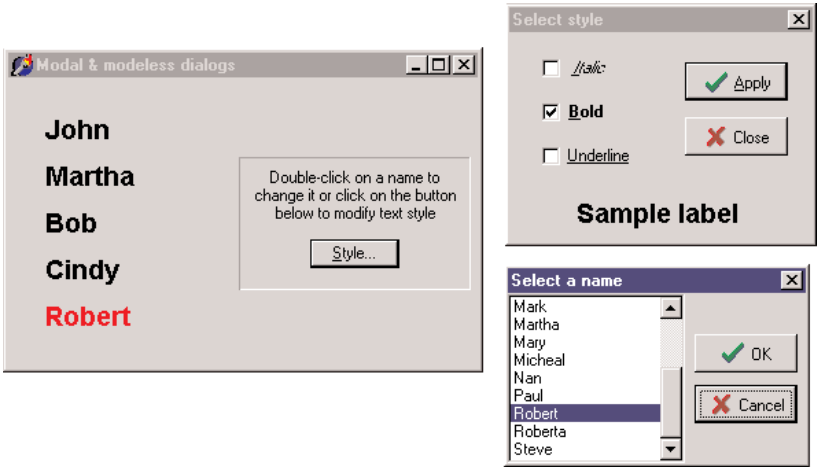
Author: Marco and Tim

Country: Italy and US

NOTE What happens internally when the user clicks the OK or Cancel button of the dialog box? A modal dialog box is closed by setting its `ModalResult` property, and it returns the value of this property. You can indicate the return value by setting the `ModalResult` property of the button. When the user clicks on the button, its `ModalResult` value is copied to the form, which closes the form and returns the value as the result of the `ShowModal` function.

A Modeless Dialog Box

The second example of dialog boxes shows a more complex modal dialog box that uses the standard approach as well as a modeless dialog box. The main form of the DlgApply example (and of the identical CLX-based QDlgApply demo) has five labels with names, as you can see in Figure 9.14 and by viewing the source code on the companion CD.



Double-click on a name to change it or click on the button below to modify text style

FIGURE 9.14: The three forms (a main form and two dialog boxes) of the DlgApply example at run time

If the user clicks a name, its color turns to red; if the user double-clicks it, the program displays a modal dialog box with a list of names to choose from. If the user clicks the Style button, a modeless dialog box appears, allowing the user to change the font style of the main form's labels. The five labels of the main form are connected to two methods, one for the `OnClick` event and the second for the `OnDoubleClick` event. The first method turns the last label a user has clicked to red, resetting to black all the others (which have the `Tag` property set to 1, as a sort of group index). Notice that the same method is associated with all of the labels:

```
procedure TForm1.LabelClick(Sender: TObject);
var
  I: Integer;
begin
  for I := 0 to ComponentCount - 1 do
   if (Components[I] is TLabel) and (Components[I].Tag = 1) then
     TLabel (Components[I]).Font.Color := clBlack;
  // set the color of the clicked label to red
  (Sender as TLabel).Font.Color := clRed;
end;
```

The second method common to all of the labels is the handler of the `OnDoubleClick` event. The `LabelDoubleClick` method selects the `Caption` of the current label (indicated by the `Sender` parameter) in the list box of the dialog and then shows the modal dialog box. If the user closes the dialog box by clicking OK and an item of the list is selected, the selection is copied back to the label's caption:

```
procedure TForm1.LabelDoubleClick(Sender: TObject);
begin
  with ListDial.Listbox1 do
  begin
    // select the current name in the list box
    ItemIndex := Items.IndexOf (Sender as TLabel).Caption);
    // show the modal dialog box, checking the return value
    if (ListDial.ShowModal = mrOk) and (ItemIndex >= 0) then
      // copy the selected item to the label
      (Sender as TLabel).Caption := Items [ItemIndex];
  end;
end;
```

TIP Notice that all the code used to customize the modal dialog box is in the LabelDoubleClick method of the main form. The form of this dialog box has no added code.

The modeless dialog box, by contrast, has a lot of coding behind it. The main form simply displays the dialog box when the Style button is clicked (notice that the button caption ends with three dots to indicate that it leads to a dialog box), by calling its Show method. You can see the dialog box running in Figure 9.14 above.

Two buttons, Apply and Close, replace the OK and Cancel buttons in a modeless dialog box. (The fastest way to obtain these buttons is to select the bkOK or bkCancel value for the Kind property and then edit the Caption.) At times, you may see a Cancel button that works as a Close button, but the OK button in a modeless dialog box usually has no meaning. Instead, there might be one or more buttons that perform specific actions on the main window, such as Apply, Change Style, Replace, Delete, and so on.

If the user clicks one of the check boxes of this modeless dialog box, the style of the sample label's text at the bottom changes accordingly. You accomplish this by adding or removing the specific flag that indicates the style, as in the following OnClick event handler:

```
procedure TStyleDial.ItalicCheckBoxClick(Sender: TObject);
begin
  if ItalicCheckBox.Checked then
    LabelSample.Font.Style := LabelSample.Font.Style + [fsItalic]
  else
    LabelSample.Font.Style := LabelSample.Font.Style - [fsItalic];
end;
```

When the user selects the Apply button, the program copies the style of the sample label to each of the form's labels, rather than considering the values of the check boxes:

```
procedure TStyleDial.ApplyBitBtnClick(Sender: TObject);
begin
  Form1.Label1.Font.Style := LabelSample.Font.Style;
  Form1.Label2.Font.Style := LabelSample.Font.Style;
  ...
```

As an alternative, instead of referring to each label directly, you can look for it by calling the FindComponent method of the form, passing the label name as a parameter, and then casting the result to the TLabel type. The advantage of this approach is that we can create the names of the various labels with a for loop:

```
procedure TStyleDial.ApplyBitBtnClick(Sender: TObject);
var
  I: Integer;
begin
  for I := 1 to 5 do
    (Form1.FindComponent ('Label' + IntToStr (I)) as TLabel).Font.Style :=
      LabelSample.Font.Style;
end;
```

TIP The ApplyBitBtnClick method could also be written by scanning the Controls array in a loop, as I've already done in other examples. I decided to use the FindComponent method, instead, to demonstrate a different technique.

This second version of the code is certainly slower, because it has more operations to do, but you won't notice the difference, because it is very fast anyway. Of course, this second approach is also more flexible; if you add a new label, you only need to fix the higher limit of the for loop, provided all the labels have consecutive numbers. Notice that when the user clicks the Apply button, the dialog box does not close. Only the Close button has this effect. Consider also that this dialog box needs no initialization code because the form is not destroyed, and its components maintain their status each time the dialog box is displayed.

Predefined Dialog Boxes

Besides building your own dialog boxes, Delphi allows you to use some default dialog boxes of various kinds. Some are predefined by Windows; others are simple dialog boxes (such as message boxes) displayed by a Delphi routine. The Delphi Component Palette contains a page of dialog box components. Each of these dialog boxes—known as *Windows common dialogs*—is defined in the system library ComDlg32.DLL.

Windows Common Dialogs

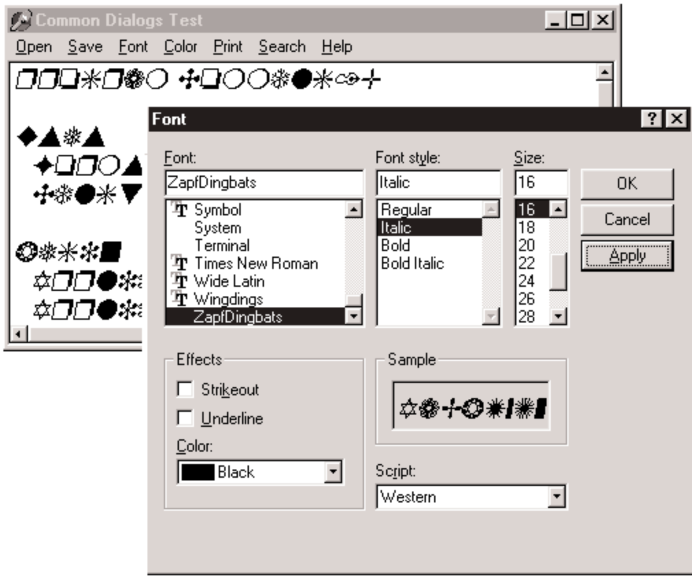
I have already used some of these dialog boxes in several examples in the previous chapters, so you are probably familiar with them. Basically, you need to put the corresponding component on a form, set some of its properties, run the dialog box (with the Execute method, returning a Boolean value), and retrieve the properties that have been set while running it. To help you experiment with these dialog boxes, I've built the CommDlg test program.

What I want to do is simply highlight some key and nonobvious features of the common dialog boxes, and let you study the source code of the example for the details:

- The Open Dialog Component can be customized by setting different file extensions filters, using the `Filter` property, which has a handy editor and can be assigned directly with a string like `Text File (*.txt)|*.txt`. Another handy feature is to let the dialog check whether the extension of the selected file matches the default extension, by checking the ofExtensionDifferent flag of the `Options` property after executing the dialog. Finally, this dialog allows multiple selections by setting its ofAllowMultiSelect option. In this case you can get the list of the selected files by looking at the `Files` string list property.
- The SaveDialog component is used in similar ways and has similar properties, although you cannot select multiple files, of course.
- The OpenPictureDialog and SavePictureDialog components provide similar features but have a customized form, which shows a preview of an image. Of course, it makes sense to use them only for opening or saving graphical files.
- The FontDialog component can be used to show and select from all types of fonts, fonts useable on both the screen and a selected printer (WYSIWYG), or only TrueType fonts. You can show or hide the portion related to the special effects, and obtain other different versions by setting its `Options` property. You can also activate an Apply button simply by providing an event handler for its `OnApply` event and using the fdApplyButton option. A Font dialog box with an Apply button (see Figure 9.15) behaves almost like a modeless dialog box (but isn't one).

FIGURE 9.15:

The Font selection dialog box with an Apply button



Font: ZapfDingbats
Font style: Italic
Size: 16
☐ Strikeout
☐ Underline
Color: Black
Script: Western

- The ColorDialog component is used with different options, to show the dialog fully open at first or to prevent it from opening fully. These settings are the cdFullOpen or cdPreventFullOpen values of the `Options` property.
- The Find and Replace dialog boxes are truly modeless dialogs, but you have to implement the find and replace functionality yourself, as I've partially done in the CommDlg example. The custom code is connected to the buttons of the two dialog boxes by providing the `OnFind` and `OnReplace` events.

NOTE Qt offers a similar set of predefined dialog boxes, only the set of options is often more limited. I've created the QCommDlg version of the example you can use to experiment with these settings. The CLX program has fewer menu items, as some of the options are not available and there are other minimal changes in the source code.

A Parade of Message Boxes

The Delphi message boxes and input boxes are another set of predefined dialog boxes. There are many Delphi procedures and functions you can use to display simple dialog boxes:

- The `MessageDlg` function shows a customizable message box, with one or more buttons and usually a bitmap. The `MessageDlgPos` function is similar to the `MessageDlg` function, but the message box is displayed in a given position, not in the center of the screen.
- The `ShowMessage` procedure displays a simpler message box, with the application name as the caption and just an OK button. The `ShowMessagePos` procedure does the same, but you also indicate the position of the message box. The `ShowMessageFmt` procedure is a variation of `ShowMessage`, which has the same parameters as the `Format` function. It corresponds to calling `Format` inside a call to `ShowMessage`.
- The `MessageBox` method of the `Application` object allows you to specify both the message and the caption; you can also provide various buttons and features. This is a simple and direct encapsulation of the `MessageBox` function of the Windows API, which passes as a main window parameter the handle of the `Application` object. This handle is required to make the message box behave like a modal window.
- The `InputBox` function asks the user to input a string. You provide the caption, the query, and a default string. The `InputQuery` function asks the user to input a string, too. The only difference between this and the `InputBox` function is in the syntax. The `InputQuery` function has a Boolean return value that indicates whether the user has clicked OK or Cancel.

To demonstrate some of the message boxes available in Delphi, I've written another sample program, with a similar approach to the preceding CommDlg example. In the MBParade example, you have a high number of choices (radio buttons, check boxes, edit boxes, and spin edit controls) to set before you click one of the buttons that displays a message box. The similar QMbParade example misses only the possibility of the help button, not available in the CLX message boxes.

About Boxes and Splash Screens

Applications usually have an About box, where you can display information, such as the version of the product, a copyright notice, and so on. The simplest way to build an About box is to use the `MessageDlg` function. With this method, you can show only a limited amount of text and no special graphics.

Therefore, the usual method for creating an About box is to use a dialog box, such as the one generated with one of the Delphi default templates. In this about box you might want to add some code to display system information, such as the version of Windows or the amount of free memory, or some user information, such as the registered user name.

Building a Splash Screen

Another typical technique used in applications is to display an initial screen before the main form is shown. This makes the application seem more responsive, because you show something to the user while the program is loading, but it also makes a nice visual effect. Sometimes, this same window is displayed as the application's About box.

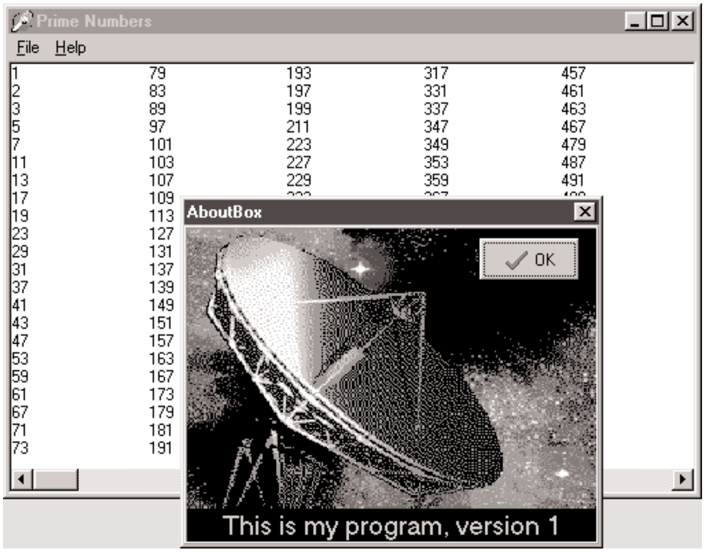
For an example in which a splash screen is particularly useful, I've built a program displaying a list box filled with prime numbers. The prime numbers are computed on program startup, so that they are displayed as soon as the form becomes visible:

```
procedure TForm1.FormCreate(Sender: TObject);
var
  I: Integer;
begin
  for I := 1 to 30000 do
    if IsPrime (I) then
      ListBox1.Items.Add (IntToStr (I));
end;
```

This method calls an `IsPrime` function I've added to the program. This function, which you can find in the source code, computes prime numbers in a terribly slow way; but I needed a slow form creation to demonstrate my point. The numbers are added to a list box that covers the full client area of the form and allows multiple columns to be displayed, as you can see in Figure 9.16.

FIGURE 9.16:

The main form of the Splash example, with the About box activated from the menu



```
1     79    193   317   457
2     83    197   331   461
3     89    199   337   463
5     97    211   347   467
7     101   223   349   479
11    103   227   353   487
13    107   229   359   491
17    109
19    113
23    127
29    131
31    137
37    139
41    149
43    151
47    157
53    163
59    167
61    173
67    179
71    181
73    191
```

This is my program, version 1

There are three versions of the Splash program (plus the three corresponding CLX versions). As you can see by running the Splash0 example, the problem with this program is that the initial operation, which takes place in the `FormCreate` method, takes a lot of time. When you start the program, it takes several seconds to display the main form. If your computer is very fast or very slow, you can change the upper limit of the `for` loop of the `FormCreate` method to make the program faster or slower.

This program has a simple dialog box with an image component, a simple caption, and a bitmap button, all placed inside a panel taking up the whole surface of the About box. This form is displayed when you select the Help ➢ About menu item. But what we really want is to display this About box while the program starts. You can see this effect by running the Splash1 and Splash2 examples, which show a splash screen using two different techniques.

First of all, I've added a method to the `TAboutBox` class. This method, called `MakeSplash`, changes some properties of the form to make it suitable for a splash form. Basically it removes the border and caption, hides the OK button, makes the border of the panel thick (to replace the border of the form), and then shows the form, repainting it immediately:

```
procedure TAboutBox.MakeSplash;
begin
  BorderStyle := bsNone;
  BitBtn1.Visible := False;
  Panel1.BorderWidth := 3;
```

```
    Show;
    Update;
  end;
```

This method is called after creating the form in the project file of the Splash1 example. This code is executed before creating the other forms (in this case only the main form), and the splash screen is then removed before running the application. These operations take place within a `try/finally` block. Here is the source code of the main block of the project file for the Splash2 example:

```
var
  SplashAbout: TAboutBox;

begin
  Application.Initialize;

  // create and show the splash form
  SplashAbout := TAboutBox.Create (Application);
  try
    SplashAbout.MakeSplash;
    // standard code...
    Application.CreateForm(TForm1, Form1);
    // get rid of the splash form
    SplashAbout.Close;
  finally
    SplashAbout.Free;
  end;

  Application.Run;
end.
```

This approach makes sense only if your application's main form takes a while to create, to execute its startup code (as in this case), or to open database tables. Notice that the splash screen is the first form created, but because the program doesn't use the `CreateForm` method of the `Application` object, this doesn't become the main form of the application. In this case, in fact, closing the splash screen would terminate the program!

An alternative approach is to keep the splash form on the screen a little longer and use a timer to get rid of it after a while. I've implemented this second technique in the Splash2 example. This example also uses a different approach for creating the splash form: instead of creating it in the project source code, it creates the form at the very beginning of the `FormCreate` method of the main form.

```
procedure TForm1.FormCreate(Sender: TObject);
var
  I: Integer;
  SplashAbout: TAboutBox;
```

```
begin
  // create and show the splash form
  SplashAbout := TAboutBox.Create (Application);
  SplashAbout.MakeSplash;
  // standard code...
  for I := 1 to 30000 do
    if IsPrime (I) then
      ListBox1.Items.Add (IntToStr (I));
  // get rid of the splash form, after a while
  SplashAbout.Timer1.Enabled := True;
end;
```

The timer is enabled just before terminating the method. After its interval has elapsed (in the example, 3 seconds) the `OnTimer` event is activated, and the splash form handles it by closing and destroying itself:

```
procedure TAboutBox.Timer1Timer(Sender: TObject);
begin
  Close;
  Release;
end;
```

NOTE The `Release` method of a form is similar to the `Free` method of objects, only the destruction of the form is delayed until all event handlers have completed execution. Using `Free` inside a form might cause an access violation, as the internal code, which fired the event handler, might refer again to the form object.

There is one more thing to fix. The main form will be displayed later and in front of the splash form, unless you make this a top-most form. For this reason I've added one line to the `MakeSplash` method of the About box in the Splash2 example:

```
FormStyle := fsStayOnTop;
```

What's Next?

In this chapter we've explored some important form properties. Now you know how to handle the size and position of a form, how to resize it, and how to get mouse input and paint over it. You know more about dialog boxes, modal forms, predefined dialogs, splash screens, and many other techniques, including the funny effect of alpha blending. Understanding the details of working with forms is critical to a proper use of Delphi, particularly for building complex applications (unless, of course, you're building services or Web applications with no user interface).

In the next chapter we'll continue by exploring the overall structure of a Delphi application, with coverage of the role of two global objects, `Application` and `Screen`. I'll also discuss MDI development as you learn some more advanced features of forms, such as visual form inheritance. I'll also discuss frames, visual component containers similar to forms.

In this chapter, I've also provided a short introduction to direct painting and to the use of the `TCanvas` class. More about graphics in Delphi forms can also be found in the bonus chapter "Graphics in Delphi" on the companion CD.

CHAPTER 10

The Architecture of Delphi Applications

- The *Application* and *Screen* global objects
- Messages and multitasking in Windows
- Finding the previous instance of an application
- MDI applications
- Visual form inheritance
- Frames
- Base forms and interfaces

Although together we've built Delphi applications since the beginning of the book, we've never really focused on the structure and the architecture of an application built with Delphi's class library. For example, there hasn't been much coverage about the global `Application` object, about techniques for keeping tracks of the forms we've created, about the flow of messages in the system, and other such elements.

In the last chapter you saw how to create applications with multiple forms and dialog boxes, but we haven't discussed how these forms can be related one to the other, how can you share similar features of forms, and how you can operate on multiple similar forms in a coherent way. All of this is the ambitious goal of this chapter, which covers both basic and advanced techniques, including visual form inheritance, the use of frames, and MDI development, but also the use of interfaces for building complex hierarchies of form classes.

The *Application* Object

I've already mentioned the `Application` global object on multiple occasions, but as in this chapter we are focusing on the structure of Delphi applications, it is time to delve into some more details of this global object and its corresponding class. `Application` is a global object of the `TApplication` class, defined in the Forms unit and created in the Controls unit.

The `TApplication` class is a component, but you cannot use it at design time. Some of its properties can be directly set in the Application page of the Project Options dialog box; others must be assigned in code.

To handle its events, instead, Delphi includes a handy ApplicationEvents component. Besides allowing you to assign handlers at design time, the advantage of this component is that it allows for multiple handlers. If you simply place two instances of the ApplicationEvents component in two different forms, each of them can handle the same event, and both event handlers will be executed. In other words, multiple ApplicationEvents components can chain the handlers.

Some of these application-wide events, including `OnActivate`, `OnDeactivate`, `OnMinimize`, and `OnRestore`, allow you to keep track of the status of the application. Other events are forwarded to the application by the controls receiving them, as in `OnActionExecute`, `OnActionUpdate`, `OnHelp`, `OnHint`, `OnShortCut`, and `OnShowHint`. Finally, there is the `OnException` global exception handler we used in Chapter 3, the `OnIdle` event used for background computing, and the `OnMessage` event, which fires whenever a message is posted to any of the windows or windowed controls of the application.

Although its class inherits directly from `TComponent`, the `Application` object has a window associated with it. The application window is hidden from sight but appears on the Taskbar. This is why Delphi names the window *Form1* and the corresponding Taskbar icon *Project1*.

The window related to the Application object—the application window—serves to keep together all the windows of an application. The fact that all the top-level forms of a program have this invisible owner window, for example, is fundamental when the application is activated. In fact, when the windows of your program are behind those of other programs, clicking one window in your application will bring all of that application's windows to the front. In other words, the unseen application window is used to connect the various forms of the application. Actually the application window is not *hidden*, because that would affect its behavior; it simply has zero height and width, and therefore it is not visible.

TIP In Windows, the Minimize and Maximize operations are associated by default with system sounds and a visual animated effect. Applications built with Delphi (starting with version 5) produce the sound and display the visual effect by default.

When you create a new, blank application, Delphi generates a code for the project file, which includes the following:

```
begin
  Application.Initialize;
  Application.CreateForm(TForm1, Form1);
  Application.Run;
end.
```

As you can see in this standard code, the Application object can create forms, setting the first one as the MainForm (one of the Application properties) and closing the entire application when this main form is destroyed. Moreover, it contains the Windows message loop (started by the Run method) that delivers the system messages to the proper windows of the application. A message loop is required by any Windows application, but you don't need to write one in Delphi because the Application object provides a default one.

If this is the main role of the Application object, it manages few other interesting areas as well:

- Hints (discussed at the end of Chapter 7)
- The help system, which in Delphi 6 includes the ability to define the type of help viewer (something not covered in detail in this book)
- Application activation, minimize, and restore
- A global exceptions handler, as discussed in Chapter 3 in the ErrorLog example
- General application information, including the MainForm, executable file name and path (ExeName), the Icon, and the Title displayed in the Windows taskbar and when you scan the running applications with the Alt+Tab keys

TIP

To avoid a discrepancy between the two titles, you can change the application's title at design time. As an alternative, at run time, you can copy the form's caption to the title of the application with this code: `Application.Title := Form1.Caption`.

In most applications, you don't care about the application window, apart from setting its `Title` and icon and handling some of its events. There are some simple operations you can do anyway. Setting the `ShowMainForm` property to False in the project source code indicates that the main form should not be displayed at startup. Inside a program, instead, you can use the `MainForm` property of the `Application` object to access the main form, which is the first form created in the program.

Displaying the Application Window

There is no better proof that a window indeed exists for the `Application` object than to display it. Actually, we don't need to show it—we just need to resize it and set a couple of window attributes, such as the presence of a caption and a border. We can perform these operations by using Windows API functions on the window indicated by the `Handle` property of the `Application` object:

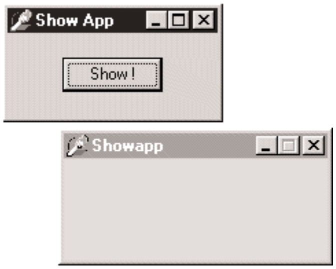
```
procedure TForm1.Button1Click(Sender: TObject);
var
  OldStyle: Integer;
begin
  // add border and caption to the app window
  OldStyle := GetWindowLong (Application.Handle, gwl_Style);
  SetWindowLong (Application.Handle, gwl_Style,
    OldStyle or ws_ThickFrame or ws_Caption);
  // set the size of the app window
  SetWindowPos (Application.Handle, 0, 0, 0, 200, 100,
    swp_NoMove or swp_NoZOrder);
end;
```

The two `GetWindowLong` and `SetWindowLong` API functions are used to access the system information related to the window. In this case, we are using the `gwl_Style` parameter to read or write the styles of the window, which include its border, title, system menu, border icons, and so on. The code above gets the current styles and adds (using an `or` statement) a standard border and a caption to the form. As we'll see later in this chapter, you seldom need to use these low-level API functions in Delphi, because there are properties of the `TForm` class that have the same effect. We need this code here because the application window is not a form.

Executing this code displays the project window, as you can see in Figure 10.1. Although there's no need to implement something like this in your own programs, running this program will reveal the relation between the application window and the main window of a Delphi program. This is a very important starting point if you want to understand the internal structure of Delphi applications.

FIGURE 10.1:

The hidden application window revealed by the ShowApp program



The Application System Menu

Unless you write a very odd program like the example we've just looked at, users will only see the application window in the Taskbar. There, they can activate the window's system menu by right-clicking it. As I mentioned in the SysMenu example in Chapter 6, when discussing the system menu, an application's menu is not the same as that of the main form. In that example, I added custom items to the system menu of the main form. Now in the SysMenu2 example, I want to customize the system menu of the application window in the Taskbar.

First we have to add the new items to the system menu of the application window when the program starts. Here is the updated code of the `FormCreate` method:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  // add a separator and a menu item to the system menu
  AppendMenu (GetSystemMenu (Handle, FALSE), MF_SEPARATOR, 0, '');
  AppendMenu (GetSystemMenu (Handle, FALSE), MF_STRING, idSysAbout,
    '&About...');
  // add the same items to the application system menu
  AppendMenu (GetSystemMenu (Application.Handle, FALSE), MF_SEPARATOR, 0, '');
  AppendMenu (GetSystemMenu (Application.Handle, FALSE), MF_STRING, idSysAbout,
    '&About...');
end;
```

The first part of the code adds the new separator and item to the system menu of the main form. The other two calls add the same two items to the application's system menu, simply by referring to `Application.Handle`. This is enough to display the updated system menu, as you can see by running this program. The next step is to handle the selection of the new menu item.

To handle form messages, we can simply write new event handlers or message-handling methods. We cannot do the same with the application window, simply because inheriting from the `TApplication` class is quite a complex issue. Most of the time we can just handle the OnMessage event of this class, which is activated for every message the application retrieves from the message queue.

To handle the OnMessage event of the global Application object, simply add an ApplicationEvents component to the main form, and define a handler for the OnMessage event of this component. In this case, we only need to handle the wm_SysCommand message, and we only need to do that if the wParam parameter indicates that the user has selected the menu item we've just added, idSysAbout:

```
procedure TForm1.ApplicationEvents1Message(var Msg: tagMSG;
  var Handled: Boolean);
begin
  if (Msg.Message = wm_SysCommand) and (Msg.wParam = idSysAbout) then
  begin
    ShowMessage ('Mastering Delphi: SysMenu2 example');
    Handled := True;
  end;
end;
```

This method is very similar to the one used to handle the corresponding system menu item of the main form:

```
procedure WMSysCommand (var Msg: TWMSysCommand);
  message wm_SysCommand;
...
procedure TForm1.WMSysCommand (var Msg: TWMSysCommand);
begin
  // handle a specific command
  if Msg.CmdType = idSysAbout then
    ShowMessage ('Mastering Delphi: SysMenu2 example');
  inherited;
end;
```

Activating Applications and Forms

To show how the activation of forms and applications works, I've written a simple, self-explanatory example, available on the companion CD, called ActivApp. This example has two forms. Each form has a Label component (LabelForm) used to display the status of the form. The program uses text and color for this, as the handlers of the OnActivate and OnDeactivate events of the first form demonstrate:

```
procedure TForm1.FormActivate(Sender: TObject);
begin
  LabelForm.Caption := 'Form2 Active';
  LabelForm.Color := clRed;
end;

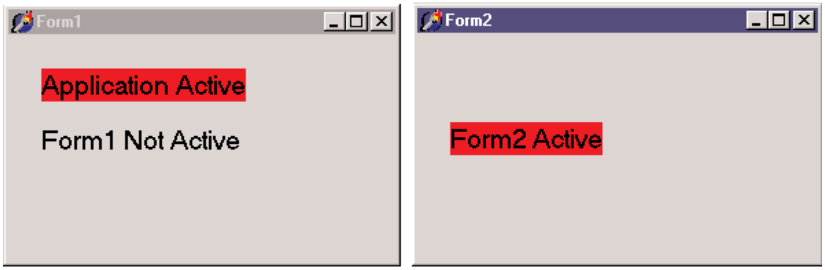
procedure TForm1.FormDeactivate(Sender: TObject);
begin
  LabelForm.Caption := 'Form2 Not Active';
  LabelForm.Color := clBtnFace;
end;
```

The second form has a similar label and similar code. The main form also displays the status of the entire application. It uses an ApplicationEvents component to handle the `OnActivate` and `OnDeactivate` events of the `Application` object. These two event handlers are similar to the two listed previously, with the only difference being that they modify the text and color of a second label of the form.

If you try running this program, you'll see whether this application is the active one and, if so, which of its forms is the active one. By looking at the output (see Figure 10.2) and listening for the beep, you can understand how each of the activation events is triggered by Delphi. Run this program and play with it for a while to understand how it works. We'll get back to other events related to the activation of forms in a while.

FIGURE 10.2:

The ActivApp example shows whether the application is active and which of the application's forms is active.



Tracking Forms with the *Screen* Object

We have already explored some of the properties and events of the `Application` object. Other interesting global information about an application is available through the `Screen` object, whose base class is `TScreen`. This object holds information about the system display (the screen size and the screen fonts) and also about the current set of forms in a running application. For example, you can display the screen size and the list of fonts by writing:

```
Label1.Caption := IntToStr (Screen.Width) + 'x' + IntToStr (Screen.Height);
ListBox1.Items := Screen.Fonts;
```

`TScreen` also reports the number and resolution of monitors in a multimonitor system. What I want to focus on now, however, is the list of forms held by the `Forms` property of the `Screen` object, the top-most form indicated by the `ActiveForm` property, and the related `OnActiveFormChange` event. Note that the forms the `Screen` object references are the forms of the application and not those of the system.

These features are demonstrated by the Screen example on the CD, which maintains a list of the current forms in a list box. This list must be updated each time a new form is created, an existing form is destroyed, or the active form of the program changes. To see how this works, you can create secondary forms by clicking the button labeled New:

```
procedure TMainForm.NewButtonClick(Sender: TObject);
var
  NewForm: TSecondForm;
begin
  // create a new form, set its caption, and run it
  NewForm := TSecondForm.Create (Self);
  Inc (nForms);
  NewForm.Caption := 'Second ' + IntToStr (nForms);
  NewForm.Show;
end;
```

One of the key portions of the program is the `OnCreate` event handler of the form, which fills the list a first time and then connects a handler to the `OnActiveFormChange` event:

```
procedure TMainForm.FormCreate(Sender: TObject);
begin
  FillFormsList (Self);
  // set the secondary forms counter to 0
  nForms := 0;
  // set an event handler on the screen object
  Screen.OnActiveFormChange := FillFormsList;
end;
```

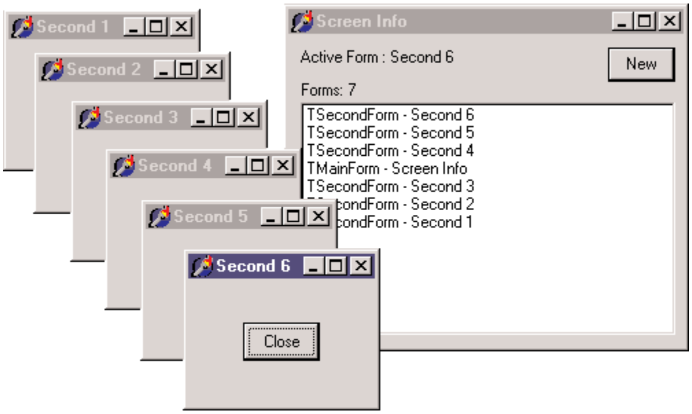
The code used to fill the Forms list box is inside a second procedure, `FillFormsList`, which is also installed as an event handler for the `OnActiveFormChange` event of the `Screen` object:

```
procedure TMainForm.FillFormsList (Sender: TObject);
var
  I: Integer;
begin
  // skip code in destruction phase
  if Assigned (FormsListBox) then
  begin
    FormsLabel.Caption := 'Forms: ' + IntToStr (Screen.FormCount);
    FormsListBox.Clear;
    // write class name and form title to the list box
    for I := 0 to Screen.FormCount - 1 do
      FormsListBox.Items.Add (Screen.Forms[I].ClassName + ' - ' +
        Screen.Forms[I].Caption);
    ActiveLabel.Caption := 'Active Form : ' + Screen.ActiveForm.Caption;
  end;
end;
```

WARNING It is very important not to execute this code while the main form is being destroyed. As an alternative to testing for the listbox not to be set to `nil`, you could as well test the form's `ComponentState` for the csDestroying flag. Another approach would be to remove the `OnActiveFormChange` event handler before exiting the application; that is, handle the `OnClose` event of the main form and assign `nil` to `Screen.OnActiveFormChange`.

The `FillFormsList` method fills the list box and sets a value for the two labels above it to show the number of forms and the name of the active one. When you click the New button, the program creates an instance of the secondary form, gives it a new title, and displays it. The Forms list box is updated automatically because of the handler we have installed for the `OnActiveFormChange` event. Figure 10.3 shows the output of this program when some secondary windows have been created.

FIGURE 10.3: The output of the Screen example with some secondary forms



Active Form : Second 6

Forms: 7

```
TSecondForm - Second 6
TSecondForm - Second 5
TSecondForm - Second 4
TMainForm - Screen Info
TSecondForm - Second 3
condForm - Second 2
condForm - Second 1
```

TIP The program always updates the text of the `ActiveLabel` above the list box to show the currently active form, which is always the same as the first one in the list box.

The secondary forms each have a Close button you can click to remove them. The program handles the `OnClose` event, setting the `Action` parameter to caFree, so that the form is actually destroyed when it is closed. This code closes the form, but it doesn't update the list of the windows properly. The system moves the focus to another window first, firing the event that updates the list, and destroys the old form only after this operation.

The first idea I had to update the windows list properly is to introduce a delay, posting a user-defined Windows message. Because the posted message is queued and not handled immediately, if we send it at the last possible moment of life of the secondary form, the main form will receive it when the other form is destroyed.

The trick is to post the message in the OnDestroy event handler of the secondary form. To accomplish this, we need to refer to the MainForm object, by adding a uses statement in the implementation portion of this unit. I've posted a wm_User message, which is handled by a specific message method of the main form, as shown here:

```
public
  procedure ChildClosed (var Message: TMessage);
    message wm_User;
```

Here is the code for this method:

```
procedure TMainForm.ChildClosed (var Message: TMessage);
begin
  FillFormsList (Self);
end;
```

The problem here is that if you close the main window before closing the secondary forms, the main form exists, but its code cannot be executed anymore. To avoid another system error (an Access Violation Fault), you need to post the message only if the main form is not closing. But how do you know that? One way is to add a flag to the TMainForm class and change its value when the main form is closing, so that you can test the flag from the code of the secondary window.

This is a good solution—so good that the VCL already provides something similar. There is a barely documented ComponentState property. It is a Pascal set that includes (among other flags) a csDestroying flag, which is set when the form is closing. Therefore, we can write the following code:

```
procedure TSecondForm.FormDestroy(Sender: TObject);
begin
  if not (csDestroying in MainForm.ComponentState) then
    PostMessage (MainForm.Handle, wm_User, 0, 0);
end;
```

With this code, the list box always lists all of the forms in the application. Note that you need to disable the automatic creation of the secondary form by using the Forms page of the Project Options dialog box.

After giving it some thought, however, I found an alternative and much more Delphi-oriented solution. Every time a component is destroyed, it tells its owner about the event by calling the Notification method defined in the TComponent class. Because the secondary forms are owned by the main one, as specified in the code of the NewButtonClick method, we can override this method and simplify the code. In the form class, simply write

```
protected
  procedure Notification(AComponent: TComponent;
    Operation: TOperation); override;
```

Here is the code of the method:

```
procedure TMainForm.Notification(AComponent: TComponent;
  Operation: TOperation);
begin
  inherited Notification(AComponent, Operation);
  if (Operation = opRemove) and Showing and (AComponent is TForm) then
    FillFormsList;
end;
```

You'll find the complete code of this version in the Screen2 directory on the CD.

NOTE In case the secondary forms were not owned by the main one, we could have used the `FreeNotification` method to get the secondary form to notify the main form when they are destroyed. `FreeNotification` receives as parameter the component to notify when the current component is destroyed. The effect is a call to the `Notification` method coming from a component other than the owned ones. `FreeNotification` is generally used by component writers to safely connect components on different forms or data modules.

The last feature I've added to both versions of the program is a simple one. When you click an item in the list box, the corresponding form is activated, using the `BringToFront` method:

```
procedure TMainForm.FormsListBoxClick(Sender: TObject);
begin
  Screen.Forms [FormsListBox.ItemIndex].BringToFront;
end;
```

Nice—well, almost nice. If you click the list box of an inactive form, the main form is activated first, and the list box is rearranged, so you might end up selecting a different form than you were expecting. If you experiment with the program, you'll soon realize what I mean. This minor glitch in the program is an example of the risks you face when you dynamically update some information and let the user work on it at the same time.

Events, Messages, and Multitasking in Windows

To understand how Windows applications work internally, we need to spend a minute discussing how multitasking is supported in this environment. We also need to understand the role of timers (and the Timer component) and of background (or *idle*) computing.

In short, we need to delve deeper into the event-driven structure of Windows and its multitasking support. Because this is a book about *Delphi* programming, I won't discuss this topic in detail, but I will provide an overview for readers who have limited experience with Windows API programming.

Event-Driven Programming

The basic idea behind event-driven programming is that specific events determine the control flow of the application. A program spends most of its time waiting for these events and provides code to respond to them. For example, when a user clicks one of the mouse buttons, an event occurs. A message describing this event is sent to the window currently under the mouse cursor. The program code that responds to events for that window will receive the event, process it, and respond accordingly. When the program has finished responding to the event, it returns to a waiting or “idle” state.

As this explanation shows, events are serialized; each event is handled only after the previous one is completed. When an application is executing event-handling code (that is, when it is not waiting for an event), other events for that application have to wait in a message queue reserved for that application (unless the application uses multiple threads). When an application has responded to a message and returned to a waiting state, it becomes the last in the list of programs waiting to handle additional messages. In every version of Win32 (9*x*, NT, Me, and 2000), after a fixed amount of time has elapsed, the system interrupts the current application and immediately gives control to the next one in the list. The first program is resumed only after each application has had a turn. This is called preemptive multitasking.

So, an application performing a time-consuming operation in an event handler doesn’t prevent the system from working properly, but is generally unable even to repaint its own windows properly, with a very nasty effect. If you’ve never experienced this problem, try for yourself: Write a time-consuming loop executed when a button is pressed, and try to move the form or move another window on top of it. The effect is really annoying. Now try adding the call `Application.ProcessMessages` within the loop, and you’ll see that the operation becomes much slower, but the form will be immediately refreshed.

If an application has responded to its events and is waiting for its turn to process messages, it has no chance to regain control until it receives another message (unless it uses multithreading). This is a reason to use timers, a system component that will send a message to your application every time a time interval elapses.

One final note—when you think about events, remember that input events (using the mouse or the keyboard) account for only a small percentage of the total message flow in a Windows application. Most of the messages are the system’s internal messages or messages exchanged between different controls and windows. Even a familiar input operation such as clicking a mouse button can result in a huge number of messages, most of which are internal Windows messages. You can test this yourself by using the WinSight utility included in Delphi. In WinSight, choose to view the Message Trace, and select the messages for all of the windows. Select Start, and then perform some normal operations with the mouse. You’ll see hundreds of messages in a few seconds.

Windows Message Delivery

Before looking at some real examples, we need to consider another key element of message handling. Windows has two different ways to send a message to a window:

- The PostMessage API function is used to place a message in the application's message queue. The message will be handled only when the application has a chance to access its message queue (that is, when it receives control from the system), and only after earlier messages have been processed. This is an asynchronous call, since you do not know when the message will actually be received.
- The SendMessage API function is used to execute message-handler code immediately. SendMessage bypasses the application's message queue and sends the message directly to a target window or control. This is a synchronous call. This function even has a return value, which is passed back by the message-handling code. Calling SendMessage is no different than directly calling another method or function of the program.

The difference between these two ways of sending messages is similar to that between mailing a letter, which will reach its destination sooner or later, and sending a fax, which goes immediately to the recipient. Although you will rarely need to use these low-level functions in Delphi, this description should help you determine which one to use if you do need to write this type of code.

Background Processing and Multitasking

Suppose that you need to implement a time-consuming algorithm. If you write the algorithm as a response to an event, your application will be stopped completely during all the time it takes to process that algorithm. To let the user know that something is being processed, you can display the hourglass cursor, but this is not a user-friendly solution. Win32 allows other programs to continue their execution, but the program in question will freeze; it won't even update its own user interface if a repaint is requested. In fact, while the algorithm is executing, the application won't be able to receive and process any other messages, including the paint messages.

The simplest solution to this problem is to call the ProcessMessages method of the Application object many times within the algorithm, usually inside an internal loop. This call stops the execution, allows the program to receive and handle a message, and then resumes execution. The problem with this approach, however, is that while the program is paused to accept messages, the user is free to do any operation and might again click the button or press the keystrokes that started the algorithm. To fix this, you can disable the buttons and commands you don't want the user to select, and you can display the hourglass cursor (which technically doesn't prevent a mouse click event, but it does suggest that the user should wait before doing any other operation). An alternative solution is to split the algorithm into smaller pieces and execute each of them in turn, letting the application respond to pending messages in between processing the pieces. We can use a timer to let the system notify us once a time interval has elapsed. Although you can use timers to implement some form of background computing, this is far from a good solution. A slightly better technique would be to execute each step of the program when the Application object receives the OnIdle event.

The difference between calling ProcessMessages and using the OnIdle events is that by calling ProcessMessages, you will give your code more processing time than with the OnIdle approach. Calling ProcessMessages is a way to let the system perform other operations while your program is computing; using the OnIdle event is a way to let your application perform background tasks when it doesn't have pending requests from the user.

NOTE All these techniques for background computing were necessary in 16-bit Windows days. In Win32, you should generally use secondary threads to perform lengthy or background operations.

Checking for a Previous Instance of an Application

One form of multitasking is the execution of two or more instances of the same application. Any application can generally be executed by a user in more than one instance, and it needs to be able to check for a previous instance already running, in order to disable this default behavior and allow for one instance at most. This section demonstrates several ways of implementing such a check, allowing me to discuss some interesting Windows programming techniques.

Looking for a Copy of the Main Window

To find a copy of the main window of a previous instance, use the FindWindow API function and pass it the name of the window class (the name used to register the form's window type, or WNDCLASS, in the system) and the caption of the window for which you are looking. In a Delphi application, the name of the WNDCLASS window class is the same as the Object Pascal name for the form's class (for example, TForm1). The result of the FindWindow function is either a handle to the window or zero (if no matching window was found).

The main code of your Delphi application should be written so that it will execute only if the FindWindow result is zero:

```
var
  Hwnd: THandle;
begin
  Hwnd := FindWindow ('TForm1', nil);
  if Hwnd = 0 then
```

```
    begin
      Application.Initialize;
      Application.CreateForm(TForm1, Form1);
      Application.Run;
    end
    else
      SetForegroundWindow (Hwnd)
  end.
```

To activate the window of the previous instance of the application, you can use the `SetForegroundWindow` function, which works for windows owned by other processes. This call produces its effect only if the window passed as parameter hasn't been minimized. When the main form of a Delphi application is minimized, in fact, it is hidden, and for this reason the activation code has no effect.

Unfortunately, if you run a program that uses the `FindWindow` call just shown from within the Delphi IDE, a window with that caption and class may already exist: the design-time form. Thus, the program won't start even once. However, it will run if you close the form and its corresponding source code file (closing only the form, in fact, simply hides the window), or if you close the project and run the program from the Windows Explorer.

Using a Mutex

A completely different approach is to use a *mutex*, or mutual exclusion object. This is a typical Win32 approach, commonly used for synchronizing threads, as we'll see later in this chapter. Here we are going to use a mutex for synchronizing two different applications, or (to be more precise) two instances of the same application.

Once an application has created a mutex with a given name, it can test whether this object is already owned by another application, calling the `WaitForSingleObject` Windows API function. If the mutex has no owner, the application calling this function becomes the owner. If the mutex is already owned, the application waits until the time-out (the second parameter of the function) elapses. It then returns an error code.

To implement this technique, you can use the following project source code, which you'll find in the OneCopy example:

```
var
  hMutex: THandle;
begin
  HMutex := CreateMutex (nil, False, 'OneCopyMutex');
  if WaitForSingleObject (hMutex, 0) <> wait_TimeOut then
  begin
    Application.Initialize;
    Application.CreateForm(TForm1, Form1);
    Application.Run;
    end;
  end.
```

If you run this example twice, you'll see that it creates a new, temporary copy of the application (the icon appears in the Taskbar) and then destroys it when the time-out elapses. This approach is certainly more robust than the previous one, but it lacks a feature: how do we enable the existing instance of the application? We still need to find its form, but we can use a better approach.

Searching the Window List

When you want to search for a specific main window in the system, you can use the `EnumWindows` API functions. Enumeration functions are quite peculiar in Windows, because they usually require another function as a parameter. These enumeration functions require a pointer to a function (often described as a *callback* function) as parameter. The idea is that this function is applied to each element of the list (in this case, the list of main windows), until the list ends or the function returns False. Here is the enumeration function from the OneCopy example:

```
function EnumWndProc (hwnd: THandle;
  Param: Cardinal): Bool; stdcall;
var
  ClassName, WinModuleName: string;
  WinInstance: THandle;
begin
  Result := True;
  SetLength (ClassName, 100);
  GetClassName (hwnd, PChar (ClassName), Length (ClassName));
  ClassName := PChar (ClassName);
  if ClassName = TForm1.ClassName then
  begin
    // get the module name of the target window
    SetLength (WinModuleName, 200);
    WinInstance := GetWindowLong (hwnd, GWL_HINSTANCE);
    GetModuleFileName (WinInstance,
      PChar (WinModuleName), Length (WinModuleName));
    WinModuleName := PChar(WinModuleName); // adjust length
    // compare module names
    if WinModuleName = ModuleName then
    begin
      FoundWnd := Hwnd;
      Result := False; // stop enumeration
    end;
  end;
end;
```

This function, called for each nonchild window of the system, checks the name of each window's class, looking for the name of the TForm1 class. When it finds a window with this string in its class name, it uses GetModuleFilename to extract the name of the executable file of the application that owns the matching form. If the module name matches that of the current program (which was extracted previously with similar code), you can be quite sure that you have found a previous instance of the same program. Here is how you can call the enumerated function:

```
var
  FoundWnd: THandle;
  ModuleName: string;
begin
  if WaitForSingleObject (hMutex, 0) <> wait_TimeOut then
    ...
  else
  begin
    // get the current module name
    SetLength (ModuleName, 200);
    GetModuleFileName (HInstance, PChar (ModuleName), Length (ModuleName));
    ModuleName := PChar (ModuleName); // adjust length
    // find window of previous instance
    EnumWindows (@EnumWndProc, 0);
```

Handling User-Defined Window Messages

I've mentioned earlier that the SetForegroundWindow call doesn't work if the main form of the program has been minimized. Now we can solve this problem. You can ask the form of another application—the previous instance of the same program in this case—to restore its main form by sending it a user-defined window message. You can then test whether the form is minimized and post a new user-defined message to the old window. Here is the code; in the OneCopy program, it follows the last fragment shown in the preceding section:

```
    if FoundWnd <> 0 then
    begin
      // show the window, eventually
      if not IsWindowVisible (FoundWnd) then
        PostMessage (FoundWnd, wm_User, 0, 0);
      SetForegroundWindow (FoundWnd);
    end;
```

Again, the PostMessage API function sends a message to the message queue of the application that owns the destination window. In the code of the form, you can add a special function to handle this message:

```
public
  procedure WMUser (var msg: TMessage);
    message wm_User;
```

Now you can write the code of this method, which is simple:

```
procedure TForm1.WMUser (var msg: TMessage);
begin
  Application.Restore;
end;
```

Creating MDI Applications

A common approach for the structure of an application is MDI (Multiple Document Interface). An MDI application is made up of several forms that appear inside a single main form. If you use Windows Notepad, you can open only one text document, because Notepad isn't an MDI application. But with your favorite word processor, you can probably open several different documents, each in its own child window, because they are MDI applications. All these document windows are usually held by a *frame*, or *application*, window.

NOTE Microsoft is departing more and more from the MDI model stressed in Windows 3 days. Starting with Resource Explorer in Windows 95 and even more with Office 2000, Microsoft tends to use a specific main window for every document, the classic SDI (Single Document Interface) approach. In any case, MDI isn't dead and can sometimes be a useful structure.

MDI in Windows: A Technical Overview

The MDI structure gives programmers several benefits automatically. For example, Windows handles a list of the child windows in one of the pull-down menus of an MDI application, and there are specific Delphi methods that activate the corresponding MDI functionality, to tile or cascade the child windows. The following is the technical structure of an MDI application in Windows:

- The main window of the application acts as a frame or a container.
- A special window, known as the *MDI client*, covers the whole client area of the frame window. This MDI client is one of the Windows predefined controls, just like an edit box or a list box. The MDI client window lacks any specific user-interface element, but it is visible. In fact, you can change the standard system color of the MDI work area (called the Application Background) in the Appearance page of the Display Properties dialog box in Windows.
- There are multiple child windows, of the same kind or of different kinds. These child windows are not placed in the frame window directly, but each is defined as a child of the MDI client window, which in turn is a child of the frame window.

Frame and Child Windows in Delphi

Delphi makes the development of MDI applications easy, even without using the MDI Application template available in Delphi (see the Applications page of the File ➢ New dialog box). You only need to build at least two forms, one with the FormStyle property set to fsMDIForm and the other with the same property set to fsMDIChild. Set these two properties in a simple program and run it, and you'll see the two forms nested in the typical MDI style.

Generally, however, the child form is not created at startup, and you need to provide a way to create one or more child windows. This can be done by adding a menu with a New menu item and writing the following code:

```
var
  ChildForm: TChildForm;
begin
  ChildForm := TChildForm.Create (Application);
  ChildForm.Show;
```

Another important feature is to add a "Window" pull-down menu and use it as the value of the WindowMenu property of the form. This pull-down menu will automatically list all the available child windows. Of course, you can choose any other name for the pull-down menu, but Window is the standard.

To make this program work properly, we can add a number to the title of any child window when it is created:

```
procedure TMainForm.New1Click(Sender: TObject);
var
  ChildForm: TChildForm;
begin
  WindowMenu := Window1;
  Inc (Counter);
  ChildForm := TChildForm.Create (Self);
  ChildForm.Caption := ChildForm.Caption + ' ' + IntToStr (Counter);
  ChildForm.Show;
end;
```

You can also open child windows, minimize or maximize each of them, close them, and use the Window pull-down menu to navigate among them. Now suppose that we want to close some of these child windows, to unclutter the client area of our program. Click the Close boxes of some of the child windows and they are minimized! What is happening here? Remember that when you close a window, you generally hide it from view. The closed forms in Delphi still exist, although they are not visible. In the case of child windows, hiding them won't work, because the MDI Window menu and the list of windows will still list existing child windows, even if they are hidden. For this reason, Delphi minimizes the MDI child windows when you try to close them. To solve this problem, we need to delete the child windows when they are closed, setting the Action reference parameter of the OnClose event to caFree.

Building a Complete Window Menu

Our first task is to define a better menu structure for the example. Typically the Window pull-down menu has at least three items, titled Cascade, Tile, and Arrange Icons. To handle the menu commands, we can use some of the predefined methods of TForm that can be used only for MDI frames:

- The Cascade method cascades the open MDI child windows. The windows overlap each other. Iconized child windows are also arranged (see ArrangeIcons below).
- The Tile method tiles the open MDI child windows; the child forms are arranged so that they do not overlap. The default behavior is horizontal tiling, although if you have several child windows, they will be arranged in several columns. This default can be changed by using the TileMode property (either tbHorizontal or tbVertical).
- The ArrangeIcons procedure arranges all the iconized child windows. Open forms are not moved.

As a better alternative to calling these methods, you can place an ActionList in the form and add to it a series of predefined MDI actions. The related classes are TWindowArrange, TWindowCascade, TWindowClose, TWindowTileHorizontal, TWindowTileVertical, and TWindowMinimizeAll. The connected menu items will perform the corresponding actions and will be disabled if no child window is available. The MdiDemo example, which we'll look at next, demonstrates the use of the MDI actions, among other things.

There are also some other interesting methods and properties related strictly to MDI in Delphi:

- ActiveMDIChild is a run-time and read-only property of the MDI frame form, and it holds the active child window. The user can change this value by selecting a new child window, or the program can change it using the Next and Previous procedures, which activate the child window following or preceding the currently active one.
- The ClientHandle property holds the Windows handle of the MDI client window, which covers the client area of the main form.
- The MDIChildren property is an array of child windows. You can use this and the MDIChildCount property to cycle among all of the child windows. This can be useful for finding a particular child window or to operate on each of them.

NOTE Note that the internal order of the child windows is the reverse order of activation. This means that the last child window selected is the active window (the first in the internal list), the second-to-last child window selected is the second, and the first child window selected is the last. This order determines how the windows are arranged on the screen. The first window in the list is the one above all others, while the last window is below all others, and probably hidden away. You can imagine an axis (the *z* axis) coming out of the screen toward you. The active window has a higher value for the *z* coordinate and, thus, covers other windows. For this reason, the Windows ordering schema is known as the *z-order*.

The MdiDemo Example

I've built a first example to demonstrate most of the features of a simple MDI application. MdiDemo is actually a full-blown MDI text editor, because each child window hosts a Memo component and can open and save text files. The child form has a `Modified` property used to indicate whether the text of the memo has changed (it is set to True in the handler of the memo's `OnChange` event). `Modified` is set to False in the `Save` and `Load` custom methods and checked when the form is closed (prompting to save the file).

As I've already mentioned, the main form of this example is based on an ActionList component. The actions are available through some menu items and a toolbar, as you can see in Figure 10.4. You can see the details of the ActionList in the source code of the example. Next, I want to focus on the code of the custom actions. Once more, this example demonstrates that using actions makes it very simple to modify the user interface of the program, without writing any extra code. In fact, there is no code directly tied to the user interface.

One of the simplest actions is the `ActionFont` object, which has both an `OnExecute` handler, which uses a FontDialog component, and an `OnUpdate` handler, which disables the action (and hence the associated menu item and toolbar button) when there are no child forms:

```
procedure TMainForm.ActionFontExecute(Sender: TObject);
begin
  if FontDialog1.Execute then
    (ActiveMDIChild as TChildForm).Memo1.Font := FontDialog1.Font;
end;

procedure TMainForm.ActionFontUpdate(Sender: TObject);
begin
  ActionFont.Enabled := MDIChildCount > 0;
end;
```

FIGURE 10.4:

The MdiDemo program uses a series of predefined Delphi actions connected to a menu and a toolbar.

Country=039,850,C:\WINDOWS\COMMAND\country.sys
```

The action named New creates the child form and sets a default filename. The Open action calls the `ActionNewExcecute` method prior to loading the file:

```
procedure TMainForm.ActionNewExecute(Sender: TObject);
var
  ChildForm: TChildForm;
begin
  Inc (Counter);
  ChildForm := TChildForm.Create (Self);
  ChildForm.Caption :=
    LowerCase (ExtractFilePath (Application.Exename)) + 'text' +
    IntToStr (Counter) + '.txt';
  ChildForm.Show;
end;

procedure TMainForm.ActionOpenExecute(Sender: TObject);
begin
  if OpenDialog1.Execute then
  begin
    ActionNewExecute (Self);
    (ActiveMDIChild as TChildForm).Load (OpenDialog1.FileName);
  end;
end;
```

The actual file loading is performed by the Load method of the form. Likewise, the Save method of the child form is used by the Save and Save As actions. Notice the OnUpdate handler of the Save action, which enables the action only if the user has changed the text of the memo:

```
procedure TMainForm.ActionSaveAsExecute(Sender: TObject);
begin
  // suggest the current file name
  SaveDialog1.FileName := ActiveMDIChild.Caption;
  if SaveDialog1.Execute then
  begin
    // modify the file name and save
    ActiveMDIChild.Caption := SaveDialog1.FileName;
    (ActiveMDIChild as TChildForm).Save;
  end;
end;

procedure TMainForm.ActionSaveUpdate(Sender: TObject);
begin
  ActionSave.Enabled := (MDIChildCount > 0) and
    (ActiveMDIChild as TChildForm).Modified;
end;

procedure TMainForm.ActionSaveExecute(Sender: TObject);
begin
  (ActiveMDIChild as TChildForm).Save;
end;
```

MDI Applications with Different Child Windows

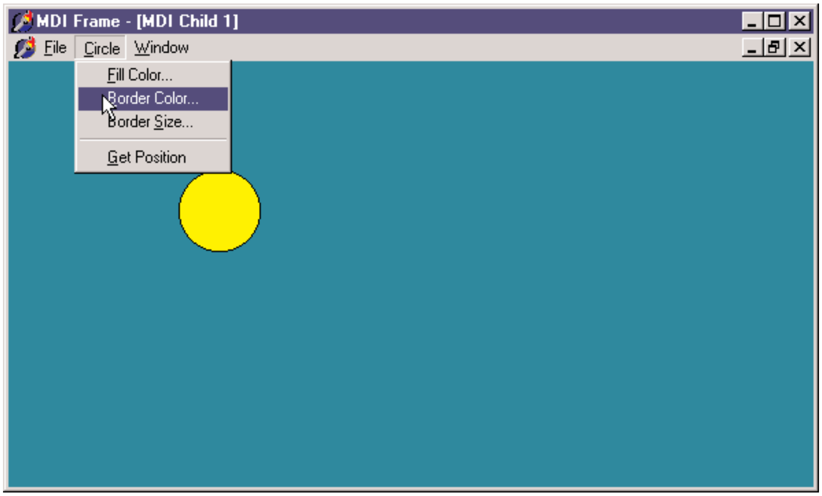
A common approach in complex MDI applications is to include child windows of different kinds (that is, based on different child forms). I will build a new example, called MdiMulti, to highlight some problems you may encounter with this approach. This example has two different types of child forms. The first type will host a circle drawn in the position of the last mouse click, while the second will contain a bouncing square. Another feature I'll add to the main form is a custom background obtained by painting a tiled image in it.

Child Forms and Merging Menus

The first type of child form can display a circle in the position where the user clicked one of the mouse buttons. Figure 10.5 shows an example of the output of the MdiMulti program. The program includes a Circle menu, which allows the user to change the color of the surface of the circle as well as the color and size of its border. What is interesting here is that to program the child form, we do not need to consider the existence of other forms or of the frame window. We simply write the code of the form, and that's all. The only special care required is for the menus of the two forms.

FIGURE 10.5:

The output of the MdiMulti example, with a child window that displays circles



If we prepare a main menu for the child form, it will replace the main menu of the frame window when the child form is activated. An MDI child window, in fact, cannot have a menu of its own. But the fact that a child window can't have any menus should not bother you, because this is the standard behavior of MDI applications. You can use the menu bar of the frame window to display the menus of the child window. Even better, you can merge the menu bar of the frame window and that of the child form. For example, in this program, the menu of the child form can be placed between the frame window's File and Window pull-down menus. You can accomplish this using the following `GroupIndex` values:

- File pull-down menu, main form: 1
- Window pull-down menu, main form: 3
- Circle pull-down menu, child form: 2

Using these settings for the menu group indexes, the menu bar of the frame window will have either two or three pull-down menus. At startup, the menu bar has two menus. As soon as you create a child window, there are three menus, and when the last child window is closed (destroyed), the Circle pull-down menu disappears. You should also spend some time testing this behavior by running the program.

The second type of child form shows a moving image. The square, a Shape component, moves around the client area of the form at fixed time intervals, using a Timer component, and bounces on the edges of the form, changing its direction. This turning process is determined by a fairly complex algorithm, which we don't have space to examine. The main point of the example, instead, is to show you how menu merging behaves when you have an MDI frame with child forms of different types. (You can study the source code on the companion CD to see how it works.)

The Main Form

Now we need to integrate the two child forms into an MDI application. The File pull-down menu here has two separate New menu items, which are used to create a child window of either kind. The code uses a single child window counter. As an alternative, you could use two different counters for the two kinds of child windows. The Window menu uses the predefined MDI actions.

As soon as a form of this kind is displayed on the screen, its menu bar is automatically merged with the main menu bar. When you select a child form of one of the two kinds, the menu bar changes accordingly. Once all the child windows are closed, the original menu bar of the main form is reset. By using the proper menu group indexes, we let Delphi accomplish everything automatically, as you can see in Figure 10.6.

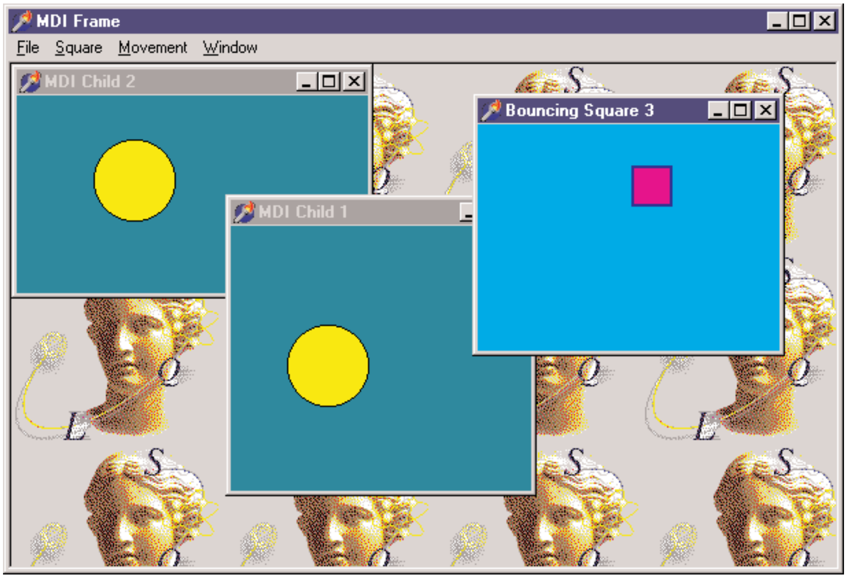


FIGURE 10.6:

The menu bar of the MdiMulti Demo4 application changes automatically to reflect the currently selected child window, as you can see by comparing the menu bar with that of Figure 10.5.

I've added a few other menu items in the main form, to close every child window and show some statistics about them. The method related to the Count command scans the MDIChildren array property to count the number of child windows of each kind (using the RTTI operator is):

```
for I := 0 to MDIChildCount - 1 do
  if MDIChildren is TBounceChildForm then
    Inc (NBounce)
  else
    Inc (NCircle);
```

Subclassing the MdiClient Window

Finally, the program includes support for a background-tiled image. The bitmap is taken from an Image component and should be painted on the form in the wm_EraseBkgnd Windows message's handler. The problem is that we cannot simply connect the code to the main form, as a separate window, the MdiClient, covers its surface.

We have no corresponding Delphi form for this window, so how can we handle its messages? We have to resort to a low-level Windows programming technique known as *subclassing*. (In spite of the name, this has little to do with OOP inheritance.) The basic idea is that we can replace the window procedure, which receives all the messages of the window, with a new one we provide. This can be done by calling the SetWindowLong API function and providing the memory address of the procedure, the function pointer.

NOTE A window procedure is a function receiving all the messages for a window. Every window must have a window procedure and can have only one. Even Delphi forms have a window procedure; although this is hidden in the system, it calls the WndProc virtual function, which you can use. But the VCL has a predefined handling of the messages, which are then forwarded to the message-handling methods of a form after some preprocessing. With all this support, you need to handle window procedures explicitly only when working with non-Delphi windows, as in this case.

Unless we have some reason to change the default behavior of this system window, we can simply store the original procedure and call it to obtain a default processing. The two function pointers referring to the two procedures (the old and the new one) are stored in two local fields of the form:

```
private
  OldWinProc, NewWinProc: Pointer;
  procedure NewWinProcedure (var Msg: TMessage);
```

The form also has a method we'll use as a new window procedure, with the actual code used to paint on the background of the window. Because this is a method and not a plain window procedure, the program has to call the MakeObjectInstance method to add a prefix to the method and let the system use it as if it were a function. All this description is summarized by just two complex statements:

```
procedure TMainForm.FormCreate(Sender: TObject);
begin
  NewWinProc := MakeObjectInstance (NewWinProcedure);
  OldWinProc := Pointer (SetWindowLong (ClientHandle, gwl_WndProc, Cardinal
    (NewWinProc)));
  OutCanvas := TCanvas.Create;
end;
```

The window procedure we install calls the default one. Then, if the message is wm_EraseBkgnd and the image is not empty, we draw it on the screen many times using the Draw method of a temporary canvas. This canvas object is created when the program starts (see the code above) and connected to the handle passed as wParam parameter by the message. With this approach, we don't have to create a new TCanvas object for every background painting operation requested, thus saving a little time in the frequent operation. Here is the code, which produces the output already seen in Figure 10.6:

```
procedure TMainForm.NewWinProcedure (var Msg: TMessage);
var
  BmpWidth, BmpHeight: Integer;
  I, J: Integer;
begin
  // default processing first
  Msg.Result := CallWindowProc (OldWinProc, ClientHandle, Msg.Msg, Msg.wParam,
    Msg.lParam);

  // handle background repaint
  if Msg.Msg = wm_EraseBkgnd then
  begin
    BmpWidth := MainForm.Image1.Width;
    BmpHeight := MainForm.Image1.Height;
    if (BmpWidth <> 0) and (BmpHeight <> 0) then
    begin
      OutCanvas.Handle := Msg.wParam;
      for I := 0 to MainForm.ClientWidth div BmpWidth do
        for J := 0 to MainForm.ClientHeight div BmpHeight do
          OutCanvas.Draw (I * BmpWidth, J * BmpHeight,
            MainForm.Image1.Picture.Graphic);
    end;
  end;
end;
```

Visual Form Inheritance

When you need to build two or more similar forms, possibly with different event handlers, you can use dynamic techniques, hide or create new components at run time, change event handlers, and use `if` or `case` statements. Or you can apply the object-oriented techniques, thanks to visual form inheritance. In short, instead of creating a form based on `TForm`, you can inherit a form from an existing one, adding new components or altering the properties of the existing ones. But what is the real advantage of visual form inheritance?

Well, this mostly depends on the kind of application you are building. If it has multiple forms, some of which are very similar to each other or simply include common elements, then you can place the common components and the common event handlers in the base form and add the specific behavior and components to the subclasses. For example, if you prepare a standard parent form with a toolbar, a logo, default sizing and closing code, and the handlers of some Windows messages, you can then use it as the parent class for each of the forms of an application.

You can also use visual form inheritance to customize an application for different clients, without duplicating any source code or form definition code; just inherit the specific versions for a client from the standard forms. Remember that the main advantage of visual inheritance is that you can later change the original form and automatically update all the derived forms. This is a well-known advantage of inheritance in object-oriented programming languages. But there is a beneficial side effect: polymorphism. You can add a virtual method in a base form and override it in a subclassed form. Then you can refer to both forms and call this method for each of them.

NOTE Delphi includes another feature, frames, which resembles visual form inheritance. In both cases, you can work at design time on two versions of a form/frame. However, in visual form inheritance, you are defining two different classes (parent and derived), whereas with frames, you work on a class and an instance. Frames will be discussed in detail later in this chapter.

Inheriting from a Base Form

The rules governing visual form inheritance are quite simple, once you have a clear idea of what inheritance is. Basically, a subclass form has the same components as the parent form as well as some new components. You cannot remove a component of the base class, although (if it is a visual control) you can make it invisible. What's important is that you can easily change properties of the components you inherit.

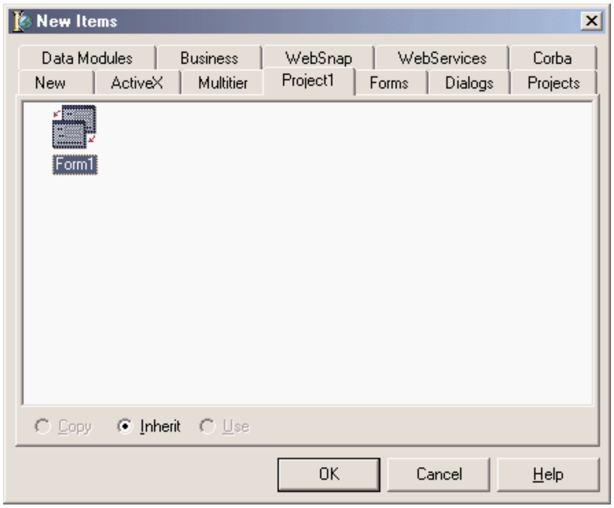
Notice that if you change a property of a component in the inherited form, any modification of the same property in the parent form will have no effect. Changing other properties of the component will affect the inherited versions, as well. You can resynchronize the two property values by using the Revert to Inherited local menu command of the Object Inspector. The same thing is accomplished by setting the two properties to the same value and recompiling the code. After modifying multiple properties, you can resynchronize them all to the base version by applying the Revert to Inherited command of the component's local menu.

Besides inheriting components, the new form inherits all the methods of the base form, including the event handlers. You can add new handlers in the inherited form and also override existing handlers.

To describe how visual form inheritance works, I've built a very simple example, called VFI. I'll describe step-by-step how to build it. First, start a new project, and add four buttons to its main form. Then select File ➢ New ➢ Other, and choose the page with the name of the project in the New Items dialog box (see Figure 10.7).

FIGURE 10.7:

The New Items dialog box allows you to create an inherited form.



In the New Items dialog, you can choose the form from which you want to inherit. The new form has the same four buttons. Here is the initial textual description of the new form:

```
inherited Form2: TForm2
  Caption = 'Form2'
end
```

And here is its initial class declaration, where you can see that the base class is not the usual TForm but the actual base class form:

```
type
  TForm2 = class(TForm1)
  private
    { Private declarations }
    public
      { Public declarations }
    end;
```

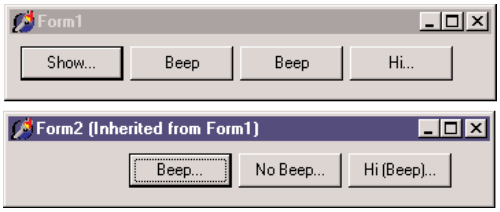
Notice the presence of the inherited keyword in the textual description; also notice that the form indeed has some components, although they are defined in the base class form. If you move the form and add the caption of one of the buttons, the textual description will change accordingly:

```
inherited Form2: TForm2
  Left = 313
  Top = 202
  Caption = 'Form2'
  inherited Button2: TButton
    Caption = 'Beep...'
  end
end
```

Only the properties with a different value are listed (and by removing these properties from the textual description of the inherited form, you can reset them to the value of the base form, as I mentioned before). I've actually changed the captions of most buttons, as you can see in Figure 10.8.

FIGURE 10.8:

The two forms of the VFI example at run time



Each of the buttons of the first form has an OnClick handler, with simple code. The first button shows the inherited form calling its Show method; the second and the third buttons call the Beep procedure; and the last button displays a simple message.

What happens in the inherited form? First we should remove the Show button, because the secondary form is already visible. However, we cannot delete a component from an inherited form. An alternative solution is to leave the component there but set its Visible property to False. The button will still be there but not visible (as you can guess from Figure 10.8). The other three buttons will be visible but with different handlers. This is simple to accomplish. If you select the OnClick event of a button in the inherited form (by double-clicking it), you'll get an empty method slightly different from the default one:

```
procedure TForm2.Button2Click(Sender: TObject);
begin
  inherited;
end;
```

The inherited keyword stands for a call to the corresponding event handler of the base form. This keyword is always added by Delphi, even if the handler is not defined in the parent class (and this is reasonable, because it might be defined later) or if the component is not present in the parent class (which doesn't seem like a great idea to me). It is very simple to execute the code of the base form and perform some other operations:

```
procedure TForm2.Button2Click(Sender: TObject);
begin
  inherited;
  ShowMessage ('Hi');
end;
```

This is not the only choice. An alternative approach is to write a brand-new event handler and not execute the code of the base class, as I've done for the third button of the VFI example: To accomplish this, simply remove the inherited keyword. Still another choice includes calling a base-class method after some custom code has been executed, calling it when a condition is met, or calling the handler of a different event of the base class, as I've done for the fourth button:

```
procedure TForm2.Button4Click(Sender: TObject);
begin
  inherited Button3Click (Sender);
  inherited;
end;
```

You probably won't do this very often, but you must be aware that you can. Of course, you can consider each method of the base form as a method of your form, and call it freely. This example allows you to explore some features of visual form inheritance, but to see its true power you'll need to look at real-world examples more complex than this book has room to explore. There is something else I want to show you here: *visual form polymorphism*.

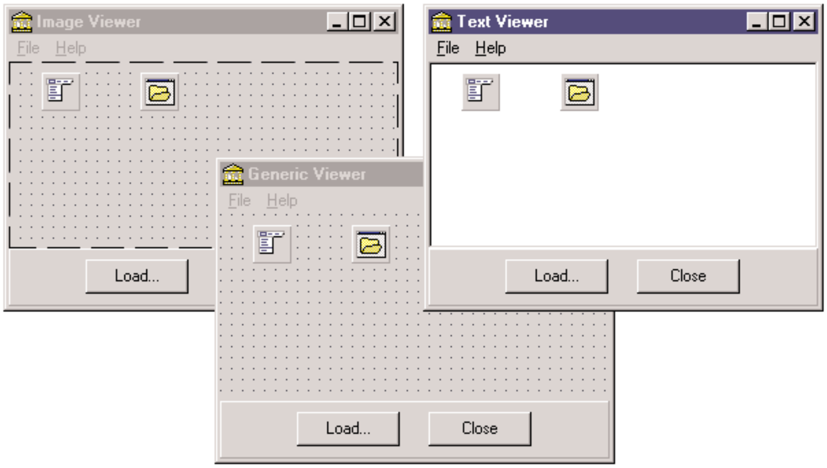
Polymorphic Forms

The problem is simple. If you add an event handler to a form and then change it in an inherited form, there is no way to refer to the two methods using a common variable of the base class, because the event handlers use static binding by default.

Confusing? Here is an example, which is intended for experienced Delphi programmers. Suppose you want to build a bitmap viewer form and a text viewer form in the same program. The two forms have similar elements, a similar toolbar, a similar menu, an OpenDialog component, and different components for viewing the data. So you decide to build a base-class form containing the common elements and inherit the two forms from it. You can see the three forms at design time in Figure 10.9.

FIGURE 10.9:

The base-class form and the two inherited forms of the PoliForm example at design time



The main form contains a toolbar panel with a few buttons (real toolbars apparently have a few problems with visual form inheritance), a menu, and an open dialog component. The two inherited forms have only minor differences, but they feature a new component, either an image viewer (`TImage`) or a text viewer (`TMemo`). They also modify the settings of the OpenDialog component, to refer to different types of files.

The main form includes some common code. The Close button and the File ➢ Close command call the `Close` method of the form. The Help ➢ About command shows a simple message box. The Load button of the base form has the following code:

```
procedure TViewerForm.ButtonLoadClick(Sender: TObject);
begin
  ShowMessage ('Error: File-loading code missing');
end;
```

The File ➢ Load command, instead, calls another method:

```
procedure TViewerForm.Load1Click(Sender: TObject);
begin
  LoadFile;
end;
```

This method is defined in the `TViewerForm` class as a virtual abstract method (so that the class of the base form is actually an abstract class). Because this is an abstract method, we will need to redefine it (and override it) in the inherited forms. The code of this `LoadFile` method simply uses the `OpenDialog1` component to ask the user to select an input file and loads it into the image component:

```
procedure TImageViewerForm.LoadFile;
begin
```

```
    if OpenDialog1.Execute then
      Image1.Picture.LoadFromFile (OpenDialog1.Filename);
  end;
```

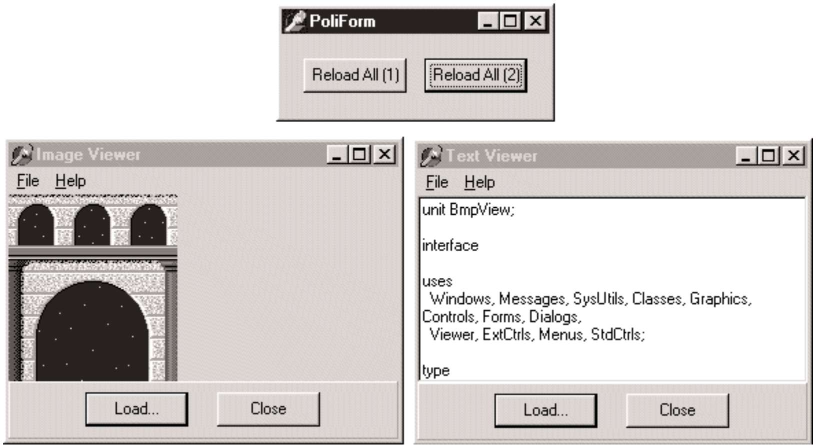
The other inherited class has similar code, loading the text into the memo component. The project has one more form, a main form with two buttons, used to reload the files in each of the viewer forms. The main form is the only form created by the project when it starts. The generic viewer form is never created: it is only a generic base class, containing common code and components of the two subclasses. The forms of the two subclasses are created in the `OnCreate` event handler of the main form:

```
procedure TMainForm.FormCreate(Sender: TObject);
var
  I: Integer;
begin
  FormList [1] := TTextViewerForm.Create (Application);
  FormList [2] := TImageViewerForm.Create (Application);
  for I := 1 to 2 do
    FormList[I].Show;
end;
```

See Figure 10.10 for the resulting forms (with text and image already loaded in the viewers). `FormList` is a *polymorphic* array of generic `TViewerForm` objects, declared in the `TMainForm` class.

FIGURE 10.10:

The PoliForm example at run time



```
unit BmpView;

interface

uses
  Windows, Messages, SysUtils, Classes, Graphics,
Controls, Forms, Dialogs,
  Viewer, ExtCtrls, Menus, StdCtrls;

type
```

Note that to make this declaration in the class, you need to add the Viewer unit (but not the specific forms) in the `uses` clause of the interface portion of the main form. The array of forms is used to load a new file in each viewer form when one of the two buttons is pressed. The handlers of the two buttons' OnClick events use different approaches:

```
procedure TMainForm.ReloadButton1Click(Sender: TObject);
var
  I: Integer;
begin
  for I := 1 to 2 do
    FormList [I].ButtonLoadClick (Self);
end;

procedure TMainForm.ReloadButton2Click(Sender: TObject);
var
  I: Integer;
begin
  for I := 1 to 2 do
    FormList [I].LoadFile;
end;
```

The second button simply calls a virtual method, and it will work without any problem. The first button calls an event handler and will always reach the generic TFormView class (displaying the error message of its ButtonLoadClick method). This happens because the method is static, not virtual.

Is there a way to make this approach work? Sure. Declare the ButtonLoadClick method of the TFormView class as virtual, and declare it as overridden in each of the inherited form classes, as we do for any other virtual method:

```
type
  TViewerForm = class(TForm)
    // components and plain methods...
    procedure ButtonLoadClick(Sender: TObject); virtual;
  public
    procedure LoadFile; virtual; abstract;
  end;
...
type
  TImageViewerForm = class(TViewerForm)
    Image1: TImage;
    procedure ButtonLoadClick(Sender: TObject); override;
  public
    procedure LoadFile; override;
  end;
```

This trick really works, although it is never mentioned in the Delphi documentation. This ability to use virtual event handlers is what I actually mean by visual form polymorphism. In other (more technical) words, you can assign a virtual method to an event property, which will take the address of the method according to the instance available at run time.

Understanding Frames

Chapter 1 briefly discussed frames, which were introduced in Delphi 5. We've seen that you can create a new frame, place some components in it, write some event handlers for the components, and then add the frame to a form. In other words, a frame is similar to a form, but it defines only a portion of a window, not a complete window. This is certainly not a feature worth a new construct. The totally new element of frames is that you can create multiple instances of a frame at design time, and you can modify the class and the instance at the same time. This makes frames an effective tool for creating customizable composite controls at design time, something close to a visual component-building tool.

In visual form inheritance you can work on both a base form and a derived form at design time, and any changes you make to the base form are propagated to the derived one, unless this overrides some property or event. With frames, you work on a class (as usual in Delphi), but the difference is that you can also customize one or more instances of the class at design time. When you work on a form, you cannot change a property of the `TForm1` class for the `Form1` object at design time. With frames, you can.

Once you realize you are working with a class and one or more of its instances at design time, there is nothing more to understand about frames. In practice, frames are useful when you want to use the same group of components in multiple forms within an application. In this case, in fact, you can customize each of the instances at design time. Wasn't this already possible with component templates? It was, but component templates were based on the concept of copying and pasting some components and their code. There was no way to change the original definition of the template and see the effect in every place it was used. That is what happens with frames (and in a different way with visual form inheritance); changes to the original version (the class) are reflected in the copies (the instances).

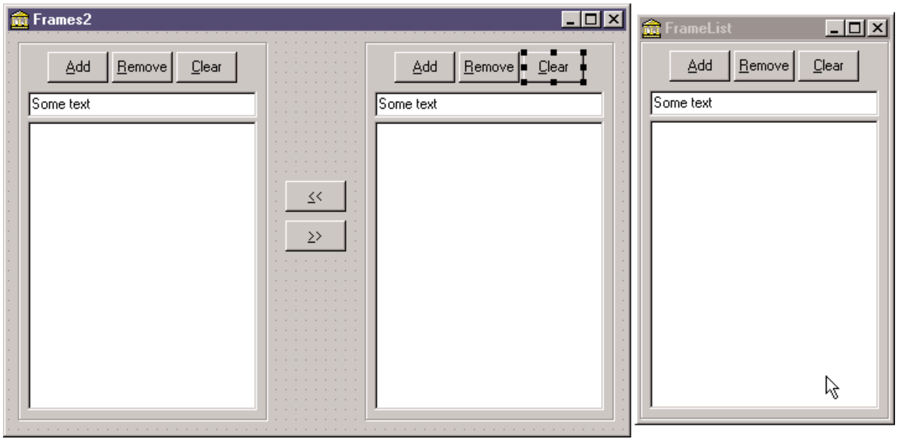
Let's discuss a few more elements of frames with an example from the CD, called Frames2. This program has a frame with a list box, an edit box, and three buttons with simple code operating on the components. The frame also has a bevel aligned to its client area, because frames have no border. Of course, the frame has also a corresponding class, which looks like a form class:

```
type
  TFrameList = class(TFrame)
    ListBox: TListBox;
    Edit: TEdit;
    btnAdd: TButton;
    btnRemove: TButton;
    btnClear: TButton;
    Bevel: TBevel;
    procedure btnAddClick(Sender: TObject);
    procedure btnRemoveClick(Sender: TObject);
    procedure btnClearClick(Sender: TObject);
  private
    { Private declarations }
  public
    { Public declarations }
  end;
```

What is different is that you can add the frame to a form. I've used two instances of the frame in the example (as you can see in Figure 10.11) and modified the behavior slightly. The first instance of the frame has the list box items sorted. When you change a property of a component of a frame, the DFM file of the hosting form will list the differences, as it does with visual form inheritance:

FIGURE 10.11:

A frame and two instances of it at design time, in the Frames2 example



```
object FormFrames: TFormFrames
  Caption = 'Frames2'
  inline FrameList1: TFrameList
    Left = 8
    Top = 8
    inherited ListBox: TListBox
      Sorted = True
    end
  end
  inline FrameList2: TFrameList
    Left = 232
    Top = 8
    inherited btnClear: TButton
      OnClick = FrameList2btnClearClick
    end
  end
end
```

As you can see from the listing, the DFM file for a form that has frames uses a new DFM keyword, `inline`. The references to the modified components of the frame, instead, use the `inherited` keyword, although this term is used with an extended meaning. `inherited` here doesn't refer to a base class we are inheriting from, but to the class we are instancing (or inheriting) an object from. It was probably a good idea, though, to use an existing feature of visual form inheritance and apply it to the new context. The effect of this approach, in fact, is that you can use the Revert to Inherited command of the Object Inspector or of the form to cancel the changes and get back to the default value of properties.

Notice also that unmodified components of the frame class are not listed in the DFM file of the form using the frame, and that the form has two frames with different names, but the components on the two frames have the same name. In fact, these components are not owned by the form, but are owned by the frame. This implies that the form has to reference those components through the frame, as you can see in the code for the buttons that copy items from one list box to the other:

```
procedure TFormFrames.btnLeftClick(Sender: TObject);
begin
  FrameList1.ListBox.Items.AddStrings (FrameList2.ListBox.Items);
end;
```

Finally, besides modifying properties of any instance of a frame, you can change the code of any of its event handlers. If you double-click one of the buttons of a frame while working on the form (not on the stand-alone frame), Delphi will generate this code for you:

```
procedure TFormFrames.FrameList2btnClearClick(Sender: TObject);
begin
  FrameList2.btnClearClick(Sender);
end;
```

The line of code automatically added by Delphi corresponds to a call to the inherited event handler of the base class in visual form inheritance. This time, however, to get the default behavior of the frame we need to call an event handler and apply it to a specific instance—the frame object itself. The current form, in fact, doesn't include this event handler and knows nothing about it.

Whether you leave this call in place or remove it depends on the effect you are looking for. In the example I've decided to conditionally execute the default code, depending on the user confirmation:

```
procedure TFormFrames.FrameList2btnClearClick(Sender: TObject);
begin
  if MessageDlg ('OK to empty the list box?', mtConfirmation,
      [mbYes, mbNo], 0) = idYes then
    // execute standard frame code
    FrameList2.btnClearClick(Sender);
end;
```

TIP By the way, note that because the event handler has some code, leaving it empty and saving the form won't remove it as usual: in fact, it isn't empty! Instead, if you simply want to omit the default code for an event, you need to add at least a comment to it, to avoid it being automatically removed by the system!

Frames and Pages

When you have a dialog box with many pages full of controls, the code underlying the form becomes very complex because all the controls and methods are declared in a single form. Also, creating all these components (and initializing them) might result in a delay in the display of the dialog box. Frames actually don't reduce the construction and initialization time of equivalently loaded forms; quite the contrary, as loading frames is more complicated for the streaming system than loading simple components. However, using frames you can load only the visible pages of a multipage dialog box, reducing the *initial* load time, which is what the user perceives.

Frames can solve both of these issues. First, you can easily divide the code of a single complex form into one frame per page. The form will simply host all of the frames in a PageControl. This certainly helps you to have simpler and more focused units and makes it simpler to reuse a specific page in a different dialog box or application. Reusing a single page of a PageControl without using a frame or an embedded form, in fact, is far from simple.

As an example of this approach I've built the FramePag example, which has some frames placed inside the three pages of a PageControl, as you can see in Figure 10.12. All of the frames are aligned to the client area, using the entire surface of the tab sheet (the page) hosting them. Actually two of the pages have the same frame, but the two instances of the frame have some differences at design time. The frame, called `Frame3` in the example, has a list box that is populated with a text file at startup, and has buttons to modify the items in the list and saves them to a file. The filename is placed inside a label, so that you can easily select a file for the frame at design time by changing the `Caption` of the label.

TIP Being able to use multiple instances of a frame is one of the reasons this technique was introduced, and customizing the frame at design time is even more important. Because adding properties to a frame and making them available at design time requires some customized and complex code, it is nice to use a component to host these custom values. You have the option of hiding these components (such as the label in our example) if they don't pertain to the user interface.

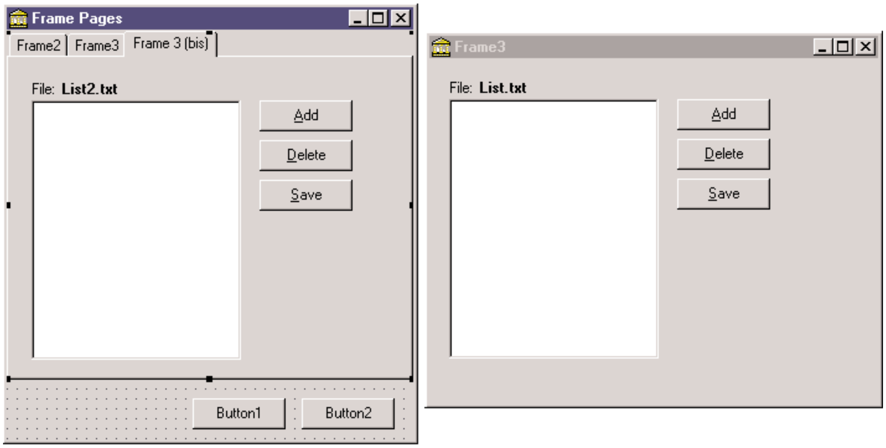


FIGURE 10.12: Each page of the FramePag example contains a frame, thus separating the code of this complex form into more manageable chunks.

In the example, we need to load the file when the frame instance is created. Because frames have no `OnCreate` event, our best choice is probably to override the `CreateWnd` method. Writing a custom constructor, in fact, doesn't work as it is executed too early—before the specific label text is available. Here is the frame class code:

```
type
  TFrame3 = class(TFrame)
    ...
  public
    procedure CreateWnd; override;
```

Within the `CreateWnd` method, we simply load the list box content from a file.

Multiple Frames with No Pages

Another approach is to avoid creating all of the pages along with the form hosting them. This can be accomplished by leaving the PageControl empty and creating the frames only when a page is displayed. Actually, when you have frames on multiple pages of a PageControl, the windows for the frames are created only when they are first displayed, as you can find out by placing a breakpoint in the creation code of the last example.

As an even more radical approach, you can get rid of the page controls and use a TabControl. Used this way, the tab has no connected tab sheets (or pages) but can display only one set of information at a time. For this reason, we'll need to create the current frame and destroy the previous one or simply hide it by setting its `Visible` property to False or by calling the `BringToFront` of the new frame. Although this sounds like a lot of work, in a large application this technique can be worth it for the reduced resource and memory usage you can obtain by applying it.

To demonstrate this approach, I've built an example similar to the previous one, this time based on a TabControl and dynamically created frames. The main form, visible at run time in Figure 10.13, has only a TabControl with one page for each frame:

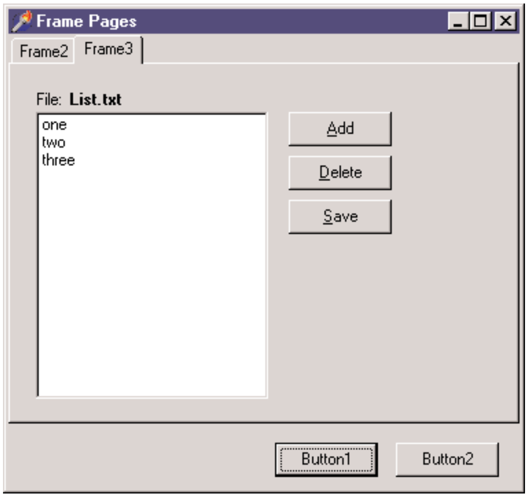

FIGURE 10.13: The first page of the FrameTab example at run time. The frame inside the tab is created at run time.

```
object Form1: TForm1
  Caption = 'Frame Pages'
  OnCreate = FormCreate
  object Button1: TButton...
  object Button2: TButton...
  object Tab: TTabControl
    Anchors = [akLeft, akTop, akRight, akBottom]
    Tabs.Strings = ( 'Frame2' 'Frame3' )
    OnChange = TabChange
  end
end
```

I've given each tab a caption corresponding to the name of the frame, because I'm going to use this information to create the new pages. When the form is created, and whenever the user changes the active tab, the program gets the current caption of the tab and passes it to the custom ShowFrame method. The code of this method, listed below, checks whether the requested frame already exists (frame names in this example follow the Delphi standard of having a number appended to the class name), and then brings it to the front. If the frame doesn't exist, it uses the frame name to find the related frame class, creates an object of that class, and assigns a few properties to it. The code makes extensive use of class references and dynamic creation techniques:

```
type
  TFrameClass = class of TFrame;

procedure TForm1.ShowFrame(FrameName: string);
var
  Frame: TFrame;
  FrameClass: TFrameClass;
begin
  Frame := FindComponent (FrameName + '1') as TFrame;
  if not Assigned (Frame) then
  begin
    FrameClass := TFrameClass (FindClass ('T' + FrameName));
    Frame := FrameClass.Create (Self);
    Frame.Parent := Tab;
    Frame.Visible := True;
    Frame.Name := FrameName + '1';
  end;
  Frame.BringToFront;
end;
```

To make this code work, you have to remember to add a call to `RegisterClass` in the initialization section of each unit defining a frame.

Base Forms and Interfaces

We have seen that when you need two similar forms inside an application, you can use visual form inheritance to inherit one from the other or both of them from a common ancestor. The advantage of visual form inheritance is that you can use it to inherit the visual definition, the DFM. However, this is not always requested.

At times, you might want several forms to exhibit a common behavior, or respond to the same commands, without having any shared component or user interface elements. Using visual form inheritance with a base form that has no extra components makes little sense to me. I rather prefer defining my own custom form class, inherited from `TForm`, and then manually editing the form class declarations to inherit from this custom base form class instead of the standard one. If all you need is to define some shared methods, or override `TForm` virtual methods in a consistent way, defining custom form classes can be a very good idea.

Using a Base Form Class

A simple demonstration of this technique is available in the FormIntf demo, showcasing also the use of interfaces for forms. In a new unit, called SaveStatusForm, I've defined the following form class (with no related DFM file—don't use the New Form command, but create a new unit and type the code in it):

```
type
  TSaveStatusForm = class (TForm)
  protected
    procedure DoCreate; override;
    procedure DoDestroy; override;
  end;
```

The two overridden methods are called at the same time of the event handler, so that I can attach extra code (allowing the event handler to be defined as usual). Inside the two methods I simply load or save the form position inside an INI file of the application, in a section marked with the form caption. Here is the code of the two methods:

```
procedure TSaveStatusForm.DoCreate;
var
  Ini: TIniFile;
begin
  inherited;
  Ini := TIniFile.Create (ExtractFileName (Application.ExeName));
  Left := Ini.ReadInteger(Caption, 'Left', Left);
  Top := Ini.ReadInteger(Caption, 'Top', Top);
  Width := Ini.ReadInteger(Caption, 'Width', Width);
  Height := Ini.ReadInteger(Caption, 'Height', Height);
  Ini.Free;
end;

procedure TSaveStatusForm.DoDestroy;
var
  Ini: TIniFile;
begin
  Ini := TIniFile.Create (ExtractFileName (Application.ExeName));
  Ini.WriteInteger(Caption, 'Left', Left);
  Ini.WriteInteger(Caption, 'Top', Top);
  Ini.WriteInteger(Caption, 'Width', Width);
  Ini.WriteInteger(Caption, 'Height', Height);
  Ini.Free;
  inherited;
end;
```

Again, this is a simple common behavior for your forms, but you can define a very complex class here. To use this as a base class of the forms you create, simply let Delphi create the forms as usual (with no inheritance) and then update the form declaration to something like:

```
type
  TFormBitmap = class(TSaveStatusForm)
    Image1: TImage;
    OpenPictureDialog1: TOpenPictureDialog;
    ...
```

Simple as it seems, this is a very powerful technique, as all you need to do is change the definition of the forms of your application to refer to this base class. If even this is too tedious, as you might want to change this base class in the life of your program, you can use an extra trick, "interposer" classes.

INI Files and the Registry in Delphi

If you want to save information about the status of an application in order to restore it the next time the program is executed, you can use the explicit support that Windows provides for storing this kind of information. INI files, the old Windows standard, are once again the preferred way to save application data. The alternative is the Registry, which is still quite popular. Delphi provides ready-to-use classes to manipulate both.

The *TIniFile* Class

For INI files, Delphi has a `TIniFile` class. Once you have created an object of this class and connected it to a file, you can read and write information to it. To create the object, you need to call the constructor, passing a filename to it, as in the following code:

```
var
  IniFile: TIniFile;
begin
  IniFile := TIniFile.Create ('myprogram.ini');
```

There are two choices for the location of the INI file. The code just listed will store the file in the Windows directory or a user folder for settings in Windows 2000. To store data locally to the application (as opposed to local to the current user), you should provide a full path to the constructor.

INI files are divided into sections, each indicated by a name enclosed in square brackets. Each section can contain multiple items of three possible kinds: strings, integers, or Booleans. The `TIniFile` class has three Read methods, one for each kind of data: `ReadBool`, `ReadInteger`, and `ReadString`. There are also three corresponding methods to write the data: `WriteBool`, `WriteInteger`, and `WriteString`. Other methods allow you to read or erase a whole section. In the Read methods, you can also specify a default value to be used if the corresponding entry doesn't exist in the INI file.

Continued on next page

By the way, notice that Delphi uses INI files quite often, but they are disguised with different names. For example, the desktop (`.dsk`) and options (`.dof`) files are structured as INI files.

The *TRegistry* and *TRegIniFile* classes

The Registry is a hierarchical database of information about the computer, the software configuration, and the user preferences. Windows has a set of API functions to interact with the Registry; you basically open a key (or folder) and then work with subkeys (or subfolders) and with values (or items), but you must be aware of the structure and the details of the Registry.

Delphi provides basically two approaches to the use of the Registry. The `TRegistry` class provides a generic encapsulation of the Registry API, while the `TRegIniFile` class provides the interface of the `TIniFile` class but saves the data in the Registry. This class is the natural choice for portability between INI-based and Registry-based versions of the same program. When you create a `TRegIniFile` object, your data ends up in the current user information, so you'll generally use a constructor like this:

```
IniFile := TRegIniFile.Create ('Software\MyCompany\MyProgram');
```

By using the `TIniFile` and the `TRegistryIniFile` classes offered by the VCL, you can move from one model of local and per-user storage to the other. Not that I think you should use the Registry a lot, as the idea of having a centralized repository for the settings of each application was a architectural error. Even Microsoft acknowledges this (without really admitting the error) by suggesting, in the Windows 2000 Compatibility Requirements, that you not use the Registry anymore for applications settings, but go back to the use of INI files.

An Extra Trick: Interposer Classes

In contrast with Delphi VCL components, which must have unique names, Delphi classes in general must be unique only within their unit. This means you can have two different units defining a class with the same name. This looks really weird, at first sight, but can be useful. For example, Borland is using this technique to provide compatibility between VCL and VisualCLX classes. Both have a `TForm` class, one defined in the Forms unit and the other in the QForms unit. How can this be interesting for the topic discussed here?

NOTE This technique is actually much older than CLX/VCL. For example, the service and control panel applet units define their own `TApplication` object, which is not related to the `TApplication` used by VCL visual GUI applications and defined in the Forms unit.

There is a technique that I've seen mentioned with the name "interposer classes" in an old issue of *The Delphi Magazine*, which suggested replacing standard Delphi class names with your own versions, having the same class name. This way you can use Delphi designer referring to Delphi standard components at design time, but using your own classes at run time.

The idea is simple. In the SaveStatusForm unit, I could have defined the new form class as follows:

```
type
  TForm = class (Forms.TForm)
  protected
    procedure DoCreate; override;
    procedure DoDestroy; override;
  end;
```

This class is called `TForm`, and inherits from `TForm` of the Forms unit (this last reference is compulsory to avoid a kind of recursive definition). In the rest of the program, at this point, you don't need to change the class definition for your form, but simply add the unit defining the interposer class (the SaveStatusForm unit in this case) in the `uses` statement *after* the unit defining the Delphi class. The order of the unit in the `uses` statement is important here, and the reason some people criticize this technique, as it is hard to know what is going on. I have to agree: I find interposer classes handy at times (more for components than for forms, I have to say), but their use makes programs less readable and at times even harder to debug.

Using Interfaces

Another technique, which is slightly more complex but even more powerful than the definition of a common base form class, is to have forms that implement specific interfaces. This way you can have forms implementing one or more of these interfaces, query each form for the interfaces it implements, and call the supported methods.

As an example (available in the same FormIntf program I began discussing in the last section), I've defined a simple interface for loading and storing:

```
type
  IFormOperations = interface
    ['{DACFDB76-0703-4A40-A951-10D140B4A2A0}']
    procedure Load;
    procedure Save;
  end;
```

Each form can optionally implement this interface, as the following `TFormBitmap` class:

```
type
  TFormBitmap = class(TForm, IFormOperations)
    Image1: TImage;
    OpenPictureDialog1: TOpenPictureDialog;
    SavePictureDialog1: TSavePictureDialog;
  public
    procedure Load;
    procedure Save;
  end;
```

You can see the actual code of the example for the code of the Load and Save methods, which use the standard dialog boxes to load or save the image. (In the example's code, the form also inherits from the TSaveStatusForm class.)

When an application has one or more forms implementing interfaces, you can apply a given interface method to all the forms supporting it, with code like this (extracted from the main form of the IntfForm example):

```
procedure TFormMain.btnLoadClick(Sender: TObject);
var
  i: Integer;
begin
  for i := 0 to Screen.FormCount - 1 do
    if Supports (Screen.Forms [i], IFormOperations) then
      (Screen.Forms [i] as IFormOperations).Load;
end;
```

Consider a business application when you can synchronize all of the forms to the data of a specific company, or a specific business event. And consider also that, unlike inheritance, you can have several forms each implementing multiple interfaces, with unlimited combinations. This is why using an architecture like this can improve a complex Delphi application a great deal, making it much more flexible and easier to adapt to implementation changes.

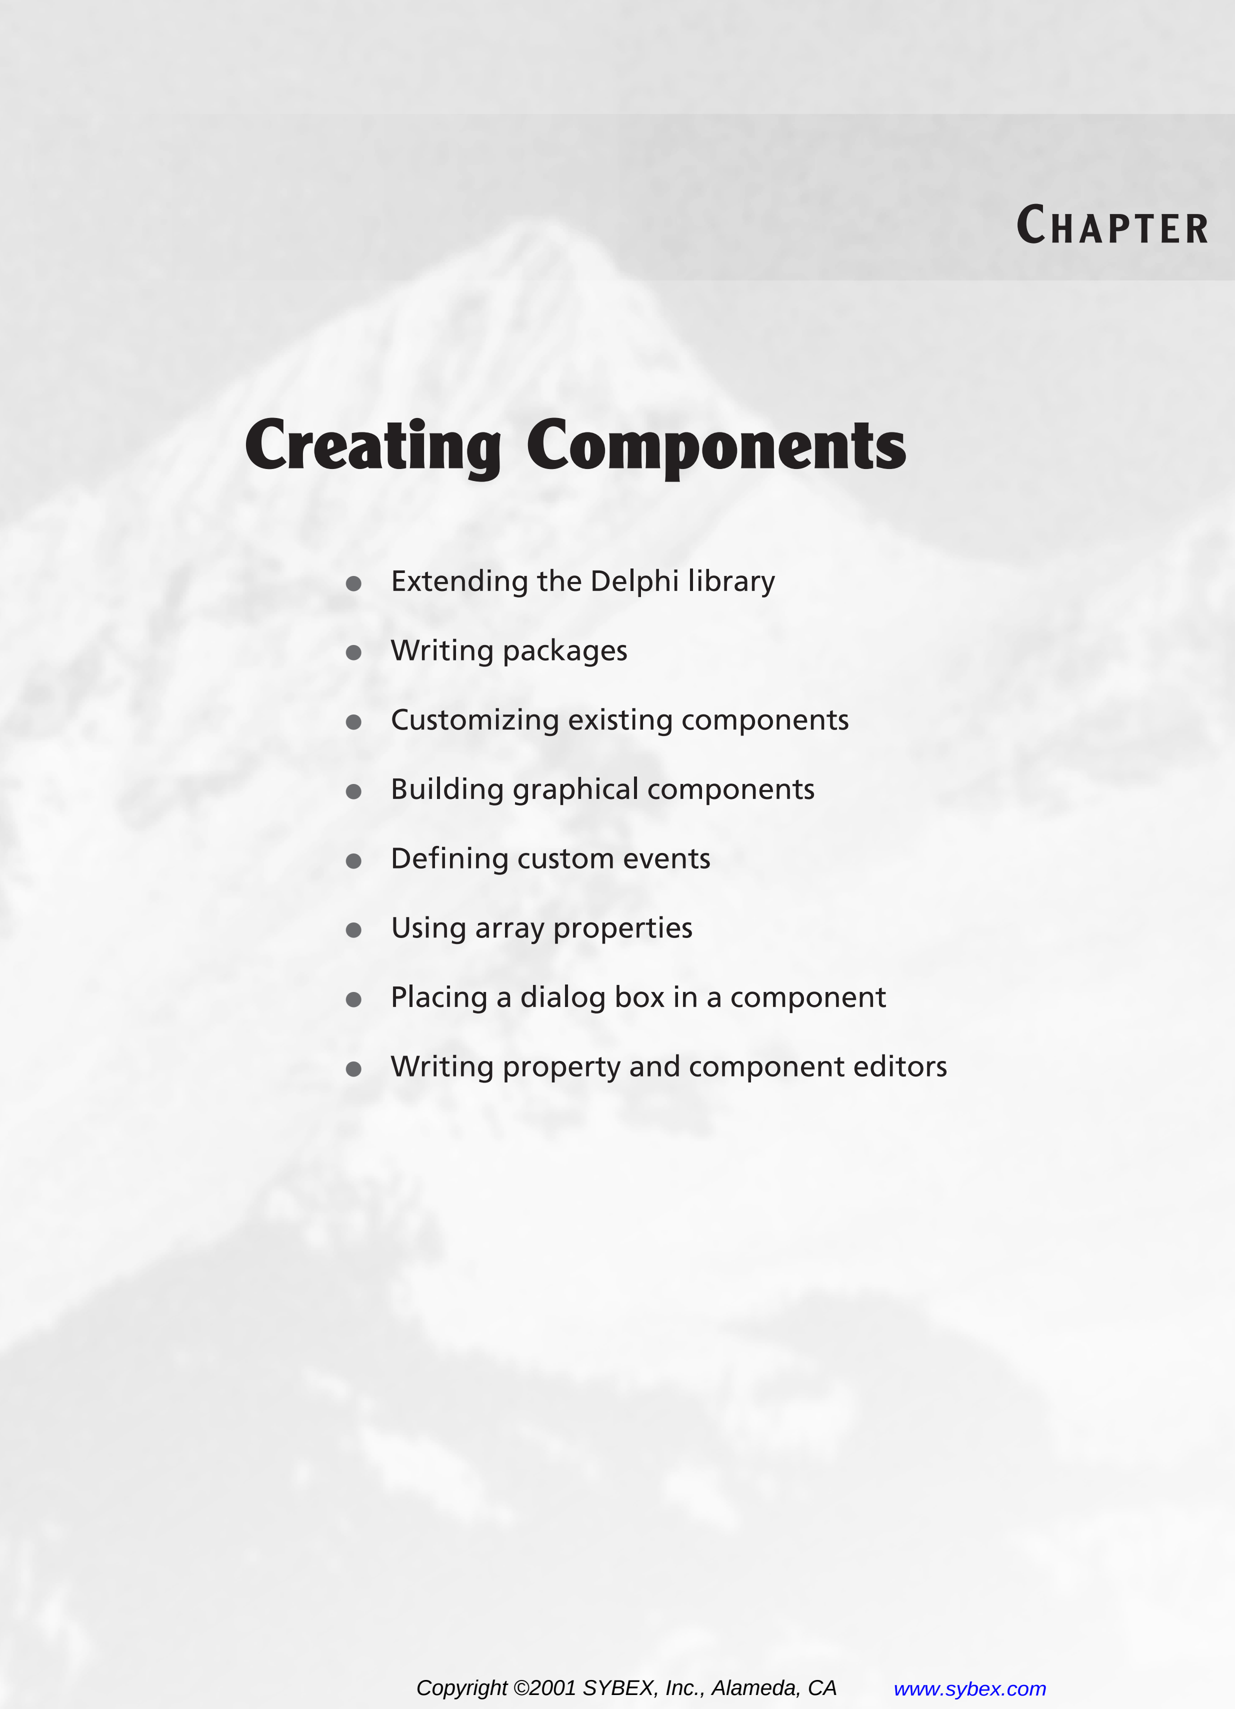
What's Next?

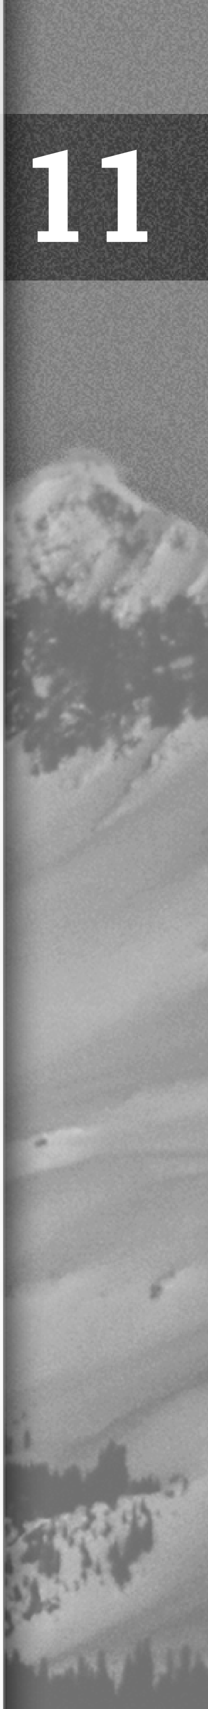
After the detailed description of forms and secondary forms in the previous chapters, I have focused on the architecture of applications, discussing both how Delphi's Application object works and how we can structure applications with multiple forms.

In particular, I've discussed MDI, visual form inheritance, and frames. Toward the end I also discussed custom architectures, with form inheritance and interfaces. Now we can move forward to another key element of non-trivial Delphi applications: building custom components to use within your programs. It is possible to write a specific book about this, so the description won't be exhaustive, but you should be able to get a comprehensive overview.

Another element related to the architecture of Delphi applications is the use of packages, which I'll introduce as a technology related to components but which really goes beyond this. In fact, you can structure the code of a large application in multiple packages, containing forms and other units. The development of programs based on multiple executable files, libraries, and packages, is discussed in Chapter 12.

After this further step, I will start delving into Delphi database programming, certainly another key element of the Borland development environment.





CHAPTER 11

Creating Components

- Extending the Delphi library
- Writing packages
- Customizing existing components
- Building graphical components
- Defining custom events
- Using array properties
- Placing a dialog box in a component
- Writing property and component editors

While most Delphi programmers are probably familiar with using existing components, at times it can also be useful to write our own components or to customize existing ones. One of the most interesting aspects of Delphi is that creating components is simple. For this reason, even though this book is intended for Delphi application programmers and not Delphi tool writers, this chapter will cover the topic of creating components and introduce Delphi add-ins, such as component and property editors.

This chapter gives an overview of writing Delphi components and presents some simple examples. There is not enough space to present very complex components, but the ideas in this chapter will cover all the basics to get you started.

NOTE You'll find a more information about writing components in Chapter 18, "Writing Database Components," including how to build data-aware components.

Extending the Delphi Library

Delphi components are classes, and the Visual Components Library (VCL) is the collection of all the classes defining Delphi components. Each time you add a new package with some components to Delphi, you actually extend VCL with a new class. This new class will be derived from one of the existing component-related classes or the generic `TComponent` class, adding new capabilities to those it inherits.

You can derive a new component from an existing component or from an *abstract component class*—one that does not correspond to a usable component. The VCL hierarchy includes many of these intermediate classes (often indicated with the `TCustom` prefix in their name) to let you choose a default behavior for your new component and to change its properties.

Component Packages

Components are added to component packages. Each component package is basically a DLL (a dynamic link library) with a BPL extension (which stands for Borland Package Library).

Packages come in two flavors: design-time packages used by the Delphi IDE and run-time packages optionally used by applications. The design-only or run-only package option determines the package's type. When you attempt to install a package, the IDE checks whether it has the design-only or run-only flags, and decides whether to let the user install the package and whether it should be added to the list of run-time packages. Since there are two nonexclusive options, each with two possible states, there are four different kinds of component packages—two main variations and two special cases:

- Design-only component packages can be installed in the Delphi environment. These packages usually contain the design-time parts of a component, such as its property editors and the registration code. Often they can also contain the components themselves, although this is not the most professional approach. The code of the components of a design-only package is usually statically linked into the executable file, using the code of the corresponding Delphi Compiled Unit (DCU) files. Keep in mind, however, that it is also technically possible to use a design-only package as a run-time package.
- Run-only component packages are used by Delphi applications at run time. They cannot be installed in the Delphi environment, but they are automatically added to the list of run-time packages when they are required by a design-only package you install. Run-only packages usually contain the code of the component classes, but no design-time support (this is done to minimize the size of the component libraries you ship along with your executable file). Run-only packages are important because they can be freely distributed along with applications, but other Delphi programmers won't be able to install them in the environment to build new programs.
- Plain component packages (having neither the design-only nor the run-only option set) cannot be installed and will not be added to the list of run-time packages automatically. This might make sense for utility packages used by other packages, but they are certainly rare.
- Packages with both flags set can be installed and are automatically added to the list of run-time packages. Usually these packages contain components requiring little or no design-time support (apart from the limited component registration code). Keep in mind, however, that users of applications built with these packages can use them for their own development.

TIP The filenames of Delphi's own design-only packages start with the letters *DCL* (for example, `DCLSTD60.BPL`); filenames of run-only packages start with the letters VCL (for example, `VCL60.BPL`). You can follow the same approach for your own packages, if you want.

In Chapter 1, "The Delphi 6 IDE," we discussed the effect of packages on the size of a program's executable file. Now we'll focus on building packages, since this is a required step in creating or installing components in Delphi.

When you compile a run-time package, you produce both a dynamic link library with the compiled code (the BPL file) and a file with only symbol information (a DCP file), including no compiled machine code. The latter file is used by the Delphi compiler to gather symbol information about the units that are part of the package without having access to the unit (DCU) files, which contain both the symbol information and the compiled machine code. This reduces compilation time and allows you to distribute just the packages without the precompiled unit files. The precompiled units are still required to statically link the components into an application. Distribution of precompiled DCU files (or source code) may make sense depending on the kind of components you develop. We'll see how to create a package after we've discussed some general guidelines and built our very first component.

NOTE DLLs are executable files containing collections of functions and classes, which can be used by an application or another DLL at run time. The typical advantage is that if many applications use the same DLL, only one copy needs to be on the disk or loaded in memory, and the size of each executable file will be much smaller. This is what happens with Delphi packages, as well. Chapter 12, "Libraries and Packages," looks at DLLs and packages in more detail.

Rules for Writing Components

Some general rules govern the writing of components. You can find a detailed description of most of them in the *Delphi Component Writer's Guide* Help file, which is required reading for Delphi component writers.

Here is my own summary of the rules for component writers:

- Study the Object Pascal language with care. Particularly important concepts are inheritance, method overriding and overloading, the difference between public and published sections of a class, and the definition of properties and events. If you don't feel confident with the Object Pascal language or the basic ideas about VCL, you can refer to the overall description of the language and library presented in Part I of the book, particularly Chapters 3 ("The Object Pascal Language: Inheritance and Polymorphism") and 5 ("Core Library Classes").
- Study the structure of the VCL class hierarchy and keep a graph of the classes at hand (such as the one included with Delphi).
- Follow the standard Delphi naming conventions. There are several of them for components, as we will see, and following these rules makes it easier for other programmers to interact with your components and further extend them.
- Keep components simple, mimic other components, and avoid dependencies. These three rules basically mean that a programmer using your components should be able to use them as easily as preinstalled Delphi components. Use similar property, method, and event names whenever possible. If users don't need to learn complex rules about the use of your component (that is, if the dependencies between methods or properties are limited) and can simply access properties with meaningful names, they'll be happy.

- Use exceptions. When something goes wrong, the component should raise an exception. When you are allocating resources of any kind, you must protect them with `try/finally` blocks and destructor calls.
- To complete a component, add a bitmap to it, to be used by Delphi's Component Palette. If you intend your component to be used by more than a few people, consider adding a Help file as well.
- Be ready to write *real* code and forget about the visual aspects of Delphi. Writing components generally means writing code without visual support (although Class Completion can speed up the coding of plain classes quite a lot). The exception to this rule is that you can use frames to write components visually.

NOTE You can also use a third-party component writing tool to build your component or to speed up its development. The most powerful third-party tool for creating Delphi components I know of is the Component Development Kit (CDK) from Eagle Software (`www.eagle-software.com`), but many others are available.

The Base Component Classes

To build a new component you generally start from an existing one, or from one of the base classes of VCL. In both cases your component is in one of three broad categories of components (introduced in Chapter 5), set by the three basic classes of the component hierarchy:

- `TWinControl` is the parent class of any component based on a window. Components that descend from this class can receive the input focus and get Windows messages from the system. You can also use their window handle when calling API functions. When creating a brand-new window control, you'll generally inherit from the derived class `TCustomControl`, which has a few extra useful features (particularly some support for painting the control).
- `TGraphicControl` is the parent class of visible components that have no Windows handle (which saves some Windows resources). These components cannot receive the input focus or respond to Windows messages directly. When creating a brand-new graphical control, you'll inherit directly from this class (which has a set of features very similar to `TCustomControl`).
- `TComponent` is the parent class of all components (including the controls) and can be used as a direct parent class for nonvisual components.

In the rest of the chapter, we will build some components using various parent classes, and we'll look at the differences among them. We'll start with components inheriting from existing components or classes at a low level of the hierarchy, and then we'll see examples of classes inheriting directly from the ancestor classes mentioned above.

Building Your First Component

Building components is an important activity for Delphi programmers. The basic idea is that any time you need the same behavior in two different places in an application, or in two different applications, you can place the shared code inside a class—or, even better, a component.

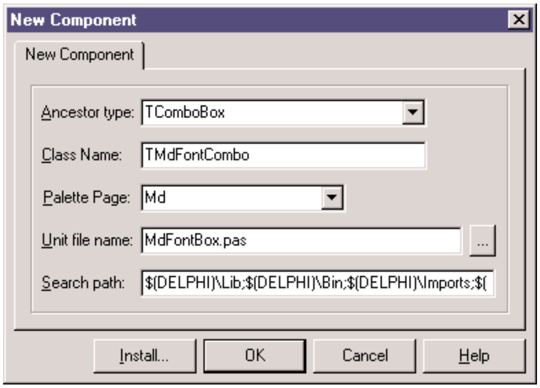
In this section I'll just introduce a couple of simple components, to give you an idea of the steps required to build one and to show you different things you can do to customize an existing component with a limited amount of code.

The Fonts Combo Box

Many applications have a toolbar with a combo box you can use to select a font. If you often use a customized combo box like this, why not turn it into a component? It would probably take less than a minute. To begin, close any active projects in the Delphi environment and start the Component Wizard, either by choosing Component ➢ New Component or by selecting File ➢ New to open the Object Repository and then choosing the Component in the New page. As you can see in Figure 11.1, the Component Wizard requires the following information:

FIGURE 11.1:

Defining the new TMdFontCombo component with the Component Wizard



New Component

Ancestor type: TComboBox

Class Name: TMdFontCombo

Palette Page: Md

Unit file name: MdFontBox.pas

Search path: $(DELPHI)\Lib;$(DELPHI)\Bin;$(DELPHI)\Imports;$(

- The name of the ancestor type: the component class you want to inherit from. In this case we can use `TComboBox`.
- The name of the class of the new component you are building; we can use `TMdFontCombo`.
- The page of the Component Palette where you want to display the new component, which can be a new or an existing page. We can create a new page, called *Md*.

- The filename of the Pascal unit where Delphi will place the source code of the new component; we can type MdFontBox.
- The current search path (which should be set up automatically).

Click the OK button, and the Component Wizard will generate the following simple Pascal source file with the structure of your component. The Install button can be used to install the component in a package immediately. Let's look at the code first, Listing 11.1, and then discuss the installation.

Listing 11.1: Code of the TMdFontCombo, generated by the Component Wizard

```
unit MdFontBox;

interface

uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
  StdCtrls;

type
  TMdFontCombo = class (TComboBox)
  private
    { Private declarations }
  protected
    { Protected declarations }
  public
    { Public declarations }
  published
    { Published declarations }
  end;

procedure Register;

implementation

procedure Register;
begin
  RegisterComponents('Md', [TMdFontCombo]);
end;

end.
```

One of the key elements of this listing is the class definition, which begins by indicating the parent class. The only other relevant portion is the Register procedure. In fact, you can see that the Component Wizard does very little work.

WARNING Starting with Delphi 4, the `Register` procedure *must* be written with an uppercase *R*. This requirement is apparently imposed for C++Builder compatibility (identifiers in C++ are case-sensitive).

TIP Use a naming convention when building components. All the components installed in Delphi should have different class names. For this reason most Delphi component developers have chosen to add a two- or three-letter signature prefix to the names of their components. I've done the same, using *Md* (for *Mastering Delphi*) to identify components built in this book. The advantage of this approach is that you can install my `TMdFontCombo` component even if you've already installed a component named `TFontCombo`. Notice that the unit names must also be unique for all the components installed in the system, so I've applied the same prefix to the unit names.

That's all it takes to build a component. Of course, in this example there isn't a lot of code. We need only copy all the system fonts to the `Items` property of the combo box at startup. To accomplish this, we might try to override the `Create` method in the class declaration, adding the statement `Items := Screen.Fonts`. However, this is not the correct approach. The problem is that we cannot access the combo box's `Items` property before the window handle of the component is available; the component cannot have a window handle until its `Parent` property is set; and that property isn't set in the constructor, but later on.

For this reason, instead of assigning the new strings in the `Create` constructor, we must perform this operation in the `CreateWnd` procedure, which is called to create the window control after the component is constructed, its `Parent` property is set, and its window handle is available. Again, we execute the default behavior, and then we can write our custom code. I could have skipped the `Create` constructor and written all the code in `CreateWnd`, but I decided to use both startup methods to demonstrate the difference between them. Here is the declaration of the component class:

```
type
  TMdFontCombo = class (TComboBox)
  private
    FChangeFormFont: Boolean;
    procedure SetChangeFormFont(const Value: Boolean);
  public
    constructor Create (AOwner: TComponent); override;
    procedure CreateWnd; override;
    procedure Change; override;
  published
    property Style default csDropDownList;
    property Items stored False;
    property ChangeFormFont: Boolean
      read FChangeFormFont write SetChangeFormFont default True;
  end;
```

And here is the source code of its two methods executed at startup:

```
constructor TMdFontCombo.Create (AOwner: TComponent);
begin
  inherited Create (AOwner);
  Style := csDropDownList;
  FChangeFormFont := True;
end;

procedure TMdFontCombo.CreateWnd;
begin
  inherited CreateWnd;
  Items.Assign (Screen.Fonts);

  // grab the default font of the owner form
  if FChangeFormFont and Assigned (Owner) and (Owner is TForm) then
    ItemIndex := Items.IndexOf ((Owner as TForm).Font.Name);
end;
```

Notice that besides giving a new value to the component's `Style` property, in the `Create` method, I've redefined this property by setting a value with the `default` keyword. We have to do both operations because adding the `default` keyword to a property declaration has no direct effect on the property's initial value. Why specify a property's default value then? Because properties that have a value equal to the default are not streamed with the form definition (and they don't appear in the textual description of the form, the DFM file). The `default` keyword tells the streaming code that the component initialization code will set the value of that property.

TIP Why is it important to specify a default value for a published property? To reduce the size of the DFM files and, ultimately, the size of the executable files (which include the DFM files).

The other redefined property, `Items`, is set as a property that should not be saved to the DFM file at all, regardless of the actual value. This is obtained with the `stored` directive followed by the value False. The component and its window are going to be created again when the program starts, so it doesn't make any sense to save in the DFM file information that will be discarded later on (to be replaced with the new list of fonts).

NOTE We could have even written the code of the `CreateWnd` method to copy the fonts to the combo box items only at run time. This can be done by using statements such as `if not (csDesigning in ComponentState) then`…. But for this first component we are building, the less efficient but more straightforward method described above offers a clearer illustration of the basic procedure.

The third property, ChangeFormFont, is not inherited but introduced by the component. It is used to determine whether the current font selection of the combo box should determine the font of the form hosting the component. Again this property is declared with a default value, set in the constructor. The ChangeFormFont property is used in the code of the CreateWnd method, shown before, to set up the initial selection of the combo depending on the font of the form hosting the component. This is generally the Owner of the component, although I could have also walked the Parent tree looking for a form component. This code isn't perfect, but the Assigned and is tests provide some extra safety.

The ChangeFormFont property and the same if test play a key role in the Changed method, which in the base class triggers the OnChange event. By overriding this method we provide a default behavior, which can be disabled by toggling the value of the property, but also allow the execution of the OnChange event, so that users of this class can fully customize its behavior. The final method, SetChangeFormFont, has been modified to refresh the form's font in case the property is being turned on. This is the complete code:

```
procedure TMdFontCombo.Change;
begin
  // assign the font to the owner form
  if FChangeFormFont and Assigned (Owner) and (Owner is TForm) then
    TForm (Owner).Font.Name := Text;
  inherited;
end;

procedure TMdFontCombo.SetChangeFormFont(const Value: Boolean);
begin
  FChangeFormFont := Value;
  // refresh font
  if FChangeFormFont then
    Change;
end;
```

Creating a Package

Now we have to install the component in the environment, using a package. For this example, we can either create a new package or use an existing one, like the default user's package.

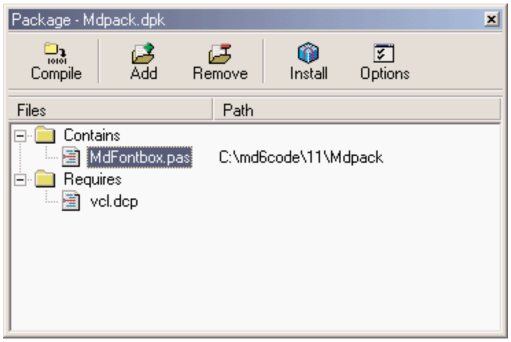
In each case, choose the Component ➢ Install Component menu command. The resulting dialog box has a page to install the component into an existing package, and a page to create a new package. In this last case, simply type in a filename and a description for the package. Clicking OK opens the Package Editor (see Figure 11.2), which has two parts:

- The Contains list indicates the components included in the package (or, to be more precise, the units defining those components).

- The `Requires` list indicates the packages required by this package. Your package will generally require the rtl and vcl packages (the main run-time library package and core VCL package), but it might also need the vcldb package (which includes most of the database-related classes) if the components of the new package do any database-related operations.

FIGURE 11.2:

The Package Editor



NOTE Package names in Delphi 6 aren't version specific any more, even if the compiled packages still have a version number in the filename. See the section "Project and Library Names in Delphi 6" in Chapter 12, "Libraries and Packages," for more details on how this is technically achieved.

If you add the component to the new package we've just defined, and then simply compile the package and install it (using the two corresponding toolbar buttons of the package editor), you'll immediately see the new component show up in the Md page of the Component Palette. The `Register` procedure of the component unit file told Delphi where to install the new component. By default, the bitmap used will be the same as the parent class, because we haven't provided a custom bitmap (we will do this in later examples). Notice also that if you move the mouse over the new component, Delphi will display as a hint the name of the class without the initial letter *T*.

What's Behind a Package?

What is behind the package we've just built? The Package Editor basically generates the source code for the package project: a special kind of DLL built in Delphi. The package project is saved in a file with the DPK (for Delphi PacKage) extension. A typical package project looks like this:

```
package MdPack;

{$R *.RES}
```

```
{$ALIGN ON}
{$BOOLEVAL OFF}
{$DEBUGINFO ON}
...
{$DESCRIPTION 'Mastering Delphi Package'}
{$IMPLICITBUILD ON}

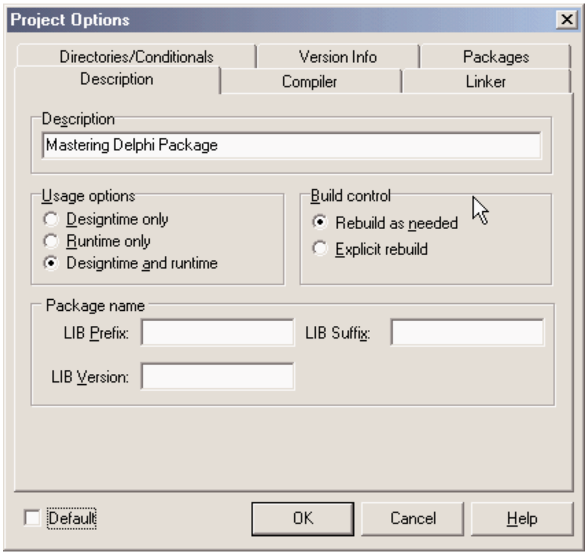
requires
  vcl;

contains
  MdFontBox in 'MdFontBox.pas';

end.
```

As you can see, Delphi uses specific language keywords for packages: the first is the `package` keyword (which is similar to the `library` keyword I'll discuss in the next chapter). This keyword introduces a new package project. Then comes a list with all the compiler options, some of which I've omitted from the listing. Usually the options for a Delphi project are stored in a separate file; packages, by contrast, include all the compiler options directly in their source code. Among the compiler options there is a `DESCRIPTION` compiler directive, used to make the package description available to the Delphi environment. In fact, after you've installed a new package, its description will be shown in the Packages page of the Project Options dialog box, a page you can also activate by selecting the Component ➢ Install Packages menu item. This dialog box is shown in Figure 11.3.

FIGURE 11.3: The Project Options for packages. You can see the new package we've just created.



Description: Mastering Delphi Package

Usage options:
○ Designtime only
○ Runtime only
● Designtime and runtime

Build control:
● Rebuild as needed
○ Explicit rebuild

LIB Prefix:
LIB Suffix:
LIB Version:

□ Default

Besides common directives like the DESCRIPTION one, there are other compiler directives specific to packages. The most common of these options are easily accessible through the Options button of the Package Editor. After this list of options come the `requires` and `contains` keywords, which list the items displayed visually in the two pages of the Package Editor. Again, the first is the list of packages required by the current one, and the second is a list of the units installed by this package.

What is the technical effect of building a package? Besides the DPK file with the source code, Delphi generates a BPL file with the dynamic link version of the package and a DCP file with the symbol information. In practice, this DCP file is the sum of the symbol information of the DCU files of the units contained in the package.

At design time, Delphi requires both the BPL and DCP files, because the first has the actual code of the components created on the design form and the symbol information required by the code insight technology. If you link the package dynamically (using it as a run-time package), the DCP file will also be used by the linker, and the BPL file should be shipped along with the main executable file of the application. If you instead link the package statically, the linker refers to the DCU files, and you'll need to distribute only the final executable file.

For this reason, as a component designer, you should generally distribute at least the BPL file, the DCP file, and the DCU files of the units contained in the package and any corresponding DFM files, plus a Help file. As an option, of course, you might also make available the source code files of the package units (the PAS files) and of the package itself (the DPK file).

WARNING Delphi, by default, will place all the compiled package files (BPL and DCP) not in the folder of the package source code but under the `\Projects\BPL` folder. This is done so that the IDE can easily locate them, and creates no particular problem. When you have to compile a project using components declared on those packages, though, Delphi might complain that it cannot find the corresponding DCU files, which are stored in the package source code folder. This problem can be solved by indicating the package source code folder in the Library Path (in the Environment Options, which affect all projects) or by indicating it in the Search Path of the current project (in the Project Options). If you choose the first approach, placing different components and packages in a single folder might result in a real time-saver.

Installing the Components of This Chapter

Having built our first package, we can now start using the component we've added to it. Before we do so, however, I should mention that I've extended the MdPack package to include all of the components we are going to build in this chapter, including different versions of the same component. I suggest you install this package. The best approach is to copy it into a directory of your path, so that it will be available both to the Delphi environment and to the programs you build with it. I've collected all the component source code files and the package definition in a single subdirectory, called MdPack. This allows the Delphi environment, or a specific project, to refer only to one directory when looking for the DCU files of this package. As suggested in the warning above, I could have collected all of the components presented in the book in a single folder on the companion CD, but I decided that keeping the chapter-based organization was actually more understandable for readers.

Remember, anyway, that if you compile an application using the packages as run-time DLLs, you'll need to install these new libraries on your clients' computers. If you instead compile the programs by statically linking the package, the DLL will be required only by the development environment and not by the users of your applications.

Using the Font Combo Box

Now you can create a new Delphi program to test the Font combo box. Move to the Component Palette, select the new component, and add it to a new form. A traditional-looking combo box will appear. However, if you open the Items property editor, you'll see a list of the fonts installed on your computer. To build a simple example, I've added a Memo component to the form with some text inside it. By leaving the `ChangeFormFont` property on, you don't need to write any other code to the program, as you'll see in the example. As an alternative I could have turned off the property and handled the `OnChange` event of the component, with code like this:

```
Memo1.Font.Name := MdFontCombo1.Text;
```

The aim of this simple program is only to test the behavior of the new component we have built. The component is still not very useful—we could have added a couple of lines of code to a form to obtain the same effect—but looking at a couple of simple components should help you get an idea of what is involved in component building.

Creating Compound Components

The next component I want to focus on is a digital clock. This example has some interesting features. First, it embeds a component (a Timer) in another component; second, it shows the live-data approach.

NOTE The first feature has become even more relevant in Delphi 6, as the Object Inspector of the latest version of Delphi allows you to expose properties of subcomponents directly. As an effect, the example presented in this section has been modified (and simplified) compared to the previous edition of the book. I'll actually mention the differences, when relevant.

Since the digital clock will provide some text output, I considered inheriting from the `TLabel` class. However, this would allow a user to change the label's caption—that is, the text of the clock. To avoid this problem, I simply used the `TCustomLabel` component as the parent class.

A TCustomLabel object has the same capabilities as a TLabel object, but few published properties. In other words, a TCustomLabel subclass can decide which properties should be available and which should remain hidden.

NOTE Most of the Delphi components, particularly the Windows-based ones, have a TCustomXxx base class, which implements the entire functionality but exposes only a limited set of properties. Inheriting from these base classes is the standard way to expose only some of the properties of a component in a customized version. In fact, you cannot hide public or published properties of a base class.

With past versions of Delphi, the component had to define a new property, Active, wrapping the Enabled property of the Timer. A *wrapper* property means that the get and set methods of this property read and write the value of the *wrapped* property, which belongs to an internal component (a wrapper property generally has no local data). In this specific case, the code looked like this:

```
function TMdClock.GetActive: Boolean;
begin
  Result := FTimer.Enabled;
end;

procedure TMdClock.SetActive (Value: Boolean);
begin
  FTimer.Enabled := Value;
end;
```

Publishing Subcomponents in Delphi 6

With Delphi 6 we can simply expose the entire subcomponent, the timer, in a property of its own, that will be regularly expanded by the Object Inspector, allowing a user to set each and every of its subproperties, and even to handle its events.

Here is the full type declaration for the TMdClock component, with the subcomponent declared in the private data and exposed as a published property (in the last line):

```
type
  TMdClock = class (TCustomLabel)
  private
    FTimer: TTimer;
  protected
    procedure UpdateClock (Sender: TObject);
  public
    constructor Create (AOwner: TComponent); override;
  published
    property Align;
    property Alignment;
    property Color;
    property Font;
    property ParentColor;
    property ParentFont;
    property ParentShowHint;
    property PopupMenu;
    property ShowHint;
    property Transparent;
    property Visible;
    property Timer: TTimer read FTimer;
  end;
```

The `Timer` property is read-only, as I don't want users to select another value for this component in the Object Inspector (or detach the component by clearing the value of this property). Developing sets of subcomponents that can be used alternately is certainly possible, but adding write support for this property in a safe way is far from trivial (considering that the users of your component might not be very expert Delphi programmers). So I suggest you to stick with read-only properties for subcomponents.

To create the Timer, we must override the constructor of the clock component. The `Create` method calls the corresponding method of the base class and creates the Timer object, installing a handler for its `OnTimer` event:

```
constructor TMdClock.Create (AOwner: TComponent);
begin
  inherited Create (AOwner);
  // create the internal timer object
  FTimer := TTimer.Create (Self);

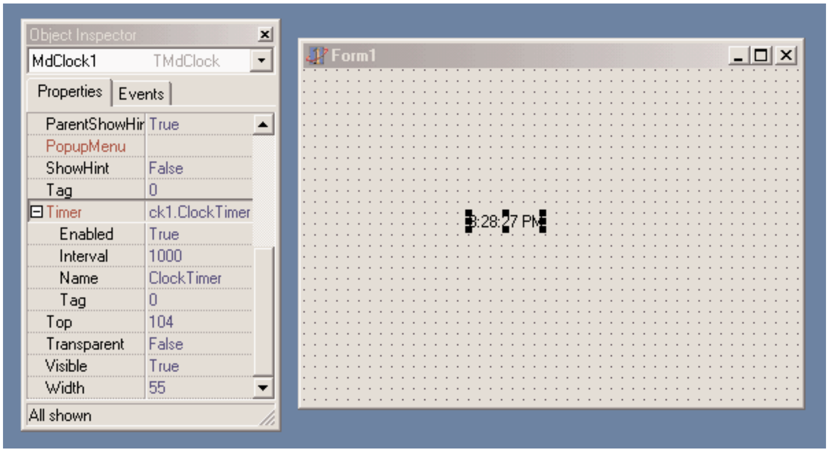
  FTimer.Name := 'ClockTimer';
  FTimer.OnTimer := UpdateClock;
  FTimer.Enabled := True;
  FTimer.SetSubComponent (True);
end;
```

The code gives the component a name, for display in the Object Inspector (see Figure 11.4), and calls the specific `SetSubComponent` method. We don't need a destructor, simply because the `FTimer` object has our `TMDClock` component as owner (as indicated by the parameter of its `Create` constructor), so it will be destroyed automatically when the clock component is destroyed.

NOTE What is the actual effect of the call to the `SetSubComponent` method in the code above? This call sets an internal flag, saved in the `ComponentStyle` property set. The flag (csSubComponent) affects the streaming system, allowing the subcomponent and its properties to be saved in the DFM file. In fact, the streaming system by default ignores components that are not owned by the form.

FIGURE 11.4:

In Delphi 6, the Object Inspector can automatically expand subcomponents, showing their properties, as in the case of the Timer property of the MdLabelClock component.



Object Inspector

MdClock1 TMdClock

Properties | Events

ParentShowHir	True
PopupMenu	
ShowHint	False
Tag	0
⊟ Timer	ck1.ClockTimer
Enabled	True
Interval	1000
Name	ClockTimer
Tag	0
Top	104
Transparent	False
Visible	True
Width	55

All shown

The key piece of the component's code is the `UpdateClock` procedure, which is just one statement:

```
procedure TMdLabelClock.UpdateClock (Sender: TObject);
begin
  // set the current time as caption
  Caption := TimeToStr (Time);
end;
```

This method uses `Caption`, which is an unpublished property, so that a user of the component cannot modify it in the Object Inspector. The result of this statement is to display the current time. This happens continuously, because the method is connected to the Timer's `OnTimer` event.

The Component Palette Bitmaps

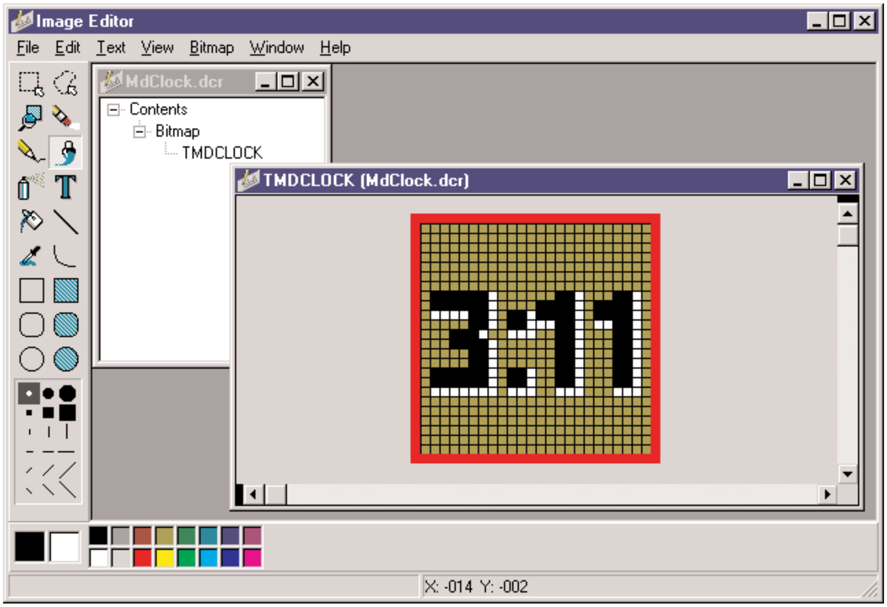
Before installing this second component, we can take one further step: define a bitmap for the Component Palette. If we fail to do so, the Palette uses the bitmap of the parent class, or a default object's bitmap if the parent class is not an installed component (as is the case of the `TCustomLabel`). Defining a new bitmap for the component is easy, once you know the rules. You can create one with the Image Editor (as shown in Figure 11.5), starting a new project and selecting the Delphi Component Resource (DCR) project type.

TIP

DCR files are simply standard RES files with a different extension. If you prefer, you can create them with any resource editor, including the Borland Resource Workshop, which is certainly a more powerful tool than the Delphi Image editor. When you finish creating the resource file, simply rename the RES file to use a DCR extension.

FIGURE 11.5:

The definition of a Component Palette bitmap in Delphi's Image Editor



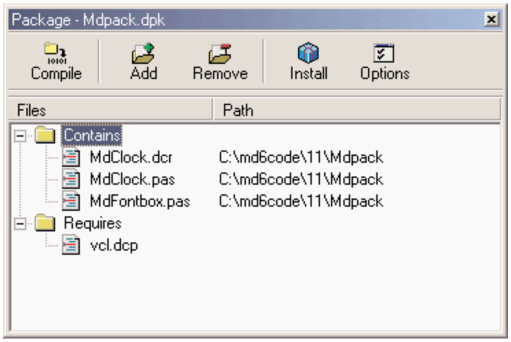
Now we can add a new bitmap to the resource, choosing a size of 24×24 pixels, and we are ready to draw the bitmap. The other important rules refer to naming. In this case, the naming rule is not just a convention; it is a requirement so that the IDE can find the image for a given component class:

- The name of the bitmap resource must match the name of the component, including the initial *T*. In this case, the name of the bitmap resource should be TMDCLOCK. The name of the bitmap resource must be uppercase—this is mandatory.
- If you want the Package Editor to recognize and include the resource file, the name of the DCR file must match the name of the compiled unit that defines the component. In this case, the filename should be `MdClock.DCR`. If you manually include the resource file, via a `$R` directive, you can give it the name you like, and also use a RES or DCR file with multiple palette icons.

When the bitmap for the component is ready, you can install the component in Delphi, by using the Package Editor's Install Package toolbar button. After this operation, the Contains section of the editor should list both the PAS file of the component and the corresponding DCR file. In Figure 11.6 you can see all the files (including the DCR files) of the final version of the MdPack package. If the DCR installation doesn't work properly, you can manually add the `{$R unitname.dcr}` statement in the package source code.

FIGURE 11.6:

The Contains section of the Package Editor shows both the units that are included in the package and the component resource files.



Files	Path
Contains	
MdClock.dcr	C:\md6code\11\Mdpack
MdClock.pas	C:\md6code\11\Mdpack
MdFontbox.pas	C:\md6code\11\Mdpack
Requires	
vcl.dcp	

Building Compound Components with Frames

Instead of building the compound component in code and hooking up the timer event manually, we could have obtained a similar effect by using a frame. Frames make the development of compound components with custom event handlers a visual operation, and thus simpler. You can share this frame by adding it to the Repository or by creating a template using the Add to Palette command of the frame's shortcut menu.

As an alternative, you might want to share the frame by placing it in a package and registering it as a component. Technically, this is not difficult. You add a `Register` procedure to the frame's unit, add the unit to a package, and build it. The new component/frame will be in the Component Palette, like any other component. In Delphi 6, when you place this component/frame on a form, you'll see its subcomponents. You cannot select these subcomponents with a mouse click in the Form Designer, but can do it in the Object TreeView. However, any change you make to these components at design time will inevitably get lost when you run the program or save and reload the form, because the changes to those subcomponents won't be streamed, contrary to what happened with standard frames you place inside a form.

If this is not what you might expect, I've found a *reasonable* way to use frames in packages, demonstrated by the MdFramedClock component, part of the examples on the CD for this chapter. The idea is to turn the components owned by the form into actual subcomponents, by calling the new `SetSubComponent` method. As I was up to it, I've also exposed the internal components with properties, even if this isn't compulsory as they can be selected in the Object TreeView anyway. This is the declaration of the component and the code of its methods:

```
type
  TMdFramedClock = class(TFrame)
    Label1: TLabel;
    Timer1: TTimer;
    Bevel1: TBevel;
```

Continued on next page

```
    procedure Timer1Timer(Sender: TObject);
  public
    constructor Create(AOnwer: TComponent); override;
  published
    property SubLabel: TLabel read Label1;
    property SubTimer: TTimer read Timer1;
  end;

constructor TMdFramedClock.Create(AOnwer: TComponent);
begin
  inherited;
  Timer1.SetSubComponent (true);
  Label1.SetSubComponent (true);
end;

procedure TMdFramedClock.Timer1Timer(Sender: TObject);
begin
  Label1.Caption := TimeToStr (Time);
end;
```

In contrast to the clock component built earlier, there is no need to set up the properties of the timer, or to connect the timer event to its handler function manually, as this is done visually and saved in the DFM file of the frame. Notice also that I haven't exposed the Bevel component—I haven't called `SetSubComponent` on it—so that you can try editing it at design time and see that all the changes get lost, as I mentioned above.

After you install this frame/component, you can use it inside any application. In this particular case, as soon as you drop the frame on the form, the timer will start to update the label with the current time. However, you can still handle its `OnTimer` event, and the Delphi IDE (recognizing that the component is inside a frame) will define a method with this predefined code:

```
procedure TForm1.MdFramedClock1Timer1Timer(Sender: TObject);
begin
  MdFramedClock1.Timer1Timer(Sender);
end;
```

As soon as this timer is connected, even at design time, the live clock will stop, as its original event handler is disconnected. After compiling and running the program, however, the original behavior will be restored (at least if you don't delete the line above) and your extra custom code will be executed as well. This is exactly what you'll expect from frames. You can find a complete demo of the use of this frame/component in the FrameClock example.

Continued on next page

As a short conclusion of this digression on frames compiled inside packages, I can certainly say that this approach is still far from linear. It is certainly much better than in Delphi 5, where frames inside packages were really unusable. The question is, is it worth the effort? In short, I'd say no. If you work alone or with a small team, it's better to use plain frames stored in the Repository. In larger organizations and for distributing your frames to a larger audience, I bet most people will rather build their components in the traditional way, without trying to use frames. In other words, I'm still hoping that Borland will address more complete support to the visual development of packaged components based on frames.

A Complex Graphical Component

The graphical component I want to build is an arrow component. You can use such a component to indicate a flow of information, or an action, for example. This component is quite complex, so I'll show you the various steps instead of looking directly at the complete source code. The component I've added to the MdPack package on the CD is only the final version of this process, which will demonstrate several important concepts:

- The definition of new enumerated properties, based on custom enumerated data types.
- The use of properties of `TPersistent`-derived classes, such as `TPen` and `TBrush`, and the issues related to their creation and destruction, and to handling their `OnChange` events internally in our component.
- The implementation of the `Paint` method of the component, which provides its user interface and should be generic enough to accommodate all the possible values of the various properties, including its `Width` and `Height`. The `Paint` method plays a substantial role in this graphical component.
- The definition of a custom event handler for the component, responding to user input (in this case, a double-click on the point of the arrow). This will require direct handling of Windows messages and the use of the Windows API for graphic regions.
- The registration of properties in Object Inspector categories and the definition of a custom category.

Defining an Enumerated Property

After generating the new component with the Component Wizard and choosing `TGraphicControl` as the parent class, we can start to customize the component. The arrow can point in any of four directions: up, down, left, or right. An enumerated type expresses these choices:

```
type
  TMdArrowDir = (adUp, adRight, adDown, adLeft);
```

This enumerated type defines a private data member of the component, a parameter of the procedure used to change it, and the type of the corresponding property. Two more simple properties are `ArrowHeight` and `Filled`, the first determining the size of the arrowhead and the second whether to fill the arrowhead with color:

```
type
  TMdArrow = class (TGraphicControl)
  private
    fDirection: TMdArrowDir;
    fArrowHeight: Integer;
    fFilled: Boolean;
    procedure SetDirection (Value: TMd4ArrowDir);
    procedure SetArrowHeight (Value: Integer);
    procedure SetFilled (Value: Boolean);
  published
    property Width default 50;
    property Height default 20;
    property Direction: TMd4ArrowDir
      read fDirection write SetDirection default adRight;
    property ArrowHeight: Integer
      read fArrowHeight write SetArrowHeight default 10;
    property Filled: Boolean read fFilled write SetFilled default False;
```

NOTE A graphic control has no default size, so when you place it in a form, its size will be a single pixel. For this reason it is important to add a default value for the `Width` and `Height` properties and set the class fields to the default property values in the constructor of the class.

The three custom properties are read directly from the corresponding field and are written using three `Set` methods, all having the same standard structure:

```
procedure TMdArrow.SetDirection (Value: TMdArrowDir);
begin
  if fDirection <> Value then
  begin
    fDirection := Value;
    ComputePoints;
    Invalidate;
  end;
end;
```

Notice that we ask the system to repaint the component (by calling `Invalidate`) only if the property is really changing its value and after calling the `ComputePoints` method, which computes the triangle delimiting the arrowhead. Otherwise, the code is skipped and the method ends immediately. This code structure is very common, and we will use it for most of the `Set` procedures of properties.

We must also remember to set the default values of the properties in the component's constructor:

```
constructor TMdArrow.Create (AOwner: TComponent);
begin
  // call the parent constructor
  inherited Create (AOwner);
  // set the default values
  fDirection := adRight;
  Width := 50;
  Height := 20;
  fArrowHeight := 10;
  fFilled := False;
```

In fact, as mentioned before, the default value specified in the property declaration is used only to determine whether to save the property's value to disk. The `Create` constructor is defined in the public section of the type definition of the new component, and it is indicated by the `override` keyword. It is fundamental to remember this keyword; otherwise, when Delphi creates a new component of this class, it will call the constructor of the base class, rather than the one you've written for your derived class.

Property-Naming Conventions

In the definition of the Arrow component, notice the use of several naming conventions for properties, access methods, and fields. Here is a summary:

- A property should have a meaningful and readable name.
- When a private data field is used to hold the value of a property, the field should be named with an *f* (field) at the beginning, followed by the name of the corresponding property.
- When a function is used to change the value of the property, the function should have the word *Set* at the beginning, followed by the name of the corresponding property.
- A corresponding function used to read the property should have the word *Get* at the beginning, again followed by the property name.

These are just guidelines to make programs more readable. The compiler doesn't enforce them. These conventions are described in the *Delphi Component Writers' Guide* and are followed by the Delphi's class completion mechanism.

Writing the *Paint* Method

Drawing the arrow in the various directions and with the various styles requires a fair amount of code. To perform custom painting, you override the `Paint` method and use the protected `Canvas` property.

Instead of computing the position of the arrowhead points in drawing code that will be executed often, I've written a separate function to compute the arrowhead area and store it in an array of points defined among the private fields of the component as:

```
fArrowPoints: array [0..3] of TPoint;
```

These points are determined by the `ComputePoints` private method, which is called every time some of the component properties change. Here is an excerpt of its code:

```
procedure TMdArrow.ComputePoints;
var
  XCenter, YCenter: Integer;
begin
  // compute the points of the arrowhead
  YCenter := (Height - 1) div 2;
  XCenter := (Width - 1) div 2;
  case FDirection of
    adUp: begin
      fArrowPoints [0] := Point (0, FArrowHeight);
      fArrowPoints [1] := Point (XCenter, 0);
      fArrowPoints [2] := Point (Width-1, FArrowHeight);
    end;
  // and so on for the other directions
```

The code computes the center of the component area (simply dividing the `Height` and `Width` properties by two) and then uses it to determine the position of the arrowhead. Besides changing the direction or other properties, we need to refresh the position of the arrowhead when the size of the component changes. What we can do is to override the `SetBounds` method of the component, which is called by VCL every time the `Left`, `Top`, `Width`, and `Height` properties of a component change:

```
procedure TMdArrow.SetBounds(ALeft, ATop, AWidth, AHeight: Integer);
begin
  inherited SetBounds (ALeft, ATop, AWidth, AHeight);
  ComputePoints;
end;
```

Once the component knows the position of the arrowhead, its painting code becomes simpler. Here is an excerpt of the `Paint` method:

```
procedure TMdArrow.Paint;
var
  XCenter, YCenter: Integer;
```

```
begin
  // compute the center
  YCenter := (Height - 1) div 2;
  XCenter := (Width - 1) div 2;

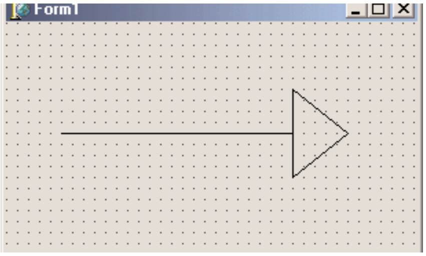
  // draw the arrow line
  case FDirection of
    adUp: begin
      Canvas.MoveTo (XCenter, Height-1);
      Canvas.LineTo (XCenter, FArrowHeight);
    end;
    // and so on for the other directions
  end;

  // draw the arrow point, eventually filling it
  if FFilled then
    Canvas.Polygon (fArrowPoints)
  else
    Canvas.PolyLine (fArrowPoints);
end;
```

You can see an example of the output of this component in Figure 11.7.

FIGURE 11.7:

The output of the Arrow component



Adding *TPersistent* Properties

To make the output of the component more flexible, I've added to it two new properties, defined with a class type (specifically, a `TPersistent` data type, which defines objects that can be automatically streamed by Delphi). These properties are a little more complex to handle, because the component now has to create and destroy these internal objects (as we did with the internal Timer of the clock component). This time, however, we also export the internal objects using some properties, so that users can directly change them from the Object Inspector. To update the component when these subobjects change, we'll also need to handle their internal OnChange property. Here is the definition of the two new TPersistent-type properties and the other changes to the definition of the component class:

```
type
  TMdArrow = class (TGraphicControl)
  private
    FPen: TPen;
    FBrush: TBrush;
    ...
    procedure SetPen (Value: TPen);
    procedure SetBrush (Value: TBrush);
    procedure RepaintRequest (Sender: TObject);
  published
    property Pen: TPen read FPen write SetPen;
    property Brush: TBrush read FBrush write SetBrush;
  end;
```

The first thing to do is to create the objects in the constructor and set their OnChange event handler:

```
constructor TMdArrow.Create (AOwner: TComponent);
begin
  ...
  // create the pen and the brush
  FPen := TPen.Create;
  FBrush := TBrush.Create;
  // set a handler for the OnChange event
  FPen.OnChange := RepaintRequest;
  FBrush.OnChange := RepaintRequest;
end;
```

These OnChange events are fired when one of the properties of these subobjects changes; all we have to do is to ask the system to repaint our component:

```
procedure TMdArrow.RepaintRequest (Sender: TObject);
begin
  Invalidate;
end;
```

You must also add to the component a destructor, to remove the two graphical objects from memory (and free their system resources):

```
destructor TMdArrow.Destroy;
begin
  FPen.Free;
  FBrush.Free;
  inherited Destroy;
end;
```

The properties related to these two components require some special handling: instead of copying the pointer to the objects, we should copy the internal data of the object passed as parameter. The standard := operation copies the pointers, so in this case we have to use the Assign method instead. Here is one of the two Set procedures:

```
procedure TMdArrow.SetPen (Value: TPen);
begin
  FPen.Assign(Value);
  Invalidate;
end;
```

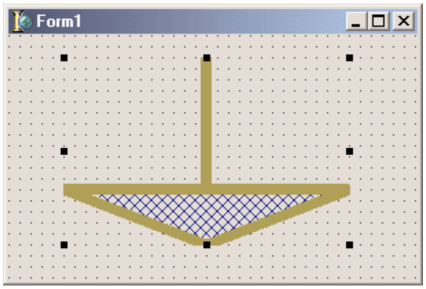
Many TPersistent classes have an Assign method that should be used when we need to update the data of these objects. Now, to actually use the pen and brush for the drawing, you have to modify the Paint method, setting the Pen and the Brush properties of the component Canvas to the value of the internal objects before drawing any line:

```
procedure TMdArrow.Paint;
begin
  // use the current pen and brush
  Canvas.Pen := FPen;
  Canvas.Brush := FBrush;
```

You can see an example of the new output of the component in Figure 11.8.

FIGURE 11.8:

The output of the Arrow component with a thick pen and a special hatch brush



Defining a New Custom Event

To complete the development of the Arrow component, let's add a custom event. Most of the time, new components use the events of their parent classes. For example, in this component, I've made some standard events available simply by redeclaring them in the published section of the class:

```
type
  TMdArrow = class (TGraphicControl)
  published
    property OnClick;
```

```
        property OnDragDrop;
        property OnDragOver;
        property OnEndDrag;
        property OnMouseDown;
        property OnMouseMove;
        property OnMouseUp;
```

Thanks to this declaration, the above events (originally declared in a parent class) will now be available in the Object Inspector when the component is installed.

Sometimes, however, a component requires a custom event. To define a brand-new event, you first need to add to the class a field of the type of the event. This type is actually a method pointer type (see Chapter 5 for details). Here is the definition I've added in the private section of the TMdArrow class:

```
fArrowDblClick: TNotifyEvent;
```

In this case I've used the TNotifyEvent type, which has only a Sender parameter and is used by Delphi for many events, including OnClick and OnDblClick events. Using this field I've defined a very simple published property, with direct access to the field:

```
property OnArrowDblClick: TNotifyEvent
  read fArrowDblClick write fArrowDblClick;
```

Notice again the standard naming convention, with event names starting with *On*. The fArrowDblClick method pointer is activated (executing the corresponding function) inside the specific ArrowDblClick dynamic method. This happens only if an event handler has been specified in the program that uses the component:

```
procedure TMdArrow.ArrowDblClick;
begin
  if Assigned (FArrowDblClick) then
    FArrowDblClick (Self);
end;
```

This method is defined in the protected section of the type definition to allow future subclasses to both call and change it. Basically, the ArrowDblClick method is called by the handler of the wm_LButtonDblClk Windows message, but only if the double-click took place inside the arrow's point. To test this condition, we can use some of the Windows API's region functions.

NOTE A *region* is an area of the screen enclosed by any shape. For example, we can build a polygonal region using the three vertices of the arrow-point triangle. The only problem is that to fill the surface properly, we must define an array of TPoints in a clockwise direction (see the description of the CreatePolygonalRgn in the Windows API Help for the details of this strange approach). That's what I did in the ComputePoints method.

Once we have defined a region, we can test whether the point where the double-click occurred is inside the region by using the PtInRegion API call. You can see the complete source code of this procedure in the following listing:

```
procedure TMdArrow.WMLButtonDblClk (
  var Msg: TWMLButtonDblClk); // message wm_LButtonDblClk;
var
  HRegion: HRgn;
begin
  // perform default handling
  inherited;

  // compute the arrowhead region
  HRegion := CreatePolygonRgn (fArrowPoints, 3, WINDING);
  try  // check whether the click took place in the region
    if PtInRegion (HRegion, Msg.XPos, Msg.YPos) then
      ArrowDblClick;
  finally
    DeleteObject (HRegion);
  end;
end;
```

Registering Property Categories

We've added to this component some custom properties and a new event. If you arrange the properties in the Object Inspector by category (a feature available since Delphi 5), all the new elements will show up in the generic Miscellaneous category. Of course, this is far from ideal, but we can easily register the new properties in one of the available categories.

We can register a property (or an event) in a category by calling one of the four overloaded versions of the RegisterPropertyInCategory function, defined in the new DesignIntf unit. When calling this function, you indicate the name of the category, and you can specify the property name, its type, or the property name and the component it belongs to. For example, we can add the following lines to the Register procedure of the unit to register the OnArrowDblClick event in the Input category and the Filled property in the Visual category:

```
uses
  DesignIntf;

procedure Register;
begin
  RegisterComponents('Md', [TMdArrow]);
  RegisterPropertyInCategory ('Input', TMdArrow, 'OnArrowDblClick');
  RegisterPropertyInCategory ('Visual', TMdArrow, 'Filled');
end;
```

In Delphi 5, the first parameter was a class indicating the category type; now the parameter is simply a string, a much simpler solution. This change also makes it straightforward to define new categories: you simply pass its name as the first parameter of the RegisterPropertyInCategory function, as in:

```
RegisterPropertyInCategory ('Arrow', TMdArrow, 'Direction');
RegisterPropertyInCategory ('Arrow', TMdArrow, 'ArrowHeight');
```

Creating a brand new category for the specific properties of our component can make it much simpler for a user to locate its specific features. Notice, though, that since we rely on the DesignIntf unit, you should compile the unit containing these registrations in a design-time package, not a run-time one (in fact, the required DesignIde unit cannot be distributed). For this reason, I've written this code in a separate unit than the one defining the component and added the new unit (MdArrReg) to the package MdDesPk, including all of the design-time-only units; this is discussed later, in the section "Installing the Property Editor."

WARNING It's debatable whether using a category for the specific properties of a component is a good idea. On one side, a user of the component can easily spot specific properties. At the same time, some of the new properties might not pertain to any of the existing categories. On the other side, however, categories can be overused. If every component introduces new categories, users may get confused. You also face the risk of having as many categories as there are properties.

Notice that my code registers the Filled property in two different categories. This is not a problem, because the same property can show up multiple times in the Object Inspector under different groups, as you can see in Figure 11.9.

To test the arrow component I've written a very simple example program, ArrowDemo, which allows you to modify most of its properties at run time. This type of test, after you have written a component or while you are writing it, is very important.

NOTE The *Localizable* property category has a special role, related to the use of the ITE (Integrated Translation Environment). When a property is part of this category, its value will be listed in the ITE as a property that can be translated into another language. (A complete discussion of the ITE is beyond the scope of this book.)

FIGURE 11.9: The Arrow component defines a custom property category, *Arrow*, as you can see in the Object Inspector.

Customizing Windows Controls

One of the most common ways of customizing existing components is to add some predefined behavior to their event handlers. Every time you need to attach the same event handler to components of different forms, you should consider adding the code of the event right into a subclass of the component. An obvious example is that of edit boxes accepting only numeric input. Instead of attaching to each of them a common `OnChar` event handler, we can define a simple new component. This component, however, won't handle the event; events are for component users only. Instead, the component can either handle the Windows message directly or override a method, as described in the next two sections.

Overriding Message Handlers: The Numeric Edit Box

To customize an edit box component to restrict the input it will accept, all you need to do is handle the `wm_Char` Windows messages that occur when the user presses any but a few specific keys (namely, the numeric characters).

One way to respond to a message for a given window (whether it's a form or a component) is to create a new *message-response* method that you declare using the `message` keyword. Delphi's message-handling system makes sure that your message-response method has a chance to respond to a given message before the form or component's default message handler does. You'll see in the next section that, instead of creating a new method (as we do here), you can override an existing virtual method that responds to a given message. Below is the code of the TMdNumEdit class:

```
type
  TMdNumEdit = class (TCustomEdit)
  private
    fInputError: TNotifyEvent;
  protected
    function GetValue: Integer;
    procedure SetValue (Value: Integer);
  public
    procedure WmChar (var Msg: TWmChar); message wm_Char;
    constructor Create (Owner: TComponent); override;
  published
    property OnInputError: TNotifyEvent read fInputError write fInputError;
    property Value: Integer read GetValue write SetValue default 0;
    property AutoSelect;
    property AutoSize;
    property BorderStyle;
    // and so on...
```

This component inherits from TCustomEdit instead of TEdit so that it can hide the Text property and surface the Integer Value property instead. Notice that I don't create a new field to store this value, because we can use the existing (but now unpublished) Text property. To do this, we'll simply convert the numeric value to and from a text string. The TCustomEdit class (or actually the Windows control it wraps) automatically paints the information from the Text property on the surface of the component:

```
function TMdNumEdit.GetValue: Integer;
begin
  // set to 0 in case of error
  Result := StrToIntDef (Text, 0);
end;

procedure TMdNumEdit.SetValue (Value: Integer);
begin
  Text := IntToStr (Value);
end;
```

The most important method is the response for the wm_Char message. In the body of this method, the component filters out all the nonnumeric characters and raises a specific event in case of an error:

```
procedure TMdNumEdit.WmChar (var Msg: TWmChar);
begin
```

```
    if not (Char (Msg.CharCode) in ['0'..'9']) and not (Msg.CharCode = 8) then
    begin
      if Assigned (fInputError) then
        fInputError (Self);
    end
    else
      inherited;
  end;
```

This method checks each character as the user enters it, testing for numerals and the Backspace key (which has an ASCII value of 8). The user should be able to use Backspace in addition to the system keys (the arrow keys and Del), so we need to check for that value. We don't have to check for the system keys, because they are surfaced by a different Windows message, wm_SysChar.

That's it. Now if you place this component on a form, you can type something in the edit box and see how it behaves. You might also want to attach a method to the OnInputError event to provide feedback to the user when a wrong key is typed.

A Numeric Edit with Thousands Separators

As a further extension to the example, when typing large numbers it would be nice for the thousands separators to automatically appear and update themselves as required by the user input. You can do this by overriding the internal Change method and formatting the number properly. There are only a couple of small problems to consider. The first is that to format the number you need to have one, but the text of the edit with the thousands separators (possibly misplaced) cannot be converted to a number directly. I've written a modified version of the StringToFloat function, called StringToFloatSkipping, to accomplish this.

The second small problem is that if you modify the text of the edit box the current position of the cursor will get lost. So you need to save the original cursor position, reformat the number, and then reapply the cursor position considering that if a separator has been added or removed, it should change accordingly. All these considerations are summarized by the following complete code of the TMdThousandEdit class:

```
  type
    TMdThousandEdit = class (TMdNumEdit)
    public
      procedure Change; override;
    end;

  function StringToFloatSkipping (s: string): Extended;
  var
    s1: string;
    I: Integer;
```

```
begin
  // remove non-numbers, but keep the decimal separator
  s1 := '';
  for i := 1 to length (s) do
   if s[i] in ['0'..'9'] then
     s1 := s1 + s[i];
  Result := StrToFloat (s1);
end;

procedure TMdThousandEdit.Change;
var
  CursorPos, // original position of the cursor
  LengthDiff: Integer; // number of new separators (+ or -)
begin
  if Assigned (Parent) then
  begin
    CursorPos := SelStart;
    LengthDiff := Length (Text);
    Text := FormatFloat ('#,###',
      StringToFloatSkipping (Text));
    LengthDiff := Length (Text) - LengthDiff;
    // move the cursor to the proper position
    SelStart := CursorPos + LengthDiff;
  end;
  inherited;
end;
```

Overriding Dynamic Methods: The Sound Button

Our next component, TMdSoundButton, plays one sound when you press the button and another sound when you release it. The user specifies each sound by modifying two String properties that name the appropriate WAV files for the respective sounds. Once again, we need to intercept and modify some system messages (wm_LButtonDown and wm_LButtonUp), but instead of handling the messages by writing a new message-response method, we'll override the appropriate *second-level* handlers.

NOTE When most VCL components handle a Windows message, they call a *second-level* message handler (usually a dynamic method), instead of executing code directly in the message-response method. This makes it simpler for you to customize the component in a derived class. Typically, a second-level handler will do its own work and then call any event handler that the component user has assigned.

Here is the code of the TMdSoundButton class, with the two protected methods that override the second-level handlers, and the two string properties that identify the sound files.

You'll notice that in the property declarations, we read and write the corresponding private fields without calling a get or set method, simply because we don't need to do anything special when the user makes changes to those properties.

```
type
  TMdSoundButton = class(TButton)
  private
    FSoundUp, FSoundDown: string;
  protected
    procedure MouseDown(Button: TMouseButton;
      Shift: TShiftState; X, Y: Integer); override;
    procedure MouseUp(Button: TMouseButton;
      Shift: TShiftState; X, Y: Integer); override;
  published
    property SoundUp: string read FSoundUp write FSoundUp;
    property SoundDown: string read FSoundDown write FSoundDown;
  end;
```

There are several reasons why overriding existing second-level handlers is generally a better approach than handling straight Windows messages. First, this technique is more sound from an object-oriented perspective. Instead of duplicating the message-response code from the base class and then customizing it, you're overriding a virtual method call that the VCL designers planned for you to override. Second, if someone needs to derive another class from one of your component classes, you'll want to make it as easy for them to customize as possible, and overriding second-level handlers is less likely to induce strange errors (if only because you're writing less code). Finally, this will make your component classes more consistent with VCL—and therefore easier for someone else to figure out. Here is the code of the two second-level handlers:

```
uses
  MMSystem;

procedure TMdSoundButton.MouseDown(Button: TMouseButton; Shift: TShiftState;
  X, Y: Integer);
begin
  inherited MouseDown (Button, Shift, X, Y);
  PlaySound (PChar (FSoundDown), 0, snd_Async);
end;

procedure TMdSoundButton.MouseUp(Button: TMouseButton; Shift: TShiftState;
  X, Y: Integer);
begin
  inherited MouseUp (Button, Shift, X, Y);
  PlaySound (PChar (FSoundUp), 0, snd_Async);
end;
```

In both cases, you'll notice that we call the inherited version of the methods *before* we do anything else. For most second-level handlers, this is a good practice, since it ensures that we execute the standard behavior before we execute any custom behavior.

Next, you'll notice that we call the PlaySound Win32 API function to play the sound. You can use this function (which is defined in the MmSystem unit to play either WAV files or system sounds, as the SoundB example demonstrates. Here is a textual description of the form of this sample program (from the DFM file):

```
object MdSoundButton1: TMdSoundButton
  Caption = 'Press'
  SoundUp = 'RestoreUp'
  SoundDown = 'RestoreDown'
end
```

NOTE Selecting a proper value for these sound properties is far from simple. Later in this chapter, I'll show you how to add a property editor to the component to simplify the operation.

Handling Internal Messages: The Active Button

The Windows interface is evolving toward a new standard, including components that become highlighted as the mouse cursor moves over them. Delphi provides similar support in many of its built-in components, but what does it take to mimic this behavior for a simple button? This might seem a complex task to accomplish, but it is not.

The development of a component can become much simpler once you know which virtual function to override or which message to hook onto. The next component, the TMdActiveButton class, demonstrates this by handling some internal Delphi messages to accomplish its task in a very simple way. (For information about where these internal Delphi messages come from, see the sidebar "Component Messages and Notifications.")

The ActiveButton component handles the cm_MouseEnter and cm_MouseExit internal Delphi messages, which are received when the mouse cursor enters or leaves the area corresponding to the component:

```
type
  TMdActiveButton = class (TButton)
  protected
    procedure MouseEnter (var Msg: TMessage);
      message cm_mouseEnter;
    procedure MouseLeave (var Msg: TMessage);
      message cm_mouseLeave;
  end;
```

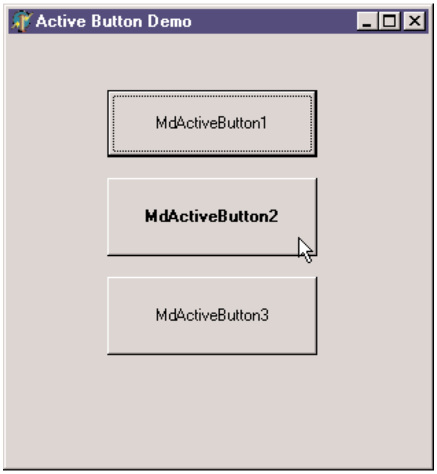
The code you write for these two methods can do whatever you want. For this example, I've decided to simply toggle the bold style of the font of the button itself. You can see the effect of moving the mouse over one of these components in Figure 11.10.

```
procedure TMdActiveButton.MouseEnter (var Msg: TMessage);
begin
  Font.Style := Font.Style + [fsBold];
end;

procedure TMdActiveButton.MouseLeave (var Msg: TMessage);
begin
  Font.Style := Font.Style - [fsBold];
end;
```

FIGURE 11.10:

An example of the use of the ActiveButton component



You can add other effects at will, including enlarging the font itself, making the button the default, or increasing its size a little. The best effects usually involve colors, but you should inherit from the TBitBtn class to have this support (TButton controls have a fixed color).

Component Messages and Notifications

To build the ActiveButton component, I've used two internal Delphi component messages, as indicated by their *cm* prefix. These messages can be quite interesting, as the example highlights, but they are almost completely undocumented by Borland. There is also a second group of internal Delphi messages, indicated as component notifications and distinguished by their *cn* prefix. I don't have enough space here to discuss each of them or provide a detailed analysis; browse the VCL source code if you want to learn more.

WARNING As this is a rather advanced topic, feel free to skip this section if you are new to writing Delphi components. But component messages are not documented in the Delphi help file, so I felt it was important to at least *list* them here.

Component Messages

A Delphi component passes *component messages* to other components to indicate any change in its state that might affect those components. Most of these messages start as Windows messages, but some of them are more complex, higher-level translations and not simple remappings. Also, components send their own messages as well as forwarding those received from Windows. For example, changing a property value or some other characteristic of the component may necessitate telling one or more other components about the change.

We can group these messages into categories:

- Activation and input focus messages are sent to the component being activated or deactivated, receiving or losing the input focus:

`cm_Activate`	Corresponds to the `OnActivate` event of forms and of the application
`cm_Deactivate`	Corresponds to `OnDeactivate`
`cm_Enter`	Corresponds to `OnEnter`
`cm_Exit`	Corresponds to `OnExit`
`cm_FocusChanged`	Sent whenever the focus changes between components of the same form (later, we'll see an example using this message)
`cm_GotFocus`	Declared but not used
`cm_LostFocus`	Declared but not used

- Messages sent to child components when a property changes:

`cm_BiDiModeChanged`

`cm_BorderChanged`

`cm_ColorChanged`

`cm_Ctl3DChanged`

`cm_CursorChanged`

`cm_EnabledChanged`

`cm_FontChanged`

`cm_IconChanged`

`cm_ShowHintChanged`

`cm_ShowingChanged`

`cm_SysFontChanged`

`cm_TabStopChanged`

`cm_TextChanged`

`cm_VisibleChanged`

Monitoring these messages can help track changes in a property. You might need to respond to these messages in a new component, but it's not likely.

- Messages related to *ParentXxx* properties: cm_ParentFontChanged, cm_ParentColorChanged, cm_ParentCtl3DChanged, cm_ParentBiDiModeChanged, and cm_ParentShowHintChanged. These are very similar to the messages of the previous group.
- Notifications of changes in the Windows system: cm_SysColorChange, cm_WinIniChange, cm_TimeChange, and cm_FontChange. Handling these messages is useful only in special components that need to keep track of system colors or fonts.
- Mouse messages: cm_Drag is sent many times during dragging operations. cm_MouseEnter and cm_MouseLeave are sent to the control when the cursor enters or leaves its surface, but these are sent by the Application object as low-priority messages. cm_MouseWheel corresponds to wheel-based operations.

  cm_Drag has a DragMessage parameter that indicates a sort of submessage, and the address of the TDragRec record that indicates the mouse position and the components involved in the dragging operation. The cm_Drag message isn't that important, because Delphi defines many drag events and drag methods you can override. However, you can respond to cm_Drag for a few things that don't generate an event or method call. This message is sent to find the target component (when the DragMessage field is dmFindTarget); to indicate that the cursor has reached a component (the dmDragEnter submessage), is being moved over it (dmDragMove), or has left it (dmDragLeave); when the drop operation is accepted (dmDragDrop); and when it is aborted (dmDragCancel).
- Application messages:

cm_AppKeyDown	Sent to the Application object to let it determine whether a key corresponds to a menu shortcut
cm_AppSysCommand	Corresponds to the wm_SysCommand message
cm_DialogHandle	Sent in a DLL to retrieve the value of the DialogHandle property (used by some dialog boxes not built with Delphi)
cm_InvokeHelp	Sent by code in a DLL to call the InvokeHelp method
cm_WindowHook	Sent in a DLL to call the HookMainWindow and UnhookMainWindow methods

You'll rarely need to use these messages yourself. There is also a cm_HintShowPause message, which is apparently never handled in VCL.

- Delphi internal messages:
  - `cm_CancelMode` Terminates special operations, such as showing the pull-down list of a combo box
  - `cm_ControlChange` Sent to each control before adding or removing a child control (handled by some common controls)
  - `cm_ControlListChange` Sent to each control before adding or removing a child control (handled by the DBCtrlGrid component)
  - `cm_DesignHitTest` Determines whether a mouse operation should go to the component or to the form designer
  - `cm_HintShow` Sent to a control just before displaying its hint (only if the `ShowHint` property is True)
  - `cm_HitTest` Sent to a control when a parent control is trying to locate a child control at a given mouse position (if any)
  - `cm_MenuChanged` Sent after MDI or OLE menu-merging operations
- Messages related to special keys:
  - `cm_ChildKey` Sent to the parent control to handle some special keys (in Delphi, this message is handled only by DBCtrlGrid components)
  - `cm_DialogChar` Sent to a control to determine whether a given input key is its accelerator character
  - `cm_DialogKey` Handled by modal forms and controls that need to perform special actions
  - `cm_IsShortCut` I haven't yet figured out the exact role of this new message.
  - `cm_WantSpecialKey` Handled by controls that interpret special keys in an unusual way (for example, using the Tab key for navigation, as some Grid components do)

- Messages for specific components:

`cm_GetDataLink`	Used by DBCtrlGrid controls (and discussed in Chapter 18)
`cm_TabFontChanged`	Used by the TabbedNotebook components
`cm_ButtonPressed`	Used by SpeedButtons to notify other sibling SpeedButton components (to enforce radio-button behavior)
`cm_DeferLayout`	Used by DBGrid components

- OLE container messages: `cm_DocWindowActivate`, `cm_IsToolControl`, `cm_Release`, `cm_UIActivate`, and `cm_UIDeactivate`.
- Dock-related messages, including `cm_DockClient`, `cm_DockNotification`, `cmFloat`, and `cm_UndockClient`.
- Method-implementation messages, such as `cm_RecreateWnd`, called inside the `RecreateWnd` method of `TControl`; `cm_Invalidate`, called inside `TControl.Invalidate`; `cm_Changed`, called inside `TControl.Changed`; and `cm_AllChildrenFlipped`, called in the `DoFlipChildren` methods of `TWinControl` and `TScrollingWinControl`. In the similar group fall two action list–related messages, `cm_ActionUpdate` and `cm_ActionExecute`.

Finally, there are messages defined and handled by specific components and declared in the respective units, such as `cm_DeferLayout` for DBGrid controls and a group of almost 10 messages for action bar components.

Component Notifications

Component notification messages are those sent from a parent form or component to its children. These notifications correspond to messages sent by Windows to the parent control's window, but logically intended for the control. For example, interaction with controls such as buttons, edit, or list boxes, causes Windows to send a `wm_Command` message to the parent of the control. When a Delphi program receives these messages, it forwards the message to the control itself, as a notification. The Delphi control can handle the message and eventually fire an event. Similar dispatching operations take place for many other commands.

The connection between Windows messages and component notification ones is so tight that you'll often recognize the name of the Windows message from the name of the notification message, simply replacing the initial *cn* with *wm*. There are several distinct groups of component notification messages:

- General keyboard messages: `cn_Char`, `cn_KeyUp`, `cn_KeyDown`, `cn_SysChar`, and `cn_SysKeyDown`.

- Special keyboard messages used only by list boxes with the lbs_WantKeyboardInput style: cn_CharToItem and cn_VKeyToItem.
- Messages related to the owner-draw technique: cn_CompareItem, cn_DeleteItem, cn_DrawItem, and cn_MeasureItem.
- Messages for scrolling, used only by scroll bar and track bar controls: cn_HScroll and cn_VScroll.
- General notification messages, used by most controls: cn_Command, cn_Notify, and cn_ParentNotify.
- Control color messages: cn_CtlColorBtn, cn_CtlColorDlg, cn_CtlColorEdit, cn_CtlColorListbox, cn_CtlColorMsgbox, cn_CtlColorScrollbar, and cn_CtlColorStatic.

Some more control notifications are defined for common controls support (in the ComCtrls unit).

An Example of Component Messages

As a very simple example of the use of some component messages, I've written the CMNTest program. This program has a form with three edit boxes, and associated labels. The first message it handles, cm_DialogKey, allows it to treat the Enter key as if it were a Tab key. The code of this method checks for the Enter key's code and sends the same message, but passes the vk_Tab key code. To halt further processing of the Enter key, we set the result of the message to 1:

```
procedure TForm1.CMDialogKey(var Message: TCMDialogKey);
begin
  if (Message.CharCode = VK_RETURN) then
  begin
    Perform (CM_DialogKey, VK_TAB, 0);
    Message.Result := 1;
  end
  else
    inherited;
end;
```

The second message, cm_DialogChar, monitors accelerator keys. This can be useful to provide custom shortcuts without defining an extra menu for them. In this case, I'm simply logging the special keys in a label:

```
procedure TForm1.CMDialogChar(var Msg: TCMDialogChar);
begin
  Label1.Caption := Label1.Caption + Char (Msg.CharCode);
  inherited;
end;
```

Finally, the form handles the cm_FocusChanged message, to respond to focus changes without having to handle the OnEnter event of each of its components. Again, the simple action is to display a description of the focused component:

```
procedure TForm1.CmFocusChanged(var Msg: TCmFocusChanged);
begin
  Label5.Caption := 'Focus on ' + Msg.Sender.Name;
end;
```

The advantage of this approach is that it works independently of the type and number of components you add to the form, and it does so without any special action on your part. Again, this is a trivial example for such an advanced topic, but if you add to this the code of the ActiveButton component, you have at least a few reasons to look into these special, undocumented messages. At times, writing the same code without their support can become extremely complex.

A Nonvisual Dialog Component

The next component we'll examine is completely different from the ones we have seen up to now. After building window-based controls and simple graphic components, I'm now going to build a nonvisual component.

The basic idea is that forms are components. When you have built a form that might be particularly useful in multiple projects, you can add it to the Object Repository or make a component out of it. The second approach is more complex than the first, but it makes using the new form easier and allows you to distribute the form without its source code. As an example, I'll build a component based on a custom dialog box, trying to mimic as much as possible the behavior of standard Delphi dialog box components.

The first step in building a dialog box in a component is to write the code of the dialog box itself, using the standard Delphi approach. Just define a new form and work on it as usual. When a component is based on a form, you can almost visually design the component. Of course, once the dialog box has been built, you have to define a component around it in a nonvisual way.

The standard dialog box I want to build is based on a list box, because it is common to let a user choose a value from a list of strings. I've customized this common behavior in a dialog box and then used it to build a component. The simple ListBoxForm form I've built has a list box and the typical OK and Cancel buttons, as shown in its textual description:

```
object MdListBoxForm: TMdListBoxForm
  BorderStyle = bsDialog
  Caption = 'ListBoxForm'
  object ListBox1: TListBox
```

```
    OnDblClick = ListBox1DblClick
  end
  object BitBtn1: TBitBtn
    Kind = bkOK
  end
  object BitBtn2: TBitBtn
    Kind = bkCancel
  end
end
```

The only method of this dialog box form relates to the double-click event of the list box, which closes the dialog box as though the user clicked the OK button, by setting the ModalResult property of the form to mrOk. Once the form works, we can start changing its source code, adding the definition of a component and removing the declaration of the global variable for the form.

NOTE For components based on a form, you can use two Pascal source code files: one for the form and the other for the component encapsulating it. It is also possible to place both the component and the form in a single unit, as I've done for this example. In theory it would be even nicer to declare the form class in the implementation portion of this unit, hiding it from the users of the component. In practice this is not a good idea. To manipulate the form visually in the Form Designer, the form class declaration must appear in the interface section of the unit. The rationale behind this behavior of the Delphi IDE is that, among other things, this constraint minimizes the amount of code the module manager has to scan to find the form declaration—an operation that must be performed often to maintain the synchronization of the visual form with the form class definition.

The most important of these operations is the definition of the TMdListBoxDialog component. This component is defined as "nonvisual" because its immediate ancestor class is TComponent. The component has one public property and these three published properties:

- Lines is a TStrings object, which is accessed via two methods, GetLines and SetLines. This second method uses the Assign procedure to copy the new values to the private field corresponding to this property. This internal object is initialized in the Create constructor and destroyed in the Destroy method.
- Selected is an integer that directly accesses the corresponding private field. It stores the selected element of the list of strings.
- Title is a string used to change the title of the dialog box.

The public property is SelItem, a read-only property that automatically retrieves the selected element of the list of strings. Notice that this property has no storage and no data: it simply accesses other properties, providing a virtual representation of data:

```
type
  TMdListBoxDialog = class (TComponent)
  private
    FLines: TStrings;
    FSelected: Integer;
    FTitle: string;
    function GetSelItem: string;
    procedure SetLines (Value: TStrings);
    function GetLines: TStrings;
  public
    constructor Create(AOwner: TComponent); override;
    destructor Destroy; override;
    function Execute: Boolean;
    property SelItem: string read GetSelItem;
  published
    property Lines: TStrings read GetLines write SetLines;
    property Selected: Integer read FSelected write FSelected;
    property Title: string read FTitle write FTitle;
  end;
```

Most of the code of this example is in the Execute method, a function that returns True or False depending on the modal result of the dialog box. This is consistent with the Execute method of most standard Delphi dialog box components. The Execute function creates the form dynamically, sets some of its values using the component's properties, shows the dialog box, and if the result is correct, updates the current selection:

```
function TMdListBoxDialog.Execute: Boolean;
var
  ListBoxForm: TListBoxForm;
begin
  if FLines.Count = 0 then
    raise EStringListError.Create ('No items in the list');
  ListBoxForm := TListBoxForm.Create (Self);
  try
    ListBoxForm.ListBox1.Items := FLines;
    ListBoxForm.ListBox1.ItemIndex := FSelected;
    ListBoxForm.Caption := FTitle;
    if ListBoxForm.ShowModal = mrOk then
    begin
      Result := True;
      Selected := ListBoxForm.ListBox1.ItemIndex;
    end
    else
      Result := False;
  finally
    ListBoxForm.Free;
  end;
end;
```

Notice that the code is contained within a try/finally block, so if a run-time error occurs when the dialog box is displayed, the form will be destroyed anyway. I've also used exceptions to raise an error if the list is empty when a user runs it. This error is by design, and using an exception is a good technique to enforce it. The other methods of the component are quite straightforward. The constructor creates the FLines string list, which is deleted by the destructor; the GetLines and SetLines methods operate on the string list as a whole; and the GetSelItem function (listed below) returns the text of the selected item:

```
function TMdListBoxDialog.GetSelItem: string;
begin
  if (Selected >= 0) and (Selected < FLines.Count) then
    Result := FLines [Selected]
  else
    Result := '';
end;
```

Of course, since we are manually writing the code of the component and adding it to the source code of the original form, we have to remember to write the Register procedure.

Using the Nonvisual Component

Once you've done that and the component is ready, you must provide a bitmap. For nonvisual components, bitmaps are very important because they are used not only for the Component Palette, but also when you place the component on a form. After preparing the bitmap and installing the component, I've written a simple project to test it. The form of this test program has a button, an edit box, and the MdListDialog component. In the program, I've added only a few lines of code, corresponding to the OnClick event of the button:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  // select the text of the edit, if corresponding to one of the strings
  MdListDialog1.Selected := MdListDialog1.Lines.IndexOf (Edit1.Text);
  // run the dialog and get the result
  if MdListDialog1.Execute then
    Edit1.Text := MdListDialog1.SelItem;
end;
```

That's all you need to run the dialog box we have placed in the component, as you can see in Figure 11.11. As you've seen, this is an interesting approach to the development of some common dialog boxes.

The ListDialDemo example shows the dialog box I've encapsulated in the ListDial component.

Defining Custom Actions

Besides defining custom components, you can define and register new standard actions, which will be made available in the Action Editor of the Action List component. Creating new actions is not complex. You have to inherit from the TAction class and override some of the methods of the base class.

There are basically three methods to override. The HandlesTarget function returns whether the action object wants to handle the operation for the current target, which is by default the control with the focus. The UpdateTarget procedure can set the user interface of the controls connected with the action, eventually disabling the action if the operation is currently not available. Finally, you can implement the ExecuteTarget method to determine the actual code to execute, so that the user can simply select the action and doesn't have to implement it.

To show you this approach in practice, I've implemented the three cut, copy, and paste actions for a list box, in a way similar to what VCL does for an edit box (although I've actually simplified the code a little). I've written a base class, which inherits from the generic TListControlAction class of the new ExtActns unit. This base class, TMdCustomListAction, adds some common code, shared by all the specific actions, and publishes a few action properties. The three derived classes have their own ExecuteTarget code, plus little more. Here are the four classes:

```
type
  TMdCustomListAction = class (TListControlAction)
  protected
    function TargetList (Target: TObject): TCustomListBox;
    function GetControl (Target: TObject): TCustomListControl;
  public
```

```
    procedure UpdateTarget (Target: TObject); override;
  published
    property Caption;
    property Enabled;
    property HelpContext;
    property Hint;
    property ImageIndex;
    property ListControl;
    property ShortCut;
    property SecondaryShortCuts;
    property Visible;
    property OnHint;
  end;

  TMdListCutAction = class (TMdCustomListAction)
  public
    procedure ExecuteTarget(Target: TObject); override;
  end;

  TMdListCopyAction = class (TMdCustomListAction)
  public
    procedure ExecuteTarget(Target: TObject); override;
  end;

  TMdListPasteAction = class (TMdCustomListAction)
  public
    procedure UpdateTarget (Target: TObject); override;
    procedure ExecuteTarget (Target: TObject); override;
  end;
```

The HandlesTarget method, one of the three key methods of actions, is provided by the TListControlAction class, with this code:

```
function TListControlAction.HandlesTarget(Target: TObject): Boolean;
begin
  Result := ((ListControl <> nil) or
    (ListControl = nil) and (Target is TCustomListControl)) and
    TCustomListControl(Target).Focused;
end;
```

The UpdateTarget method, instead, has two different implementations. The default one is provided by the base class and used by the copy and cut actions. These actions are enabled only if the target list box has at least one item and an item is currently selected. The status of the paste action depends instead on the Clipboard status:

```
procedure TMdCustomListAction.UpdateTarget (Target: TObject);
begin
  Enabled := (TargetList (Target).Items.Count > 0)
```

```
    and (TargetList (Target).ItemIndex >= 0);
end;

function TMdCustomListAction.TargetList (Target: TObject): TCustomListBox;
begin
  Result := GetControl (Target) as TCustomListBox;
end;

function TMdCustomListAction.GetControl(Target: TObject): TCustomListControl;
begin
  Result := Target as TCustomListControl;
end;

procedure TMdListPasteAction.UpdateTarget (Target: TObject);
begin
  Enabled := Clipboard.HasFormat (CF_TEXT);
end;
```

The TargetList function uses the GetControl function of the TListControlAction class, which returns either the list box connected to the action at design time or the target control, the list box control with the input focus.

Finally, the three ExecuteTarget methods simply perform the corresponding actions on the target list box:

```
procedure TMdListCopyAction.ExecuteTarget (Target: TObject);
begin
  with TargetList (Target) do
    Clipboard.AsText := Items [ItemIndex];
end;

procedure TMdListCutAction.ExecuteTarget(Target: TObject);
begin
  with TargetList (Target) do
  begin
    Clipboard.AsText := Items [ItemIndex];
    Items.Delete (ItemIndex);
  end;
end;

procedure TMdListPasteAction.ExecuteTarget(Target: TObject);
begin
  (TargetList (Target)).Items.Add (Clipboard.AsText);
end;
```

Once you've written this code in a unit and added it to a package (in this case, the MdPack package), the final step is to register the new custom actions in a given category. This is indicated as the first parameter of the `RegisterActions` procedure, while the second is the list of action classes to register:

```
procedure Register;
begin
  RegisterActions ('List',
    [TMdListCutAction, TMdListCopyAction, TMdListPasteAction], nil);
end;
```

To test the use of these three custom actions, I've written the ListTest example on the companion CD. This program has two list boxes plus a toolbar that contains three buttons connected with the three custom actions and an edit box for entering new values. The program allows a user to cut, copy, and paste list box items. Nothing special, you might think, but the strange fact is that the program has absolutely no code!

Writing Property Editors

Writing components is certainly an effective way to customize Delphi, helping developers to build applications faster without requiring a detailed knowledge of low-level techniques. The Delphi environment is also quite open to extensions. In particular, you can extend the Object Inspector by writing custom property editors and to extend the Form Designer by adding component editors.

NOTE Along with these techniques, Delphi offers some internal interfaces to add-on tool developers. Using these interfaces, known as OpenTools API, requires an advanced understanding of how the Delphi environment works and a fairly good knowledge of many advanced techniques that are not discussed in this book. You can find technical information and some examples of these techniques on my Web site, `www.marcocantu.com`, along with links to other sites where these techniques are presented.

Every property editor must be a subclass of the abstract `TPropertyEditor` class, which is defined in the DesignEditors unit of the ToolsApi and provides a standard implementation for the `IProperty` interface.

NOTE The Tools API in Delphi 6 has changed considerably, also for consistency with Kylix. For example, the DsgnIntf unit of Delphi 5 has been split into the units DesignIntf, DesignEditors, and other specific units. Borland has also introduced interfaces to define the sets of methods of each kind of editor. However, most of the simpler examples, such as those presented in this book, compile almost unchanged. As this is not an in-depth analysis of the Tools API, I'm not providing a list of changes from Delphi 5 to Delphi 6, although they are substantial. For more information, you can study the extensive source code in the `\Source\ToolsApi` directory of Delphi 6.

Delphi already defines some specific property editors for strings (the TStringProperty class), integers (the TIntegerProperty class), characters (the TCharProperty class), enumerations (the TEnumProperty class), sets (the TSetProperty class), so you can actually inherit your property editor from the one of the type of property you are working with.

In any custom property editor, you have to redefine the GetAttributes function so it returns a set of values indicating the capabilities of the editor. The most important attributes are paValueList and paDialog. The paValueList attribute indicates that the Object Inspector will show a combo box with a list of values (eventually sorted if the paSortList attribute is set) provided by overriding the GetValues method. The paDialog attribute style activates an ellipsis button in the Object Inspector, which executes the Edit method of the editor.

An Editor for the Sound Properties

The sound button we built earlier had two sound-related properties: SoundUp and SoundDown. These were actually strings, so we were able to display them in the Object Inspector using a default property editor. However, requiring the user to type the name of a system sound or an external file is not very friendly, and it's a bit error-prone.

When you need to select a file for a string property, you can reuse an existing property editor, the TMPFilenameProperty class. All you have to do is register this editor for the property using the special RegisterPropertyEditor procedure, as in:

```
RegisterPropertyEditor (TypeInfo (string), TDdhSoundButton, 'SoundUp',
  TMPFileNameProperty);
```

This editor allows you to select a file for the sound, but we want to be able to choose the name of a system sound as well. (As described earlier, system sounds are predefined names of sounds connected with user operations, associated with actual sound files in the Sounds applet of the Windows Control Panel.) For this reason, instead of using this simple approach I'll build a more complex property editor. My editor for sound strings allows a user to either choose a value from a drop-down list or display a dialog box from which to load and test a sound (from a sound file or a system sound). For this reason, the property editor provides both Edit and GetValues methods:

```
type
  TSoundProperty = class (TStringProperty)
  public
    function GetAttributes: TPropertyAttributes; override;
    procedure GetValues(Proc: TGetStrProc); override;
    procedure Edit; override;
  end;
```

TIP The default Delphi convention is to name a property editor class with a name ending with *Property* and all component editors with a name ending with *Editor*.

The GetAttributes function combines both the paValueList (for the drop-down list) and the paDialog attributes (for the custom edit box), and also sorts the lists and allows the selection of the property for multiple components:

```
function TSoundProperty.GetAttributes: TPropertyAttributes;
begin
  // editor, sorted list, multiple selection
  Result := [paDialog, paMultiSelect, paValueList, paSortList];
end;
```

The GetValues method simply calls the procedure it receives as parameter many times, once for each string it wants to add to the drop-down list (as you can see in Figure 11.12):

```
procedure TSoundProperty.GetValues(Proc: TGetStrProc);
begin
  // provide a list of system sounds
  Proc ('Maximize');
  Proc ('Minimize');
  Proc ('MenuCommand');
  Proc ('MenuPopup');
  Proc ('RestoreDown');
  Proc ('RestoreUp');
  Proc ('SystemAsterisk');
  Proc ('SystemDefault');
  Proc ('SystemExclamation');
  Proc ('SystemExit');
  Proc ('SystemHand');
  Proc ('SystemQuestion');
  Proc ('SystemStart');
  Proc ('AppGPFault');
end;
```

FIGURE 11.12:

The list of sounds provides a hint for the user, who can also type in the property value or double-click to activate the editor (shown later, in Figure 11.13).

A better approach would be to extract these values from the Windows Registry, where all these names are listed. The Edit method is very straightforward, as it simply creates and displays a dialog box. You'll notice that we could have just displayed the Open dialog box directly, but we decided to add an intermediate step to allow the user to test the sound. This is similar to what Delphi does with graphic properties. You open the preview first, and load the file only after you've confirmed that it's correct. The most important step is to load the file and test it before you apply it to the property. Here is the code of the Edit method:

```
procedure TSoundProperty.Edit;
begin
  SoundForm := TSoundForm.Create (Application);
  try
    SoundForm.ComboBox1.Text := GetValue;
    // show the dialog box
    if SoundForm.ShowModal = mrOK then
      SetValue (SoundForm.ComboBox1.Text);
  finally
    SoundForm.Free;
  end;
end;
```

The GetValue and SetValue methods called above are defined by the base class, the string property editor. They simply read and write the value of the current component's property that we are editing. As an alternative, you can access the component you're editing by using the GetComponent method (which requires a parameter indicating which of the selected components you are working on—0 indicates the first component). When you access the component directly, you also need to call the Modified method of the Designer object (a property of the base class property editor). We don't need this Modified call in the example, as the base class SetValue method does this automatically for us.

The Edit method above displays a dialog box, a standard Delphi form that is built visually, as always, and added to the package hosting the design-time components. The form is quite simple; a ComboBox displays the values returned by the GetValues method, and four buttons allow you to open a file, test the sound, and terminate the dialog box by accepting the values or canceling. You can see an example of the dialog box in Figure 11.13. Providing a drop-down list of values *and* a dialog box for editing a property causes the Object Inspector to display only the arrow button that indicates a drop-down list and to omit the ellipsis button to indicate that a dialog box editor is available.

FIGURE 11.13:

The Sound Property Editor's form displays a list of available sounds and lets you load a file and hear the selected sound.

All shown

Sound File: RestoreDown

The first two buttons of the form each have a simple method assigned to their `OnClick` event:

```
procedure TSoundForm.btnLoadClick(Sender: TObject);
begin
  if OpenDialog1.Execute then
    ComboBox1.Text := OpenDialog1.FileName;
end;

procedure TSoundForm.btnPlayClick(Sender: TObject);
begin
  PlaySound (PChar (ComboBox1.Text), 0, snd_Async);
end;
```

Unfortunately, I haven't found a simple way to determine whether a sound is properly defined and is available. (Checking the file is possible, but the system sounds create a few issues.) The `PlaySound` function returns an error code when played synchronously, but only if it can't find the default system sound it attempts to play if it can't find the sound you asked for. If the requested sound is not available, it plays the default system sound and doesn't return the error code. `PlaySound` looks for the sound in the Registry first and, if it doesn't find the sound there, checks to see whether the specified sound file exists.

TIP

If you want to further extend this example, you might add graphics to the drop-down list displayed in the Object Inspector—if you can decide which graphics to attach to particular sounds.

Installing the Property Editor

After you've written this code, you can install the component and its property editor in Delphi. To accomplish this, you have to add the following statement to the Register procedure of the unit:

```
procedure Register;
begin
  RegisterPropertyEditor (TypeInfo(string), TMdSoundButton, 'SoundUp',
    TSoundProperty);
  RegisterPropertyEditor (TypeInfo(string), TMdSoundButton, 'SoundDown',
    TSoundProperty);
end;
```

This call registers the editor specified in the last parameter for use with properties of type string (the first parameter), but only for a specific component and for a property with a specific name. These last two values can be omitted to provide more general editors. Registering this editor allows the Object Inspector to show a list of values and the dialog box called by the Edit method.

To install this component we can simply add its source code file into an existing or new package. Instead of adding this unit and the others of this chapter to the MdPack package, I built a second package, containing all the add-ins built in this chapter. The package is named MdDesPk (which stands for "*Mastering Delphi* design package"). What's new about this package is that I've compiled it using the {$DESIGNONLY} compiler directive. This directive is used to mark packages that interact with the Delphi environment, installing components and editors, but are not required at run time by applications you've built.

NOTE The source code of all of the add-on tools is in the MdDesPk subdirectory, along with the code of the package used to install them. There are no examples demonstrating how to use these design-time tools, because all you have to do is select the corresponding components in the Delphi environment and see how they behave.

The property editor's unit uses the SoundB unit, which defines the TMdSoundButton component. For this reason the new package should refer to the existing package. Here is its initial code (I'll add other units to it later in this chapter):

```
package MdDesPk;

{$R *.RES}
{$ALIGN ON}
...
{$DESCRIPTION 'Mastering Delphi DesignTime Package'}
{$DESIGNONLY}
```

```
requires
  vcl,
  Mdpack;

contains
  PeSound in 'PeSound.pas',
  PeFSound in 'PeFSound.pas' {SoundForm};
```

Writing a Component Editor

Using property editors allows the developer to make a component more user-friendly. In fact, the Object Inspector represents one of the key pieces of the user interface of the Delphi environment, and Delphi developers use it quite often. However, there is a second approach you can adopt to customize how a component interacts with Delphi: write a custom component editor.

Just as property editors extend the Object Inspector, component editors extend the Form Designer. In fact, when you right-click within a form at design time, you see some default menu items, plus the items added by the component editor of the selected component. Examples of these menu items are those used to activate the Menu Designer, the Fields Editor, the Visual Query Builder, and other editors of the environment. At times, displaying these special editors becomes the default action of a component when it is double-clicked.

Common uses of component editors include adding an About box with information about the developer of the component, adding the component name, and providing specific wizards to set up its properties.

Subclassing the *TComponentEditor* Class

A component editor should generally inherit from the `TComponentEditor` class, which provides the base implementation of the `IComponentEditor` interface. The most important methods of this interface are:

- `GetVerbCount` returns the number of menu items to add to the local menu of the Form Designer when the component is selected.
- `GetVerb` is called once for each new menu item and should return the text that will go in the local menu for each.
- `ExecuteVerb` is called when one of the new menu items is selected. The number of the item is passed as the method's parameter.
- `Edit` is called when the user double-clicks the component in the Form Designer to activate the default action.

Once you get used to the idea that a "verb" is nothing but a new menu item with a corresponding action to execute, the names of the methods of this interface become quite intuitive. This interface is actually much simpler than those of property editors we've seen before.

NOTE Like property editors, component editors were modified extensively from Delphi 5 to Delphi 6, and are now defined in the DesignEditors and DesignIntf units. But, again, the simpler examples like this one keep compiling almost unchanged, so I won't delve into the differences.

A Component Editor for the ListDialog

Now that I've introduced the key ideas about writing component editors, we can look at an example, an editor for the ListDialog component built earlier. In my component editor, I simply want to be able to show an About box, add a copyright notice to the menu (an improper but very common use of component editors), and allow users to perform a special action—previewing the dialog box connected with the dialog component. I also want to change the default action to simply show the About box after a beep (which is not particularly useful but demonstrates the technique).

To implement this property editor, the program must override the four methods listed above:

```
uses
  DesignIntf;

type
  TMdListCompEditor = class (TComponentEditor)
    function GetVerbCount: Integer; override;
    function GetVerb(Index: Integer): string; override;
    procedure ExecuteVerb(Index: Integer); override;
    procedure Edit; override;
  end;
```

The first method simply returns the number of menu items I want to add to the local menu:

```
function TMdListCompEditor.GetVerbCount: Integer;
begin
  Result := 3;
end;
```

This method is called only once, before displaying the menu. The second method, instead, is called once for each menu item, so in this case it is called three times:

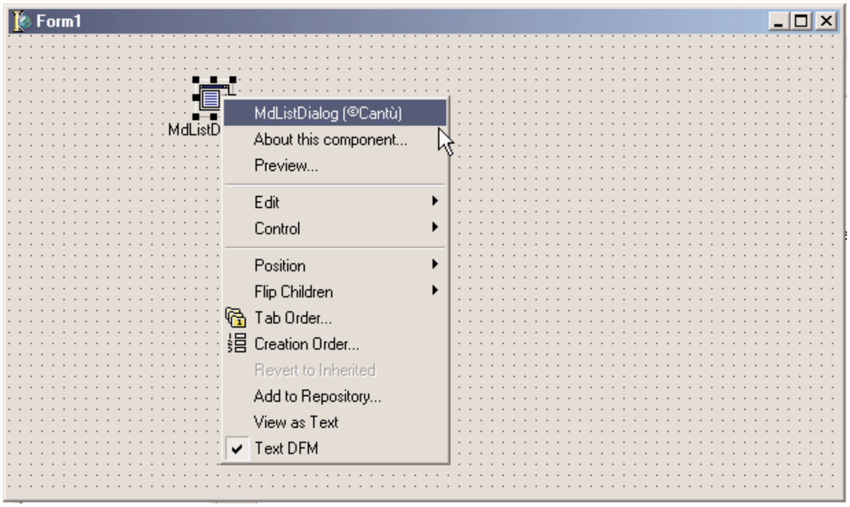
```
function TMdListCompEditor.GetVerb (Index: Integer): string;
begin
```

```
  case Index of
    0: Result := ' MdListDialog (©Cantù)';
    1: Result := '&About this component...';
    2: Result := '&Preview...';
  end;
end;
```

The effect of this code is to add the menu items to the local menu of the form, as you can see in Figure 11.14. Selecting any of these menu items just activates the ExecuteVerb method of the component editor:

```
procedure TMdListCompEditor.ExecuteVerb (Index: Integer);
begin
  case Index of
    0..1: MessageDlg ('This is a simple component editor'#13 +
      'built by Marco Cantù'#13 +
      'for the book "Mastering Delphi"', mtInformation, [mbOK], 0);
    2: with Component as TMdListDialog do
      Execute;
  end;
end;
```

FIGURE 11.14: The custom menu items added by the property editor of the ListDialog component



I decided to handle the first two items in a single branch of the case statement, although I could have skipped the code for the copyright notice item. The other command changes calls the Execute method of the component we are editing, determined using the Component property of the TComponentEditor class. Knowing the type of the component, we can easily access its methods after a dynamic type cast.

The last method refers to the default action of the component and is activated by double-clicking it in the Form Designer:

```
procedure.Edit;
begin
x
  Beep;
  ExecuteVerb (0);
end;
```

Registering the Component Editor

To make this editor available to the Delphi environment, we need to register it. Once more we can add to its unit a `Register` procedure and call a specific registration procedure for component editors:

```
procedure TMdListCompEditor.Edit;
begin
  // produce a beep and show the about box
  Beep;
  ExecuteVerb (0);
end;
```

I've added this unit to the MdDesPk package, which includes all of the design-time extensions of this chapter. After installing and activating this package you can create a new project, place a tabbed list component in it, and experiment with it.

What's Next?

In this chapter we have seen how to define various types of properties, how to add events, and how to define and override component methods. We have seen various examples of components, including simple changes to existing ones, new graphical components, and, in the final section, a dialog box inside a component. While building these components, we have faced some new Windows programming challenges. In general, programmers often need to use the Windows API directly when writing new Delphi components.

Writing components is a very handy technique for reusing software, but to make your components easier to use, you should try to integrate them as much as possible within the Delphi environment, writing property editors and component editors.

There are many more extensions of the Delphi IDE you can write, including custom wizards. I've personally built many Delphi extensions, some of which are available (with source code) on my Web site, `www.marcocantu.com`.

After discussing components and delving a little into the Delphi environment, the next chapter focuses on Delphi DLLs. We have already met DLLs in many previous chapters, and it is time for a detailed discussion of their role and how to build them. In the same chapter, I'll also further discuss the use of Delphi packages, which are a special type of DLL.

Chapter 12

Libraries and Packages

- DLLs in Windows 95, 98, and NT
- Building and using DLLs in Delphi
- Calling DLL functions at run time
- Sharing data in DLLs
- The structure of Delphi packages
- Placing forms in packages and DLLs

Windows executable files come in two flavors: *programs* and *dynamic link libraries* (DLLs). When you write a Delphi application, you typically generate a program file, an EXE. However, Delphi applications often use calls to functions stored in DLLs. Each time you call a Windows API function directly, you actually access a DLL. Delphi also allows programmers to use run-time DLLs for the component library. When you create a package, you basically create a DLL. Delphi can also generate plain dynamic link libraries. The New page of the Object Repository includes a DLL skeleton generator, which generates very few lines of source code.

It is very simple to generate a DLL in the Delphi environment. However, some problems arise from the nature of DLLs. Writing a DLL in Windows is not always as simple as it seems, because the DLL and the calling program need to agree on calling conventions, parameter types, and other details. This chapter covers the basics of DLL programming from the Delphi point of view and provides some simple examples of what you can place in a Delphi DLL. While discussing the examples, I'll also refer to other programming languages and environments, simply because one of the key reasons for writing a procedure in a DLL is to be able to call it from a program written in a different language.

The second part of the chapter will focus on a specific type of dynamic link library, the Delphi *package*. These packages are not as easy to use as they first seem, and it took Delphi programmers some time to figure out how to take advantage of them effectively. Here I'm going to share with you some of these interesting tips and techniques.

The Role of DLLs in Windows

Before delving into the development of DLLs in Delphi and other programming languages, I'll give you a short technical overview of DLLs in Windows, highlighting the key elements. We will start by looking at dynamic linking, then see how Windows uses DLLs, explore the differences between DLLs and executable files, and end with some general rules to follow when writing DLLs.

What Is Dynamic Linking?

First of all, you need to understand the difference between static and dynamic linking of functions or procedures. When a subroutine is not directly available in a source file, the compiler adds the subroutine to an internal table, which includes all external symbols. Of course, the compiler must have seen the declaration of the subroutine and know about its parameters and type, or it will issue an error.

After compilation of a normal—*static*—subroutine, the linker fetches the subroutine's compiled code from a Delphi compiled unit (or static library) and adds it to the executable. The resulting EXE file includes all the code of the program and of the units involved. The Delphi linker is smart enough to include only the minimum amount of code of the units used by the program and to link only the functions and methods that are actually used.

NOTE A notable exception to this rule is the inclusion of virtual methods. The compiler cannot determine in advance which virtual methods the program is going to call, so it has to include them all. For this reason, programs and libraries with too many virtual functions tend to generate larger executable files. While developing the VCL, the Borland developers had to balance the flexibility obtained with virtual functions against the reduced size of the executable files achieved by limiting the virtual functions.

In the case of dynamic linking, which occurs when your code calls a DLL-based function, the linker simply uses the information in the `external` declaration of the subroutine to set up some tables in the executable file. When Windows loads the executable file in memory, first it loads all the required DLLs, and then the program starts. During this loading process, Windows fills the program's internal tables with the addresses of the functions of the DLLs in memory. If for some reason the DLL is not found, the program won't even start, often complaining with nonsense error messages (such as the notorious "a device attached to your system is not functioning").

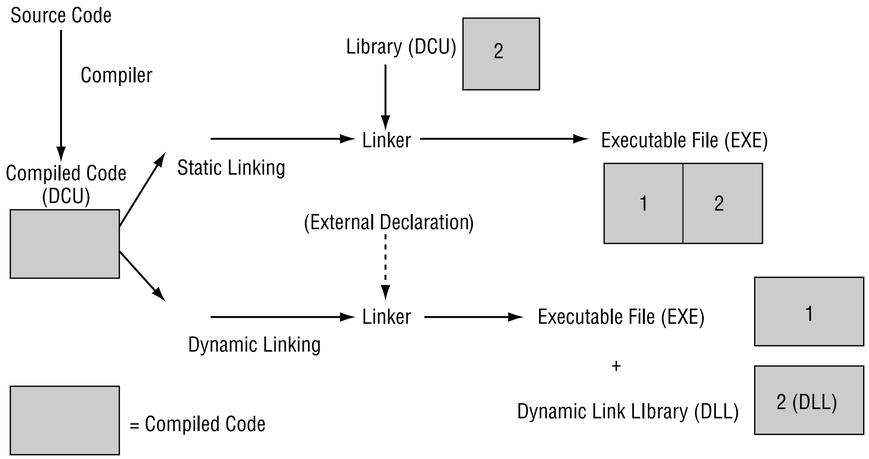
Each time the program calls an external function, it uses this internal table to forward the call to the DLL code (which is now located in the program's address space). Note that this scheme does not involve two different applications. The DLL becomes part of the running program and is loaded in the same address space. All the parameter passing takes place on the application's stack (because the DLL doesn't have a separate stack).

You can see a sketch of how the program calls statically or dynamically linked functions in Figure 12.1. Notice that I haven't yet discussed compilation of the DLL—because I wanted to focus on the two different linking mechanisms first.

NOTE The term *dynamic linking*, when referring to DLLs, has nothing to do with the late-binding feature of object-oriented programming languages. Virtual and dynamic methods in Object Pascal have nothing to do with DLLs. Unfortunately, the same term is used for both kinds of procedures and functions, which causes a lot of confusion. When I speak of dynamic linking in this chapter, I am referring not to polymorphism but to DLL functions.

FIGURE 12.1:

Static and dynamic linking in Windows



There is another approach to using DLLs, which is even more dynamic than the one we have just discussed. In fact, at run time, you can load a DLL in memory, search for a function (provided you know its name), and call the function by name. This approach requires more complex code and takes some extra time to locate the function. The execution of the function, however, has the same speed of the call of an implicitly loaded DLL. On the positive side, you don't need to have the DLL available to start the program. We will use this approach in the DynaCall example later in the chapter.

For the most part, the internal structure of a normal executable file (an EXE file) and a dynamic link library (a DLL, whatever its extension) is the same. They are both executable files. An important difference between programs and DLLs is that a DLL, even when loaded in memory, is not a running program. It is only a collection of procedures and functions that other programs can call. These procedures and functions use the stack of the calling program (the *calling thread*, to be precise). So another difference between a program and a library is that a library doesn't create its own stack—it uses the stack of the program calling it. In Win32, because a DLL is loaded into the application's address space, any memory allocations of the DLL or any global data it creates reside in the address space of the main process.

What Are DLLs For?

Now that you have a general idea of how DLLs work, we can focus on the reasons for using them in Windows:

- If different programs use the same DLL, the DLL is loaded in memory only once, thus saving system memory. DLLs are mapped into the private address space of each process (each running application), but their code is loaded in memory only once.

NOTE The operating system will try to load the DLL at the same address in each application's address space (using the preferred base address specified by the DLL). If that address is not available in a particular application's virtual address space, the DLL code image for that process will have to be relocated, an operation that is expensive in both performance and memory use. The reason is that the relocation happens on a per-process basis, not system-wide.

- You can provide a different version of a DLL, replacing the current one. If the subroutines in the DLL have the same parameters, you can run the program with the new version of the DLL without having to recompile it. If the DLL has new subroutines, it doesn't matter at all. Problems might arise only if a routine in the older version of the DLL is missing in the new one. Problems also arise if the new DLL does not implement the functions in a manner that is compatible with the operation of the old DLL.

These generic advantages apply in several cases. If you have a complex algorithm, or some complex forms required by several applications, you can store them in a DLL. This will let you reduce the executable's size and save some memory when you run several programs using those DLLs at the same time.

The second advantage is particularly applicable to complex applications. If you have a very big program that requires frequent updates and bug fixes, dividing it into several executables and DLLs allows you to distribute only the changed portions instead of one single large executable. This makes sense for Windows system libraries in particular: You generally don't need to recompile your code if Microsoft provides you an updated version of Windows system libraries—for example, in a new version of the operating system.

Another common technique is to use DLLs to store nothing except resources. You can build different versions of a DLL containing strings for different languages and then change the language at run time, or you can prepare a library of icons and bitmaps and then use them in different applications. The development of language-specific versions of a program is particularly important, and Delphi includes support for it through the Integrated Translation Environment (ITE) and the external environment, which are more advanced topics than I have room to go into.

Another key advantage is that DLLs are independent of the programming language. Most Windows programming environments, including most macro languages in end-user applications, allow a programmer to call a subroutine stored in a DLL. This means you can build a DLL in Delphi and call it from Visual Basic, Excel, and many other Windows applications.

Understanding System DLLs

The Windows system DLLs take advantage of all the key benefits of DLLs I've just highlighted. For this reason, it is worth examining them. First of all, Windows has many system DLLs. The three central portions of Windows—Kernel, User, and GDI—are implemented using DLLs (with 32-bit or 16-bit code depending on the OS version). Other system DLLs are operating-system extensions, such as the DLLs for common dialog boxes and controls, OLE, device drivers, fonts, ActiveX controls, and hundreds of others.

Dynamic system libraries are one of the technical foundations of the Windows operating systems. Since each application uses the system DLLs for anything from creating a window to producing output, every program is linked to those DLLs. When you change your printer, you do not need to rebuild your application or get a new version of the Windows GDI library, which manages the printer output. You only need to provide a specific driver, which is a DLL called by GDI to access your printer. Each printer type has its own driver DLL, which makes the system extremely flexible.

From a different point of view, version handling is important for the system itself. If you have an application compiled for Windows 95, you should be able to run it on Windows Me, Windows 2000, and (possibly) future versions of Windows, but the application might behave differently, as each version of Windows has different system code.

The system DLLs are also used as system-information archives. For example, the User DLL maintains a list of all the active windows in the system, and the GDI DLL holds the list of active pens, brushes, icons, bitmaps, and the like. The free memory area of these two system DLLs is usually called "free system resources," and the fact that it is limited plays a very important role in Windows versions still relying on 16-bit code, such as the Windows 9*x* family. On NT platforms, GDI and User resources are limited only by available system memory.

Rules for Delphi DLL Writers

In short, there are some rules for Delphi DLL programmers. A DLL function or procedure to be called by external programs must follow these guidelines:

- It has to be listed in the DLL's `exports` clause. This makes the routine visible to the outside world.
- Exported functions should also be declared as `stdcall`, to use the standard Win32 parameter-passing technique instead of the optimized `register` parameter-passing technique (which is the default in Delphi). The exception to this rule is if you want to use these libraries only from other Delphi applications.

- The types of the parameters of a DLL should be the default Windows types, at least if you want to be able to use the DLL within other development environments. There are further rules for exporting strings, as we'll see in the FirstDll example.
- A DLL can use global data that won't be shared by calling applications. Each time an application loads a DLL, it stores the DLL's global data in its own address space, as we will see in the DllMem example.

Using Existing DLLs

We have already used existing DLLs in examples in this book, when calling Windows API functions. As you might remember, all the API functions are declared in the system Windows unit. Functions are declared in the `interface` portion of the unit, as shown here:

```
function PlayMetaFile(DC: HDC; MF: HMETAFILE): BOOL; stdcall;
function PaintRgn(DC: HDC; RGN: HRGN): BOOL; stdcall;
function PolyPolygon(DC: HDC; var Points; var nPoints; p4: Integer):
  BOOL; stdcall;
function PtInRegion(RGN: HRGN; p2, p3: Integer): BOOL; stdcall;
```

Then, in the `implementation` portion, instead of providing each function's code, the unit refers to the external definition in a DLL:

```
const
  gdi32 = 'gdi32.dll';

function PlayMetaFile; external gdi32 name 'PlayMetaFile';
function PaintRgn; external gdi32 name 'PaintRgn';
function PolyPolygon; external gdi32 name 'PolyPolygon';
function PtInRegion; external gdi32 name 'PtInRegion';
```

NOTE In `Windows.PAS` there is a heavy use of the `{$EXTERNALSYM identifier}` directive. This has little to do with Delphi itself; it applies to C++Builder. This symbol prevents the corresponding Pascal symbol from appearing in the C++ translated header file. This helps keep the Delphi and C++ identifiers in synch, so that code can be shared between the two languages.

The external definition of these functions refers to the name of the DLL they use. The name of the DLL must include the .DLL extension, or the program will not work under Windows 2000 (even though it will work under Windows 9*x*). The other element is the name of the DLL function itself. The `name` directive is not necessary if the Pascal function (or procedure) name matches the DLL function name (which is case-sensitive).

To call a function that resides in a DLL, you can provide its declaration and external definition, as shown above, or you can merge the two in a single declaration. Once the function is properly defined, you can call it in the code of your Delphi application just like any other function.

Using a C++ DLL

As an example, I've written a very simple DLL in C++, with some trivial functions, just to show you how to call DLLs from a Delphi application. I won't explain the C++ code in detail (it's basically C code, anyway) but will focus instead on the calls between the Delphi application and the C++ DLL. In Delphi programming it is common to use DLLs written in C or C++.

Suppose you are given a DLL built in C or C++. You'll generally have in your hands a .DLL file (the compiled library itself), an .H file (the declaration of the functions inside the library), and a .LIB file (another version of the list of the exported functions for the C/C++ linker). This LIB file is totally useless in Delphi, while the DLL file is used as-is, and the H file has to be translated into a Pascal unit with the corresponding declarations.

In the following listing, you can see the declaration of the C++ functions I've used to build the CppDll library example. The complete source code and the compiled version of the C++ DLL and of the source code of the Delphi application using it are in the `CppDll` directory on the CD. You should be able to compile this code with any C++ compiler; I've tested it only with recent Borland C++ compilers. Here are the C++ declarations of the functions:

```
extern "C" __declspec(dllexport)
int WINAPI Double (int n);
extern "C" __declspec(dllexport)
int WINAPI Triple (int n);
__declspec(dllexport)
int WINAPI Add (int a, int b);
```

The three functions perform some basic calculations on the parameters and return the result. Notice that all the functions are defined with the `WINAPI` modifier, which sets the proper parameter-calling convention; and they are preceded by the `__declspec(dllexport)` declaration, which makes the functions available to the outside world.

Two of these C++ functions also use the C naming convention (indicated by the `extern "C"` statement), but the third one, `Add`, doesn't. This affects the way we call these functions in Delphi. In fact, the internal names of the three functions correspond to their names in the C++ source code file, except for the `Add` function. Since we didn't use the `extern "C"` clause for this function, the C++ compiler used *name mangling*. This is a technique used to include information about the number and type of parameters in the function name, which the C++ language requires in order to implement function overloading. The result when using the Borland C++ compiler is a funny function name: `@Add$qqsii`. This is actually the name we have to use in our Delphi example to call the `Add` DLL function (which explains why you'll generally avoid C++ name mangling in exported functions, and why you'll generally declare them all as `extern "C"`). The following are the declarations of the three functions in the Delphi CallCpp example:

```
function Add (A, B: Integer): Integer;
  stdcall; external 'CPPDLL.DLL' name '@Add$qqsii';
```

```
function Double (N: Integer): Integer;
  stdcall; external 'CPPDLL.DLL' name 'Double';
function Triple (N: Integer): Integer;
  stdcall; external 'CPPDLL.DLL';
```

As you can see, you can either provide or omit an alias for an external function. I've provided one for the first function (there was no alternative, because the exported DLL function name `@Add$qqsii` is not a valid Pascal identifier) and for the second, although in the second case it was unnecessary. If the two names match, in fact, you can omit the `name` directive, as I did for the third function above. If you are not sure of the actual names of the functions exported by the DLL, you can use the optional Windows viewer for executable files, with the QuickView command of Windows Explorer or Borland's TDump32 command-line program, available in the Delphi `BIN` folder.

Remember to add the `stdcall` directive to each definition, so that the caller module (the application) and the module being called (the DLL) use the same parameter-passing convention. If you fail to do so, you will get random values passed as parameters, a bug that is very hard to trace.

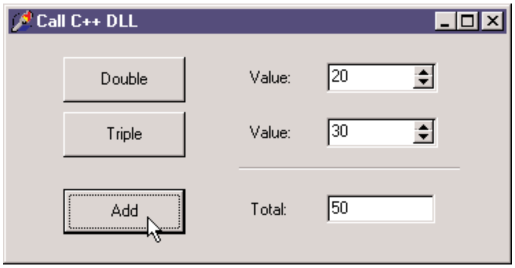
NOTE When you have to convert a large C/C++ header file to the corresponding Pascal declarations, instead of doing a manual conversion you can use a tool to partially automate the process. One of these tools is HeadConv, written by Bob Swart. You'll find a copy on his Web site, `www.drbob42.com`. Notice, though, that automatic header translation from C/C++ to Pascal is not possible, because Pascal is more strongly typed than C/C++, so you have to use types more precisely.

To use this C++ DLL, I've built a Delphi example, named CallCpp. Its simple form has buttons to call the functions of the DLL and some visual components for input and output parameters (see Figure 12.2). The code of the button event handlers looks like:

```
procedure TForm1.BtnDoubleClick(Sender: TObject);
begin
  SpinEdit1.Value := Double (SpinEdit1.Value);
end;
```

FIGURE 12.2:

The output of the CallCpp example when you have pressed each of the buttons



Value: 20

Value: 30

Total: 50

Notice that to run this application, you should have the DLL in the same directory as the project, in one of the directories on the path, or in the Windows or System directories. If you move the executable file to a new directory and try to run it, you'll get a run-time error indicating that the DLL is missing.

Creating a DLL in Delphi

Besides using DLLs written in other environments, you can use Delphi to build DLLs that can be used by Delphi programs or with any other development tool that supports DLLs. Building DLLs in Delphi is so easy that you might overuse this feature. In general, I suggest you try to build components and packages instead of plain DLLs. As I'll discuss later in this chapter, packages often contain components, but they can also include plain noncomponent classes, allowing you to write object-oriented code and to reuse it effectively.

Placing a collection of functions in a DLL is a more traditional approach to programming: DLLs cannot export classes and objects, at least unless you use Microsoft's COM technology or some other advanced techniques.

As I've already mentioned, building a DLL is useful when a portion of the code of a program is subject to frequent changes. In this case you can frequently replace the DLL, keeping the rest of the program unchanged. Similarly, when you need to write a program that provides different features to different groups of users, you can distribute different versions of a DLL to those users.

A Simple Delphi DLL

As a starting point in exploring the development of DLLs in Delphi, I'll show you a very simple library built in Delphi. The primary focus of this example will be to show the syntax you use to define a DLL in Delphi, but it will also illustrate a few considerations involved in passing string parameters. To start, select the File > New > Other command and choose the DLL option in the New page of the Object Repository. This creates a very simple source file that starts with the following definition:

```
library Project1;
```

The library statement indicates that we want to build a DLL instead of an executable file. Now we can add routines to the library and list them in an exports statement:

```
function Triple (N: Integer): Integer; stdcall;
begin
  Result := N * 3;
end;
```

```
function Double (N: Integer): Integer; stdcall;
begin
  Result := N * 2;
end;

exports
  Triple, Double;
```

In this basic version of the DLL, we don't need a `uses` statement; but in general, the main project file includes only the `exports` statement, while the function declarations are placed in a separate unit. In the final source code of the FirstDll example on the CD, I've actually changed the code slightly from the version listed above, to show a message each time a function is called. There are two ways to accomplish this. The simplest is to use the Dialogs unit and call the ShowMessage function.

The code requires Delphi to link a lot of VCL code into the application. If you statically link the VCL into this DLL, the resulting size will be about 375 KB. The reason is that the `ShowMessage` function displays a VCL form that contains VCL controls and uses VCL graphics classes; and those indirectly refer to things like the VCL streaming system and the VCL application and screen objects. For this simple case, a better alternative is to show the messages using direct API calls, using the Windows unit and calling the MessageBox function, so that the VCL code is not required. This change in code brings the size of the application down to only about 40 KB.

NOTE This huge difference in size underlines the fact that you should not overuse DLLs in Delphi, to avoid compiling the code of the VCL in multiple executable files. Of course, you can reduce the size of a Delphi DLL by using run-time packages, as detailed later in this chapter.

If you run a test program like the CallFrst example (described later) using the API-based version of the DLL, its behavior won't be correct. In fact, you can click the buttons that call the DLL functions several times without first closing the message boxes displayed by the DLL. This happens because the first parameter of the `MessageBox` API call above is zero. Its value should instead be the handle of the program's main form or the application form, information I don't have at hand in the DLL itself.

Overloaded Functions in Delphi DLLs

When you create a DLL in C++, overloaded functions use name mangling to generate a different name for each function, including the type of the parameters right in the name, as we've seen in the CppDll example.

When you create a DLL in Delphi and use overloaded functions (that is, multiple functions using the same name and marked with the overload directive), Delphi allows you to export only one of the overloaded functions with the original name, indicating its parameters list in the exports clause. If you want to export multiple overloaded functions, you should specify different names in the exports clause to distinguish the overloads. This is demonstrated by this portion of the FirstDLL code:

```
function Triple (C: Char): Integer; stdcall; overload;
function Triple (N: Integer): Integer; stdcall; overload;

exports
  Triple (N: Integer),
  Triple (C: Char) name 'TripleChar';
```

NOTE The reverse is possible as well: You can import a series of similar functions from a DLL and define them all as overloaded functions in the Pascal declaration. Delphi's OpenGL.PAS unit contains a series of examples of this technique.

Exporting Strings from a DLL

In general, functions in a DLL can use any type of parameter and return any type of value. There are two exceptions to this rule:

- If you plan to call the DLL from other programming languages, you should probably try using Windows native data types instead of Delphi-specific types. For example, to express color values, you should use integers or the Windows ColorRef type instead of the Delphi native TColor type, doing the appropriate conversions (as in the FormDLL example, described in the next section). Other Delphi types that, for compatibility, you should avoid using include objects, which cannot be used by other languages at all, and Pascal strings, which can be replaced by PChar strings. In other words, every Windows development environment must support the basic types of the API, and if you stick to them, your DLL will be usable with other development environments. Also, Pascal file variables (text files and binary file of record) should not be passed out of DLLs, but you can use Win32 file handles.
- Even if you plan to use the DLL only from a Delphi application, you cannot pass Delphi strings (and dynamic arrays) across the DLL boundary without taking some precautions. This is because of the way Delphi manages strings in memory—allocating, reallocating, and freeing them automatically. The solution to the problem is to include the ShareMem system unit both in the DLL and in the program using it. This unit must be included as the first unit of each of the projects.

NOTE Objects actually can be passed out of a DLL, if the objects are designed to be used like interfaces or pure abstract classes. All methods of these objects must be virtual, and objects must be created by the DLL. This is more or less what happens with COM objects, the approach you should use for multilanguage applications. For Delphi-only projects with libraries exporting objects, you should rather use packages, as we'll see later in this chapter.

In the FirstDLL example, I've actually included both approaches: One function receives and returns a Pascal string, and another one receives as parameter a PChar pointer, which is then filled by the function itself. The first function is very simple:

```
function DoubleString (S: string; Separator: Char): string; stdcall;
begin
  Result := S + Separator + S;
end;
```

The second one is quite complex because PChar strings don't have a simple + operator, and they are not directly compatible with characters; the separator must be turned into a string before adding it. Here is the complete code; it uses input and output PChar buffers, which are compatible with any Windows development environment:

```
function DoublePChar (BufferIn, BufferOut: PChar;
  BufferOutLen: Cardinal; Separator: Char): LongBool; stdcall;
var
  SepStr: array [0..1] of Char;
begin
  // if the buffer is large enough
  if BufferOutLen > StrLen (BufferIn) * 2 + 2 then
  begin
    // copy the input buffer in the output buffer
    StrCopy (BufferOut, BufferIn);
    // build the separator string (value plus null terminator)
    SepStr [0] := Separator;
    SepStr [1] := #0;
    // append the separator
    StrCat (BufferOut, SepStr);
    // append the input buffer once more
    StrCat (BufferOut, BufferIn);
    Result := True;
  end
  else
    // not enough space
    Result := False;
end;
```

This second version of the code is certainly more complex, but the first can be used only from Delphi. Moreover, the first version requires us to include the ShareMem unit in the DLL (and in the programs using it) and to deploy the file BorlndMM.DLL (the name stands for Borland Memory Manager) along with the program and the specific library.

Calling the Delphi DLL

How can we use the library we've just built? We can call it from within another Delphi project or from other environments. As an example, I've built the CallFrst project (stored in the `FirstDLL` directory).

To access the DLL functions, we must declare them as `external`, as we've done with the C++ DLL. This time, however, we can simply copy and paste the definition of the functions from the source code of the Delphi DLL, adding the `external` clause, as in:

```
function Double (N: Integer): Integer;
  stdcall; external 'FIRSTDLL.DLL';
```

This declaration is similar to those used to call the C++ DLL. This time, however, we have no problems with function names. The source code of the example is actually quite simple. Once they are redeclared as `external`, the functions of the DLL can simply be used as if they were local functions. Here are two examples, with calls to the string-related functions:

```
procedure TForm1.BtnDoubleStringClick(Sender: TObject);
begin
  // call the DLL function directly
  EditDouble.Text := DoubleString (EditSource.Text, ';');
end;

procedure TForm1.BtnDoublePCharClick(Sender: TObject);
var
  Buffer: string;
begin
  // make the buffer large enough
  SetLength (Buffer, 1000);
  // call the DLL function
  if DoublePChar (PChar (EditSource.Text), PChar (Buffer), 1000, '/') then
    EditDouble.Text := Buffer;
end;
```

Figure 12.3 shows the effect of this program's calls to the DLL.

Project and Library Names in Delphi 6

For a library, as for a standard application, you end up with a library name matching a Delphi project filename. Following a similar technique introduced in Kylix for compatibility with standard Linux naming conventions for shared object libraries (the Linux equivalent of Windows DLLs), Delphi 6 introduced special compiler directives you can use in libraries to determine their executable filename. Some of these directives make more sense in the Linux world than on Windows, but they've all been added anyway.

- `$LIBPREFIX` is used to add something in front of the library name. Paralleling the Linux technique of adding *lib* in front of library names, this directive is used by Kylix to add *bpl* at the beginning of package names. This is due to the fact that Linux uses a single extension (`.so`) for libraries, while in Windows you can have different library extensions, something Borland uses for packages (`.bpl`).
- `$LIBSUFFIX` is used to add text after the library name and before the extension. This can be used to specify versioning information or other variations on the library name and can be quite useful also on Windows.
- `$LIBVERSION` is used to add a version number after the extension—something very common in Linux, but you should generally avoid this on Windows.

As an example, consider the following directives, which generate a library called `MarcoNameTest60.dll`:

```
library NameTest;
{$LIBPREFIX 'Marco'}
{$LIBSUFFIX '60'}
```

NOTE Unlike past versions, Delphi 6 packages use the `$LIBSUFFIX` directive extensively. For this reason, the VCL package generates the `VCL.DCP` file and the `VCL60.BPL` file. The advantage of this approach is that you won't need to change the `requires` portions of your packages for every new version of Delphi. Of course, this will become handy to maintain Delphi 7– and Delphi 6–compatible packages, but isn't helpful now for Delphi 5 compatibility.

A Delphi Form in a DLL

Besides writing simple DLLs with functions and procedures, you can place a complete form built with Delphi into a DLL. This can be a dialog box or any other kind of form, and it can be used not only by other Delphi programs, but also by other development environments or macro languages.

To build the FormDLL example, I've built a simple form with three scroll bars you can use to select a color and two preview areas for the resulting pen and brush colors. The form also contains two bitmap buttons and has its `BorderStyle` property set to bsDialog. Aside from developing a form as usual, I've only added two new subroutines to the unit that defines the form. In the `interface` portion of the unit, I've added the following declarations:

```
function GetColor (Col: LongInt): LongInt; stdcall;
procedure ShowColor (Col: LongInt;
  FormHandle: THandle; MsgBack: Integer); stdcall;
```

In both subroutines the `Col` parameter is the initial color. Notice that I've passed it as a long integer, which corresponds to the Windows ColorRef data type. As mentioned before, using the `TColor` Delphi type might have caused problems with non-Delphi applications: Even though a `TColor` is very similar to a ColorRef, these types don't always correspond. When you write a DLL, I suggest you use only the Windows native data types (unless you are sure only Delphi programs will use the DLL).

The `GetColor` function returns the final color (which is the same as the initial color if the user clicks the Cancel button). The value is returned immediately because the function shows the form as a modal form. The `ShowColor` procedure, instead, simply displays the form (as a modeless form) and returns immediately. For this reason the form needs a way to communicate back to the calling form. In this case I've decided to pass as parameters the handle for the window of the calling form and the ID of the message to use to communicate back with it.

In the next sections, you'll see how to write the code of the two subroutines; and you'll also see what problems arise, particularly when you place a modeless form in a DLL. Of course, I'll also provide a few alternative fixes.

Using the DLL Form as Modal

When you want to place a Delphi component (such as a form) in a DLL, you can only provide functions that create, initialize, or run the component or access its properties and data. The simplest approach is to have a single function that sets the data, runs the component, and returns the result, as in the modal version. Here is the code of the function, added to the `implementation` portion of the unit that defines the form:

```
function GetColor (Col: LongInt): LongInt; stdcall;
var
  FormScroll: TFormScroll;
begin
  // default value
  Result := Col;
  try
    FormScroll := TFormScroll.Create (Application);
    try
```

```
        // initialize the data
        FormScroll.SelectedColor := Col;
        // show the form
        if FormScroll.ShowModal = mrOK then
          Result := FormScroll.SelectedColor;
      finally
        FormScroll.Free;
      end;
    except
      on E: Exception do
        MessageDlg ('Error in FormDLL: ' + E.Message, mtError, [mbOK], 0);
    end;
  end;
```

An important element is the structure of the GetColor function. The code creates the form at the beginning, sets some initial values, and then runs the form, eventually extracting the final data. What makes this different from the code we generally write in a program is the use of exception handling:

- A try/except block protects the whole function, so that any exception generated by the function will be trapped, displaying a proper message. The reason for handling every possible exception is that the calling application might be written in any language, in particular one that doesn't know how to handle exceptions. Even when the caller is a Delphi program, it is sometimes useful to use the same protective approach.
- A try/finally block protects the operations on the form, ensuring that the form object will be properly destroyed, even when an exception is raised.

By checking the return value of the ShowModal method, the program determines the result of the function. I've set the default value before entering the try block to ensure that it will always be executed (and also to avoid the compiler warning indicating that the result of the function might be undefined).

Now that we have updated the form and written the code of the unit, we can move to the project source code, which (temporarily) becomes the following:

```
library FormDLL;

uses
  ScrollF in 'SCROLLF.PAS' {FormScroll};

exports
  GetColor;
end.
```

We can now use a Delphi program to test the form we have placed in the DLL. The UseCol example is in the same directory as the previous DLL, FormDLL (and both projects are part of the FormDLL project group, the file `FormDll.BPG`). The form of the UseCol example contains a button to call the `GetColor` function of the DLL. Here is the definition of this function and the code of the `Button1Click` method:

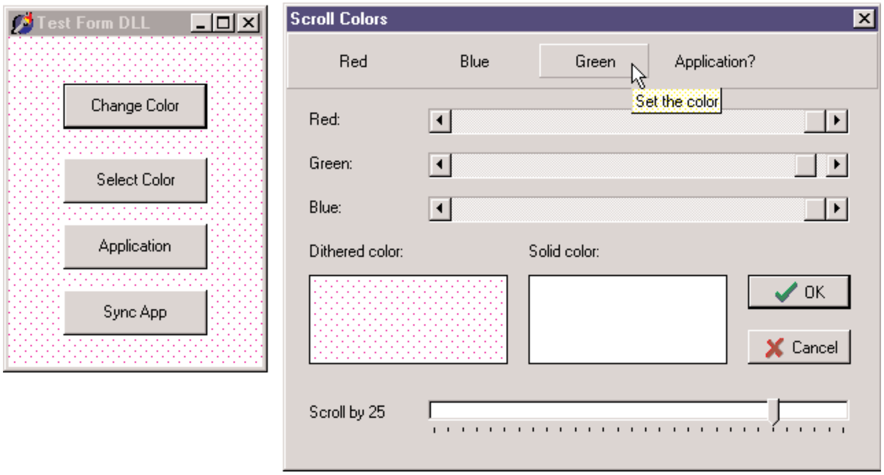
```
function GetColor (Col: LongInt): LongInt; stdcall; external 'FormDLL.DLL';

procedure TForm1.Button1Click(Sender: TObject);
var
  Col: LongInt;
begin
  Col := ColorToRGB (Color);
  Color := GetColor (Col)
end;
```

Running this program (see Figure 12.4) displays the dialog box, using the current background color of the main form. If you change the color and click OK, the program uses the new color as the background color for the main form.

FIGURE 12.4:

The execution of the UseCol test program when it calls the dialog box we have placed in the FormDLL



If you execute this as a modal dialog box, almost all the features of the form work fine. You can see the tooltips, the flat speed buttons in the toolbar behave properly, and you get no extra entry in the task bar. This might be obvious, but is not what will happen when we use the form inside the DLL as a modeless form. Even with modal forms, however, I recommend synchronizing the application objects of the DLL and the executable file, as described in the next section.

A Modeless Form in a DLL

The second subroutine of the FormDLL example uses a different approach. As mentioned, it receives three parameters: the color, the handle of the main form, and the message number for notification when the color changes. These values are stored in the private data of the form:

```
procedure ShowColor (Col: LongInt;
  FormHandle: THandle; MsgBack: Integer); stdcall;
var
  FormScroll: TFormScroll;
begin
  FormScroll := TFormScroll.Create (Application);
  try
    // initialize the data
    FormScroll.FormHandle := FormHandle;
    FormScroll.MsgBack := MsgBack;
    FormScroll.SelectedColor := Col;
    // show the form
    FormScroll.Show;
  except
    on E: Exception do
    begin
      MessageDlg ('Error in FormDLL: ' + E.Message, mtError, [mbOK], 0);
      FormScroll.Free;
    end;
  end;
end;
```

When the form is activated, it checks to see if it was created as a modal form (simply testing the FormHandle field). In this case, the form changes the caption and the behavior of the OK button, as well as the overall style of the Cancel button (you can see the modified buttons in Figure 12.5):

```
procedure TFormScroll.FormActivate(Sender: TObject);
begin
  // change buttons for modeless form
  if FormHandle <> 0 then
  begin
    BitBtn1.Caption := 'Apply';
    BitBtn1.OnClick := ApplyClick;
    BitBtn2.Kind := bkClose;
  end;
end;
```

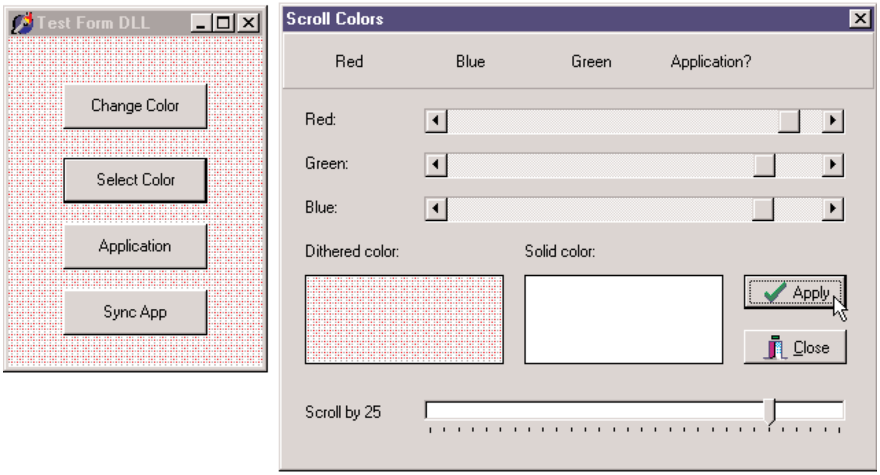


FIGURE 12.5: When the DLL-based form is used as a modeless form, its buttons are slightly modified (as you can see comparing this image with that of Figure 12.4).

The `ApplyClick` method I've manually added to the form simply sends the notification message to the main form, using one of the parameters to send back the selected color:

```
SendMessage (FormHandle, MsgBack, SelectedColor, 0);
```

Finally, the form's `OnClose` event destroys the form object, by setting the `Action` parameter to caFree. Now let's move back to the demo program. The second button of the UseForm example's form has the following code:

```
procedure TForm1.BtnSelectClick(Sender: TObject);
var
  Col: LongInt;
begin
  Col := ColorToRGB (Color);
  ShowColor (Col, Handle, wm_user);
end;
```

The form also has a message-handling method, connected with the `wm_user` message. This method reads the value of the parameter corresponding to the color and sets it:

```
procedure TForm1.UserMessage(var Msg: TMessage);
begin
  Color := Msg.WParam;
end;
```

Running this program produces some strange effects. Basically, the modeless form and the main form are not synchronized, so they both show up in the Windows Taskbar; and when you minimize the main form, the other one remains on the screen. The two forms behave as if they were part of separate applications, because two Delphi programs (the DLL and the EXE) have two separate global `Application` objects, and only the `Application` object of the executable file has an associated window.

To test this situation, I've added a button to both the main form and the DLL form, showing the numeric value of the Application object's handle. Here is the code for one of them:

```
ShowMessage ('Application Handle: ' + IntToStr (Application.Handle));
```

For the form in the DLL, you'll invariably get the value 0, while for the form in the executable you get a numeric value determined each time by Windows.

To fix the problem we can add to the DLL an initialization function that passes the handle of the application window to the library. In practice, we copy the Handle of the executable's Application object to the same property of the DLL's Application object. This is enough to synchronize the two Application objects and make the two forms behave as in a simple Delphi program. Here is the code of the function in the DLL:

```
procedure SyncApp (AppHandle: THandle); stdcall;
begin
  Application.Handle := AppHandle;
end;
```

And here is the call to it in the executable file:

```
procedure TForm1.BtnSyncClick(Sender: TObject);
begin
  SyncApp (Application.Handle);
  BtnSync.Enabled := False;
end;
```

NOTE Assigning the handle of the application object of the DLL is not a work-around for a bug but a documented operation required by the VCL. The VCL Application object supports assignment to its Handle property (unlike most other Handle properties of the VCL) specifically to allow programmers to tie DLL-based forms into the environment of a host application.

I've connected this code to a button, instead of executing it automatically at startup, to let you test the behavior in the two different cases. Before you click the Sync App button, the secondary modeless form behaves oddly. If you close it, synchronize the applications, and then create another instance of the modeless form, it will behave almost correctly. The only visible problem is that the flat speed buttons of the modeless form won't be highlighted when the mouse moves over them. We'll see how to fix this problem using run-time packages at the end of the chapter.

NOTE Technically this behavior of the speed buttons depends on the fact that the controls in the DLL form don't receive the cm_MouseEnter and cm_MouseLeave messages, because the DLL's Application.Idle method is never called. The DLL's Application object, in fact, is not running the application's message loop. You can activate it by exporting from the DLL a function that calls the internal Application.Idle routine, and call that function from the host application when its message loop goes idle. As I've mentioned, however, all these problems (and a few others) can be better solved by using run-time packages.

Calling a Delphi DLL from Visual Basic for Applications

We can also display this color dialog box from other programming languages. Calling this DLL from C or C++ is easy. To link the application, you need to generate an import library (using the `IMPLIB` command-line utility) and add the resulting LIB file to the project. Since I've already used a C++ compiler in this chapter, this time I will write a similar example using Microsoft Word for Windows and Visual Basic for Applications instead.

To start, open Microsoft Word. Then open its Macro dialog box (with the Tools ➢ Macro menu item or a similar command, depending on your version of Word), type a new macro name, such as **DelphiColor**, and click the Create button. You can now write the BASIC code, which declares the function of our DLL and calls it. The BASIC macro uses the result of the DLL function in two ways. By calling `Insert`, it adds to the current document a description of the color with the amount of red, green, and blue; and by calling `Print` it displays the numeric value in the status bar:

```
Declare Function GetColor Lib "FormDLL"(Col As Long) As Long
Sub MAIN
  NewColor = GetColor(0)
  Print "The code of the color is " + Str$(NewColor)
  Insert "Red:" + Str$(NewColor Mod 256) + Chr$(13)
  Insert "Green:" + Str$(Int(NewColor / 256) Mod 256) + Chr$(13)
  Insert "Blue:" + Str$(Int(NewColor / (256 * 256))) + Chr$(13)
End Sub
```

Unfortunately, there is no easy way to use RGB colors in Word, since Word's color schemes are based on fixed color codes. Here is an example of the output of this macro:

```
Red: 141
Green: 109
Blue: 179
```

You can find the text of this macro in the file `WORDCALL.TXT`, in the directory containing this DLL. If you want to test it, remember to first copy the DLL file into one of the directories of the path or into the Windows system directory.

NOTE A better way to integrate Delphi code with Office applications is to use OLE Automation, instead of writing custom DLLs and calling them from the macro language. We'll see examples of OLE Automation in Chapter 20.

Calling a DLL Function at Run Time

Up to now, we've always referenced in our code the functions exported by the libraries, so that the DLLs will be loaded along with the program. I mentioned earlier that we can also delay the loading of a DLL until the moment it is actually needed, so we'd be able to use the rest of the program in case the DLL is not available.

Dynamic loading of a DLL in Windows is accomplished by calling the LoadLibrary API function, which searches the DLL in the program folder, in the folders on the path, and in some system folders. If the DLL is not found, Windows will show an error message, something you can skip by calling Delphi's SafeLoadLibrary function. This function has the same effect as the API it encapsulates, but it suppresses the standard Windows error message and should be the preferred way to load libraries dynamically in Delphi.

If the library is found and loaded (something you know by checking the return value of LoadLibrary or SafeLoadLibrary), a program can call the GetProcAddress API function, which searches the DLL's exports table, looking for the name of the function passed as a parameter. If GetProcAddress finds a match, it returns a pointer to the requested procedure. Now we can simply cast this function pointer to the proper data type and call it.

Whichever loading functions you've used, don't forget to call FreeLibrary at the end, so that the DLL can be properly released from memory. In fact, the system uses a reference-counting technique for libraries, releasing them when each loading request has been followed by a freeing request.

The example I've built to show dynamic DLL loading is named DynaCall and uses the FirstDLL library we built earlier in this chapter (to make the program work, I've copied the DLL into the same folder as the DynaCall example). Instead of declaring the Double and Triple functions and using them directly, this example obtains the same effect with somewhat more complex code. The advantage, however, is that the program will run even without the DLL. Also, if new *compatible* functions are added to the DLL, we won't have to revise the program's source code and recompile it to access those new functions. Here is the core code of the program:

```
type
  TIntFunction = function (I: Integer): Integer; stdcall;

const
  DllName = 'Firstdll.dll';

procedure TForm1.Button1Click(Sender: TObject);
var
  HInst: THandle;
  FPointer: TFarProc;
  MyFunct: TIntFunction;
begin
  HInst := SafeLoadLibrary (DllName);
  if HInst > 0 then
  try
    FPointer := GetProcAddress (HInst,
      PChar (Edit1.Text));
      if FPointer <> nil then
      begin
        MyFunct := TIntFunction (FPointer);
        SpinEdit1.Value := MyFunct (SpinEdit1.Value);
      end
      else
        ShowMessage (Edit1.Text + ' DLL function not found');
    finally
      FreeLibrary (HInst);
    end
    else
      ShowMessage (DllName + ' library not found');
  end;
```

How do you call a procedure in Delphi, once you have a pointer to it? One solution is to convert the pointer to a procedural type and then call the procedure using the procedural-type variable, as in the listing above. Notice that the procedural type you define must be compatible with the definition of the procedure in the DLL. This is the Achilles' heel of this method—there is no check of the parameter types.

What is the advantage of this approach? In theory, you can use it to access any function of any DLL at any time. In practice, it is useful when you have different DLLs with compatible functions or a single DLL with several compatible functions, as in our case. What we can do is to call the `Double` and `Triple` methods simply by entering their names in the edit box. Now, if someone gives us a DLL with a new function receiving an integer as a parameter and returning an integer, we can call it simply by entering its name in the edit box. We don't even need to recompile the application.

With this code, the compiler and the linker ignore the existence of the DLL. When the program is loaded, the DLL is not loaded immediately. We might make the program even more flexible and let the user enter the name of the DLL to use. In some cases, this is a great advantage. A program may switch DLLs at run time, something the direct approach does not allow. Note that this approach to loading DLL functions is common in macro languages and is used by many visual programming environments. Also, the code of the Word macro we saw earlier in this chapter uses this approach to load the DLL and to call the external function. Well, you don't want to recompile Word, do you?

Only a system based on a compiler and a linker, such as Delphi, can use the direct approach, which is generally more reliable and also a little bit faster. I think the indirect loading approach of the DynaCall example is useful only in special cases, but it can be extremely powerful.

A DLL in Memory: Code and Data

We can use this technique, based on the GetProcAddress API function, to test which memory address of the current process a function has been mapped to, with the following code:

```
procedure TForm1.Button3Click(Sender: TObject);
var
  HDLLInst: THandle;
begin
  HDLLInst := SafeLoadLibrary ('dllmem');
  Label1.Caption := Format ('Address: %p', [
    GetProcAddress (HDLLInst, 'SetData')]);
  FreeLibrary (HDLLInst);
end;
```

This code displays, in a label, the memory address of the function, within the address space of the calling application. If you run two programs using this code, they'll generally both show the same address. This demonstrates that the code is loaded only once at a common memory address.

NOTE The memory address will be different if the DLL had to be relocated in one of the processes, or if each process has relocated the DLL to a different base address. In these cases, the code is generally not shared in memory but actually loaded multiple times, because absolute address references in the code must be rewritten to refer to the proper new addresses. As the code is modified by the loader, it cannot be shared.

If the code of the DLL is loaded only once, what about the global data? Basically, each copy of the DLL has its own copy of the data, in the address space of the calling application. However, it is indeed possible to share global data between applications using a DLL. The most common technique for sharing data is to use memory-mapped files. I'll use this technique for a DLL, but it can also be used to share data directly among applications.

This example is called DllMem and uses a project group with the same name, as in the previous examples of this chapter. The DllMem project group includes the DllMem project (the DLL itself) and the UseMem project (the demo application). The DLL code has a simple project file, which exports four subroutines:

```
library dllmem;

uses
  SysUtils,
  DllMemU in 'DllMemU.pas';

exports
  SetData, GetData,
  GetShareData, SetShareData;
end.
```

The actual code is in the secondary unit (DllMemU.PAS), which has the code of the four routines that read or write two global memory locations. These hold an integer and a pointer to an integer. Here are the variable declarations and the two Set routines:

```
var
  PlainData: Integer = 0; // not shared
  ShareData: ^Integer; // shared

procedure SetData (I: Integer); stdcall;
begin
  PlainData := I;
end;

procedure SetShareData (I: Integer); stdcall;
begin
  ShareData^ := I;
end;
```

Sharing Data with Memory-Mapped Files

For the data that isn't shared, there isn't anything else to do. To access the shared data, however, the DLL has to create a memory-mapped file and then get a pointer to this memory area. These two operations require two Windows API calls:

- CreateFileMapping requires as parameters the filename (or $FFFFFFFF to use a virtual file in memory), some security and protection attributes, the size of the data, and an internal name (which must be the same to share the mapped file from multiple calling applications).
- MapViewOfFile requires as parameters the handle of the memory mapped file, some attributes and offsets, and the size of the data (again).

Here is the source code of the initialization section, executed every time the DLL is loaded into a new process space (that is, once for each application that uses the DLL):

```
var
  hMapFile: THandle;

const
  VirtualFileName = 'ShareDllData';
  DataSize = sizeof (Integer);

initialization
  // create memory mapped file
  hMapFile := CreateFileMapping ($FFFFFFFF, nil,
    Page_ReadWrite, 0, DataSize, VirtualFileName);
  if hMapFile = 0 then
    raise Exception.Create ('Error creating memory-mapped file');
```

```
// get the pointer to the actual data
ShareData := MapViewOfFile (
  hMapFile, File_Map_Write, 0, 0, DataSize);
```

When the application terminates and the DLL is released, it has to free the pointer to the mapped file and the file mapping itself:

```
finalization
  UnmapViewOfFile (ShareData);
  CloseHandle (hMapFile);
```

The code of the program using this DLL, UseMem, is very simple. The form of this application has four edit boxes (two with an UpDown control connected), five buttons, and a label. The first button saves the value of the first edit box in the DLL data, getting the value from the connected UpDown control:

```
SetData (UpDown1.Position);
```

If you click the second button, the program copies the DLL data to the second edit box:

```
Edit2.Text := IntToStr(GetData);
```

The third button is used to display the memory address of a function, with the source code shown at the beginning of this section, and the last two buttons have basically the same code as the first two, but they call the `SetShareData` procedure and `GetShareData` function.

If you run two copies of this program, you can see that each copy has its own value for the plain global data of the DLL, while the value of the shared data is common. Set different values in the two programs and then get them in both, and you'll see what I mean. This situation is illustrated in Figure 12.6.

FIGURE 12.6:

If you run two copies of the UseMem program, you'll see that the global data in its DLL is not shared.

WARNING Memory-mapped files reserve a minimum of a 64 KB range of virtual addresses and consume physical memory in 4 KB pages. The example's use of 4-byte Integer data in shared memory is rather expensive, especially if you use the same approach for sharing multiple values. If you need to share several variables, you should place them all in a single shared memory area (accessing the different variables using pointers or building a record structure for all of them).

Using Delphi Packages

In Delphi, component packages are an important type of DLL. Packages allow you to bundle a group of components and then link the components either statically (adding their compiled code to the executable file of your application) or dynamically (keeping the component code in a DLL, the run-time package that you'll distribute along with your program). In the last chapter, you saw how to build a package. Now I want to underline some advantages and disadvantages of the two forms of linking for a package. There are many elements to keep in mind:

- Using a package as a DLL makes the executable files much smaller.
- Linking the package units into the program allows you to distribute only part of the package code. Generally, the size of the executable file of an application plus the size of the required package DLLs that it requires is much bigger than the size of the statically linked program. The linker includes only the code actually used by the program, whereas a package must link in all the functions and classes declared in the interface sections of all the units contained in the package.
- If you distribute several Delphi applications based on the same packages, you might end up distributing less code, because the run-time packages are shared. In other words, once the users of your application have the standard Delphi run-time packages, you can ship them very small programs.
- If you run several Delphi applications based on the same packages, you can save some memory space at run time; the code of the run-time packages is loaded in memory only once between the multiple Delphi applications.
- Don't worry too much about distributing a large executable file. Keep in mind that when you make minor changes to a program, you can use any of various tools to create a *patch file*, so that you distribute only a file containing the differences, not a complete copy of the files.
- If you place a few of your program's forms in a run-time package, you can share them among programs. When you modify these forms, however, you'll generally need to recompile the main program as well, and distribute both of them again to your users. The next section discusses this complex topic in detail.

Package Versioning

A very important and often misunderstood element is the distribution of updated packages. When you update a DLL, you can ship the new version, and the executable programs requiring this DLL will generally still work (unless you've removed existing exported functions or changed some of their parameters).

When you distribute a Delphi package, however, if you update the package and modify the interface portion of any unit of the package, you might need to recompile all the applications that use the package. This is required if you add methods or properties to a class, but not if you add new global symbols (or modify anything not used by client applications). There is no problem at all for changes affecting only the implementation section of the package's units.

A DCU file in Delphi has a version tag based on its timestamp and a checksum computed from the interface portion of the unit. When you change the interface portion of a unit, every other unit based on it should be recompiled. The compiler compares the timestamp and checksum of the unit of previous compilations with the new timestamp and checksum, and decides whether the dependent unit must be recompiled. This is why you have to recompile each unit when you get a new version of Delphi, which has modified system units.

A package is a collection of units. In Delphi 3, a checksum of the package, obtained from the checksum of the units it contains and the checksum of the packages it requires, was added as an extra entry function to the package library, so that any executable based on an older version of the package would fail at startup.

Delphi 4 and following versions have relaxed the run-time constraints of the package. The design-time constraints on DCU files remain identical, though. The checksum of the packages is not checked anymore, so you can directly modify the units that are part of a package and deploy a new version of the package to be used with the existing executable file. Since methods are referenced by name, you cannot remove any existing method. You cannot even change its parameters, because of name-mangling techniques specifically added to the packages to protect against changes in parameters.

Removing a method referenced from the calling program will stop the program during the loading process. If you make other changes, however, the program might fail unexpectedly during its execution. For example, if you replace a component placed on a form compiled in a package with a similar component, the calling program might still able to access the one in that memory location, although it is now a different component!

If you decide to follow this treacherous road of changing the interface of units in a package without recompiling all the programs that use it, you should at least limit your changes. When you add new properties or nonvirtual methods to the form, you should be able to maintain full compatibility with existing programs already using the package. Also, adding fields and virtual methods might affect the internal structure of the class, leading to problems with existing programs that expect a different class data and virtual method table (VMT) layout. Of course, this applies to the binary compatibility between the EXE and the BPL (Borland Package Library).

WARNING Here I'm referring to the distribution on compiled programs divided between EXE and packages, not to the distribution of components to other Delphi developers. In this latter case the versioning rules are more stringent, and you must take extra care in package versioning.

Having said this, I recommend never changing the interface of any unit exported by your packages. To accomplish this, you can add to your package a unit with form-creation functions (as in the DLL with forms presented earlier) and use it to access another unit, which defines the form. Although there is no way to *hide* a unit that is linked into a package, if you never directly use the class defined in a unit, but use it only through other routines, you'll have more flexibility in modifying it. You can also use form inheritance to modify a form within a package without really affecting the original version.

The most stringent rule for packages is the following one used by component writers: For long-term deployment and maintenance of code in packages, plan on having a major release with minor maintenance releases. A major release of your package will require all client programs to be recompiled from source; the package file itself should be renamed with a new version number, and the interface sections of units can be modified. Maintenance releases of that package should be restricted to implementation changes to preserve full compatibility with existing executables and units.

Forms Inside Packages

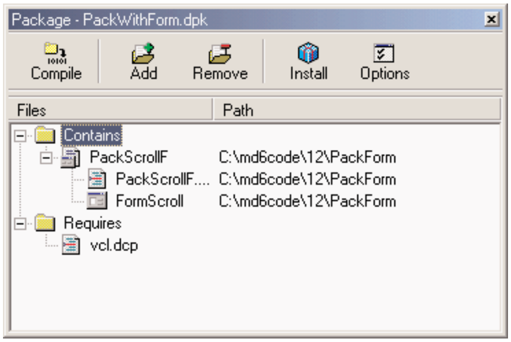
We've already discussed (in Chapter 11, "Creating Components") the use of component packages in Delphi applications. As I'm discussing the use of packages and DLLs for partitioning an application, here I'll start discussing the development of packages holding forms. We've seen earlier in this chapter that you can use forms inside DLLs, but this sometimes causes a few problems. If you are building both the library and the executable file in Delphi, using packages results in a much better and cleaner solution.

At first sight, you might believe that Delphi packages are a way to distribute components to be installed in the environment. Instead, you can use packages as a way to structure your code but, unlike DLLs, retain the full power of Delphi's OOP. Consider this: A package is a collection of compiled units and your program uses several units. The units the program refers to will be compiled inside the executable file, unless you ask Delphi to place them inside a package.

So how do you set up an application so that its code is split among one or more packages and a main executable file? You only need to compile some of the units in a package and then set up the options of the main program to dynamically link this package. For example, I've made a copy of the "usual" color selection form and renamed its unit as PackScrollF, then I've created a new package and added the unit to it, as you can see in Figure 12.7.

FIGURE 12.7:

The structure of the package hosting a form in Delphi's Package Editor



Files	Path
Contains	
PackScrollF	C:\md6code\12\PackForm
PackScrollF....	C:\md6code\12\PackForm
FormScroll	C:\md6code\12\PackForm
Requires	
vcl.dcp	

Before compiling this package, you should change its default output directories to refer to the current folder, not the standard `/Projects/Bpl` subfolder of Delphi. To do this, go to the Directories/Conditional page of the package Project Options, and set the current directory (a single dot, for short) for the Output directory (for the BPL) and DCP output directory. Then compile the package and do not install it in Delphi—there's no need to.

At this point, you can create a normal application and write the standard code you'll use in a program to show a secondary form, as in the following listing:

```
uses
  PackScrollF;

procedure TForm1.BtnChangeClick(Sender: TObject);
var
  FormScroll: TFormScroll;
begin
  FormScroll := TFormScroll.Create (Application);
  try
    // initialize the data
    FormScroll.SelectedColor := Color;
    // show the form
    if FormScroll.ShowModal = mrOK then
      Color := FormScroll.SelectedColor;
  finally
    FormScroll.Free;
  end;
end;
```

```
procedure TForm1.BtnSelectClick(Sender: TObject);
var
  FormScroll: TFormScroll;
begin
  FormScroll := TFormScroll.Create (Application);
  // initialize the data and UI
  FormScroll.SelectedColor := Color;
  FormScroll.BitBtn1.Caption := 'Apply';
  FormScroll.BitBtn1.OnClick := FormScroll.ApplyClick;
  FormScroll.BitBtn2.Kind := bkClose;
  // show the form
  FormScroll.Show;
end;
```

One of the advantages of this approach is that you can refer to a form compiled into a package with the exact same code you'll use for a form compiled in the program. In fact, if you simply compile this program, the unit of the form will actually be bound to it. To keep it in the package, you'll have to use run-time packages for the application and manually add the PackWithForm package to the list of run-time packages (this is not suggested by the Delphi IDE as we have not installed the package in the development environment).

Once you've done this step, compile the program and it will behave exactly as usual. But now the form is in a DLL package, and you can even modify the form in the package, recompile it, and simply run the application to see the effects. Notice, though, that for most changes affecting the interface portion of the units of the package (for example, adding a component or a method to the form), you should also recompile the executable program calling the package.

NOTE You can find the package and the program testing it in the `PackForm` folder of the source code related to the current chapter. The code of the next example is in the same folder.

Loading Packages at Run Time

In the example above, I indicated that the PackWithForm package is a run-time package to be used by the application. This means that the package is required to run the application and is loaded when the program starts. Both aspects can be avoided by loading the package dynamically, as we've done with DLLs. The resulting program will be more flexible, start more quickly, and use less memory.

An important element to keep in mind is that you'll need to call the `LoadPackage` and `UnloadPackage` Delphi functions rather than the `LoadLibrary` and `FreeLibrary` Windows API functions. The difference is that the functions provided by Delphi load the packages, but also call their proper initialization and finalization code.

Besides this important element—easy to accomplish once you know about it—the program will require some extra code, as we cannot refer from the main program to the unit hosting the form. We cannot use the form class directly, nor access to its properties or components. At least not with the standard Delphi code. Both issues, however, can be solved using class references, class registration, and RTTI (run-time type information). Let me start with the first one. In the form unit, in the package, I've added this initialization code:

```
initialization
  RegisterClass (TFormScroll);
```

As the package is loaded, the main program can use Delphi's `GetClass` function to get the class reference of the registered class and then call the `Create` constructor for this class reference.

To solve the second problem, I've made the `SelectedColor` property of the form in the package a published property, so that it is accessible via RTTI. Then I've replaced the code accessing this property (`FormScroll.Color`) with the following:

```
SetPropValue (FormScroll, 'SelectedColor', Color);
```

Summing up all of these changes, here is the code used by the main program (the DynaPackForm application) to show the modal form from the dynamically loaded package:

```
procedure TForm1.BtnChangeClick(Sender: TObject);
var
  FormScroll: TForm;
  FormClass: TFormClass;
  HandlePack: HModule;
begin
  // try to load the package
  HandlePack := LoadPackage ('PackWithForm.bpl');
  if HandlePack > 0 then
  begin
    FormClass := TFormClass(GetClass ('TFormScroll'));
    if Assigned (FormClass) then
    begin
      FormScroll := FormClass.Create (Application);
      try
        // initialize the data
        SetPropValue (FormScroll, 'SelectedColor', Color);
        // show the form
        if FormScroll.ShowModal = mrOK then
          Color := GetPropValue (FormScroll, 'SelectedColor');
      finally
        FormScroll.Free;
      end;
    end
    else
      ShowMessage ('Form class not found');
      UnloadPackage (HandlePack);
    end
    else
      ShowMessage ('Package not found');
  end;
```

Notice that the program unloads the package as soon as it is done with it. This is not compulsory. I could have moved the `UnloadPackage` call in the `OnDestroy` handler of the form, and avoided reloading the package after the first time.

Now you can try running this program without the package available, and you'll see that it will start properly, only to complain it cannot find the package as you click the Change button. In this program, you don't need to use run-time packages to keep the unit outside of your executable file, as you are not referring to the unit in your code. Also, the PackWithForm package doesn't need to be listed in the run-time packages. However, you must use run-time packages, or else your program will include the VCL global variables (as the `Application` object) and the dynamically loaded package will include another version, because it will refer to the VCL packages anyway.

Using Interfaces in Packages

Accessing the classes of the forms by means of methods and properties is much simpler than using RTTI all over the place. To build a larger application, I definitely try to use interfaces and to have multiple forms, each implementing a few standard interfaces defined by the program. An example cannot really do justice to this type of architecture, which becomes relevant for a large program, but I've tried nonetheless to build a program to show how this idea can be applied in practice.

NOTE If you don't know much about interfaces, I suggest you to refer to the related portion of Chapter 3 before reading this section.

To architect the IntfPack project, I've used three packages plus a demo application. Two of the three packages (called IntfFormPack and IntfFormPack2) define alternative forms used to select a color. The third package (called IntfPack) hosts a shared unit, used by both other packages. This unit basically includes the definition of the interface. I couldn't add it to both other packages because you cannot load two packages with a unit having the same name (even by run-time loading).

The only file of the IntfPack package is the IntfColSel unit, displayed in Listing 12.1. This unit defines the common interface (and you'll probably have a number of them in real-world application) plus a list of registered classes, which mimics Delphi's `RegisterClass` approach, but makes available the complete list so that you can easily scan it.

Listing 12.1: The IntfColSel unit of the IntfPack package

```
unit IntfColSel;

interface

uses
  Graphics, Contnrs;

type
  IColorSelect = interface
  ['{3F961395-71F6-4822-BD02-3B475FF516D4}']
    function Display (Modal: Boolean = True): Boolean;
    procedure SetSelColor (Col: TColor);
    function GetSelColor: TColor;
    property SelColor: TColor
      read GetSelColor write SetSelColor;
  end;

procedure RegisterColorSelect (AClass: TClass);

var
  ClassesColorSelect: TClassList;

implementation

procedure RegisterColorSelect (AClass: TClass);
begin
  if ClassesColorSelect.IndexOf (AClass) < 0 then
    ClassesColorSelect.Add (AClass);
end;

initialization
  ClassesColorSelect := TClassList.Create;

finalization
  ClassesColorSelect.Free;

end.
```

Once we have this interface available, we can define forms that implement it, as in the following example, taken form the IntfFormPack:

```
type
  TFormSimpleColor = class(TForm, IColorSelect)
    ...
  private
    procedure SetSelColor (Col: TColor);
    function GetSelColor: TColor;
  public
    function Display (Modal: Boolean = True): Boolean;
```

The two access methods simply read and write the value of the color from some components of the form (a simple ColorGrid in this specific case), while the `Display` method internally calls either `Show` or `ShoModal`, depending on the parameter:

```
function TFormSimpleColor.Display(Modal: Boolean): Boolean;
begin
  Result := True; // default
  if Modal then
    Result := (ShowModal = mrOK)
  else
  begin
    BitBtn1.Caption := 'Apply';
    BitBtn1.OnClick := ApplyClick;
    BitBtn2.Kind := bkClose;
    Show;
  end;
end;
```

The form is structured like that of the last example, still available in the second package, and has an OK button that is turned into an Apply button. Finally, the unit has the registration code in the `initialization` section, so that it is executed when the package is dynamically loaded:

```
RegisterColorSelect (TFormSimpleColor);
```

With this architecture in place, we can build a rather elegant and flexible main program, which is based on a single form. When the form is created, it defines a list of packages (called `HandlesPackages`) and loads them all. I've hard-coded the package in the code of the example, but of course you can as well search for the packages of the current folder or use a configuration file to make the application structure more flexible. Finally, after loading the packages, the program shows the registered classes in a list box. This is the code of the `LoadDynaPackage` and `FormCreate` methods:

```
procedure TFormUseIntf.FormCreate(Sender: TObject);
var
  I: Integer;
begin
  // loads all runtime packages
  HandlesPackages := TList.Create;
  LoadDynaPackage ('IntfFormPack.bpl');
  LoadDynaPackage ('IntfFormPack2.bpl');

  // add class names and select the first
  for I := 0 to ClassesColorSelect.Count - 1 do
    lbClasses.Items.Add (ClassesColorSelect [I].ClassName);
  lbClasses.ItemIndex := 0;
end;
```

```
procedure TFormUseIntf.LoadDynaPackage(PackageName: string);
var
  Handle: HModule;
begin
  // try to load the package
  Handle := LoadPackage (PackageName);
  if Handle > 0 then
    // add to the list for later removal
    HandlesPackages.Add (Pointer(Handle))
  else
    ShowMessage ('Package ' + PackageName + ' not found');
end;
```

The main reason for keeping the list of package handles is to be able to unload them all when the program ends. In fact, we don't need these handles to access the forms defined in those packages. The run-time code used to create and show a form simply uses the corresponding component classes. This is a snippet of code used to display a modeless form (an option controlled by a check box):

```
var
  AComponent: TComponent;
  ColorSelect: IColorSelect;
begin
  AComponent := TComponentClass
    (ClassesColorSelect[LbClasses.ItemIndex]).Create (Application);
  ColorSelect := AComponent as IColorSelect;
  ColorSelect.SelColor := Color;
  ColorSelect.Display (False);
```

The program actually uses the `Supports` function to check that the form really does support the interface before using it, and also accounts for the modal version of the form, but its essence is properly depicted in the four statements above. By the way, notice that the code doesn't actually require a form. A nice exercise would be to add to the architecture a package with a component encapsulating the color selection dialog box or inheriting from it.

WARNING The main program refers to the unit hosting the interface definition but should not link this file in. Rather, it should use the run-time package containing this unit, as the dynamically loaded packages do. Otherwise the main program will use a different copy of the same code, including a different list of global classes. It is this list of global classes, not the use of the same interface, that should not be duplicated in memory.

Packages Versus DLLs

In the preceding section, we've seen that using packages is a fine alternative to using DLLs for sharing compiled code among multiple Delphi applications or splitting a large executable into multiple (and partially independent) modules. As a summary, here are a few of the differences between the two approaches:

- DLLs are collections of functions; packages can easily "export" classes and objects.
- Dynamically loading a DLL implies losing any safety in the function call, in case you pass the wrong parameters. Dynamically loading packages requires some extra coding as well, but is definitely simpler and safer, particularly if you use interfaces.
- Packages force you to use the VCL run-time package for the application, although even when using DLLs, run-time packages help solve quite a few difficulties (as we'll discuss shortly).
- DLLs can be used across programming languages and development environments, but packages are limited to Delphi and C++Builder. If you need libraries in a Delphi-only environment, packages are the native solution and should generally be preferred.

Using DLLs also accounts for a few extra troubles that you can partially solve by letting the DLLs share run-time packages. The following sections discuss the problem briefly, as this is not the recommended approach anyway.

Executables and DLLs Sharing the VCL Packages

In the FormDLL example, we faced a problem: When you place forms inside a DLL, you don't get the proper behavior for the flat buttons even if you synchronize the two application objects. Moreover, both the executable file and the DLL contain the compiled code of the VCL library, leading to useless duplication. As discussed earlier, the simplest solution to this issue is to use a package instead of a DLL.

Another solution is to keep the DLL in its format, but let it use run-time packages, so that no global objects will be duplicated between the executable and the library. In this case there will be only one `Application` object, shared by the program and the DLL, instead of two separate objects, so we don't need the synchronization code any more.

Another simplification to the program comes from the fact that the modeless form inside the DLL can communicate back to the main form by accessing the list of the forms (available to the shared global `Screen` object) or simply using the `Application.MainForm` property. This is what I've done in the FormDllP example on the CD.

With this approach, you face the risk of having the main form and the form in the DLL not synchronized at all, with two entries in the Taskbar; also, this code still has all the other problems of the first version of the FormDLL example. The problem lies in the fact that when you run the program, the DLL is initialized before the application, so it is the DLL that initializes the Forms unit of the VCL. Within a DLL, the VCL creates the Application object but doesn't create the corresponding window.

There are two radically different approaches to this initialization issue: One is to change the initialization order by loading the DLL dynamically after the application has started; the second is to add some extra initialization code in the program. None of these techniques provides a better solution than using packages altogether!

Dynamically Loading the DLL with Packages

The first solution is demonstrated by the FirstDLLD library and the UseDyna example, which dynamically loads the DLL built with run-time packages. The main program loads the DLL at startup, in the OnCreate event handler of the form:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  hInstDll := SafeLoadLibrary ('FormDllD.dll');
  if hInstDll <= 0 then
    raise Exception.Create ('FormDllD library not found');
end;
```

In the program I haven't declared the functions exported by the DLL, to avoid the implicit link of the library. Instead I've declared two procedure types:

```
type
  TGetColorProc = function (Col: LongInt): LongInt; stdcall;
  TShowColorProc = procedure (Col: LongInt); stdcall;
```

These types are used for converting the generic pointer returned by the GetProcAddress function, as we've already seen in the DynaCall example:

```
procedure TForm1.BtnChangeClick(Sender: TObject);
var
  Col: LongInt;
  GetColorProc: TGetColorProc;
  FPointer: TFarProc;
begin
  FPointer := GetProcAddress (hInstDll, 'GetColor');
  if FPointer = nil then
    raise Exception.Create ('GetColor DLL function not found');
  GetColorProc := TGetColorProc (FPointer);
  // original code
  Col := ColorToRGB (Color);
  Color := GetColorProc (Col);
end;
```

Using dynamic loading is the correct approach, officially supported by Delphi. Still, you have to call the functions dynamically, which requires a little extra coding.

Fixing the Initialization Code

An alternate solution is to keep the external functions defined in the main program, let the DLL start first and initialize the VCL, and let the VCL create the `Application` object without the connected window. In fact, we can add one line of code to the library to ask for the creation of the window of the `Application` object during the library initialization process (before the executable creates its own main objects). We accomplish this by writing the code in the initialization section of one of the units of the DLL:

```
initialization
  Application.CreateHandle;
```

Because this code is in the DLL, the application fails to load its icon. The solution is actually very simple. In the `OnCreate` event handler of the main form (in the main program), simply reload the current icon:

```
Application.Icon.Handle := LoadIcon (HInstance, 'MAINICON');
```

Exploring the Structure of a Package

You might wonder: is it possible to know whether a unit has been linked in the executable file or if it's part of a run-time package? Not only is this possible in Delphi, but you can also explore the overall structure of an application. A component can use the undocumented `ModuleIsPackage` global variable, declared in the SysInit unit. You should never need this, but it is technically possible for a component to have different code depending on whether it is packaged or not. The following code extracts the name of the run-time package hosting the component, if any:

```
var
  fPackName: string;
begin
  // get package name
  SetLength (fPackName, 100);
  if ModuleIsPackage then
  begin
    GetModuleFileName (HInstance, PChar (fPackName), Length (fPackName));
    fPackName := PChar (fPackName) // string length fixup
  end
  else
    fPackName := 'Not packaged';
```

Besides accessing package information from within a component (as in the code above), you can also do so from a special entry point of the package libraries, the `GetPackageInfoTable` function. This function returns some specific package information that Delphi stores as resources and includes in the package DLL. Fortunately, we don't need to use low-level techniques to access this information, since Delphi provides some high-level functions to manipulate it.

You can use two functions to access package information:

- `GetPackageDescription` returns a string that contains a description of the package. To call this function, you must supply the name of the module (the package library) as the only parameter.
- `GetPackageInfo` doesn't directly return information about the package. Instead, you pass it a function that it calls for every entry in the package's internal data structure. In practice, `GetPackageInfo` will call your function for every one of the package's contained units and required packages. In addition, `GetPackageInfo` sets several flags in an Integer variable.

These two function calls allow us to access internal information about a package, but how do we know which packages our application is using? You could determine this by looking at an executable file using low-level functions, but Delphi helps you again by supplying a simpler approach. The `EnumModules` function doesn't directly return information about an application's modules but allows you to pass it a function, which it calls for each module of the application, the main executable file, and for each of the packages the application relies on.

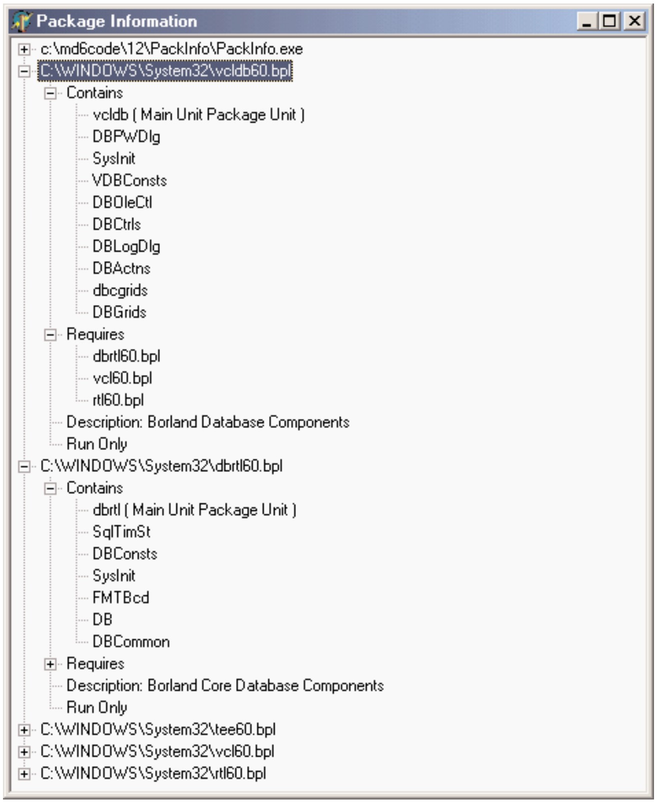
To demonstrate this approach, I've built a simple example program that displays the module and package information in a TreeView component. Each first-level node corresponds to a module, and within each module I've built a subtree that displays the contained and required packages for that module, as well as the package description and compiler flags (`RunOnly` and `DesignOnly`). You can see the output of this example in Figure 12.8.

In addition to the TreeView component, I've added several other components to the main form, but hidden them from view: a DBEdit, a Chart, and a FilterComboBox. I added these components simply to include more run-time packages in the application, beyond the ubiquitous `VCL60.BPL`. The only method of the form class is `FormCreate`, which calls the module enumeration function:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  EnumModules(ForEachModule, nil);
end;
```

FIGURE 12.8:

The output of the PackInfo example, with the details of the packages it uses



```

⊞ C:\WINDOWS\System32\rtl60.bpl
```

The EnumModules function accepts two parameters. The first is the callback function (in our case, ForEachModule), and the second is a pointer to a data structure that the callback function will use (in our case, nil, since we didn't need this). The callback function must accept two parameters—an HInstance value and an untyped pointer—and must return a Boolean value. The EnumModules function will, in turn, call our callback function for each module, passing the instance handle of each module as the first parameter and the data structure pointer (nil in our example) as the second.

```
function ForEachModule (HInstance: Longint;
  Data: Pointer): Boolean;
var
  Flags: Integer;
```

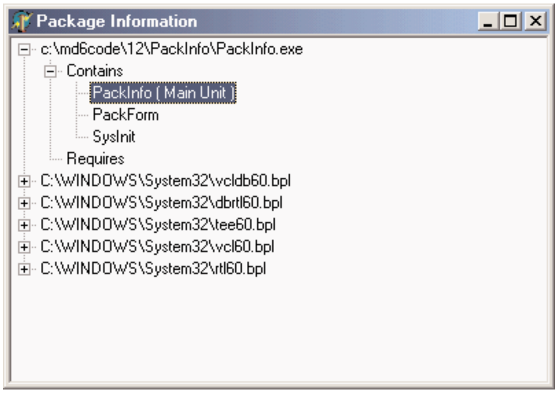
```
    ModuleName, ModuleDesc: string;
    ModuleNode: TTreeNode;
  begin
    with Form1.TreeView1.Items do
    begin
      SetLength (ModuleName, 200);
      GetModuleFileName (HInstance,
        PChar (ModuleName), Length (ModuleName));
      ModuleName := PChar (ModuleName); // fixup
      ModuleNode := Add (nil, ModuleName);

      // get description and add fixed nodes
      ModuleDesc := GetPackageDescription (PChar (ModuleName));
      ContNode := AddChild (ModuleNode, 'Contains');
      ReqNode := AddChild (ModuleNode, 'Requires');

      // add information if the module is a package
      GetPackageInfo (HInstance, nil, Flags, ShowInfoProc);
      if ModuleDesc <> '' then
      begin
        AddChild (ModuleNode, 'Description: ' + ModuleDesc);
        if Flags and pfDesignOnly = pfDesignOnly then
          AddChild (ModuleNode, 'Design Only');
        if Flags and pfRunOnly = pfRunOnly then
          AddChild (ModuleNode, 'Run Only');
      end;
    end;
    Result := True;
  end;
```

As you can see in the preceding code, the ForEachModule function begins by adding the module name as the main node of the tree (by calling the Add method of the TreeView1.Items object and passing nil as the first parameter). It then adds two fixed child nodes, which are stored in the ContNode and ReqNode variables declared in the implementation section of this unit.

Next, the program calls the GetPackageInfo function and passes it another callback function, ShowInfoProc, which I'll discuss shortly. The program adds the details for the main module (see Figure 12.9), simply because this will provide a list of the application's units. At the end of this function, we add more information if the module is a package, such as its description and compiler flags (we know it's a package if its description isn't an empty string).



Package Information

```
c:\md6code\12\PackInfo\PackInfo.exe
  Contains
    PackInfo ( Main Unit )
    PackForm
    SysInit
  Requires
C:\WINDOWS\System32\vcldb60.bpl
C:\WINDOWS\System32\dbrtl60.bpl
C:\WINDOWS\System32\tee60.bpl
C:\WINDOWS\System32\vcl60.bpl
C:\WINDOWS\System32\rtl60.bpl
```

FIGURE 12.9: The PackInfo example also lists the units that are part of the current application.

Earlier, I mentioned passing another callback function, the ShowInfoProc procedure, to the GetPackageInfo function, which in turn calls our callback function for each contained or required package of a module. This procedure creates a string that describes the package and its main flags (added within parentheses), and then inserts that string under one of the two nodes (ContNode and ReqNode), depending on the type of the module. We can determine the module type by examining the NameType parameter. Here is the complete code of our second callback function:

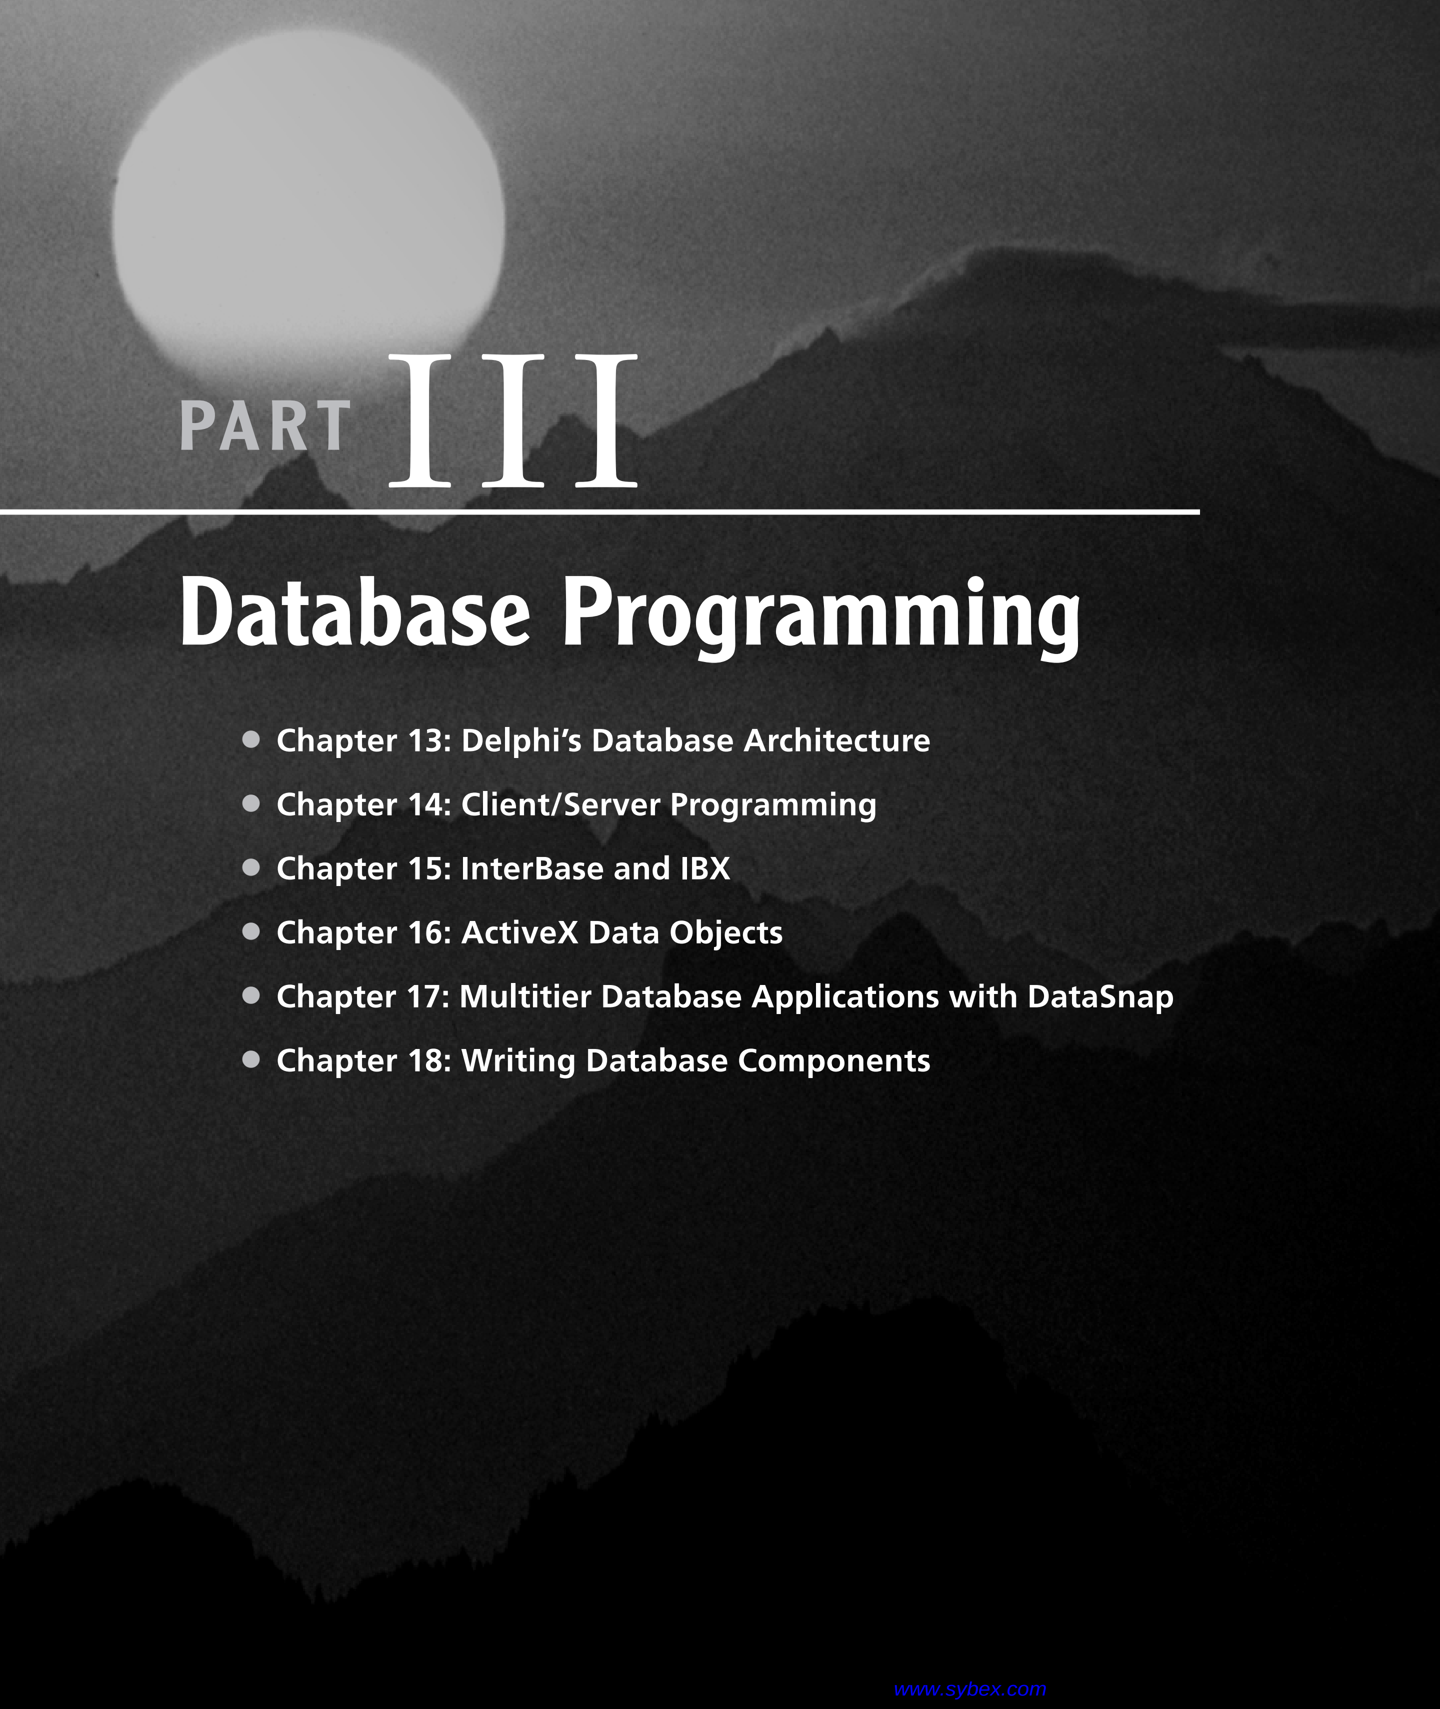
```
procedure ShowInfoProc (const Name: string; NameType: TNameType; Flags: Byte;
  Param: Pointer);
var
  FlagStr: string;
begin
  FlagStr := ' ';
  if Flags and ufMainUnit <> 0 then
    FlagStr := FlagStr + 'Main Unit ';
  if Flags and ufPackageUnit <> 0 then
    FlagStr := FlagStr + 'Package Unit ';
  if Flags and ufWeakUnit <> 0 then
    FlagStr := FlagStr + 'Weak Unit ';
  if FlagStr <> ' ' then
    FlagStr := ' (' + FlagStr + ')';
  with Form1.TreeView1.Items do
    case NameType of
      ntContainsUnit: AddChild (ContNode, Name + FlagStr);
      ntRequiresPackage: AddChild (ReqNode, Name);
    end;
end;
```

Here, you'll notice that the Flags parameter doesn't contain flag style information, as the online help seems to imply. If you want to investigate this topic further, examine the SysUtils unit.

What's Next?

In this chapter we have seen how you can call functions that reside in DLLs, how to create DLLs using Delphi, and how to use strings and place Delphi forms inside a library. Another technique for placing Delphi forms and other classes in libraries is to use packages, special DLLs that the IDE uses for installing components, but that you can use for dividing an application into multiple executable files.

I will get back to the topics of libraries that expose objects and classes when I discuss COM and OLE in Chapters 19 and 20. For the moment, instead, we'll move to a totally different topic, the development of database-oriented and client/server applications with Delphi.



PART III

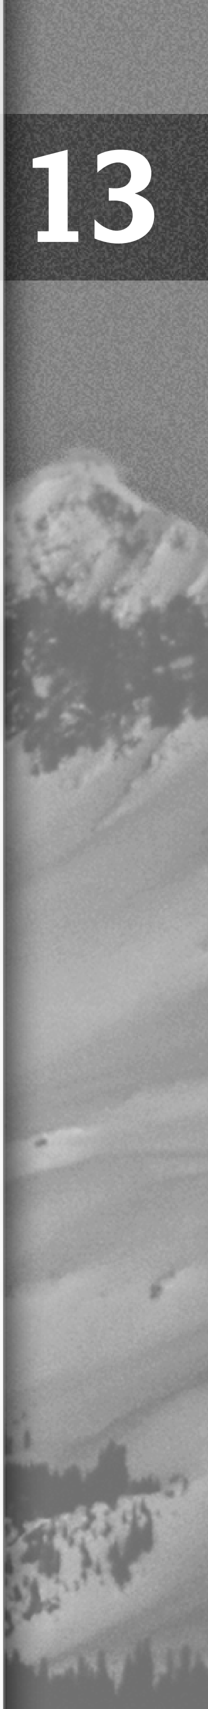
Database Programming

- Chapter 13: Delphi’s Database Architecture
- Chapter 14: Client/Server Programming
- Chapter 15: InterBase and IBX
- Chapter 16: ActiveX Data Objects
- Chapter 17: Multitier Database Applications with DataSnap
- Chapter 18: Writing Database Components

CHAPTER 13

Delphi's Database Architecture

- Delphi's database components
- Database access alternatives
- Using data-aware controls
- The DBGrid and multirecord objects
- Manipulating table fields
- Database applications with standard controls



Delphi's support for database applications is one of the key features of the programming environment. Many programmers spend most of their time writing data-access code, which needs to be the most robust portion of a database application. This chapter provides an overview of Delphi's extensive support for database programming.

What you won't find here is a discussion of the theory of database design. I'm assuming that you already know the fundamentals of database design and have already designed the structure of a database. I won't delve into database-specific problems; my goal is to help you understand how Delphi supports database access.

I'll begin with an explanation of the alternatives Delphi offers in terms of data access, and then I'll provide an overview of the database components that are available in Delphi. This chapter includes an overview of the `TDataSet` class, an in-depth analysis of the `TField` components, and the use of data-aware controls. The following chapters will provide information on more advanced database programming topics, such as client/server programming, the use of dbGo, dbExpress, and InterBase Express.

Accessing a Database: BDE, dbExpress, and Other Alternatives

In the first few versions of Delphi, the only available technology to access database data was to use the Borland Database Engine (BDE). Starting with Delphi 3, the portion of VCL related to Database access has been restructured to open it up to multiple database access solutions. Delphi 5 saw the introduction of specific sets of components supporting Microsoft's ActiveX Data Objects (ADO) and InterBase Express (IBX). Delphi 6 adds to the picture dbExpress, which is a brand-new cross-platform and database-independent data-access technology provided by Borland with Kylix on Linux and Delphi 6 on Windows.

With all these alternatives, it is easy to get confused on which approach to use. In the following sections I've provided a short description of the key elements of these data-access technologies available in Delphi, trying to suggest in which case you'll want to use each of them.

Borland Database Engine (BDE)

The BDE originated with Paradox, well before Delphi existed, and was extended by Borland to support other local databases and many SQL servers. The BDE has direct access to dBASE, Paradox, ASCII, FoxPro, and Access tables. A series of drivers (called SQL Links and available only in Delphi Enterprise) allows access to some SQL servers, including Oracle, Sybase, Microsoft, Informix, InterBase, and DB2 servers. If you need access to a different database, the BDE can also interface with ODBC drivers.

The advantage of using a common database engine is that your application will be portable among different servers of the same category (porting from a local database to an SQL server is generally much more complex). The specific advantages of using the BDE are that this technology is very well integrated in Delphi; its elements are very well documented; and it is the only viable solution for accessing local files such as Paradox and dBase tables.

The disadvantages of this solution: Borland has stopped developing it (there will be no further updates); you'll have to install and configure it on the client computers; it is quite a "heavyweight" engine, with large installation files and memory requirements; and it is available only on Windows. If you have existing Delphi BDE applications accessing local files, there is no hurry to convert them and get rid of the BDE, unless you want to move your applications to Linux. If you are using an SQL server, migrating to another data-access technology will probably be easier.

BDE is still a good solution, if you balance advantages and disadvantages, but its long-term viability is certainly in doubt. I'll keep using the BDE for the simpler examples of this chapter, but only for the sake of simplicity. In any case, I'll try to stress the elements common to all the dataset components rather than focus on specific features of BDE or Paradox.

The Delphi components related to the BDE are all hosted in the Data Access page of the Components palette. There are three dataset components, Table, Query, and StoredProc, plus the UpdateSQL used in connection with the Query component. The Database and Session components are used to set up the database connection. The BatchMove component is for copying data; the rarely used NestedTable component allows you to nest master-detail data in a sub-table; and the BDEClientDataSet component, introduced in Delphi 6, merges a ClientDataSet with a BDE-related data-access component.

ActiveX Data Objects (ADO)

ADO, which stands for ActiveX Data Objects, is Microsoft's high-level interface for database access. ADO is implemented on Microsoft's data-access OLE DB technology, which provides access to relational and non-relational databases as well as e-mail and file systems and custom business objects. ADO is an engine with features comparable to the BDE: database server independence supporting local and SQL servers alike, a really heavyweight engine, and a simplified configuration (because it is not centralized). Installation should in theory not be an issue, as the engine is part of recent versions of Windows. However, the limited compatibility among versions of ADO will force you to upgrade your users' computers to the same version you've used for developing the program—and the sheer size of the MDAC (Microsoft Data Access Components) installation, which updates large portions of the operating system, makes this operation far from simple.

ADO offers some definite advantages if you plan on using Access or SQL Server, as Microsoft's drivers for their own databases are of better quality than the average OLE DB providers. For Access databases, specifically, using Delphi's ADO components is a good solution. But if you plan using other SQL servers, first check the availability of a good quality driver, as you might have some surprises. ADO is very powerful, but you have to learn living with it, as it really stands in the way between your program and the database, providing services but occasionally also issuing different commands than you are expecting. On the negative side, do not even think of using ADO if you plan future cross-platform development: this Microsoft-specific technology is not available on Linux or other operating systems.

In short, use ADO if you plan working only on Windows, want to use Access or other Microsoft databases, or you find a good OLE DB provider for each of the database servers you plan working with (at the moment, for example, this excludes InterBase and many other SQL servers).

ADO components (part of a package Borland called ADO Express in Delphi 5 and now calls dbGo in Delphi 6) are all grouped in the ADO page of the Components palette. The three core components are ADOConnection (for database connection), ADOCommand (for executing SQL commands), and ADODataSet (for executing requests that return a result set). There are also three compatibility components—ADOTable, ADOQuery, and ADOStoredProc—which you can use for porting BDE-based applications to ADO. Finally, there is the RDSConnection component, for accessing data in remote multitier applications.

NOTE Chapter 16, "ActiveX Data Objects," covers ADO and related technologies in great detail.

The dbExpress Library

One of the relevant new features of Delphi 6 is the introduction of the dbExpress database library for the Windows platform. I say "library" because, unlike BDE and ADO, dbExpress uses a lightweight approach; and I underline "Windows" because the same library is available also for Linux in Borland Kylix.

Being light and portable are actually the two key characteristics of dbExpress and the reasons it has been introduced by Borland, along with the development of the Kylix project. There are certainly other database libraries you could use in the past and can still use with Delphi, but this new offering is worth a thought. Consider also it requires basically no configuration on the user machines.

Compared to other powerhouses, dbExpress is really limited in its capabilities. It can access only SQL servers (no local files); it has no caching capabilities and provides only unidirectional access to the data; it can natively work only with SQL queries and is unable of generating the corresponding SQL update statements.

At first sight, you might think that these limitations make the library pretty useless. On the contrary, these are *features* that make it interesting. Unidirectional datasets with no direct update are the norm if you need to produce reporting, including generating HTML pages showing the content of a database. If you want to build a user interface to edit the data, instead, consider that Delphi includes specific components (the ClientDataSet and Provider, in particular) that provide caching and query resolution. These components allow your dbExpress-based application to have much more control than you can have with a separate (and monolithic) database engine, which does extra things for you but often does it the way it wants, not the way you would like.

Considering that Borland is pushing this library, and it is the only viable database-independent solution on Linux, I really urge you to consider it for new applications, and even to think about updating existing Delphi applications to this new architecture.

InterBase Express (IBX)

Delphi includes components for native access to Borland's own open-source (and free) InterBase server. Unlike BDE, ADO, and dbExpress, this is not a server-independent database engine, but a technology for accessing a specific database server. If you plan using only InterBase as your back-end RDBMS, using a specific set of components can give you more control of the server, provide the best performance, and allow you also to configure and maintain the server from within a custom client application.

NOTE The use of InterBase Express highlights the case of database-specific custom datasets, which are available from third-party vendors for many servers (there are other dataset components for InterBase, as there are for Oracle, Access, dBase files, and many others).

In short, you can consider using InterBase Express (or other comparable sets of components) if you are sure you won't change your database and want to achieve best performance and control at the expense of flexibility and portability. The down side is that the extra performance and control you gain might be limited, and you'll have to learn how to use another set of components with a specific behavior, compared to learning how to use a generic engine and applying your knowledge to different situations.

The ClientDataSet Component

Finally, there is a component derived from `TDataSet` that has a peculiar behavior and can be combined with other data-access components. The ClientDataSet component, in fact, is a dataset accessing data kept in memory. The in-memory data can be totally temporary (lost as you exit the program), saved to a local file as a snapshot, and imported by another dataset using a Provider component. This last situation is certainly the most common: You can hook a ClientDataSet to any other local dataset, or use Borland's multitier support (discussed in

Chapter 17, "Multitier Database Applications with DataSnap") to retrieve data from a dataset hosted by a different application, possibly running on a separate computer.

The ClientDataSet component becomes particularly useful if the data-access components you are using provide limited or no caching. This is particularly true of the new dbExpress engine, but can equally help you when using the BDE or other native components. On the other hand, ADO already provides most of the services of the ClientDataSet component and using these two at the same time can be useful only in limited situations.

Classic BDE Components

Each of the database-access solutions discussed above has its own set of data-access, database connection, and extra utility components on a specific page of the Component palette. In Delphi 6, the classic BDE components have been moved to the new BDE page and include the Table, Query, and StoredProc components. The ADO, dbExpress, and InterBase Express components are each in specific pages, and all include specific dataset components and others that tend to mimic the BDE components, simplifying the porting of existing applications. The Data Access page of the Component palette in Delphi 6 includes only the Data Source component and others not specifically related with any single data access technology.

Besides the data-access component of your choice, a Delphi visual application generally uses some data-aware controls (in the Data Controls page) and the DataSource component. Data-aware controls are visual components used to view and edit the data in a form and are extensions of standard components such as edit and list boxes, radio buttons, images, and the grid. The DataSource component has the role of connector between the data-aware controls and a dataset component.

Tables and Queries

The simplest traditional way to specify data access in Delphi was to use the BDE Table component. A Table object simply refers to a database table. When you use a Table component, you need to indicate the name of the database you want to use in its `DatabaseName` property. You can enter an alias or the path of the directory with the table files. The Object Inspector lists the available names, which depend on the aliases installed in the BDE.

You also need to indicate a proper value in the `TableName` property. The Object Inspector lists the available tables of the current database (or directory), so you should generally select the `DatabaseName` property first.

Another classic dataset is the BDE Query component. A query requires a SQL language command. You can customize a query using SQL more easily than you can customize a table (as long as you know at least the basic elements of SQL, of course). The Query component has a DatabaseName property like the Table component, but it does not have a TableName property. The table is indicated in the SQL statement, stored in the SQL property.

For example, you can write a simple SQL statement like this:

```
select * from Country
```

where Country is the name of a table and the asterisk (*) indicates that you want to use all of the fields in the table.

The efficiency of a table or a query varies depending on the database you are using. In general, we can say that the Table component tends to be faster on local tables, while the Query component tends to be faster on SQL servers, although this is just a very general rule, and in many cases you might have the opposite effect. We'll see some efficiency issues while discussing client/server development in Chapter 14, "Client/Server Programming."

The third BDE dataset component is StoredProc, which refers to stored procedures of a SQL server database. You can run these procedures and get the results in the form of a database table. Stored procedures can only be used with SQL servers.

Specific Table Features

The BDE Table component has specific features not shared by all datasets. For example, it has filters, ranges, and specific techniques for locating records. A filter, set in the Filter property and activated by toggling the Filtered property, is available in each dataset, although its role changes depending on the underlying implementation. A range, instead, is specific to a Table and allows you to specify the two extreme values and consider only the record falling within that interval.

When using a Table, and particularly a local one, there are specific methods you can use to find a record, such as GotoKey, FindKey, GotoNearest, FindNearest, and Locate. The Locate method is shared by all datasets, and I'll discuss it later along with other general features of the TDataSet class. The other methods are specific of the TTable class and work in conjunction with the index set in the ndexFieldNames property of the component.

The simplest approach is to use the FindNearest method for the approximate search and the FindKey method to look for an exact match:

```
// goto
Table1.FindNearest ([EditName.Text]);

// go near
if not Table1.FindKey ([EditName.Text]) then
  MessageDlg ('Name not found', mtError, [mbOk], 0);
```

Both find methods use as parameters an array of constants. Each array element corresponds to one of the fields of the current index. You can also pass only the value for the initial field or fields of the index, so the following fields will not be considered.

NOTE I won't discuss these features in details, showing complete examples, because some of them are limited to the BDE and makes sense only for local tables, not for SQL server–based tables. Actually if you set a filter or a range over a Table connected with a SQL server, the BDE will try to generate a proper select statement, avoiding fetching all the data and filtering it locally. The problem is that this isn't always possible and you lose most of your control, two good reasons to use the Query component when working with SQL servers.

A Query with Parameters

When you need slightly different versions of the same SQL query, instead of modifying the text of the Query (stored in the `SQL` property) each time, you can write a query with a parameter and simply change the value of the parameter. For example, if you decide to have a user choose the countries of a continent (using the Country table of the DBDEMOS database), you can write the following parametric query:

```
select *
from Country
where Continent = :Continent
```

In this SQL clause, `:Continent` is a parameter. We can set its data type and startup value, using the editor of the `Params` property collection of the Query component. When the Parameters collection editor is open, as shown in Figure 13.1, you see a list of the parameters defined in the SQL statement and set the data type and the initial value of these parameters.

FIGURE 13.1: Editing the collection of parameters of a Query component

⊞Value	North America

All shown

Editing Query1.Params

0 - Continent

The form displayed by this program, called ParQuery and available on the companion CD, uses a list box to provide all the available values for the parameters. Instead of preparing the items of the list box at design time, we can extract the available continents from the same database table as the program starts. This is accomplished using a second query component, with this SQL statement:

```
select distinct Continent
from Country
```

After activating this query, the program scans its result set, extracting all the values and adding them to the list box:

```
procedure TQueryForm.FormCreate(Sender: TObject);
begin
  // get the list of continents
  Query2.Open;
  while not Query2.EOF do
  begin
    ListBox1.Items.Add (Query2.Fields [0].AsString);
    Query2.Next;
  end;
  ListBox1.ItemIndex := 0;

  // open the first query
  Query1.Params[0].Value := ListBox1.Items [0];
  Query1.Open;
end;
```

Before opening the query, the program selects as its parameter the first item of the list box, which is also activated by setting the ItemIndex property to 0. When the list box is selected, the program closes the query and changes the parameter:

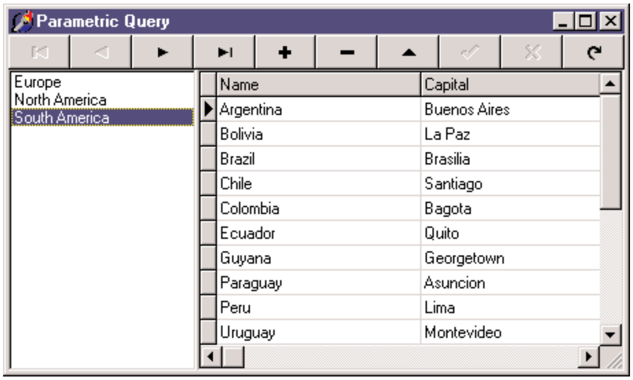
```
procedure TQueryForm.ListBox1Click(Sender: TObject);
begin
  Query1.Close;
  Query1.Params[0].Value := ListBox1.Items [Listbox1.ItemIndex];
  Query1.Open;
end;
```

This displays the countries of the selected continent in the list box, as you can see in Figure 13.2. The final refinement is that when the user enters a record with a new continent, it is added automatically to the list box. Instead of refreshing the entire list, with the same code executed in the FormCreate method, we can do this by handling the BeforePost event and adding the continent to the list if it is not already there:

```
procedure TQueryForm.Query1BeforePost(DataSet: TDataSet);
var
  StrNewCont: string;
begin
  // add the continent, if not already in the list
  StrNewCont := Query1.FieldByName ('Continent').AsString;
  if ListBox1.Items.IndexOf (StrNewCont) < 0 then
    ListBox1.Items.Add (StrNewCont);
end;
```

FIGURE 13.2:

The ParQuery example at run time



Europe
North America

Name	Capital
Argentina	Buenos Aires
Bolivia	La Paz
Brazil	Brasilia
Chile	Santiago
Colombia	Bagota
Ecuador	Quito
Guyana	Georgetown
Paraguay	Asuncion
Peru	Lima
Uruguay	Montevideo

We can add a little extra code to this program to take advantage of a specific feature of parameterized queries. To react faster to a change in the parameters, these queries can be optimized, or *prepared*. Simply call the `Prepare` method before the program first opens the query (after setting the `Active` property of the Query component to `False` at design time) and call `Unprepare` once the query won't be used anymore:

```
procedure TQueryForm.FormCreate(Sender: TObject);
begin
  ...
  // prepare and open the first query
  Query1.Prepare;
  Query1.Params[0].Value := ListBox1.Items [0];
  Query1.Open;
end;

procedure TQueryForm.FormDestroy(Sender: TObject);
begin
  Query1.Close;
  Query1.Unprepare;
end;
```

Prepared parameterized queries are very important when you work on a complex query. In fact, the BDE or the SQL server must read the text of the query and determine how to process it. If you use the same query (even if a parametric one) over and over, the engine doesn't need to reprocess the query but already knows how to handle it.

Master/Detail Structures

Often you need to relate tables, which have a one-to-many relationship. This means that for a single record of the master table, there are many detailed records in a secondary table. A classic example is that of an invoice and the items of the invoice; another is a list of customers and the orders each customer has made. This is very common situation in database programming, and Delphi provides explicit support for it with the master/detail structure. We'll see this structure for BDE Table and Query components, but the same technique applies to almost all of the datasets available in Delphi.

NOTE The `TDataSet` class has a generic `DataSource` property for setting up a master data source, but the Table component, for example, uses a different property (`MasterSource`) to express the same concept.

Master/Detail with Tables

The simplest ways to create a master/detail structure in Delphi is to use the Database Form Wizard, selecting a master/detail form in the first page. To accomplish the same effect manually, place two table components in a form or data module, connect them with the same database, and connect each with a table. In the MastDet example, I've used the customer and orders tables of the DBDEMOS database, and I've used a data module. Now add a DataSource component for each table, and for the secondary table set a master source to the data source connected to the first table. Finally relate the secondary table to a field (called `MasterField`) of the main table, using the special property editor provided.

A Data Module for Data-Access Components

To build a Delphi database application, you can place data-access components and the data-aware controls in a form. This is handy for a simple program, but having the user interface and the data access and data model in a single, often large, unit is far from a good idea. For this reason, Delphi implements the idea of *data module*, a container of nonvisual components I already introduced in Chapter 1, "The Delphi 6 IDE."

At design time, a data module is similar to a form, but at run time it exists only in memory. The `TDataModule` class derives directly from `TComponent`, so it is completely unrelated to the Windows concept of a window (and is fully portable among different operating systems). Unlike a form, a data module has just a few properties and events. For this reason, it's useful to think of data modules as components and method containers.

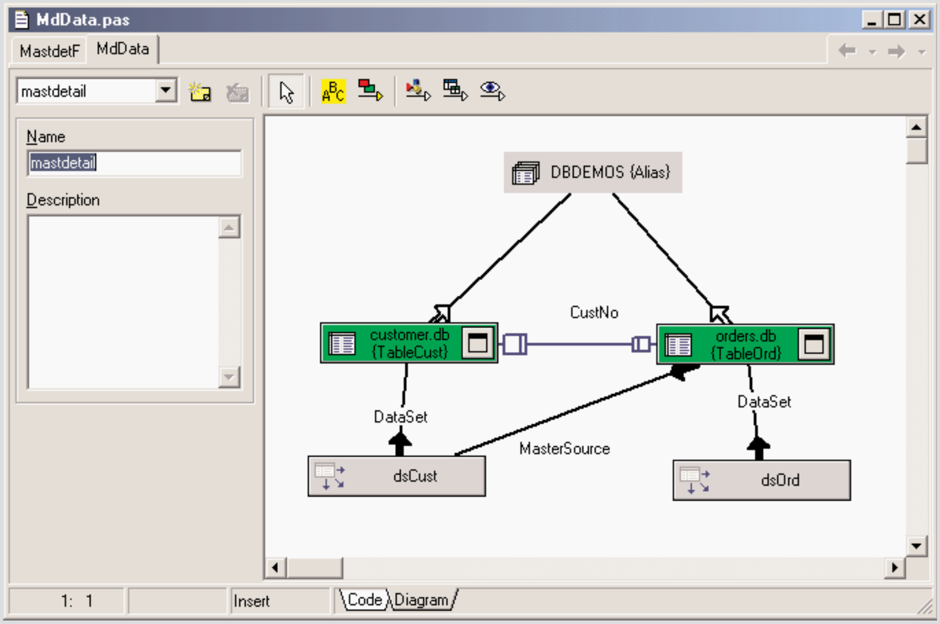
Like a form or a frame, a data module has a designer. This means Delphi creates for a data module a specific Object Pascal unit for the definition of its class and a form definition file that lists its components and their properties.

There are several reasons to use data modules. The simplest one is to share data-access components among multiple forms, as I'll demonstrate at the beginning of the next chapter. This technique works in conjunction with visual form linking, the ability to access components of another form or data module at design time (with the File ➢Use Unit command). The second

Continued on next page

reason is to separate the data from the user interface, improving the structure of an application. Data modules in Delphi even exist in versions specific for multitier applications (remote data modules) and server-side HTTP applications (Web data modules).

Finally, remember that you can use the Diagram page of the editor, introduced in Chapter 1, to see a graphical representation of the connections among the components of a data module, as you can see in this example for the MastDet application:



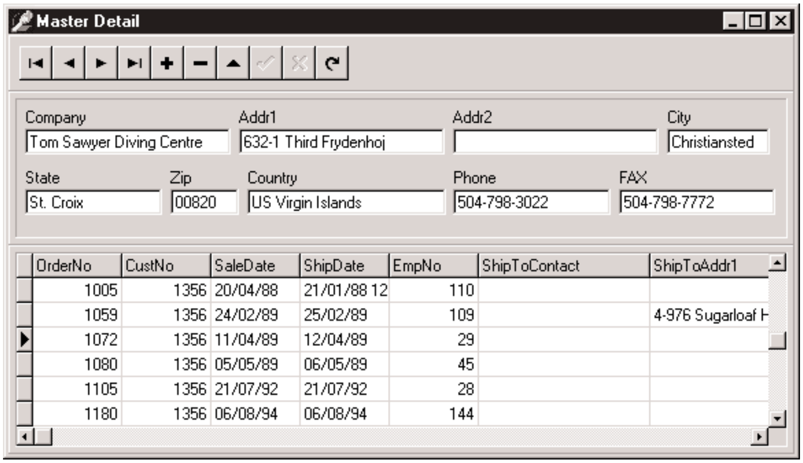
The following is the complete listing (only without the irrelevant positional properties) of the Data Module used by the MastDet program on the CD:

```
object DataModule1: TDataModule1
  OnCreate = DataModule1Create
  object TableCust: TTable
    DatabaseName = 'DBDEMOS'
    TableName = 'customer.db'
  end
  object TableOrd: TTable
    DatabaseName = 'DBDEMOS'
    IndexName = 'CustNo'
    MasterFields = 'CustNo'
    MasterSource = dsCust
    TableName = 'orders.db'
  end
  object dsCust: TDataSource
    DataSet = TableCust
  end
  object dsOrd: TDataSource
    DataSet = TableOrd
  end
end
```

TIP Starting with Delphi 5, you can also create a master/detail structure using the Data Diagram view of a data module.

In Figure 13.3 you can see an example of the main form of the MastDet program at run time. I've placed data-aware controls related to the master table in the upper portion, and I've placed a grid connected with the detail table in the lower portion of the form. This way, for every master record, you immediately see the list of the connected detail record, in this case all the orders by the current client. Each time you select a new customer, the grid below displays only the orders pertaining to that customer.

FIGURE 13.3: The MastDet example at run time



Company	Addr1	Addr2	City
Tom Sawyer Diving Centre	632-1 Third Frydenhoj		Christiansted

1080	1356	05/05/89	06/05/89	45		
1105	1356	21/07/92	21/07/92	28		
1180	1356	06/08/94	06/08/94	144		

A Master/Detail Structure with Queries

The previous example used two tables to build a master/detail form. As an alternative, you can define this type of join using a SQL statement. After setting the master DataSource for the detailed query, you simply set up its SQL statement with a parameter having the same name of the field of the master dataset this data source refers to.

For this example (called Orders), I've joined the ORDERS.DB table with ITEMS.DB, which describes the items of each order. The two tables can be joined using the `OrderNo` field. When you generate the code, the program behaves exactly like the previous one, MastDet. This time, however, the trick is in the SQL statements of the second query object:

```
select OrderNo, ItemNo, PartNo, Qty
from items
where OrderNo = :OrderNo
```

As you can see, this SQL statement uses a parameter, `OrderNo`. This parameter is connected directly to the first query, because the `DataSource` property of `QueryItems` is set to `dsOrders`, which is connected to `QueryOrders`. In other words, the second query is considered to be a data control connected to the first data source. Each time the current record in the first data source changes, the `QueryItems` component is updated, just like any other component connected to `dsOrders`. The field used for the connection, in this case, is the field having the same name as the query parameter.

Other BDE Related Components

Along with Table, Query, StoredProc, and DataSource, other components are on the Data Access page of the Component palette, the BDE page. I'll cover these components in the next chapter, but here is a short summary:

- The Database component is used for transaction control, security, and connection control. It is generally used only to connect to remote databases in client/server applications or to avoid the overhead of connecting to the same database in several forms. The Database component is also used to set a local alias, one used only inside a program. Once this local alias is set to a given path, the Table and Query components of the application can refer to the local database alias. This is much better than replicating the hard-coded path in each DataSet component of the program.

TIP The Borland Database Engine (BDE) uses an alias to refer to a database file or directory. You can define new aliases for databases by using the Database Explorer or the Database Engine Configuration utility. It is also possible to define them by writing code in Delphi that calls the `AddStandardAlias` and `AddAlias` methods of the `Session` global object, followed by a call to `SaveConfigFile` to make the alias persistent. The alternative is the low-level `DbiAddAlias` BDE function. In some of the program of this chapter I'll use the DBDEMOS database alias, which refers to Delphi's demo database, installed by default in the `C:\Program Files\Common Files\Borland Shared\Data` directory.

- The Session component provides global control over database connections for an application, including a list of existing databases and aliases and an event to customize database login.
- The BatchMove component is used to perform batch operations, such as copying, appending, updating, or deleting values, on one or more databases.
- The UpdateSQL component allows you to write SQL statements to perform various update operations on the dataset, when using a read-only query (that is, when working with a complex query). This component is used as the value of the `UpdateObject` property of tables or queries.

Using Data-Aware Controls

Once you've set up the proper data-access components, you can build a user interface to let a user view the data and eventually edit it. Delphi provides many components that resemble the usual Windows controls but are data-aware. For example, the DBEdit component is similar to the Edit component, and the DBCheckBox component corresponds to the CheckBox component. You can find all of these components in the Data Controls page of the Delphi Component palette.

All of these components are connected to a data source using the corresponding property, `DataSource`. Some of them relate to the entire dataset, such as the DBGrid and DBNavigator components, while the others refer to a specific field of the data source, as indicated by the `DataField` property. Once you select the `DataSource` property, the `DataField` property will have a list of values available in the drop-down combo box of the Object Inspector.

NOTE In Chapter 18, "Writing Database Components," we'll discuss the technical details of these controls, as we'll see how to write custom data-aware components.

Notice that all the data-aware components are totally unrelated to the data-access technology, provided the data-access component inherits from `TDataSet`. This means that your investment on the user interface is totally preserved when you change the data-access technology. What is true, however, is that some of the lookup components and an extended use of the DBGrid, displaying a lot of data, only make more sense when working with local data, and should generally be avoided in a client/server situation, as we'll see in the next chapter.

Data in a Grid

The DBGrid is a grid capable of displaying a whole table at once. It allows scrolling and navigation, and you can edit the grid's contents. It is an extension of the other Delphi grid controls.

You can customize the DBGrid by setting the various flags of its Options property and modifying its Columns collection. The grid allows a user to navigate the data, using the scrollbars, and perform all the mayor actions. A user can edit the data directly, insert a new record in a given position by pressing the Insert key, append a new record at the end by going to the last record and pressing the Down arrow key, and delete the current record by pressing Ctrl+Del.

The Columns property is a collection where you can choose the fields of the table you want to see in the grid and set column and title properties (color, font, width, alignment, caption, and so on) for each field. Some of the more advanced properties, such as ButtonStyle and DropDownRows, can be used to provide custom editors for the cells of a grid or a drop-down list of values (indicated in the PickList property of the column).

An alternative to the DBGrid is the DBCtrlGrid component, a multirecord grid that can host panels with other data-aware controls. These controls are duplicated in each panel for each record of the dataset. I'll discuss the DBCtrlGrid control at the end of this chapter.

DBNavigator and Dataset Actions

DBNavigator is a collection of buttons used to navigate and perform actions on the database. You can disable some of the buttons of the DBNavigator control, by removing some of the elements of the VisibleButtons set.

The buttons perform basic actions on the connected dataset, so you can easily replace them with your own toolbar, particularly if you use an ActionList component with the predefined database actions provided by Delphi. In this case, in fact, you get all the standard behaviors, but you'll also see the various buttons enabled only when their action is legitimate.

TIP If you use the standard actions, you can avoid connecting them to a specific DataSource component, and the actions will be applied to the dataset connected to the visual control that currently has the input focus. This way a single toolbar can be used for multiple datasets displayed by a form.

Text-Based Data-Aware Controls

There are multiple text-oriented components:

- DBText displays the contents of a field that cannot be modified by the user. It is a data-aware Label graphical control. It can be very useful, but users might confuse this control with the plain labels that indicate the content of each field-based control.

- DBEdit lets the user edit a field (change the current value) using an Edit control. At times, you might want to disable editing and use a DBEdit as if it were a DBText, but highlighting the fact that this is data coming from the database.
- DBMemo lets the user see and modify a large text field, eventually stored in a memo or BLOB (binary large object) field. It resembles the Memo component and has full editing capabilities, but all the text is rendered in a single font.
- DBRichEdit is a component that lets the user edit a formatted text file; it is based on a RichEdit Windows common control and, in contrast to DBMemo, it allows text with multiple fonts and paragraph styles.

List-Based Data-Aware Controls

For letting a user choose a value in a predefined list (which reduces input errors), you can use many different components. DBListBox, DBComboBox, and DBRadioGroup are similar, providing a list of strings in the `Items` property, but they do have some differences:

- The DBListBox component allows selection of predefined items (“closed selection”), but not text input, and can be used to list many elements. Generally it’s best to show only about six or seven items, to avoid using up too much space on the screen.
- The DBComboBox component can be used both for closed selection and for user input. The `csDropDown` style of the DBComboBox, in fact, allows a user to enter a new value, besides selecting one of the available ones. The component also uses a smaller area of the form because the drop-down list is usually displayed only on request.
- The DBRadioGroup component presents radio buttons (which permit only one selection), allows only closed selection, and should be used only for a limited number of alternatives. A nice features of this component is that the values displayed can be exactly those you want to insert in the database, but you can also choose to provide some sort of mapping. The values of the user interface (some descriptive strings stored in the `Items` property) will map to corresponding values stored in the database (some numeric or character-based codes listed in the `Values` property). For example, you can map some numeric codes indicating departments to a few descriptive strings:

```
object DBRadioGroup1: TDBRadioGroup
  Caption = 'Department'
  DataField = 'Department'
  DataSource = DataSource1
  Items.Strings = (
    'Sales'
    'Accounting'
    'Production'
    'Management')
    Values.Strings = (
      '1'
      '2'
      '3'
      '4')
  end
```

A slightly different component is the DBCheckBox, used to show and toggle an option, corresponding to a Boolean field. It is a limited list, because it has only two possible values, plus the undetermined state for fields with null values. You can determine which are the values to send back to the database by setting the `ValueChecked` and `ValueUnchecked` properties of this component.

The usage of a DBRadioGroup control, with the settings discussed above, and a DBCheckBox control is highlighted by the DbAware example.

Creating Local Tables with FieldDefs

The DbAware example would be a rather simple program if it didn't have an extra feature: It can create a new table for the DBDEMOS database. Delphi allows you to set the definition of the fields of a table—its internal structure—at design time, using the collection editor of the `FieldDefs` property. Once you've defined the fields, you can then right-click the table component at design time and select the Create Table command.

This list of field definitions is generally extracted from the database, but if you set the `StoreDefs` property of the table to `True`, it will be saved in the DFM file along with the other table properties. The effect of the `StoreDefs` property is more complex than it seems at first. If you right-click the form, you'll notice that its local menu offers an Update Table Definition option, along with the expected Delete Table and Rename Table. That is, you can store the field definitions locally, but if the structure of the physical table changes, you should update this definition as well. Until Delphi 4, the field definitions were invariably loaded from the database table at run time; now you can preload them, speeding up the table opening. However, if the local and the actual table definitions do not match, you can get in trouble.

In the DbAware example, I've used this technique to create a new database table, called Workers, which stores data about the employees of a company. This is the definition of the fields of the table, along with the other key properties:

```
object Table1: TTable
  DatabaseName = 'DBDEMOS'
  FieldDefs = <
    item
      Name = 'LastName'
      DataType = ftString
```

Continued on next page

```
          Size = 20
        end
        item
          Name = 'FirstName'
          DataType = ftString
          Size = 20
        end
        item
          Name = 'Department'
          DataType = ftSmallint
        end
        item
          Name = 'Branch'
          DataType = ftString
          Size = 20
        end
        item
          Name = 'Senior'
          DataType = ftBoolean
        end
        item
          Name = 'HireDate'
          DataType = ftDate
        end>
      StoreDefs = True
      TableName = 'Workers'
    end
```

Regardless of the fact you might have created the table at design time, the program must do so the first time it is executed on a different computer. In practice, when the program starts, it checks whether the table already exists and creates one if it doesn't:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  if not Table1.Exists then
    Table1.CreateTable;
  Table1.Open;
end;
```

Finally, the program has some code to fill in the table with random values. As this is kind of tedious but not too complex, I won't discuss the details here, but let you look at the source code of the DbAware example if you are interested. I'll use the table produced by this program in other examples in this book, so you might want to run it once and create the table anyway.

Using Lookup Controls

If the list of values is extracted from another dataset, then instead of the DBListBox and DBComboBox controls you should use the specific DBLookupListBox or DBLookupComboBox components. These components are used every time you want to select for a field a record of another dataset.

For example, if you build a standard form for taking orders, the orders dataset will generally have a field hosting a number indicating the customer who made the order. Working directly with the customer number is not the most natural way; most users will prefer to work with customer names. However, in the database, the names of the customers are stored in a different table, to avoid duplicating the customer data for each order by the same customer. To get around such a situation, with local databases or small lookup tables, you can use a DBLookupComboBox control. (This technique doesn't port very well to client/server architecture with large lookup tables, as discussed in the next chapter.)

The DBLookupComboBox component can be connected to two data sources at the same time, one source containing the actual data and a second containing the display data. Basically, I've built a standard form using the ORDERS.DB tables of the DBDEMOS database, with several DBEdit controls (you can as well use the Database Form Wizard to build this plain form). The example actually uses a Query component selecting most fields of the orders table.

At this point we want to remove the standard DBEdit component connected to the customer number and replace it with a DBLookupComboBox component (and a DBText component for understanding what exactly is going on). The lookup component (and the DBText) is connected with the DataSource for the order and with the CustNo field. To let the lookup component show the information extracted from another table, CUSTOMER.DB, we need to add another table component referring to it, and new data source connected to the table.

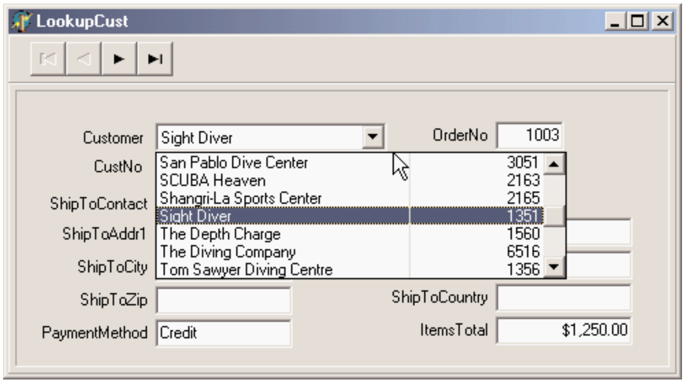
For the program to work, you need to set several properties of the `DBLookupComboBox1` component. Here is a list of the relevant values:

```
object DBLookupComboBox1: TDBLookupComboBox
  DataField = 'CustNo'
  DataSource = DataSourceOrders
  KeyField = 'CustNo'
  ListField = 'Company;CustNo'
  ListSource = DataSourceCustomer
  DropDownWidth = 300
end
```

The first two properties determine the main connection, as usual. The other three properties determine the secondary source (`ListSource`), the field used for the join (`KeyField`), and the information to display (`ListField`). Besides entering the name of a single field, you can provide multiple fields, as I've done in the example. Only the first field is displayed as combo box text, but if you set a large value for the `DropDownWidth` property, the pull-down list of the combo box will include multiple columns of data. You can see this output in Figure 13.4.

FIGURE 13.4:

The output of the CustLookup example, with the DBLookupComboBox showing multiple fields in its drop-down list



Customer: Sight Diver
OrderNo: 1003
CustNo:
ShipToContact:
ShipToAddr1:
ShipToCity:
ShipToZip:
ShipToCountry:
PaymentMethod: Credit
ItemsTotal: $1,250.00

San Pablo Dive Center	3051
SCUBA Heaven	2163
Shangri-La Sports Center	2165
Sight Diver	1351
The Depth Charge	1560
The Diving Company	6516
Tom Sawyer Diving Centre	1356

TIP If you set the index of the table connected with the DBLookupComboBox to the `Company` field, the drop-down list will show the companies in alphabetical order instead of customer-number order. This is what I've done in the example.

What about the code of this program? Well, there is none. Everything works just by setting the correct properties. The three joined data sources do not need custom code. This demonstrates that using master/detail and lookup connections can be very fast to set up and very efficient. The only real drawback is that these techniques, particularly the lookup, cannot be used when the number of records becomes too large, particularly in a networked or client/server environment. Moving hundreds of thousands of records just to make a nice-looking lookup combo box probably won't be very effective.

NOTE In Delphi 6, both the `TDBLookupComboBox` and `TDBLookupListBox` controls have a `NullValueKey` property, which indicates the shortcut that can be used to set the value to null, by calling the `Clear` method of the corresponding field.

Graphical Data-Aware Controls

Finally, Delphi includes two graphical data-aware controls:

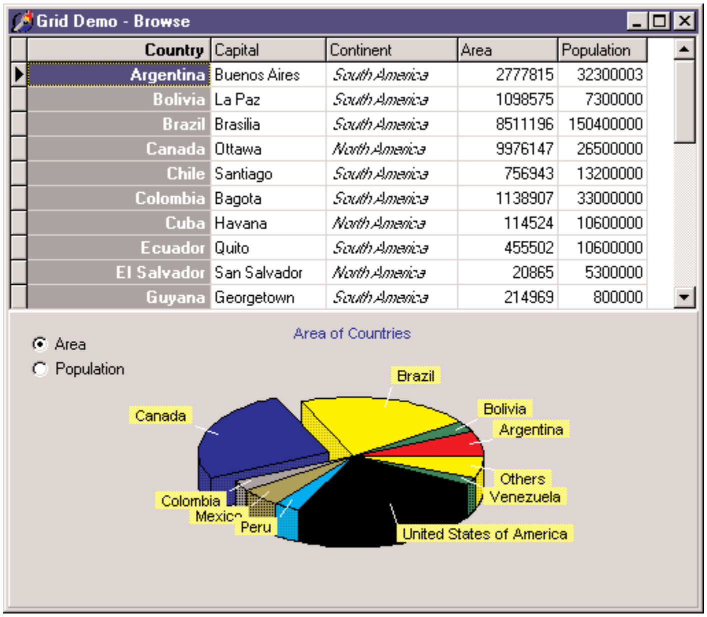
- DBImage is an extension of an Image component that shows a picture stored in a BLOB field (provided the database uses a graphic format that the Image component supports, such as BMP and JPEG).

- DBChart is a data-aware business graphic component or the data-aware version of the TeeChart control built by David Berneda.

To demonstrate the use of the DBChart control, I've added this component to a simple example showing a data grid. The application, called ChartDB, shows a pie chart with the surface of each country of the COUNTRY.DB table, as you can see in Figure 13.5.

FIGURE 13.5:

The output of the ChartDB example, which is based on the `TDbChart` control



Grid Demo - Browse

Country	Capital	Continent	Area	Population
Argentina	Buenos Aires	South America	2777815	32300003
Bolivia	La Paz	South America	1098575	7300000
Brazil	Brasilia	South America	8511196	150400000
Canada	Ottawa	North America	9976147	26500000
Chile	Santiago	South America	756943	13200000
Colombia	Bagota	South America	1138907	33000000
Cuba	Havana	North America	114524	10600000
Ecuador	Quito	South America	455502	10600000
El Salvador	San Salvador	North America	20865	5300000
Guyana	Georgetown	South America	214969	800000

● Area
○ Population

Area of Countries

The program has almost no code, as all the settings can be done using the specific component editor, which has several options but is quite easy to use. Here are some of the key properties of the component, taken from the form description:

```
object DBChart1: TDBChart
  Legend.Visible = False
  Align = alClient
  object Series1: TPieSeries
    Marks.ArrowLength = 8
    Marks.Visible = True
    DataSource = Table1
    XLabelsSource = 'Name'
    ExplodeBiggest = 3
    OtherSlice.Style = poBelowPercent
    OtherSlice.Text = 'Others'
    OtherSlice.Value = 2
    PieValues.ValueSource = 'Area'
  end
end
```

What I've done is show the area field as the data source for the pie chart (the PieValues .ValueSource property of the series), use the name field for the labels (the XLabelsSource property of the series), and condense all the countries with a value below 2 percent in a single section indicated as Others (the OtherSlide subproperties).

As a minor addition to the code, I've added two radio buttons you can use to toggle between the area and the population. The code of the two radio buttons simply sets the source of the series, after casting it to the proper series type, as in:

```
procedure TForm1.RadioPopulationClick(Sender: TObject);
begin
  DBChart1.Title.Text [0] := 'Population of Countries';
  (DBChart1.Series [0] as TPieSeries).PieValues.ValueSource := 'Population';
end;
```

The DataSet Component

Instead of focusing right away on the use of a specific dataset, I prefer starting with a generic introduction of the features of the TDataSet class, which are shared by all inherited data-access classes. The DataSet component is a very complex one, so I won't list all of its capabilities but only discuss its core elements.

The idea behind this component is to provide access to a series of records that are read from some source of data, kept in internal buffers (for performance reasons), and eventually modified by a user, with the possibility of writing back changes to the persistent storage. This approach is generic enough to be applied to different types of data (even non-database data) but has a few rules. First, there can be only one active record at a time, so if you need to access data in multiple records, you must move to each of them, read the data, then move again, and so on. You'll find an example of this and related techniques in the section about navigation.

Second, you can edit only the active record: you cannot modify a set of records at the same time, as you can in a relational database. Moreover, you can modify data in the active buffer only after you explicitly declare you want to do so, by giving the Edit command to the dataset. You can also use the Insert command to create a new blank record, and close both operations (insert or edit) by giving a Post command.

Other interesting elements of a dataset I will explore in the following sections are its status (and the status change events), navigation and record positions, and the role of the field objects. As a summary of the capabilities of the DataSet component, I've included the public methods of its class in Listing 13.1 (the code has been edited and commented for clarity). Not all of these methods are directly used everyday, but I decided to keep them all in the listing. In

Chapter 18, I'll also discuss the virtual methods of the protected portion of the class, which we'll need to override to build custom dataset components.

Listing 13.1: The public interface of the *TDataSet* class (excerpted)

```
TDataSet = class(TComponent, IProviderSupport)
...
public
  // create and destroy, open and close
  constructor Create(AOwner: TComponent); override;
  destructor Destroy; override;
  procedure Open;
  procedure Close;

```

The Status of a Dataset

When you operate on a dataset in Delphi, you can work in different states, indicated by a specific State property, which can assume several different values:

dsBrowse indicates that the dataset is in normal browse mode, used to look at the data and scan the records.

dsEdit indicates that the dataset is in edit mode. A dataset enters this state when the program calls the Edit method or the DataSource has the AutoEdit property set to True, and the user starts editing a data-aware control, such as a DBGrid or DBEdit. When the changed record is posted, the dataset exits the dsEdit state.

dsInsert indicates that a new record is being added to the dataset. Again, this might happen when calling the Insert method, moving to the last line of a DBGrid, or using the corresponding command of the DBNavigator component.

dsInactive is the state of a closed dataset.

dsSetKey indicates that we are preparing a search on the dataset. This is the state between a call to the SetKey method and a call to the GotoKey or GotoNearest methods (see the Search example later in this chapter).

dsCalcFields is the state of a dataset while a field calculation is taking place; that is, during a call to an OnCalcFields event handler. Again, I'll show this in an example.

dsNewValue, dsOldValue, and dsCurValue are the states of a dataset when an update of the cache is in progress.

dsFilter is the state of a dataset while setting a filter; that is, during a call to an OnFilterRecord event handler.

In simple examples, the transitions between these states are handled automatically, but it is important to understand them because there are many events referring to the state transitions. For example, every dataset fires events before and after any state change. When a program requests an Edit operation, the component fires the BeforeEdit event just before entering in edit mode (an operation you can stop by raising an exception). Immediately after entering edit mode, the dataset receives the AfterEdit event. After the user has finished editing and requests to store the data, executing the Post command, the dataset fires a BeforePost event, which can be used to check the input before sending the data to the database, and an AfterPost event after the operation has been successfully completed.

Another more general state-change tracking technique is to handle the OnStateChange event of the DataSource component. As a very simple example you can show the current status with code like this:

```
procedure TForm1.DataSource1StateChange(Sender: TObject);
var
  strStatus: string;
begin
  case Table1.State of
    dsBrowse: strStatus := 'Browse';
    dsEdit: strStatus := 'Edit';
    dsInsert: strStatus := 'Insert';
  else
    strStatus := 'Other state';
  end;
  StatusBar.Panels[0].Text := strStatus;
end;
```

The code considers only the three most common states a dataset component, ignoring the inactive state and other special cases.

The Fields of a Dataset

I mentioned earlier that a dataset has only one record that is the current, or active, one. The record is stored in a buffer, and you can operate on it with some generic methods, but to access the data of the record you need to use the field objects of the dataset. This explains why field components (technically instances of class derived from the TField class) play a fundamental role in every Delphi database application. Data-aware controls are directly connected to these field objects, which correspond to database fields.

By default, Delphi automatically creates the TField components at run time, each time the program opens a dataset component. This is done after reading the metadata associated with the table or the query the dataset refers to. These field components are stored in the Fields array property of a dataset. You can access these values by number (accessing the array directly) or by name (using the FieldByName method). Each field can be used for reading or modifying the data of the current record, using its Value property or type-specific properties, like AsDate, AsString, AsInteger, and so on:

```
var
  strName: string;
begin
  strName := Table1.Fields[0].AsString
  strName := Table1.FieldByName('LastName').AsString
```

Value is a variant type property, so using the type-specific access properties is a little more efficient. The dataset component has also a shortcut property for accessing the variant-type value of a field, the default FieldValues property. Being a default property means you can omit it from the code by applying the square brackets directly to the dataset:

```
strName := Table1.FieldValues ['LastName'];
strName := Table1 ['LastName'];
```

Creating the field components each time a dataset is opened is only a default behavior. As an alternative, you can create the field components at design time, using the Fields editor (double-click a dataset to see the Fields editor in action, or activate its local menu and choose the Fields Editor command). After creating a field for the LastName column of a table, for example, you can refer to its value by applying one of the AsXxx methods to the proper field object:

```
strName := Table1LastName.AsString;
```

Besides being used to access the value of a field, each field object also has properties for controlling visualization and editing of its value, including range of values, edit masks, display format, constraints, and many others. These properties, of course, depend on the type of the field—that it is, on the specific class of the field object. If you create persistent fields you can set some properties at design time, instead of writing code at run time, maybe in the AfterOpen event of the dataset.

NOTE Although the Fields editor is similar to the editors of the collections used by Delphi, fields are not part of a collection. They are components created at design time, listed in its published section of the form class, and available in the drop-down combo box at the top of the Object Inspector.

As you open the Fields editor for a dataset, it appears empty. You have to activate the local menu of this editor to access its capabilities. The simplest operation you can do is to select the Add command, which allows you to add any other fields in the dataset to the list of fields. Figure 13.6 shows the Add Fields dialog box, which lists all the fields that are available in a table. These are the database table fields that are not already present in the list of fields in the editor.

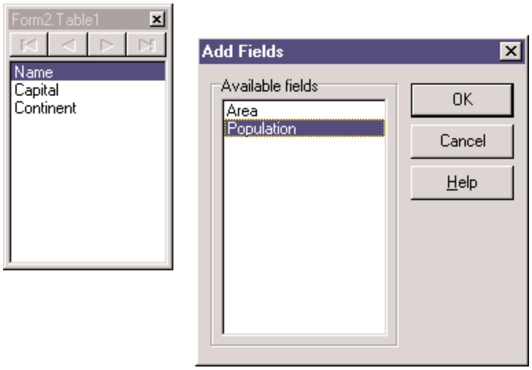

FIGURE 13.6:
The Fields editor with the Add Fields dialog box

The Define command of the Fields editor, instead, lets you define a new calculated field, lookup field, or field with a modified type. In this dialog box, you can enter a descriptive field name, which might include blank spaces. Delphi generates an internal name—the name of the field component—which you can further customize. Next, select a data type for the field. If this is a calculated field or a lookup field, and not just a copy of a field redefined to use a new data type, simply check the proper radio button. We'll see how to define a calculated field in the section "Adding a Calculated Field" and a lookup field in two following sections.

NOTE A `TField` component has both a `Name` property and a `FieldName` property. The `Name` property is the usual component name. The `FieldName` property is either the name of the column in the database table or the name you define for the calculated field. It can be more descriptive than the `Name`, and it allows blank spaces. The `FieldName` property of the `TField` component is copied to the `DisplayLabel` property by default, but this field name can be changed to any suitable text. It is used, among other things, to search a field in the `FieldByName` method of the `TDataSet` class and when using the array notation.

All of the fields that you add or define are included in the Fields editor and can be used by data-aware controls or displayed in a database grid. If a field of the original database table is not in this list, it won't be accessible. When you use the Fields editor, Delphi adds the declaration of the available fields to the class of the form, as new components (much as the Menu Designer adds `TMenuItem` components to the form). The components of the `TField` class, or more specifically its subclasses, are fields of the form, and you can refer to these components directly in the code of your program to change their properties at run time or to get or set their value.

In the Fields editor, you can also drag the fields to change their order. Proper field ordering is particularly important when you define a grid, which arranges its columns using this order.

TIP An even better feature of the Fields editor is that you can drag fields from this editor to the surface of a form and have Delphi automatically create a corresponding data-aware control (such as a DBEdit, a DBMemo, or a DBImage). The type of control created depends on the data type of the field. This is a very fast way to generate custom forms, and I suggest you try it out if you've never used it before. This is my preferred way to build database-related forms, much better than using the Database Form Wizard.

Using Field Objects

Before we look at an example, let's go over the use of the TField class. The importance of this component should not be underestimated. Although it is often used behind the scenes, its role in database applications is fundamental. As I already mentioned, even if you do not define specific objects of this kind, you can always access the fields of a table or a query using their Fields array property, the FieldValues indexed property, or the FieldByName method. Both the Fields property and the FieldByName function return an object of type TField, so you sometimes have to use the as operator to downcast their result to its actual type (like TFloatField or TDateField) before accessing specific properties of these subclasses.

The FieldAcc example is a simple extension of a form generated by the Database Form Wizard. I've added to it three speed buttons in the toolbar panel, accessing various field properties at run time. The first button changes the formatting of the population column of the grid. To do this, we have to access the DisplayFormat property, a specific property of the TFloatField class. For this reason we have to write:

```
procedure TForm2.SpeedButton1Click(Sender: TObject);
begin
  (Table1.FieldByName ('Population') as
    TFloatField).DisplayFormat := '###,###,###';
end;
```

When you set field properties related to data input or output, the change applies to every record in the table. When you set properties related to the value of the field, instead, you always refer to the current record only. For example, we can output the population of the current country in a message box by writing:

```
procedure TForm2.SpeedButton2Click(Sender: TObject);
begin
  ShowMessage (string (Table1 ['Name']) +': '+ string (Table1 ['Population']));
end;
```

When you access the value of a field, you can use a series of *As* properties to handle the current field value using a specific data type (if this is available; otherwise, an exception is raised):

```
AsBoolean: Boolean;
AsDateTime: TDateTime;
AsFloat: Double;
AsInteger: LongInt;
AsString: string;
AsVariant: Variant;
```

These properties can be used to read or change the value of the field. Changing the value of a field is possible only if the dataset is in edit mode. As an alternative to the *As* properties indicated above, you can access the value of a field by using its `Value` property, which is defined as a `variant`.

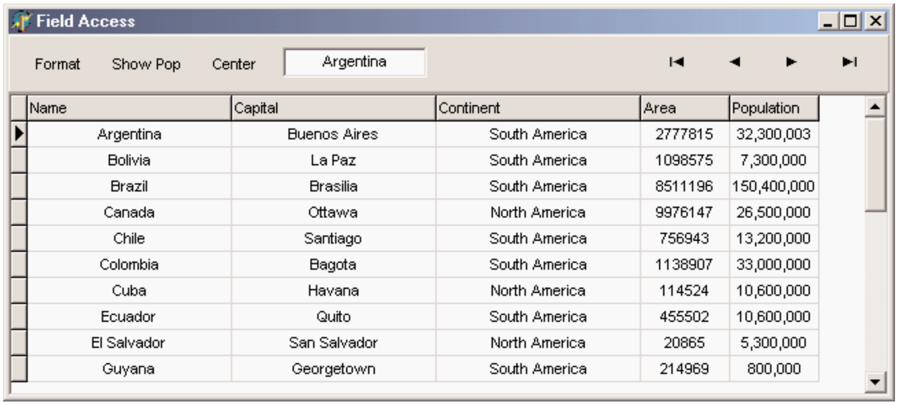
Most of the other properties of the `TField` component, such as `Alignment`, `DisplayLabel`, `DisplayWidth`, and `Visible`, reflect elements of the field's user interface and are used by the various data-aware controls, particularly DBGrid. In the FieldAcc example, clicking the third speed button changes the `Alignment` of every field:

```
procedure TForm2.SpeedButton3Click(Sender: TObject);
var
  I: Integer;
begin
  for I := 0 t7 Table1.FieldCount - 1 do
    Table1.Fields[I].Alignment := taCenter;
end;
```

This affects the output of the DBGrid, and of the DBEdit control I've added to the toolbar, which shows the name of the country. You can see this effect, along with the new display format, in Figure 13.7.

FIGURE 13.7:

The output of the FieldAcc example after the Center and Format buttons have been pressed



Name	Capital	Continent	Area	Population
Argentina	Buenos Aires	South America	2777815	32,300,003
Bolivia	La Paz	South America	1098575	7,300,000
Brazil	Brasilia	South America	8511196	150,400,000
Canada	Ottawa	North America	9976147	26,500,000
Chile	Santiago	South America	756943	13,200,000
Colombia	Bagota	South America	1138907	33,000,000
Cuba	Havana	North America	114524	10,600,000
Ecuador	Quito	South America	455502	10,600,000
El Salvador	San Salvador	North America	20865	5,300,000
Guyana	Georgetown	South America	214969	800,000

A Hierarchy of Field Classes

There are several field class types in VCL. Delphi automatically uses one of them depending on the data definition in the database, when you open a table at run time or when you use the Fields editor at design time. Table 13.1 shows the complete list of subclasses of the TField class.

TABLE 13.1: The Subclasses of TField

Subclass	Base Class	Definition
TADTField	TObjectField	An ADT (Abstract Data Type) field, corresponding to an object field in an object relational database.
TAggregateField	TField	An aggregate field represents a maintained aggregate. It is used in the ClientDataSet component and discussed in Chapter 14, "Client/Server Programming."
TArrayField	TObjectField	An array of objects in an object relational database.
TAutoIncField	TIntegerField	Whole positive number connected with a Paradox auto-increment field of a table, a special field automatically assigned a different value for each record. Note that Paradox AutoInc fields do not always work perfectly, as discussed in the next chapter.
TBCDField	TNumericField	Real numbers, with a fixed number of digits after the decimal point.
TBinaryField	TField	Generally not used directly. This is the base class of the next two classes.
TBlobField	TField	Binary data and no size limit (BLOB stands for binary large object). The theoretical maximum limit is 2 GB.
TBooleanField	TField	Boolean value.
TBytesField	TBinaryField	Arbitrary data with a large (up to 64 KB characters) but fixed size.
TCurrencyField	TFloatField	Currency values, with the same range as the new Real data type.
TDataSetField	TObjectField	An object corresponding to a separate table in an object relational database.
TDateField	TDateTimeField	Date value.
TDateTimeField	TField	Date and time value.
TFloatField	TNumericField	Floating-point numbers (8 byte).
TFMTBCDField	TNumericField	(New field type in Delphi 6) A true binary-coded decimal (BCD), as opposed to the existing TBCDField type, which converted BCD values to the Currency type. This field type is used automatically only by dbExpress datasets.
TGraphicField	TBlobField	Graphic of arbitrary length.
TGuidField	TStringField	A field representing a COM Globally Unique Identifier, part of the ADO support.

Continued on next page

TABLE 13.1 continued: The Subclasses of TField

Subclass	Base Class	Definition
TIDispatchField	TInterfaceField	A field representing pointers to IDispatch COM interfaces, part of the ADO support.
TIntegerField	TNumericField	Whole numbers in the range of long integers (32 bits).
TInterfacedField	TField	Generally not used directly. This is the base class of fields that contain pointers to interfaces (IUnknown) as data.
TLargeIntField	TIntegerField	Very large integers (64 bit).
TMemoField	TBlobField	Text of arbitrary length.
TNumericField	TField	Generally not used directly. This is the base class of all the numeric field classes.
TObjectField	TField	Generally not used directly. The base class for the fields providing support for object relational databases.
TReferenceField	TObjectField	A pointer to an object in an object relational database.
TSmallIntField	TIntegerField	Whole numbers in the range of integers (16 bits).
TSQLTimeStampField	TField	(New field type in Delphi 6) Supports the date/time representation used in dbExpress drivers
TStringField	TField	Text data of a fixed length (up to 8192 bytes).
TTimeField	TDateTimeField	Time value.
TVarBytesField	TBytesField	Arbitrary data, up to 64 KB characters. Very similar to the TBytes-Field base class.
TVariantField	TField	A field representing a variant data type, part of the ADO support.
TWideStringField	TStringField	A field representing a Unicode (16 bits per character) string.
TWordField	TIntegerField	Whole positive numbers in the range of words or unsigned integers (16 bits).

The availability of any particular field type, and the correspondence with the data definition, depends on the database in use. This is particularly true for the new field types that provide support for object relational databases.

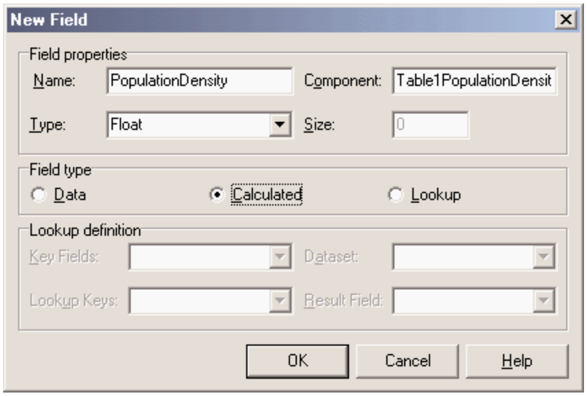
Adding a Calculated Field

Now that you've been introduced to TField objects and seen an example of their run-time use, it is time to build a simple example based on the declaration of field objects at design time using the Fields editor. We can start again from the first example we built, GridDemo, and add a calculated field. The COUNTRY.DB database table we are accessing has both the population and the area of each country, so we can use this data to compute the population density.

To build the new example, named Calc, select the Table component in the form, and open the Fields editor. In this editor, choose the Add Fields command, and select some of the fields. (I've decided to include them all.) Now select the New Field command, and enter a proper name and data type (`TFloatField`) for the new calculated field, as you can see in Figure 13.8.

FIGURE 13.8:

The definition of a calculated field in the Calc example



New Field

Field properties

Name: PopulationDensity

Component: Table1PopulationDensit

Type: Float

Size: 0

Field type

○ Data ● Calculated ○ Lookup

WARNING It is obvious that as you create some field components at design time using the Fields editor, the fields you skip won't get a corresponding object. What might not be obvious is that the fields you skip will not be available even at run time, with Fields or `FieldByName`. When a program opens a table at run time, if there are no design-time field components, Delphi creates field objects corresponding to the table definition. If there are some design-time fields, however, Delphi uses those fields without adding any extra ones.

Of course, we also need to provide a way to calculate the new field. This is accomplished in the `OnCalcFields` event of the Table component, which has the following code (at least in a first version):

```
procedure TForm2.Table1CalcFields(DataSet: TDataSet);
begin
  Table1PopulationDensity.Value := Table1Population.Value / Table1Area.Value;
end;
```

NOTE Calculated fields are computed for each record and recalculated each time the record is loaded in an internal buffer, invoking the `OnCalcFields` event over and over again. For this reason, a handler of this event should be extremely fast to execute, and cannot alter the status of the dataset, by accessing different records. A more time-efficient (but less memory-efficient) version of a calculated field is provided by the ClientDataSet component with "internally calculated" fields, which are evaluated only once, when they are loaded, with the result stored in memory for future requests.

Everything fine? Not at all! If you enter a new record and do not set the value of the population and area, or if you accidentally set the area to zero, the division will raise an exception, making it quite problematic to continue using the program. As an alternative, we could have handled every exception of the division expression and simply set the resulting value to zero:

```
try
  Table1PopulationDensity.Value := Table1Population.Value / Table1Area.Value;
except
  on Exception do
    Table1PopulationDensity.Value := 0;
end;
```

However, we can do even better. We can check if the value of the area is defined—if it is not null—and if it is not zero. It is better to avoid using exceptions when you can anticipate the possible error conditions:

```
if not Table1Area.IsNull and
    (Table1Area.Value <> 0) then
  Table1PopulationDensity.Value := Table1Population.Value / Table1Area.Value
else
    Table1PopulationDensity.Value := 0;
```

The code of the Table1CalcFields method above (in each of the three versions) accesses some fields directly. This is possible because I used the Fields editor, and it automatically created the corresponding field declarations, as you can see in this excerpt of the interface declaration of the form:

```
type
  TCalcForm = class(TForm)
    Table1: TTable;
    Table1PopulationDensity: TFloatField;
    Table1Area: TFloatField;
    Table1Population: TFloatField;
    Table1Name: TStringField;
    Table1Capital: TStringField;
    Table1Continent: TStringField;
    procedure Table1CalcFields(DataSet: TDataset);
    ...
```

Each time you add or remove fields in the Fields editor, you can see the effect of your action immediately in the grid present in the form. Of course, you won't see the values of a calculated field at design time; they are available only at run time, because they result from the execution of compiled Pascal code.

Since we have defined some components for the fields, we can use them to customize some of the visual elements of the grid. For example, to set a display format that adds a comma to separate thousands, we can use the Object Inspector to change the DisplayFormat property of some field components to "###,###,###". This change has an immediate effect on the grid at design time.

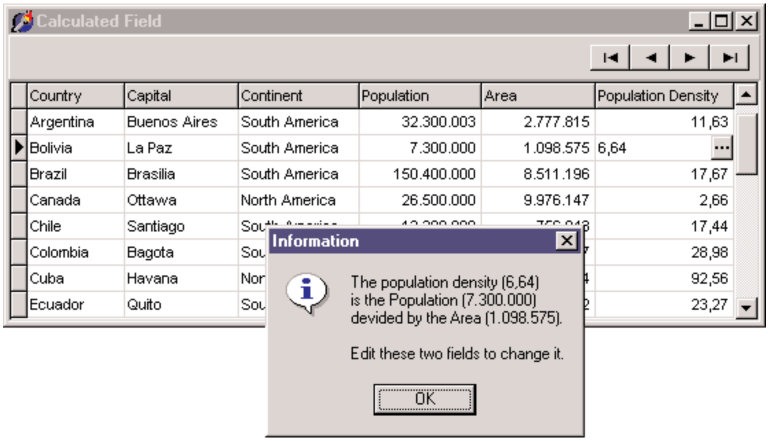
NOTE The display format I've just mentioned (and used in the previous example) uses the Windows International Settings to format the output. When Delphi translates the numeric value of this field to text, the comma in the format string is replaced by the proper `ThousandSeparator` character. For this reason, the output of the program will automatically adapt itself to different International Settings. On computers that have the Italian configuration, for example, the comma is replaced by a period.

After working on the table components and the fields, I've customized the DBGrid using its `Columns` property editor. I've set the Population Density column to read-only and set its `ButtonStyle` property to cbsEllipsis, to provide a custom editor. When you set this value, a small button with an ellipsis is displayed when the user tries to edit the grid cell. Pressing the button invokes the `OnEditButtonClick` event of the DBGrid:

```
procedure TCalcForm.DBGrid1EditButtonClick(Sender: TObject);
begin
  MessageDlg (Format (
    'The population density (%.2n)'#13 +
    'is the Population (%.0n)'#13 +
    'divided by the Area (%.0n).'#13#13 +
    'Edit these two fields to change it.',
    [Table1PopulationDensity.AsFloat,
    Table1Population.AsFloat,
    Table1Area.AsFloat]),
    mtInformation, [mbOK], 0);
end;
```

Actually, I haven't provided a real editor, but rather a message describing the situation, as you can see in Figure 13.9, which shows the values of the calculated fields. To create an editor, you might build a secondary form to handle special data entries.

FIGURE 13.9: The output of the Calc example. Notice the Population Density calculated column, the ellipsis button, and the message displayed when you select it.



Country	Capital	Continent	Population	Area	Population Density
Argentina	Buenos Aires	South America	32.300.003	2.777.815	11,63
Bolivia	La Paz	South America	7.300.000	1.098.575	6,64 ...

Edit these two fields to change it.

Lookup Fields

As an alternative to placing a DBLookupComboBox component in a form (discussed earlier in this chapter under "Using Lookup Controls"), we can also define a lookup field, which can be displayed with a drop-down lookup list inside a DBGrid component. We've seen that to add a fixed selection to a DBGrid, we can simply edit the `PickList` subproperty of the `Columns` property. To customize the grid with a live lookup, instead, we have to define a lookup field using the Fields editor.

As an example, I've built the FieldLookup program, which has a grid displaying orders with a lookup field to display the name of the employee who took the order, instead of the code number of this employee. To accomplish this, I added to the data module a Table component referring to the EMPLOYEE.DB table. Then I opened the Fields editor for the ORDERS table and added all the fields. I selected the `EmpNo` field and set its `Visible` property to False, to remove it from the grid (we cannot remove it altogether, because it is used to build the cross-reference with the corresponding field of the EMPLOYEE table).

Now it is time to define the lookup field. If you've followed the preceding steps, you can use the Fields editor of the ORDERS table and select the New Field command, obtaining the New Field dialog box. (As an alternative in Delphi 5, it's possible to use the Diagram page of the editor, drop the two tables there, and drag a lookup relation from the ORDERS table to the EMPLOYEE table, connecting the two in the resulting New Field dialog box. In Delphi 6, though, the lookup relation button is still part of the Diagram page but doesn't seem to be working at all.)

The values you specify in the New Lookup Field dialog box will affect the properties of a new `TField` added to the table, as demonstrated by the DFM description of the field:

```
object Table2Employee: TStringField
  FieldKind = fkLookup
  FieldName = 'Employee'
  LookupDataSet = Table2
  LookupKeyFields = 'EmpNo'
  LookupResultField = 'LastName'
  KeyFields = 'EmpNo'
  Size = 30
  Lookup = True
end
```

This is all that is needed to make the drop-down list work (see Figure 13.10) and to view the value of the cross-references field at design time, too. Notice that there is no need to customize the `Columns` property of the grid, because the drop-down button and the value of seven rows are taken by default. This doesn't mean you cannot use this property to further customize these and other visual elements of the grid.

FIGURE 13.10: The output of the FieldLookup example, with the drop-down list inside the grid displaying values taken from another database table

Handling Null Values with Field Events

Beyond a few interesting properties, the field objects have a few key events. The `OnValidate` event can be used to provide extended validation of the value of a field, and should be used whenever you need a complex rule that the ranges and constraints provided by the field cannot express. This event is triggered before the data is written to the record buffer, whereas the `OnChange` event is fired soon after the data has been written.

Two more events, `OnGetText` and `OnSetText`, can be used to customize the output of a field. These two events are extremely powerful: they allow you to use data-aware controls even when the representation of a field you want to display is different from the one Delphi will provide by default.

An example of the use of these events is the handling of null value. On SQL servers, storing an empty value or a null value for a field are two separate operations. The latter tends to be more correct, but Delphi by default uses empty values and displays the same output for an empty or a null field. Although this can be useful in general for strings and numbers, it becomes extremely important for dates, where it is hard to set a reasonable default value and where if the user blanks out the field you might have an invalid input.

The NullDates program displays a specific text for dates that have a null value and clears the field (setting it to the null value) when the user uses an empty string in input. Here is the relevant code of the two event handlers for the field:

```
procedure TForm1.Table1ShipDateGetText(Sender: TField;
  var Text: String; DisplayText: Boolean);
begin
```

```
    if Sender.IsNull then
      Text := '<undefined>'
    else
      Text := Sender.AsString;
  end;

  procedure TForm1.Table1ShipDateSetText(Sender: TField; const Text: String);
  begin
    if Text = '' then
      Sender.Clear
    else
      Sender.AsString := Text;
  end;
```

In Figure 13.11 you can see an example of the output of this program, with undefined (or null) values for some shipping dates.

FIGURE 13.11: By handling the OnGetText and OnSetText events of a date field, the NullDates example displays a specific output for null values

Navigating a Dataset

We've seen that a dataset has only one active record, and you can imagine that the active record changes often, in response of user actions or because of internal commands given to the dataset. To move around the dataset and change the active record, there are methods of the TDataSet class, as you can see in Listing 13.1, particularly in the section commented as "position, movement." You can move to the next or previous record, jump back and forth by a given number of records (with MoveBy), or go directly to the first or last record of the dataset. These operations of the dataset are generally available in the DBNavigator component or in the standard dataset actions, and they are not particularly complex to understand.

What is not obvious, though, is how a dataset handles the extreme positions. If you open any dataset with a navigator attached, you can see that as you move on record by record, the Next button remains enabled even when you've reached the last record. It's only when you try to move forward after the last record that the current record apparently doesn't change and the button is disabled. This is because the Eof test (end of file) succeeds only when the cursor has been moved to a special position after the last record. If you jump to the end with the Last button, instead, you'll immediately be at the very end. You'll see exactly the same behavior for the first record (and the Bof test). As we'll see in a while, this approach is very handy, as we can scan a dataset testing for Eof to be True and, at this point, we know we've also already processed the last record of the dataset.

NOTE Handling this special record positions before the beginning and after the end of the dataset, which are called *cracks*, is very important (and quite confusing) when you write a custom dataset, as we'll see in Chapter 18.

Besides moving around record by record or by a given number of records, programs might need to jump to specific records or positions. Some datasets support the RecordCount property and allow movement to a record at a given position in the dataset using the RecNo property. These properties can be used only for datasets that support positions natively, which basically excludes all client/server architectures, unless you grab all of the records in a local cache (something you'll generally want to avoid) and then navigate on the cache. As we'll see in the next chapter, when you open a query on a SQL server you fetch only the records you are using, so Delphi doesn't know the record count, at least not in advance.

There are two alternatives you can use to refer to a record in a dataset, regardless of its type:

- You can save a reference to the current record and then jump back to it after moving around. This is accomplished by using bookmarks, either in the TBookmark or the more modern TBookmarkStr form. This approach is discussed in the upcoming section "Using Bookmarks."
- You can locate a record of the dataset matching given criteria, using the Locate method. This even works after you close and reopen the dataset, because you're working at a logical (and not physical) level. This approach is presented in the next section.

Locating Records in a Table

To show you an example of the use of the Locate method, I've built the Search example, which has a table connected to EMPLOYEE.DB. The form I've prepared has the data-aware edit boxes inside a scroll box aligned to the client area, so that a user can freely resize the form without any problems. When the form becomes too small, scroll bars will appear automatically in the area holding the edit boxes. Another feature is a toolbar with buttons connected to some of the predefined dataset actions available in the ActionList component plus two custom actions to host the search code.

The searching capabilities are activated by the two buttons connected to custom actions. The first button is connected to `ActionGoto`, used for an exact match, and the second to `ActionGoNear`, for a partial match. In both cases, we want to compare the text in the edit box with the `LastName` fields of the EMPLOYEE table. If the local table has an index on the field (as in the specific case) `Locate` will use it, but the method will work with or without indexes (only at a different speed).

If you've never used `Locate`, at first sight the help file won't be terribly clear. The idea is that you must provide a list of fields you want to search, and a list of values, one for each field. If you pass only one field, the value is passed directly, as in the case of the example:

```
procedure TSearchForm.ActionGotoExecute(Sender: TObject);
begin
  if not Table1.Locate ('LastName', EditName.Text, []) then
    MessageDlg ('"' + EditName.Text + '" not found', mtError, [mbOk], 0);
end;
```

If you search for multiple fields, you have to pass a variant array with the list of the values you want to match. The variant array can be created from a constant array with the `VarArrayOf` function or from scratch using the `VarArrayCreate` call. This is a code snippet from the example:

```
Table1.Locate ('LastName;FirstName', VarArrayOf (['Cook', 'Kevin']), [])
```

Finally, we can use the same method to look for a record even if we know only the initial portion of the field we are looking for. Simply add the `loPartialKey` flag to the `Options` parameter (the third) of the `Locate` call.

NOTE

Using `Locate` makes sense specifically for local tables, but doesn't port very well to client/server applications. In fact, on local tables this technique is rather optimized by letting the dataset read in only the records it is looking for, using local indexes. On a SQL server, instead, similar client-side techniques imply moving all the data to the client application first, which is generally a bad idea. Locating the data should be performed with restricted SQL statements. You can still call `Locate` after you're retrieved a limited dataset. For example, you can search a customer by name after you've selected all the customer of a given town or area, obtaining a result set of a limited size. There's more on this topic in the next chapter, which is devoted to client/server development.

The Total of a Table Column

So far in our examples, the user can view the current contents of a database table and manually edit the data or insert new records. Now we will see how we can change some data in the table through the program code. The idea behind this example is quite simple. The EMPLOYEE table we have been using has a Salary field. A manager of the company could indeed browse through the table and change the salary of a single employee. But what will be the total salary expense for the company? And what if the manager wants to give a 10 percent salary increase (or decrease) to everyone?

These are the two aims of the Total example, which is an extension of the previous program. The toolbar of this new example has some more buttons and actions. There are a few other minor changes from the previous example. I opened the Fields editor of the table and removed the Table1Salary field, which was defined as a TFloatField. Then I selected the New Field command and added the same field, with the same name, but using the TCurrencyField data type. This is not a calculated field; it's simply a field converted into a new (but equivalent) data type. Using this new field type the program will default to a new output format, suitable for currency values.

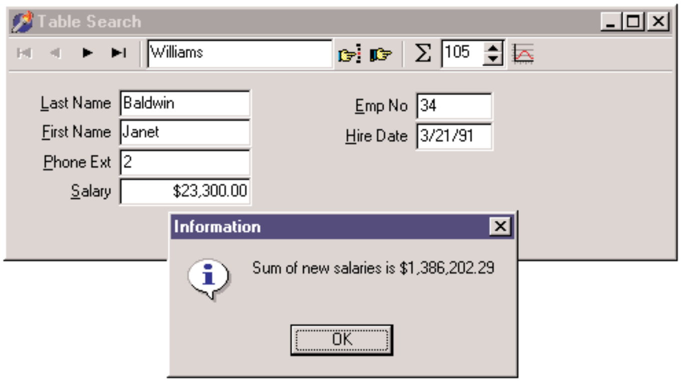
Now we can turn our attention to the code of this new program. First, let's look at the code of the total action. This action lets you calculate the sum of the salaries of all the employees, then edit some of the values, and compute a new total. Basically, we need to scan the table, reading the value of the Table1Salary field for each record:

```
var
  Total: Real;
begin
  Total := 0;
  Table1.First;
  while not Table1.EOF do
  begin
    Total := Total + Table1Salary.Value;
    Table1.Next;
  end;
  MessageDlg ('Sum of new salaries is ' +
    Format ('%m', [Total]), mtInformation, [mbOk], 0);
end
```

This code works, as you can see from the output in Figure 13.12, but it has some problems. One problem is that the record pointer is moved to the last record, so the previous position in the table is lost. Another is that the user interface is refreshed many times during the operation.

FIGURE 13.12:

The output of the Total program, showing the total salaries of the employees



Sum of new salaries is $1,386,202.29

Last Name: Baldwin
First Name: Janet
Phone Ext: 2
Salary: $23,300.00
Emp No: 34
Hire Date: 3/21/91

Using Bookmarks

To avoid these two problems, we need to disable updates and to store the current position of the record pointer in the table and restore it at the end. This can be accomplished using a *table bookmark*, a special variable storing the position of a record in a database table. Delphi's traditional approach is to declare a variable of the TBookmark data type, and initialize it while getting the current position from the table:

```
var
  Bookmark: TBookmark;
begin
  Bookmark := Table1.GetBookmark;
```

At the end of the ActionTotalExecute method, we can restore the position and delete the bookmark with the following two statements:

```
Table1.GotoBookmark (Bookmark);
Table1.FreeBookmark (Bookmark);
```

As a better (and more up-to-date) alternative, we can use the Bookmark property of the TDataset class, which refers to a bookmark that is disposed of automatically. (This is technically implemented as an *opaque string*, a structure subject to string lifetime management, but it is not a string, so you're not supposed to look at what's inside it.) This is how you can modify the code above:

```
var
  Bookmark: TBookmarkStr;
begin
  Bookmark := Table1.Bookmark;
  ...
  Table1.Bookmark := Bookmark;
```

To avoid the other side effect of the program (we see the records scrolling while the routine browses through the data), we can temporarily disable the visual controls connected with the table. The table has a DisableControls method we can call before the while loop starts and an EnableControls method we can call at the end, after the record pointer is restored.

TIP Disabling the data-aware controls connected with a table during long operations not only improves the user interface (since the output is not changing constantly), it also speeds up the program considerably. In fact, the time spent to update the user interface is much greater than the time spent performing the calculations. To test this, try commenting out the DisableControls and EnableControls methods of the Total example, and see the speed difference.

Finally, we face some dangers from errors in reading the table data, particularly if the program is reading the data from a server using a network. If any problem occurs while retrieving the data, an exception takes place, the controls remain disabled, and the program cannot resume its normal behavior. So we should use a try/finally block. Actually, if you want to make the program 100 percent error-proof, you should use two nested try/finally blocks. Including this change and the two discussed above, here is the resulting code:

```
procedure TSearchForm.ActionTotalExecute(Sender: TObject);
var
  Bookmark: TBookmarkStr;
  Total: Real;
begin
  Bookmark := Table1.Bookmark;
  try
    Table1.DisableControls;
    Total := 0;
    try
      Table1.First;
      while not Table1.EOF do
      begin
        Total := Total + Table1Salary.Value;
        Table1.Next;
      end;
    finally
      Table1.EnableControls;
  end
  finally
    Table1.Bookmark := Bookmark;
  end;
  MessageDlg ('Sum of new salaries is ' +
    Format ('%m', [Total]), mtInformation, [mbOK], 0);
end;
```

NOTE I've written this code to show you an example of a loop to browse the contents of a table, but keep in mind that there is an alternative approach based on the use of a SQL query returning the sum of the values of a field. When you use a SQL server, the speed advantage of a SQL call to compute the total can be very large, since you don't need to move all the data of each field from the server to the client computer. The server sends the client only the final result.

Editing a Table Column

The code of the increase action is similar to the one we have just seen. The `ActionIncreaseExecute` method also scans the table, computing the total of the salaries, as the previous method did. Although it has just two more statements, there is a key difference. When you increase the salary, you actually change the data in the table. The two key statements are within the `while` loop:

```
while not Table1.EOF do
begin
  Table1.Edit;
  Table1Salary.Value := Round (Table1Salary.Value * SpinEdit1.Value) / 100;
  Total := Total + Table1Salary.Value;
  Table1.Next;
end;
```

The first statement brings the table into edit mode, so that changes to the fields will have an immediate effect. The second statement computes the new salary, multiplying the old one by the value of the SpinEdit component (by default, 105) and dividing it by 100. That's a 5 percent increase, although the values are rounded to the nearest dollar. With this program, you can change salaries by any amount—even double the salary of each employee—with the click of a button.

WARNING Notice that the table enters the edit mode every time the `while` loop is executed. This is because in a dataset, edit operations can take place only one record at a time. You must finish the edit operation, calling `Post` or moving to a different record as in the code above. At that time, if you want to change another record, you have to enter edit mode once more.

Customizing a Database Grid

Unlike most other data-aware controls, which are quite simple to use, the DBGrid control has many options and is more powerful than you might think. The following sections explore some of the advanced operations you can do using a DBGrid control. A first example shows how to draw in a grid, a second one shows how to clone the behavior of a check box for a

Boolean selection inside a grid, and the final example shows how to use the multiple-selection feature of the grid.

Painting a DBGrid

There are many reasons you might want to customize the output of a grid. A good example is to highlight specific fields or records. Another is to provide some form of output for fields that usually don't show up in the grid, such as BLOB, graphic, and memo fields.

To thoroughly customize the drawing of a DBGrid control, you have to set its `DefaultDrawing` property to False and handle its `OnDrawColumnCell` event. In fact, if you leave the value of `DefaultDrawing` set to True, the grid will display the default output before the method is called. This way, all you can do is add something to the default output of the grid, unless you decide to draw over it, which will take extra time and cause flickering.

The alternative approach is to call the `DefaultDrawColumnCell` method of the grid, perhaps after changing the current font or restricting the output rectangle. In this last case you can provide an extra drawing in a cell and let the grid fill the remaining area with the standard output. This is what I've done in the DrawData program.

The DBGrid control in this example, which is connected to the commonly used `BIOLIFE` table of the DBDEMOS database, has the following properties:

```
object DBGrid1: TDBGrid
  Align = alClient
  DataSource = DataSource1
  DefaultDrawing = False
  Font.Height = -16
  Font.Name = 'MS Sans Serif'
  Font.Style = [fsBold]
  TitleFont.Height = -11
  TitleFont.Name = 'MS Sans Serif'
  TitleFont.Style = []
  OnDrawColumnCell = DBGrid1DrawColumnCell
end
```

The `OnDrawColumnCell` event handler is called once for every cell of the grid and has several parameters, including the rectangle corresponding to the cell, the index of the column we have to draw, the column itself (with the field, its alignment, and other subproperties), and the status of the cell. How can we set the color of specific cells to red? We can simply change it in the special cases:

```
procedure TForm1.DBGrid1DrawColumnCell(Sender: TObject;
  const Rect: TRect; DataCol: Integer; Column: TColumn;
  State: TGridDrawState);
begin
```

```
    // red font color if length > 100
    if (Column.Field = Table1Lengthcm) and (Table1Lengthcm.AsInteger > 100) then
      DBGrid1.Canvas.Font.Color := clRed;

    // default drawing
    DBGrid1.DefaultDrawDataCell (Rect, Column.Field, State);
  end;
```

The next step is to draw the memo and the graphic fields. For the memo we can simply implement the memo field's OnGetText and OnSetText events. In fact, the grid will even allow editing on a memo field if its OnSetText event is not nil. Here is the code of the two event handlers. I've used Trim to remove trailing nonprinting characters, which make the text appear to be empty when editing:

```
procedure TForm1.Table1NotesGetText(Sender: TField;
  var Text: String; DisplayText: Boolean);
begin
  Text := Trim (Sender.AsString);
end;

procedure TForm1.Table1NotesSetText(Sender: TField; const Text: String);
begin
  Sender.AsString := Text;
end;
```

For the image, the simplest approach is to create a temporary TBitmap object, assign the graphics field to it, and paint the bitmap to the Canvas of the grid. As an alternative, I've removed the graphic field from the grid, by setting its Visible property to False, and added the image to the fish name, with the following extra code in the OnDrawColumnCell event handler:

```
var
  Bmp: TBitmap;
  OutRect: TRect;
  BmpWidth: Integer;
begin
  // default output rectangle
  OutRect := Rect;

  if Column.Field = Table1Common_Name then
  begin
    // draw the image
    Bmp := TBitmap.Create;
    try
      Bmp.Assign (Table1Graphic);
      BmpWidth := (Rect.Bottom - Rect.Top) * 2;
      OutRect.Right := Rect.Left + BmpWidth;
    DBGrid1.Canvas.StretchDraw (OutRect, Bmp);
  finally
    Bmp.Free;
  end;
  // reset output rectangle, leaving space for the graphic
  OutRect := Rect;
  OutRect.Left := OutRect.Left + BmpWidth;
end;

// red font color if length > 100 (omitted - see above)

// default drawing
DBGrid1.DefaultDrawDataCell (OutRect, Column.Field, State);
```

As you can see in the code above, the program shows the image in a small rectangle on the left of the grid cell and then changes the output rectangle to the remaining area before activating the default drawing. You can see the effect in Figure 13.13.

FIGURE 13.13:

A Check Box Cell

Another common extension of the DBGrid control, found in many third-party components, is the use of check boxes to select the status of Boolean field values. A simple way to do this is to place a DBCheckBox control in front of the grid when the user selects the corresponding item. I've done this in the CheckDbg example, which uses the Workers table created in the DbAware example discussed earlier in this chapter.

The form displayed by the program contains only the grid and the check box. This is a summary of the textual description of the form:

```
object DbaForm: TDbaForm
  OnCreate = FormCreate
  object DBGrid1: TDBGrid
```

```
      Align = alClient
      DataSource = DataSource1
      OnColEnter = DBGrid1ColEnter
      OnDrawColumnCell = DBGrid1DrawColumnCell
      OnKeyPress = DBGrid1KeyPress
    end
    object DBCheckBox1: TDBCheckBox
      Caption = 'Senior'
      DataField = 'Senior'
      DataSource = DataSource1
      ValueChecked = 'True'
      ValueUnchecked = 'False'
      Visible = False
    end
    object Table1: TTable
      DatabaseName = 'DBDEMOS'
      TableName = 'Workers'
    end
  end
```

Notice that the check box is initially hidden and that the program handles several events of the DBGrid control. The first is the OnDrawColumnCell event, which is not used to customize the drawing (the DefaultDrawing property is set to True), but only to compute the position of the check box when a cell of the corresponding field is selected:

```
procedure TDbaForm.DBGrid1DrawColumnCell(Sender: TObject;
  const Rect: TRect; DataCol: Integer; Column: TColumn;
  State: TGridDrawState);
begin
  if (gdFocused in State) and (Column.Field = Table1Senior) then
  begin
    DBCheckBox1.SetBounds (
      Rect.Left + DBGrid1.Left + 1,
      Rect.Top + DBGrid1.Top + 1,
      Rect.Right - Rect.Left + 1,
      Rect.Bottom - Rect.Top + 1);
  end;
end;
```

The check box itself is displayed or hidden as the user enters or exits the corresponding column, by the handler of the OnColEnter event. Note that we cannot refer to the column by position, since a user can move the columns:

```
procedure TDbaForm.DBGrid1ColEnter(Sender: TObject);
begin
  if DBGrid1.Columns [DBGrid1.SelectedIndex].Field = Table1Senior then
    DBCheckBox1.Visible := True
  else
    DBCheckBox1.Visible := False;
end;
```

Finally, as an extra extension, when the check box is visible (that is, when the user has activated the corresponding field), the program intercepts the keyboard input in the grid, toggling the selection of the check box instead of accepting the input:

```
procedure TDbaForm.DBGrid1KeyPress(Sender: TObject; var Key: Char);
begin
  if DBCheckBox1.Visible and (Ord (Key) > 31) then
  begin
    Key := #0;
    Table1.Edit;
    DBCheckBox1.Checked := not DBCheckBox1.Checked;
    DBCheckBox1.Field.AsBoolean := DBCheckBox1.Checked;
  end;
end;
```

To make this work we must not only toggle the status of the check box, but also go into edit mode and update the data of the field. You can see an example of the output of this program in Figure 13.14.

FIGURE 13.14: The grid of the CheckDbg example uses a check box for selecting the value of a Boolean field.

A Grid Allowing Multiple Selection

The third and last example of customizing the DBGrid control relates to multiple selection. You can set up the DBGrid so that a user can select multiple rows (that is, multiple records). This is very easy, since all you have to do is toggle the `dgMultiSelect` element of the `Options` property of the grid. Once you've selected this option, a user can keep the Ctrl key pressed and click with the mouse to select multiple rows of the grid, with the effect you can see in Figure 13.15.

FIGURE 13.15:

The MltGrid example has a DBGrid control that allows the selection of multiple rows.

	Name	Capital	Continent

	Paraguay	Asuncion	South Ame

Canada
Cuba
Guyana
Jamaica

Since the database table can have only one active record, what information is stored in the grid for the selected items? The grid simply keeps a list of bookmarks to the selected records. This list is available in the `SelectedRows` property, which is of type `TBookmarkList`. Besides accessing the number of objects in the list with the `Count` property, you can get to each bookmark with the `Items` property, which is the default array property. Each item of the list is on a `TBookmarkStr` type, which represents a bookmark pointer you can assign to the `Bookmark` property of the table.

NOTE The `TBookmarkStr` is a string type for convenience, but its data should be considered "opaque" and volatile. You shouldn't rely on any particular structure to the data you may find if you peek at a bookmark's value, and you shouldn't hold on to the data too long or store it in a separate file. Bookmark data will vary with database driver and index configuration, and it may be rendered unusable when rows are added to or deleted from the dataset (by you or by other users of the database).

To summarize the steps, here is the code of the MltGrid example, activated by pressing the button to move the Name field of the selected records to the list box:

```
procedure TForm1.Button1Click(Sender: TObject);
var
  I: Integer;
  BookmarkList: TBookmarkList;
  Bookmark: TBookmarkStr;
begin
  // store the current position
  Bookmark := Table1.Bookmark;
  try
    // empty the list box
    ListBox1.Items.Clear;
    // get the selected rows of the grid
    BookmarkList := DbGrid1.SelectedRows;
    for I := 0 to BookmarkList.Count - 1 do
    begin
      // for each, move the table to that record
      Table1.Bookmark := BookmarkList[I];
      // add the name field to the listbox
      ListBox1.Items.Add (Table1.FieldByName ('Name').AsString);
    end;
  finally
    // go back to the initial record
    Table1.Bookmark := Bookmark;
  end;
end;
```

Dragging to a Grid

Another interesting technique is to use dragging with grids. Dragging *from* a grid is not particularly difficult, as you know which are the current record and the column the user has selected. Dragging *to* a grid, instead, is apparently hard to program. You might remember that in Chapter 3, "The Object Pascal Language: Inheritance and Polymorphism," I mentioned the "protected hack;" this is the technique I'm going to use to implement dragging to a grid.

The example, called DragToGrid, has a grid connected to the COUNTRY.DB demo table, an edit where you can type the new value for a field, and a label you can drag over a cell of the grid to modify the related field. The real problem is how to determine this field. The code is only a few lines, as you can see below, but it is certainly cryptic, and requires some explanation:

```
type
  TDBGHack = class (TDbGrid)
  end;

procedure TFormDrag.DBGrid1DragDrop(Sender, Source: TObject; X, Y: Integer);
var
  gc: TGridCoord;
begin
  gc := TDBGHack (DbGrid1).MouseCoord (x, y);
  if (gc.y > 0) and (gc.x > 0) then
  begin
    DbGrid1.DataSource.DataSet.MoveBy (gc.y - TDBGHack(DbGrid1).Row);
    DbGrid1.DataSource.DataSet.Edit;
    DBGrid1.Columns.Items [gc.X - 1].Field.AsString := EditDrag.Text;
  end;
  DBGrid1.SetFocus;
end;
```

The first operation is to determine the cell over which the mouse was released. Starting with the `X` and `Y` mouse coordinates, we can call the protected `MouseCoord` method to access the row and column of the cell. Unless the drag target is the very first row (usually hosting the titles) or the first column (usually hosting the indicator), the program moves the current record by the difference between the requested row (`gc.y`) and the current active row (the protected `Row` property of the grid). The next step is to put the dataset into edit mode, grab the field of the target column (`Columns.Items [gc.X - 1].Field`), and change its text.

Database Applications with Standard Controls

Although it is generally faster to write Delphi applications based on data-aware controls, this is certainly not required. When you need to have very precise control over the user interface of a database application, you might want to customize the transfer of the data from the field objects to the visual controls. My personal view is that this is necessary only in very specific cases, as you can customize the data-aware controls extensively by setting the properties and handling the events of the field objects. However, trying to work without the data-aware controls should help you understand the default behavior of Delphi, and it will help me introduce some more database-related events (discussed in the sections "Database Events" and "Field Events").

The development of an application not based on data-aware controls can follow two different approaches. You can mimic the standard Delphi behavior in code, possibly departing from it in specific cases, or you can go for a much more customized approach. I'll demonstrate the first technique in the NonAware example and the latter in the SendToDb example.

Mimicking Delphi Data-Aware Controls

If you want to build an application that doesn't use data-aware controls but behaves like a standard Delphi application, you can simply write event handlers for the operations that would be performed automatically by data-aware controls. Basically you need to place the dataset in edit mode as the user changes the content of the visual controls, and update the field objects of the dataset as the user exits from the controls, moving the focus to another element.

TIP This approach can be handy for integrating a control that's not data-aware into a standard application. A good example is the use of the DateTimePicker control for selecting a date, as demonstrated later in the section "Editing Dates with a Calendar."

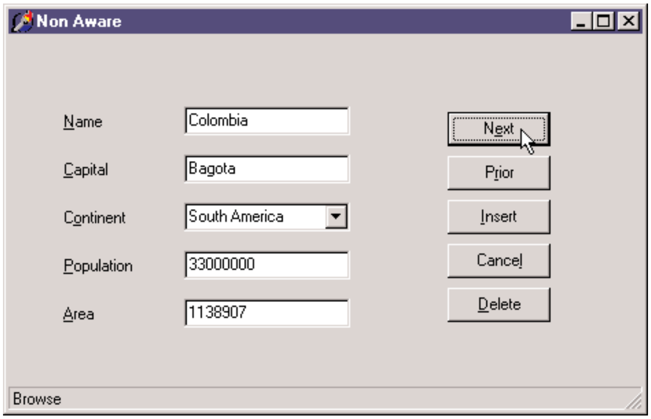
The other element of the NonAware example is a list of buttons corresponding to some of those in the DBNavigator control and connected to five custom actions. I cannot use the standard dataset actions for this example simply because they automatically hook to the data source associated with the control having the focus, a mechanism that fails with the non–data-aware edit boxes of this example.

The program has several event handlers we've not used for past applications using data-aware controls. First of all, we have to show the data of the current record in the visual controls (as in Figure 13.16), by handling the `OnDataChange` event of the `DataSource1` component:

```
procedure TForm1.DataSource1DataChange(Sender: TObject; Field: TField);
begin
  EditName.Text := Table1Name.AsString;
  EditCapital.Text := Table1Capital.AsString;
  ComboContinent.Text := Table1Continent.AsString;
  EditArea.Text := Table1Area.AsString;
  EditPopulation.Text := Table1Population.AsString;
end;
```

FIGURE 13.16:

The output of the Non-Aware example in Browse mode. The program manually fetches the data every time the current record changes.



Non Aware

Name	Colombia
Capital	Bagota
Continent	South America
Population	33000000
Area	1138907

Browse

The handler of the `OnStateChange` event of the control displays the status of the table in a status bar control. As the user starts typing in one of the edit boxes or drops down the combo box list, the program sets the table in edit mode:

```
procedure TForm1.EditKeyPress(Sender: TObject; var Key: Char);
begin
  if not (Table1.State in [dsEdit, dsInsert]) then
    Table1.Edit;
end;
```

This method is connected with the `OnKeyPress` event of the five components and is similar to the `OnDropDown` event handler of the combo box. As the user leaves one of the visual controls, the handler of the OnExit event copies the data to the corresponding field, as in this case:

```
procedure TForm1.EditCapitalExit(Sender: TObject);
begin
  if (Table1.State in [dsEdit, dsInsert]) then
    Table1Capital.AsString := EditCapital.Text;
end;
```

The operation takes place only if the table is in edit mode; that is, only if the user has typed in this or another control. This is not really ideal, because extra operations are done even if the text of the edit box didn't change, but the extra steps happen fast enough not to be a concern. For the first edit box, we check the text before copying it, raising an exception if the edit box is empty:

```
procedure TForm1.EditNameExit(Sender: TObject);
begin
  if (Table1.State in [dsEdit, dsInsert])then
    if EditName.Text <> '' then
      Table1Name.AsString := EditName.Text
    else
    begin
      EditName.SetFocus;
      raise Exception.Create ('Undefined Country');
    end;
end;
```

An alternative approach for testing the value of a field is to handle the BeforePost event of the dataset. Keep in mind that in this example, the posting operation is not handled by a specific button but takes place as soon as a user moves to a new record or inserts a new one:

```
procedure TForm1.Table1BeforePost(DataSet: TDataSet);
begin
  if Table1Area.Value < 100 then
    raise Exception.Create ('Area too small');
end;
```

In each of these cases, an alternative to raising an exception is to set a default value. However, if a field has a default value it is better to set it up front, so that a user can see which value will be sent to the database. To accomplish this, you can handle the AfterInsert event of a dataset, which is fired immediately after a new record has been created (we could have used the OnNewRecord event, as well):

```
procedure TForm1.Table1AfterInsert(DataSet: TDataSet);
begin
  Table1Continent.Value := 'Asia';
end;
```

Sending Requests to the Database

You can further customize the user interface of your application if you decide not to handle the same sequence of editing operations as in standard Delphi data-aware controls. This allows you complete freedom, although there might be some side effects (such as limited ability to handle concurrency, something I'll discuss in the next chapter).

For this new example, I've replaced the first edit box with another combo box, and replaced all the buttons related to table operations (which corresponded to DBNavigator buttons) with two custom ones, used to get the data from the database and send an update to it. To underline the difference of this example, I've even removed the DataSource component.

The `GetData` method, connected with the corresponding button, simply gets the fields corresponding to the record indicated in the first combo box:

```
procedure TForm1.GetData;
begin
  Table1.FindNearest ([ComboName.Text]);
  ComboName.Text := Table1Name.AsString;
  EditCapital.Text := Table1Capital.AsString;
  ComboContinent.Text := Table1Continent.AsString;
  EditArea.Text := Table1Area.AsString;
  EditPopulation.Text := Table1Population.AsString;
end;
```

This method is called whenever the user presses the button, selects an item of the combo box, or presses the Enter key while in the combo box:

```
procedure TForm1.ComboNameClick(Sender: TObject);
begin
  GetData;
end;

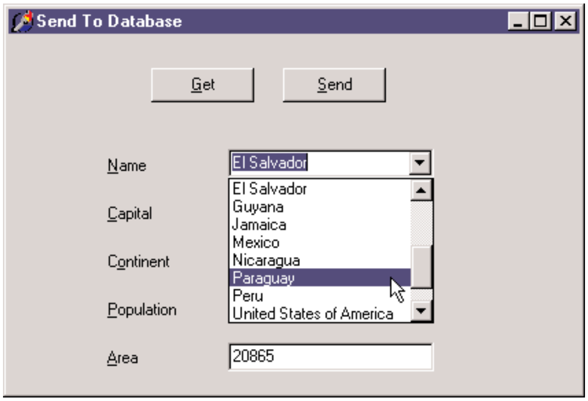
procedure TForm1.ComboNameKeyPress(Sender: TObject; var Key: Char);
begin
  if Key = #13 then
    GetData;
end;
```

To make this example work smoothly, at start-up the combo box is filled with all the names of the countries of the table:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  // fill the list of names
  Table1.Open;
  while not Table1.Eof do
  begin
```

```
      ComboName.Items.Add (Table1Name.AsString);
      Table1.Next;
    end;
  end;
```

With this approach, the combo box becomes a sort of selector of the record, as you can see in Figure 13.17. Notice that thanks to this selection, the program doesn't need navigational buttons.



Name: El Salvador

El Salvador
Guyana
Jamaica
Mexico
Nicaragua
Paraguay
Peru
United States of America

Area: 20865

FIGURE 13.17: In the SendToDb example, you can select the record you want to see in a combo box.

Finally, the user can change the values of the controls and click the Send button. The code to be executed depends on whether the operation is an update or an insert. We can determine this by looking at the name (although with this code, a wrong name cannot be modified any more):

```
procedure TForm1.SendData;
begin
  // raise an exception if there is no name
  if ComboName.Text = '' then
    raise Exception.Create ('Insert the name');

  // check if the record is already in the table
  if Table1.FindKey ([ComboName.Text]) then
  begin
    // modify found record
    Table1.Edit;
    Table1Capital.AsString := EditCapital.Text;
    Table1Continent.AsString := ComboContinent.Text;
    Table1Area.AsString := EditArea.Text;
    Table1Population.AsString := EditPopulation.Text;
    Table1.Post;
  end
  else
```

```
begin
  // insert new record
  Table1.InsertRecord ([ComboName.Text, EditCapital.Text,
    ComboContinent.Text, EditArea.Text, EditPopulation.Text]);
  // add to list
  ComboName.Items.Add (ComboName.Text)
end;
```

Before sending the data to the table, you can do any sort of validation test on the values. In this case, it doesn't make much sense to handle the events of the database components, because we have full control on when the update or insert operation is done.

Database Events

To further illustrate how you can use the events of a database application, I've written a simple program that logs all the events being fired. This program handles all of the events of a table and a data source component (although some of these events won't actually be executed, unless you add some extra code, as described later). For each event, I simply send its description to a list box, with the effect you can see in Figure 13.18.

FIGURE 13.18:

The output of the DbEvts program, which logs all the events related to database components

```

Most of the event handlers simply display the name of the component and that of the event, as in

```
procedure TForm1.Table1AfterEdit(DataSet: TDataset);
begin
  AddToList ('Table: AfterEdit');
end;
```

The field events are slightly more complex, but they use a single handler for the various field components:

```
procedure TForm1.FieldChange(Sender: TField);
begin
  AddToList ('Field ' + Sender.FieldName + ': OnChange');
end;
```

The form's AddToList method adds a new item to the list box and selects it, automatically scrolling the list if required:

```
procedure TForm1.AddToList(Str: string);
begin
  // add item and select it
  Listbox1.ItemIndex := Listbox1.Items.Add (Str);
end;
```

Finally, the program has a pop-up menu connected to the list box to clear the list or save the items to a file. The menu also has a command you can use to add a blank line, thus separating blocks of events. This operation is also done automatically by a timer, which adds a blank line to the list box unless the last item is already an empty string. This makes the output more readable, as you can see in Figure 13.18.

It is very important to study the output of this program as well as its code. You can try doing all the various operations on the table using the DBGrid, such as inserting, editing, and deleting records, and see the corresponding effect in terms of events fired by the VCL components. To see even more events, you can set the Filtered property of the table to True, define a calculated field, try to cause errors (for example, by duplicating the value of the name field), add a check box to open or close the table, and so forth.

Field Events

The DbEvts program shows the calls to the OnChange and OnValidate events of the field objects. Two other events, OnSetText and OnGetText, are not shown, because the handlers of these events are not simply called to indicate that an operation occurred. On the contrary, their event handlers must perform the operation of getting data from or setting it to the corresponding field objects.

These two events are quite special, and their use is not as simple as it might seem at first sight. For this reason, they require a separate example, named FldText. This is only a slight revision of the DbAware example described earlier in this chapter, replacing the DBRadioGroup control with a DBListbox control. The problem is that a DBListBox control directly connects with a string field, while I want to connect it with an integer field, with each value indicating an option. Of course, I don't want a user to see or select a number, so I have to map the numbers stored in the database to the strings visible on the screen. In the earlier example, the DBRadioGroup control provided that mapping. Now I have to use an alternative approach.

In the FldText example, the Department field has two handlers for the `OnGetText` and `OnSetText` events. In the `OnGetText` event handler, you can extract the numeric value of the `Sender` field and set the value of the `Text` reference parameter:

```
procedure TDbaForm.Table1DepartmentGetText(Sender: TField;
  var Text: String; DisplayText: Boolean);
begin
  case Sender.AsInteger of
    1: Text := 'Sales';
    2: Text := 'Accounting';
    3: Text := 'Production';
    4: Text := 'Management';
  else
    Text := '[Error]';
  end;
end;
```

WARNING In the code of the `OnGetText` event handler you cannot refer to the text of the field, for example, using the `DisplayText` property or the `GetData` method, since they would call the `OnGetText` event, in an infinite recursion.

In the `OnSetText` event handler, you can examine the string and decide the value of the field according to the conversion rule, in this case a simple mapping of values done with an `if/then/else` statement:

```
procedure TDbaForm.Table1DepartmentSetText(Sender: TField; const Text: String);
begin
  if Text = 'Sales' then
    Sender.Value := 1
  else if Text = 'Accounting' then
    Sender.Value := 2
  else if Text = 'Production' then
    Sender.Value := 3
  else if Text = 'Management' then
    Sender.Value := 4
  else
    raise Exception.Create ('Error in Department field conversion');
end;
```

The effect is that not only is the value visible in the DBListBox (as you can see in Figure 13.19), it also shows up in the DBGrid. By contrast, in the DbAware example, the grid displayed the numeric value.

Editing Dates with a Calendar

As a final example of the use of non–data-aware controls, the DbDates application shows how to use a MonthCalendar component to handle dates with a nice graphical component instead of a plain edit box. This example is based on the Events table from the DBDEMOS database, which lists Olympic events. The example uses (for the first time) a DBImage control, with the following settings (whose effect is illustrated in Figure 13.20):

```
object DBImage1: TDBImage
  DataField = 'Event_Photo'
  DataSource = DataSource1
  Stretch = True
end
```

NOTE Graphic, memo, and BLOB fields in Delphi are handled exactly like other fields. Just connect the proper editor or viewer, and most of the work is done behind the scenes by the system.

FIGURE 13.20: The selection of a date with the monthly calendar

Although the DBImage control works with no extra effort on our part, we must connect the MonthCalendar control with the corresponding field by handling two events of the DataSource control:

```
procedure TForm1.DataSource1DataChange(Sender: TObject; Field: TField);
begin
  MonthCalendar1.Date := Table1Event_Date.Value;
end;

procedure TForm1.DataSource1UpdateData(Sender: TObject);
begin
  Table1Event_Date.Value := MonthCalendar1.Date;
end;
```

Besides copying the data back and forth, with the code listed above, the program must also put the table into edit mode as the user clicks the calendar control. The most obvious approach is to write a handler for the `OnClick` event of the control:

```
procedure TForm1.MonthCalendar1Click(Sender: TObject);
begin
  Table1.Edit;
end;
```

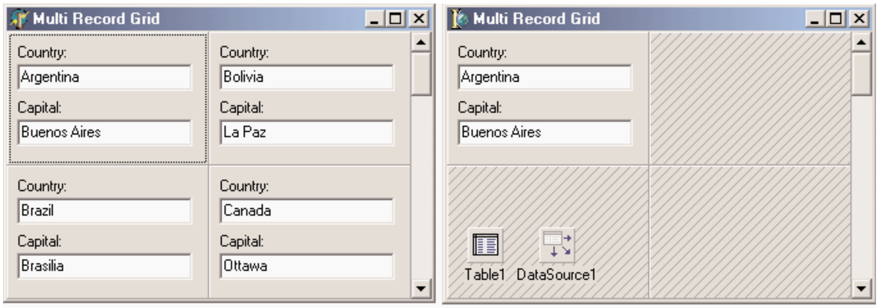
However, this code doesn't work properly. As you set the table in edit mode, the OnDataChange event is executed once more, resetting the selection in the calendar. The overall effect is that the user's first click doesn't change the selection. To avoid this problem we can set a flag in the OnClick event handler and test it in the OnDataChange event handler, or we can temporarily disconnect the second event handler. In the following code, I've taken the second approach:

```
procedure TForm1.MonthCalendar1Click(Sender: TObject);
begin
  // disconnect handler
  DataSource1.OnDataChange := nil;
  // set table in edit mode
  Table1.Edit;
  // reconnect handler
  DataSource1.OnDataChange := DataSource1DataChange;
end;
```

A Multirecord Grid

So far we have seen that you can either use a grid to display records of a database table or build a form with specific data-aware controls for the various fields, accessing the records one by one. There is a third alternative: use a multirecord object (a DBCtrlGrid), which allows you to place many data-aware controls in a small area of a form and automatically duplicate these controls for multiple records.

Here is what we can do to build the Multi1 example. Create a new blank form, place a Table component and a DataSource component in it, and connect them to the COUNTRY.DB table. Now place a DBCtrlGrid on the form, set its size and the number of rows and columns, and place two edit components connected with the Name and Capital fields of the table. To place these DBEdit components, you can also open the Fields editor and drag the two fields to the control grid. At design time, you simply work on the active portion of the grid (see Figure 13.21, on the right), and at run time, you can see these controls replicated multiple times (see Figure 13.21, on the left).



Country: Argentina
Capital: Buenos Aires

Country: Bolivia

Country: Canada
Capital: Ottawa

Country: Argentina
Capital: Buenos Aires

FIGURE 13.21: The DBCtrlGrid of the Multi1 example at design time (on the right) and at run time (on the left)

You can simply set the number of columns and rows. Then each time you resize the control, the width and height of each panel are set accordingly. What is not available is a way to align the grid automatically to the client area of the form.

Moving Control Grid Panels

To improve the last example, we might resize the grid using the FormResize method. We could simply write the following code (in the Multi2 example):

```
procedure TForm1.FormResize(Sender: TObject);
begin
  DBCtrlGrid1.Height := ClientHeight - Panel1.Height;
  DBCtrlGrid1.Width := ClientWidth;
end;
```

This works, but it is not what I want. I'd like to increase the number of panels, not enlarge them. To accomplish this, we can define a minimum height for the panels and compute how many panels can fit in the available area each time the form is resized. For example, in Multi2, I've added one more statement to the FormResize method above, which now becomes

```
procedure TForm1.FormResize(Sender: TObject);
begin
  DBCtrlGrid1.RowCount := (ClientHeight - Panel1.Height) div 100;
  DBCtrlGrid1.Height := ClientHeight - Panel1.Height;
  DBCtrlGrid1.Width := ClientWidth;
end;
```

Instead of doing the same for the columns of the control grid component, I've added a TrackBar component to a panel. When the position of the trackbar changes (the range is from 2 to 10), the program sets the number of columns of the control grid and resizes it. In fact, if you simply set the number of columns, they'll have the same width as before. Here is the code of the trackbar's OnChange event handler:

```
procedure TForm1.TrackBar1Change(Sender: TObject);
begin
  LabelCols.Caption := Format ('%d Columns', [TrackBar1.Position]);
  DBCtrlGrid1.ColCount := TrackBar1.Position;
  DBCtrlGrid1.Width := ClientWidth;
end;
```

This code and the FormResize method above allow you to change the configuration of the control grid at run time in various ways. You can see an example of a crammed version of the form in Figure 13.22.

FIGURE 13.22:

Handling Database Errors

Another important element of database programming is handling database errors in custom ways. Of course, you can let Delphi show an exception message each time a database error occurs, but you might want to try to correct the errors or simply show more details. There are basically three approaches you can use to handle database-related errors:

- You can wrap a `try/except` block around risky database operations, such as a call to the `Open` method of a Query or to the `Post` method of a dataset. This is not possible when the operation is generated by the interaction with a data-aware control.
- You can install a handler for the `OnException` event of the global `Application` object or use the ApplicationEvents component, as described in the next example.
- You can handle specific events of the datasets related to errors, as `OnPostError`, `OnEditError`, `OnDeleteError`, and `OnUpdateError`. These events will be discussed later in the example.

While most of the exception classes in Delphi simply deliver an error message, with database exceptions you see a list of errors, showing local BDE error codes and also the native error codes of the SQL server you are connected to. Besides the Message property, the EDBEngineError class has two more properties, ErrorCount and Errors. This last property is a list of errors:

```
property Errors[Index: Integer]: TDBError;
```

Each item within this list is an object of the class TDBError, which has the following properties:

```
type
  TDBError = class
    ...
  public
    property Category: Byte read GetCategory;
    property ErrorCode: DBIResult read FErrorCode;
    property SubCode: Byte read GetSubCode;
    property Message: string read FMessage;
    property NativeError: Longint read FNativeError;
  end;
```

I've used this information to build a simple database program showing the details of the errors in a memo component. To handle all of the errors, the DBError example installs a handler for the OnException event of an ApplicationEvents component. The event handler simply calls a specific method used to show the details of the database error, in case it is an EDBEngineError:

```
procedure TForm1.ApplicationEvents1Exception (Sender: TObject; E: Exception);
begin
  Beep;
  if E is EDBEngineError then
    ShowError (EDBEngineError (E))
  else
    ShowMessage (E.Message);
end;
```

I decided to separate the code used to show the error to make it easier for you to copy this code and use it in different contexts. Here is the code of the ShowError method, which outputs all of the available information to the Memo1 component that I've added to the form:

```
procedure TForm1.ShowError(E: EDBEngineError);
var
  I: Integer;
begin
```

```
    Memo1.Lines.Add('');
    Memo1.Lines.Add('Error: ' + (E.Message));
    Memo1.Lines.Add('Number of errors: ' + IntToStr(E.ErrorCount));
    // iterate through the Errors records
    for I := 0 to E.ErrorCount - 1 do
    begin
      Memo1.Lines.Add('Message: ' + E.Errors[I].Message);
      Memo1.Lines.Add('   Category: ' + IntToStr(E.Errors[I].Category));
      Memo1.Lines.Add('   Error Code: ' + IntToStr(E.Errors[I].ErrorCode));
      Memo1.Lines.Add('   SubCode: ' + IntToStr(E.Errors[I].SubCode));
      Memo1.Lines.Add('   Native Error: ' + IntToStr(E.Errors[I].NativeError));
      Memo1.Lines.Add('');
    end;
  end;
```

Besides this error-handling code, the program has a table and a query, along with the error-related event handlers. As already mentioned, you can install an event handler related to specific errors of a dataset. The three events OnPostError, OnDeleteError, and OnEditError have the same structure. Their handlers receive as parameters the dataset, the error itself, and an action you can request from the system; this can be set to daFail, daAbort, or daRetry:

```
procedure TForm1.Table1PostError(DataSet: TDataSet; E: EDatabaseError;
  var Action: TDataAction);
begin
  Memo1.Lines.Add (' -> Post Error: ' + E.Message);
end;
```

If you don't specify an action, as in the code above, the default daFail is used, and the exception reaches the global handler. Using daAbort stops the exception and can be used if your event handler already displays a message. Finally, if you have a way to determine the cause of the error and fix it, you can use the daRetry action.

NOTE The fourth error event, OnUpdateError, has a different structure and is used along with cached updates as the information is sent back from the local cache to the database. This handler is important for handling update conflicts among different users as described in the next example.

The example has also a DBGrid connected with the table. You can use the DBGrid to perform some illegal operations, such as adding a new record with the same key as an existing one or trying to execute illegal SQL queries. Pressing the four buttons on the left of the memo generate errors, as you can see in Figure 13.23.

FIGURE 13.23:

The third button of the DBError form generates an exception with 17 database errors!

What's Next?

In this chapter, we have seen examples of database access from Delphi programs. I have covered the basic data-aware components as well as the development of database applications based on standard controls. We've explored the internal architecture of the TDataSet class and of field objects, and discussed many of the events and properties shared by all datasets and used by all database applications. Even though most of the demonstrations used BDE tables and queries, in the entire text there was little or no code specific to those components. Most of what I've described equally applies to client/server applications, built with BDE, dbExpress, IBX, ADO or other dataset components.

We've discussed calculated fields, lookup fields, customizations of the DBGrid control, and many rather advanced techniques. What we really haven't delved into is the database and data-access side of the picture, which depends on the actual type of database engine and server you plan using. The next chapter will start focusing in this topic, with an in-depth overview of client/server development. Following chapters will put the accent on specific data-access technologies and provide even more advanced information.

CHAPTER 14

Client/Server Programming

- Overview of client/server
- Porting local applications
- Elements of database design
- Client/server with BDE
- The dbExpress library
- Using the ClientDataSet component
- Local databases with MyBase

In the last chapter, we examined Delphi's support for database programming, using local files (particularly Paradox) in most of examples but not focusing on any specific database technology. This chapter moves on to the use of SQL server databases, focusing on client/server development with the BDE and the new dbExpress technology. A single chapter cannot cover this complex topic in detail, so I'll simply introduce it from the perspective of the Delphi developer and add some tips and hints. The next chapter extends our discussion of client/server programming, providing some real-world examples. I'll use InterBase in both chapters, because this is the RDBMS (relational database management system), or SQL server, that is included in the Enterprise edition of Delphi and because it is a free and open-source server.

In a rapid application development tool such as Delphi, you can indeed take the same components and code developed for a local database application and use them in a client/server environment. However, this handy feature may prove to be dangerous to beginners, as a standard technique that works well for local access might become extremely inefficient in a client/server application.

An Overview of Client/Server Programming

The database applications in previous chapters used the BDE to access data stored in files either on the local machine or on a networked computer. In both cases we used a file server, whose only role was to store the file on a hard disk, because the database engine (the BDE) was running exclusively on the computer that also hosted the application. In this configuration, when we query one of the tables, its data is first copied into a local cache of the BDE and then processed.

As an example, consider taking a table like EMPLOYEE (part of the InterBase sample database, which ships with Delphi), adding thousands of records to it, and placing it on a networked computer working as a file server. If we want to know the highest salary paid by the company, we can open a Table component (`EmpTable`) connected with the database table and run this code:

```
EmpTable.Open;
EmpTable.First;
MaxSalary := 0;
while not EmpTable.Eof do
begin
  if EmpTable.FieldByName ('Salary').AsCurrency > MaxSalary then
    MaxSalary := EmpTable.FieldByName ('Salary').AsCurrency;
  EmpTable.Next;
end;
```

The effect of this approach is to move all the data of the (large) table from the networked computer to the local machine, an operation that might take minutes. Because Delphi includes a Query component, you might think of using the following SQL code to compute this maximum value:

```
select Max(Salary) from Employee
```

In case of a local table, this query would be processed by the local SQL engine of the BDE, and the entire dataset of the table would still have to be moved from the networked computer to the local one, with similarly poor performance. But if you use InterBase and let the server execute the SQL code, only the result set—a single number—will need to be transferred to the local computer.

NOTE The two code excerpts above are part of the GetMax example, which includes some code to time the two approaches. Using the Table component on the small EMPLOYEE table takes about ten times longer than using the query, even if the InterBase server is installed on the client computer.

If you want to store a large amount of data on a central computer and avoid moving the data to client computers for processing, the only solution is to let the central computer manipulate the data and send back to the client only a limited amount of information. This is the foundation of client/server programming.

In general, you'll use an existing program on the server (an RDBMS) and write a custom client application that connects to it. Sometimes, however, you might even want to write both a custom client and a custom server, as in three-tier applications. Delphi support for this type of program—what has been called the MIDAS architecture—is covered in Chapter 17, "Multitier Database Applications with DataSnap."

The *upsizing* of an application—that is, the transfer of data from local files to a SQL server database engine—is generally done for performance reasons and to allow for larger amounts of data. Going back to the previous example, in a client/server environment, the query used to select the maximum salary would be computed by the RDBMS, which would send back to the client computer only the final result, a single number! With a powerful server computer (such as a multiprocessor Sun SparcStation), the total time required to compute the result might be minimal.

However, there are also other reasons to choose a client/server architecture:

The amount of data A Paradox table cannot exceed 2 GB, but even around 300 MB you might start having serious speed problems, and errors in the indexes become more frequent.

The need for concurrent access to the data Paradox uses the `Paradox.NET` file to keep track of which user is accessing the various tables and records. The Paradox approach to handling multiple users is based on *pessimistic locking*. When a user starts an editing operation on a record, none of the other users can do the same (to avoid any update conflict), as we saw in the last chapter. In a system with tens of users, this might lead to serious problems, because a single user might block the work of many others. SQL server databases, by contrast, generally use *optimistic locking*, an approach that allows multiple users to work on the same data and delays the concurrency control until the time the users send back some updates.

Protection and security An RDBMS usually has many more protection mechanisms than the simple password you can add to a Paradox table. When your application is based on files, a malicious or careless user might simply delete those vital files. When SQL servers are based on robust operating systems, instead, they provide multiple levels of protection, make backup easier, and often allow only the database administrator to modify the structure of the tables.

Programmability An RDBMS database can host business rules, in the form of stored procedures, triggers, table views, and other techniques we'll discuss in this and the next chapter. Choosing how to divide the application code between the client and the server is one of the main issues of client/server programming.

Transaction control Local files offer some support for transactions, but the transaction support provided by an RDBMS database is generally much greater. This is another important aspect of the overall robustness of the system.

From Local to Client/Server

Now we can start focusing on particular techniques useful for client/server programming. Keep in mind that the general goal is to distribute the workload properly between the client and the server and reduce the network bandwidth required to move information back and forth.

The foundation of this approach is good database design, which involves both table structure and appropriate data validation and constraints, or business rules. Enforcing the validation of the data on the server is important, as the integrity of the database is one of the key aims of any program. However, the client side should include data validation as well, to improve the user interface and make the input and the processing of the data more user-friendly. It makes little sense to let the user enter invalid data and then receive an error message from the server, when we can prevent the wrong input in the first place.

NOTE If you use a CASE tool for the definition of the database, or import the definition in such a tool afterward, you can use Delphi's Case Wizard to generate a corresponding data dictionary and have the field objects created at design time automatically import the constraints specified on the server.

Unidirectional Cursors

In local databases, tables are sequential files whose order is either the physical order or is defined by an index. By contrast, SQL servers work on logical sets of data, not related to a physical order. A *relational* database server handles data according to the relational model, a mathematical model based on set theory.

What is important for the present discussion is that in a relational database, the records (sometimes called tuples) of a table are identified not by position but exclusively through a primary key, based on one or more fields. Once you've obtained a set of records, the server adds to each of them a reference to the following one, which makes it fast to move from a record to the following one but terribly slow to move back to the previous record. For this reason, it is common to say that an RDBMS uses a *unidirectional* cursor. Connecting such a table or query to a DBGrid control is practically impossible, as this would make it terribly slow when browsing the grid backward.

The BDE helps a lot to handle unidirectional cursors, as it keeps in a local cache the records already loaded in the table. Thus, when we move to following records, they are requested from the SQL server; but when we go back, the BDE jumps in and provides the data. In other words, the BDE makes these cursors fully bidirectional, although this might use quite a lot of memory. When using dbExpress, which doesn't provide a similar caching system, a program needs to keep in memory the records it has already accessed. This can be easily accomplished by means of the ClientDataSet component.

NOTE The simple case of a DBGrid used to browse an entire table is common in local programs but should generally be avoided in a client/server environment. It's better to filter out only part of the records and only the fields you are interested in. Do you need to see a list of names? Return all those starting with the letter *A*, then those with *B*, and so on, or ask the user for the initial letter of the name.

If proceeding backward might result in problems, keep in mind that jumping to the last record of a table is even worse; usually this operation implies fetching all the records! A similar situation applies to the `RecordCount` property of datasets. Computing the number of records often implies moving them all to the client computer. This is the reason why the thumb of the vertical scrollbar of the DBGrid works for a local table but not for a remote one. If you need to know the number of records, run a separate query to let the server (and not the client) compute it. For example, you can see how many records will be selected from the EMPLOYEE table if you are interested in those records having a salary field higher than 50,000:

```
select count(*)
from Employee
where Salary > 50000
```

TIP Using the SQL instruction count(*) is a handy way to compute the number of records returned by a query. Instead of the * wildcard, we could have used the name of a specific field, as in count(First_Name), possibly combined with either distinct or all, to count only records with different values for the field or all the records having a non-null value.

Parametric Queries and Null Values

Parametric queries are a very useful technique. Essentially, they allow you to run multiple queries with different result sets while the server only needs to work out the access strategy for solving the query once.

You can force this initial preparation of the query access strategy by calling the Prepare method of a Query component. With this operation, the server receives the query, checks its syntax, and while compiling it determines how to use indexes and other access techniques. Multiple executions of the query will be faster because these initial operations have already been executed once for all. Of course, you should call Prepare again if you change the SQL text of the query. Also, remember to call Unprepare at the end, to free some BDE resources.

Note that some powerful SQL servers can do the same operation by caching the requests and automatically determining that you are sending the same request twice. If the server is smart enough, preparing the query might result in little or no performance gain.

NOTE When you write parametric queries against a SQL server, you should consider null values with care. In fact, to test for a null value, you should not write a field = null test, but use the specific expression field is null instead.

Elements of Database Design

Although this is a book on Delphi programming and not on databases, I feel it's quite important to discuss a few elements of good (and modern) database design. The reason is simple: if your database design is incorrect or convoluted, you'll either have to write terribly complex SQL statements and server-side code, or write a lot of Delphi code to access your data, possibly even fighting against the design of the TDataSet class.

Entities and Relations

The *classic* relational database design approach, based on the entity–relation (E-R) model, involves having one table for every entity you need to represent in your database, with one field for each data element you need plus one field for every one-to-one or one-to-many relation to another entity (or table). For many-to-many relations, instead, you'll need a separate table.

As an example of a one-to-one relation, consider a table representing a university course. This would have a field for each relevant data element (name and description, room where it is held, and so on) plus a single field indicating the teacher. The data of the teacher, in fact, should not be stored within the course data, but in a separate table, as it might be referenced from elsewhere.

The schedule of each course can include an undefined number of hours in different days, so they cannot be added inside the same table describing the course. Instead, this information must be placed on a separate table, including all of the schedules, with a field referring to the class each schedule is for. In a one-to-many relation, such as this, "many" records of the schedule table point back to the same "one" record of the course table.

A more complex situation is required to store which student is taking which class. Students cannot be listed directly in the course table, as their number is not fixed, and the classes cannot be stored within the student's data for the same reason. In a similar many-to-many relation, the only approach is to have an extra table representing the relation, which lists references to students and courses.

Normalization Rules

The *classic* design principles include a series of so-called *normalization* rules. The goal of these rules is to avoid duplicating data in your database (not only for saving space, but mainly to avoid ending up with incongruous data). For example, you don't repeat all of the customer details in each order, but refer to a separate customer entity. This way you save memory, but when the customer details change (for example, because of a change of address) all of the orders of this customer will reflect the new data. Other tables that relate to the same customer will probably be automatically updated as well.

Normalization rules imply using codes for commonly repeated values. For example, if you have a few different shipment options, you won't use a string-based description for these options within the orders table, but would rather use a short numeric code, mapped to a description in a separate lookup table.

This last rule, which should not be taken to the extreme, is to avoid having to join a large number or table for every query. You can either account for some de-normalization (leaving a short shipment description within the orders table) or use the client program to provide the description, again ending up with a formally incorrect database design. This last option is practical only when you use a single development environment (let's say, Delphi) to access this database.

From Primary Keys to OIDs

In a relational database, records are not identified by a physical position (as in Paradox and other local databases) but only by the data within the record itself. Typically, you don't need the data of all of the fields to identify a record, but only a subset of the data, forming the so-called *primary key*. If the fields that are part of the primary key must identify an individual record, their value must be different for each possible record of the table.

NOTE Technically, many database servers add internal record identifiers to the tables, but this happens only for internal optimizations and has little to do with the logical design of a relational database. Also, these internal identifiers work differently in different SQL servers and might even change among versions, a good reason not to rely on them.

The early incarnations of the relational theory dictated the use of *logical keys*, which means selecting one or more records that indicate an entity without risk of any confusion. This is often easier to say than to accomplish. For example, company names are not generally unique, and even the company name and its location don't provide a complete guarantee. Moreover, if a company changes its name (not an unlikely event, as Borland can teach us) or its location, and you have references to the company within other tables, you must change all those references as well, with the risk of ending up with dangling references.

For this reason, and also for efficiency (using strings for references implies using a lot of space in secondary tables, where references often occurs), logical keys have been invariably phased out for physical or surrogate keys. *Physical keys* refer to a single field of the table identifying an element in a unique way. For example, each person in the U.S. has a Social Security number (SSN), but almost every country has a tax ID or other government-assigned number that identifies each person. The same typically exists for companies. Although these ID numbers are guaranteed to be unique, they might change depending on the country (creating troubles for the database of a company also selling its goods abroad) or even within a single country (to account for new tax laws). They are also often inefficient, as they might be quite large (Italy, for example, uses a 16-character code, letters and numbers, to identify people).

Another common approach is to use *surrogate keys*, which are basically numbers identifying each record, in the form of client codes, order numbers, and so on. These surrogate keys are commonly used in database design. However, in many cases, these end up being some sort of *logical identifiers*, with client codes showing up all over the places, not a great idea overall.

WARNING The situation becomes particularly troublesome when these surrogate keys also have a meaning and must follow specific rules. For example, companies must number invoices with unique and consecutive numbers, without leaving holes in the numbering sequence. This situation is extremely complex to handle programmatically, if you consider that only the database can determine these unique consecutive numbers when we send new data to it. At the same time, we need to identify the record before we send it to the database, otherwise we won't be able to fetch it again. Practical examples of how to solve this situation are discussed in the next chapter.

OIDs to the Extreme

An extension to the use of surrogate keys is the use of a unique identifier, also called object identifier (OID). An OID is a number, or a string with sequence of numbers and digits, added to each record of each table representing an entity (and at times even to records of tables representing relations). Differently from client codes, invoice numbers, SSN, or purchase order numbers, OIDs are totally random, without any sequencing rule, and never visible to the end user. This means you can still use surrogate keys (if your company is used to them) along with OIDs, but all the external references to the table will be based on OIDs.

Another common rules suggested by the promoters of this approach (which is part of the theories supporting object-relational mapping) is the use of system-wide unique identifiers. If you have a table of client companies and a table of employees, you might wonder why you should use a unique ID for such diverse data. The reason is that, if you do so, you'll be able to sell goods to an employee without having to duplicate the employee information into the customers table, but simply referring to the employee in your order and invoice. An order is placed by someone identified by an OID, and this OID can refer to many different tables (but of course not all of them).

NOTE Using OIDs and the object-relational mapping is an advanced element of the design of Delphi database applications. My personal suggestion is to investigate this topic before embracing medium or large-size Delphi projects, as the benefit can be relevant (after some investment in studying this approach and building some basic support code).

External Keys and Referential Integrity

Getting back to the standard database design, the keys identifying a record (whichever their type) can be used as external keys in other tables, for example to represent the various types of relations discussed earlier. All SQL servers are capable of verifying these external references, so that you cannot refer to a nonexistent record of another table. These referential integrity constraints are expressed when you create a table.

Besides not being allowed to add references to nonexistent records, you're generally prevented from deleting a record if there are external references to it. Some SQL servers go one step further: As you delete a record, instead of simply denying the operation, they can automatically delete all records that refer to it from other tables.

More Constraints

Besides the uniqueness of primary keys and the referential constraints, you can generally use the database to impose more validity rules on the data. You can ask for specific columns (such as those referring to a tax ID or a purchase order number) to include only unique values. You can impose uniqueness of the values of multiple columns—for example, to indicate you cannot run two classes in the same room at the same time.

In general, simple rules can be expressed imposing constraints on a table, while more complex rules generally imply the execution of stored procedures activated by triggers (every time the data changes, for instance, or there is new data).

Again, there is much more to proper database design, but the simple elements discussed in this section can provide a starting point, or a good refresher.

NOTE For more on the Data Definition Language and Data Manipulation Language of SQL, see the bonus chapter "Essential SQL" on the *Mastering Delphi* CD.

Client/Server with the BDE

Now let's consider how Delphi fits into the client/server picture. How does it help us build client/server applications? As I've mentioned, you can still use all the components and techniques discussed in the Chapter 13, "Delphi's Database Architecture," although in some cases alternate approaches will help you leverage the power of the RDBMS your application is dealing with.

As a starting point, let's cover a few considerations on Delphi client/server development using the BDE and its components. After this I'll move to dbExpress, which in Delphi 6 is the recommended general solution for client/server development.

NOTE For a list of the alternative approaches Delphi 6 offers for database access, see the initial part of the preceding chapter.

SQL Links

The BDE doesn't know how to handle the RDBMS; it uses some further drivers, called SQL Links, to perform this operation. As an alternative, the BDE can also interact with ODBC drivers. Borland provides native BDE drivers for InterBase, Oracle, Informix, Microsoft SQL Server, Sybase, and DB2.

If the BDE is still required on the local machines, it can actually be very efficient. For example, when you use the pass-through mode for queries, the BDE doesn't try to interpret the SQL code but passes it directly to the RDBMS server. This allows you to use a server's specific SQL commands and also to speed up the execution. The pass-through mode is activated using the BDE Administrator utility.

Having the BDE between the client and the server can also help in building applications designed to work with multiple servers. In practice, however, it's not easy to do this and still obtain the best performance, because of differences in the SQL dialects understood by each SQL server. In particular, data types are handled differently by the various servers. If the same table were placed on two servers that have data type differences, Delphi would need to use two different TField objects (which creates a few headaches if you want to define the fields at design time).

The Database Component

In local BDE applications, programmers usually refer to the database by indicating the alias of the file path in the DatabaseName property of the Table and Query components. A better approach is to use the Database component to define a local alias and then let all the DataSet components refer to this local alias.

As an example, consider the components of the GetMax application mentioned at the beginning of this chapter:

```
object Database1: TDatabase
  AliasName = 'IBLOCAL'
  Connected = True
  DatabaseName = 'IB'
  LoginPrompt = False
  Params.Strings = (
    'USER NAME=SYSDBA'
    'PASSWORD=masterkey')
  SessionName = 'Default'
end
object EmpTable: TTable
  DatabaseName = 'IB'
  TableName = 'EMPLOYEE'
end
```

```
object EmpQuery: TQuery
  DatabaseName = 'IB'
  SQL.Strings = (
    'select Max(Salary) from Employee ')
end
```

In a client/server application, using the Database component is almost mandatory, as it is required to define connectivity and login parameters (the user name and password, as you can see in the `Params` property above) and to handle transactions.

Keep in mind that the Database component establishes a connection with the RDBMS, representing one of the clients of the system. As such, on most servers it requires a license, and your organization is typically paying for a fixed number of licenses. If the same application or the same computer uses multiple connections to the server, it can count as multiple clients! Fortunately, by setting the `KeepConnection` property of the Database component, you can specify whether to keep the database connection active even when there is no active DataSet component using the connection. If your program can fetch some data and then operate on it locally, disconnecting from the server might help you conserve licenses.

BDE Table and Query Components in Client/Server

In Delphi there are two BDE components you use to access an existing database table: Table and Query. When building client/server applications, programmers tend to use the Query component exclusively, but that is certainly not mandatory, and there are cases in which using the simpler Table component has no drawback. Here's a quick look at the pros and cons of both components:

- While the Table component should not be used to access a large table, it can work perfectly well with a small lookup table. By opening a Table component, you don't transfer the entire content of the table to the local machine; the data is moved only when you access specific records.
- Consider also that with the Table component, the BDE asks the server first for the table structure and then for the table data. These two steps are necessary for setting up the proper internal structures of the BDE, and they are not executed by the Query component. If you activate the BDE's Schema Caching feature, the logical structure of the table will be kept locally, saving this extra step. Of course, this might create problems if the logical structure of the table changes on the server.
- One problem with the Table component is that the BDE mimics a bidirectional cursor by caching the data locally. With a Query component, instead, you can specify whether you want this caching or not with the `Unidirectional` property.

- Another point to consider is that you can generally edit the result of a simple query, sending the data back to the SQL server. This is accomplished by setting the `RequestLive` property to True. For more complex queries, however, you'll need to use an UpdateSQL component, something we'll discuss later in this chapter.
- When trying to minimize the data moved between the server and the client, you need to consider the size of each record as well as the total number of them. When you select only a few fields with a query, only part of the data is considered. A Table component, instead, always entails transferring the entire record to the local machine, even if you've filtered out some fields using the Fields editor. The same problem takes place when you ask for a live query (by setting the `RequestLive` property). In this case, the BDE needs to see the entire record in order to send back the proper update commands. This means that selecting all the records of a table with a live query is equivalent to using the Table component.
- The Query component is not limited to `select` SQL statements; you can also use it to insert or delete records. When the Query component returns a dataset, you generally activate it with the `Open` method (or with the equivalent operation, setting the `Active` property to True). When the Query component is used to perform an operation on the server, you activate it by calling the `ExecSQL` method.

Using Table and Query Filters

One way to limit the amount of data returned by a table is to filter it. Using the `Filter` property of the Table component, you can specify a condition similar to the `where` clause of a query. When you work with local databases, the filter is applied by the BDE, but with a SQL server, the BDE passes the condition to the server in the query generated for the table. This makes filtered tables very portable between local and client/server applications.

WARNING The situation is different if you filter the records in the Pascal code, using the `OnFilterRecord` event. In this case, all the records are sent to the client application, which does its own custom filtering.

If you use a filter with a Query component, the filtering operation will always be performed locally by the BDE, even when you are working with a SQL server. In this case, the BDE asks the server for the entire result set of the query. This would be reasonable only when the user of the application changes the filtering condition often. For a query, only the local filter will be modified, and the data in the local cache will be used. For a table, the BDE will generate an updated query to be executed.

Live Queries and Cached Updates

When working with local data, it is very common to use grids and other visual controls, edit the data, and send it back to the database. We've already seen that using a DBGrid might cause problems when working with an RDBMS, as moving on the grid might send numerous data requests to the server, creating a huge amount of network traffic.

When you use the Query component to connect to some data, you cannot edit the data unless its `RequestLive` property is set to True. If you are working with local tables, the query is always elaborated by the BDE with the Local SQL engine. The BDE will allow for a live query only if it is quite simple: All joins should be outer joins; there cannot be a `distinct` key; there can be no aggregation, no `group by` or `having` clause, no subqueries, and no `order by` unless supported by an index; and there are other rules you can find in Delphi's Help.

If you are working with a SQL server, setting a live query will put the BDE in control of the query, instead of the server. When connected to a SQL server, a live query behaves like a Table component. (So it makes sense to use the table anyway, in these cases.)

TIP Most SQL servers, including InterBase, allow you to define updateable views based on the result of a `select` statement that the Local SQL engine of the BDE won't consider updateable. Then you can simply hook a Table component to the view, letting the SQL server do the work and bypassing the Local SQL engine of the BDE.

If the BDE determines that the dataset cannot be updated, it sets the `CanModify` property to False. The DataSource component checks this value before allowing an editing operation. A solution to this problem is to avoid the use of data-aware controls, as discussed in the last chapter, and use specific SQL queries to update, insert, and delete records.

A better approach is to automate this process (retaining the capabilities of the data-aware controls) by using the UpdateSQL component together with the Query component. The UpdateSQL can be used only in conjunction with cached updates, a topic discussed in the last chapter. The basic idea is that the update operations are kept in a local cache until the program calls the `ApplyUpdates` method of the Query component. This operation corresponds to the execution of a series of `update`, `insert`, and `delete` SQL operations on the server, using the data in the cache. The required SQL commands are held by the UpdateSQL component, which has a design-time editor you can use to generate these SQL commands almost automatically.

Cached updates solve the live queries issue, reduce network traffic, define a standard way to solve updates conflicts, and reduce the server load, but they require more memory on the client computer.

TIP A much better approach than using cached updates is to rely on the ClientDataSet component, which is extremely powerful and allows you to do similar things yet leaving you a lot more programmatic control.

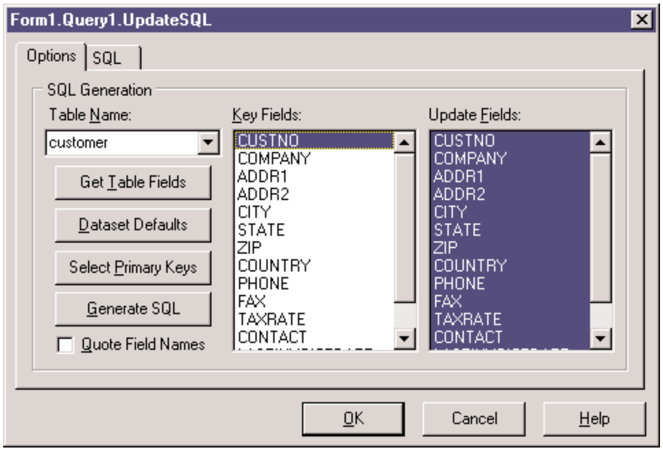
The UpdateSQL Component

The role of the UpdateSQL component is to provide a query with the update statements required to make its result set editable. Its key properties are `DeleteSQL`, `InsertSQL`, and `ModifySQL`, but the most important element is the `UpdateObject` property of the related Query component. The update SQL statements are executed when you apply the cached updates, sending the changes to the server. Because cached updates maintain the information on the original records, the updates usually indicate which record to update by passing the original data. This is the only way we have to identify a record on a SQL server, and this technique also helps the server to track any updates on the same record done by other users.

All this setup might seem to imply a lot of work, but it is actually very simple. After you've written a query, you can connect the UpdateSQL component to it and activate the component editor, as shown in Figure 14.1.

FIGURE 14.1:

The UpdateSQL component editor in action



This component editor has two tabs. The first indicates the criteria used to generate the SQL statements for adding, deleting, or modifying records. With a join, you can select the table to update and the fields involved. When you've completed this step, click the Generate SQL button and the editor will move to the second tab, where you can inspect the generated SQL code for the three operations.

The UpdateSQL Example

To demonstrate the real power of the UpdateSQL component, I've built a complex example called UpdateSQL, based on the Employee, Department, and Job tables of the IBLocal database we've used in the past. Here is the textual description of the UpdateSQL component of the example:

```
object EmpUpdate: TUpdateSQL
  ModifySQL.Strings = (
    'update EMPLOYEE'
    'set'
    '   FIRST_NAME = :FIRST_NAME,'
    '   LAST_NAME = :LAST_NAME,'
    '   SALARY = :SALARY,'
    '   DEPT_NO = :DEPT_NO,'
    '   JOB_CODE = :JOB_CODE,'
    '   JOB_GRADE = :JOB_GRADE,'
    '   JOB_COUNTRY = :JOB_COUNTRY'
    'where'
    '   EMP_NO = :OLD_EMP_NO')
  InsertSQL.Strings = (
    'insert into EMPLOYEE'
    '   (FIRST_NAME, LAST_NAME, SALARY, DEPT_NO, JOB_CODE,
    '   JOB_GRADE, JOB_COUNTRY)'
    'values'
    '   (:FIRST_NAME, :LAST_NAME, :SALARY, :DEPT_NO, :JOB_CODE, '
    '   :JOB_GRADE, :JOB_COUNTRY)')
  DeleteSQL.Strings = (
    'delete from EMPLOYEE'
    'where'
    '   EMP_NO = :OLD_EMP_NO')
  end
```

To delete the employee records, the program uses a stored procedure, which is already available in the sample database and is connected to the following component:

```
object spDelEmployee: TStoredProc
  DatabaseName = 'AppDB'
  StoredProcName = 'DELETE_EMPLOYEE'
  ParamData = <
    item
      DataType = ftInteger
      Name = 'EMP_NUM'
      ParamType = ptInput
    end>
end
```

The OnUpdateRecord event of the Query component uses the stored procedure instead of the default UpdateSQL component for deleting records. Here is the code of the event handler:

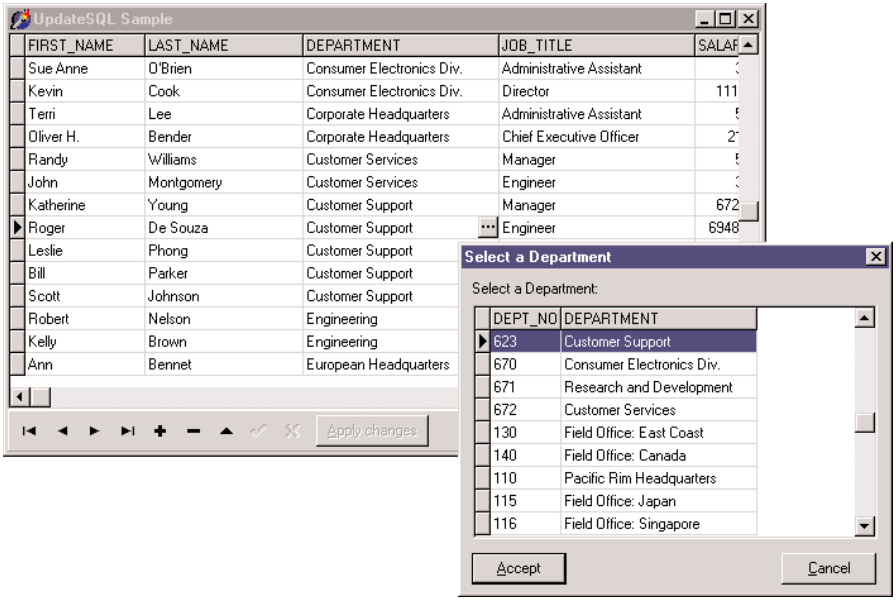
```
procedure TdmData.qryEmployeeUpdateRecord(DataSet: TDataSet;
  UpdateKind: TUpdateKind; var UpdateAction: TUpdateAction);
begin
  // when deleting the record, use the stored procedure
  if UpdateKind = ukDelete then
  begin
    // assign emp_no value
    with dmData do
      spDelEmployee.Params[0].Value := qryEmployeeEMP_NO.OldValue;
    try
      // invoke stored procedure that tries to delete employee
      dmData.spDelEmployee.ExecProc;
      UpdateAction := uaApplied; // success
    except
      UpdateAction := uaFail;
    end;
  end
  else
  try
    // apply updates
    dmData.EmpUpdate.Apply(UpdateKind);
    UpdateAction := uaApplied;
  except
    UpdateAction := uaFail;
  end;
end;
```

Notice that because we perform the update operation directly, we must indicate in the UpdateAction parameter whether it succeeds or not. This code is part of the data module. The main form, visible at run time in Figure 14.2, has a couple of extra features. If the user closes the form with any updates pending, the OnCloseQuery event of the form displays a warning message, allowing the user to apply the updates or skip them:

```
procedure TMainForm.FormCloseQuery(Sender: TObject;
  var CanClose: Boolean);
var
  Res: Integer;
begin
  with dmData do
    if qryEmployee.UpdatesPending then
    begin
      Res := MessageDlg (CloseMsg, mtInformation, mbYesNoCancel, 0);
      if Res = mrYes then
        AppDB.ApplyUpdates ([qryEmployee]);
      CanClose := Res <> mrCancel;
    end;
end;
```

FIGURE 14.2:

The main form of the UpdateSql example along with a secondary form



FIRST_NAME	LAST_NAME	DEPARTMENT	JOB_TITLE	SALAF
Sue Anne	O'Brien	Consumer Electronics Div.	Administrative Assistant	3
Kevin	Cook	Consumer Electronics Div.	Director	111
Terri	Lee	Corporate Headquarters	Administrative Assistant	5
Oliver H.	Bender	Corporate Headquarters	Chief Executive Officer	27
Randy	Williams	Customer Services	Manager	5
John	Montgomery	Customer Services	Engineer	3
Katherine	Young	Customer Support	Manager	672
Roger	De Souza	Customer Support	Engineer	6948
Leslie	Phong	Customer Support		
Bill	Parker	Customer Support		
Scott	Johnson	Customer Support		
Robert	Nelson	Engineering		
Kelly	Brown	Engineering		
Ann	Bennet	European Headquarters		

Select a Department:

DEPT_NO	DEPARTMENT
623	Customer Support
670	Consumer Electronics Div.
671	Research and Development
672	Customer Services
130	Field Office: East Coast
140	Field Office: Canada
110	Pacific Rim Headquarters
115	Field Office: Japan
116	Field Office: Singapore

The second feature is the use of a secondary form to update the fields that are related to other tables—the fields involved in the joins. The program uses two secondary dialog boxes, which get the data from other two Query components. The dialog boxes are displayed when the user clicks the ellipsis button of the DBGrid control, in the `OnEditButtonClick` event. Here is the first part of this event handler, related to the selection of the department:

```
procedure TMainForm.DBGrid1EditButtonClick(Sender: TObject);
begin
  // check whether this is the department field
  if DBGrid1.SelectedField = dmData.qryEmployeeDEPARTMENT then
    with TfrmDepartments.Create(self) do
    try
      dmData.qryDepartment.Locate('DEPT_NO',
        dmData.qryEmployeeDEPT_NO.Value, []);
      if ShowModal = mrOk then
        with dmData do
        begin
          if not (qryEmployee.State in [dsEdit, dsInsert]) then
            qryEmployee.Edit;
          qryEmployeeDEPT_NO.Value := qryDepartment.Fields[0].Value;
          qryEmployeeDEPARTMENT.Value := qryDepartment.Fields[1].Value;
        end;
    finally
      Free;
    end
  else // similar code for the job fields...
```

Finally, the Apply button simply calls the ApplyUpdates method if there are pending updates and then refreshes the data of the query:

```
procedure TMainForm.btnApplyClick(Sender: TObject);
begin
  with dmData do
    if qryEmployee.UpdatesPending then
    begin
      AppDB.ApplyUpdates([qryEmployee]);
      // refresh the data
      qryEmployee.Close;
      qryEmployee.Open;
      btnApply.Enabled := False;
    end;
end;
```

If you run this program, you'll notice that even if the underlying query is read-only, you can change data directly in the DBGrid, as you would do with a regular Table component. The visual operations you do are temporarily stored in the cache; then, when you issue the update operation, the UpdateSQL and the StoredProc components provide the actual code. Also keep in mind that the Salary field has some constraints (defined in the sample database), so you have to change it carefully to avoid errors on the server when the changes are applied.

Update Conflicts

When you are working with local tables, using cached updates might cause concurrency problems. A plain edit operation usually places a lock on the table, so that the other users cannot modify the same record until the first user has posted the updates. The previous chapter covered locking and concurrency issues in detail.

When working with SQL servers, however, the default locking behavior is optimistic. Multiple users can update the same records, and only when the data is sent back does the server verify the original data of the record before updating it, potentially raising an error. More precisely, the update statement uses one or more original fields to locate the record you want to update. If you use all fields and another user has changed the record, then the server will not find the original record and will cause an update error.

You can manually control this behavior either in the code of the UpdateSQL component (indicating to include all the fields read in the query) or by using the UpdateMode property of the Table and Query components. The default value, upWhereAll, indicates that the update query will have a where clause with all the original fields of the record. In many cases, the fact that another user has modified a field different from those we have modified is not an error. We can set the upWhereChanged mode to let Delphi generate an exception and show an error message only if the current and the other user have both modified the same fields. The third alternative is to use the key field only to identify the record, which means that update conflicts will be ignored and that the last user posting the data will simply override any previous change. As you can imagine, this is generally an option to avoid in a client/server, multiuser environment.

Using Transactions

Whether you are working with a SQL server, you should use *transactions* to make your applications more robust. The idea of a transaction can be described as a series of operations to be considered as a single, "atomic" whole that cannot be split.

An example may help to clarify the concept. Suppose you have to raise the salary of each employee of a company by a fixed rate, as we did in the Total example of the preceding chapter. Now if during the operation an error occurs, you might want to undo the previous changes. If you consider the operation "raise the salary of each employee" as a single transaction, it should either be completely done or completely ignored. Or consider the analogy with financial transactions—if only part of the operation is performed, because of an error, you might end up with a missed credit or with some extra money!

Working with database operations as transactions serves a useful purpose. You can start a transaction and do several operations that should all be considered parts of a single larger operation; then, at the end, you can either commit the changes or *roll back* the transaction, discarding all the operations done up to now. Typically, you might want to roll back a transaction if an error occurred during its operations.

Handling transactions in Delphi is quite simple. By default, each edit/post operation is considered a single *implicit* transaction, but you can alter this behavior by handling them explicitly. Simply use the following three methods of the BDE Database component (other database connection components have similar methods):

StartTransaction marks the beginning of a transaction.

Commit confirms all the updates to the database done during the transaction.

Rollback returns the database to its state prior to starting the transaction.

The Database component determines the transaction isolation level using the `TransIsolation` property. When one user starts a transaction and modifies data, should such changes be visible to other users? And what happens if the user rolls back the transaction? To such questions there isn't a universal answer; every programmer should try to answer them according to the requirements or business rules of the application. There are three alternative values for transaction isolation in the BDE:

tiDirtyRead makes the updates of a transaction immediately visible to other transactions and users even before they are committed. This is the only possibility for local databases, which have very limited transaction support.

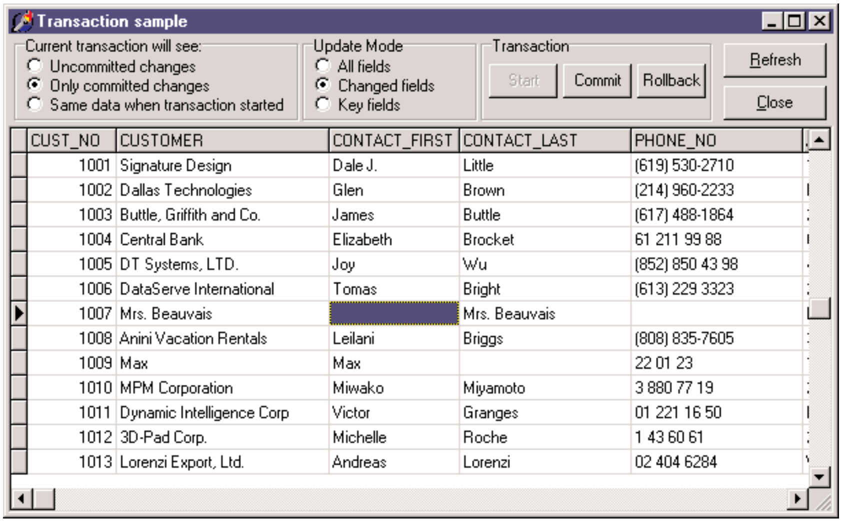
tiReadCommitted makes available to other transactions only the updates already committed.

tiRepeatableRead hides every other transaction started by other users after the current one. Following repeat calls within a transaction will always produce the same result, as if the database took a snapshot of the data when the current transaction started.

Most but not all SQL servers support only the most advanced levels. The default choice should be tiReadCommitted, which is quite powerful but not too heavy on the SQL server (as it adds very few internal locks).

As a general suggestion, transactions should involve only a minimal number of updates (only those strictly related and part of a single atomic operation) and should be kept short in time. You should avoid transactions that wait for user input to complete them, as the user might be temporarily gone and the transaction might remain active for a long time. Using `update` statements on multiple records and using cached updates can help us make the transactions small and fast.

To further inspect transactions and experiment with the update mode of the Table component, you can use the TranSample application. As you can see in Figure 14.3, you can simply use the radio buttons to choose the alternatives, and click the push buttons on the right of the toolbar to manually start, commit, and roll back a transaction. To get a real idea of the different effects, you should run multiple copies of the program (provided you have enough licenses on your InterBase server).



Current transaction will see:
○ Uncommitted changes
● Only committed changes
○ Same data when transaction started

Update Mode
○ All fields
● Changed fields
○ Key fields

Transaction

The TranSample application allows you to test the transaction isolation of a database and the update modes of a table.

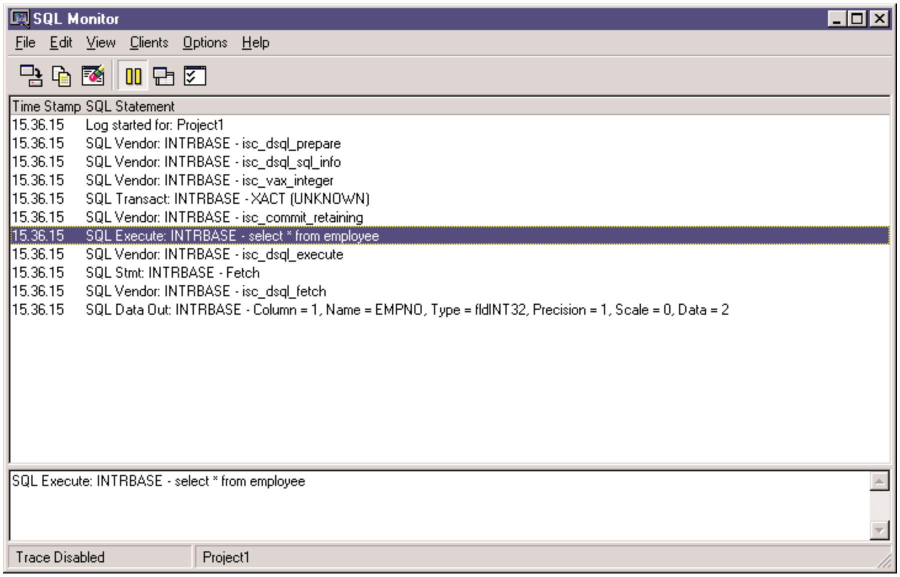
Using SQL Monitor

Just as you need a debugger to test a Delphi application, you need some tools to test how a client/server application behaves and to speed it up if possible. In particular, it is very important to look at the information moving from the client to the server (the explicit SQL requests our program does and those added by the BDE) and from the server to the client (the actual data). This is what the SQL Monitor tool included in Delphi Enterprise is for.

NOTE Notice that the SQL Monitor tool is specific to the BDE. The dbExpress and InterBase Express component sets have similar monitoring capabilities, directly embedded inside specific components.

As you can see in Figure 14.4, the central window of SQL Monitor shows a list of the low-level commands sent to the server. The bottom portion of the window shows the selected line of the above list on multiple rows, which helps when the line is too long.

FIGURE 14.4: The SQL Monitor running



```
Time Stamp SQL Statement
15.36.15   Log started for: Project1
15.36.15   SQL Vendor: INTRBASE - isc_dsql_prepare
15.36.15   SQL Vendor: INTRBASE - isc_dsql_sql_info
15.36.15   SQL Vendor: INTRBASE - isc_vax_integer
15.36.15   SQL Transact: INTRBASE - XACT (UNKNOWN)
15.36.15   SQL Vendor: INTRBASE - isc_commit_retaining
15.36.15   SQL Execute: INTRBASE - select * from employee
15.36.15   SQL Vendor: INTRBASE - isc_dsql_execute
15.36.15   SQL Stmt: INTRBASE - Fetch
15.36.15   SQL Vendor: INTRBASE - isc_dsql_fetch
15.36.15   SQL Data Out: INTRBASE - Column = 1, Name = EMPNO, Type = fldINT32, Precision = 1, Scale = 0, Data = 2
```

```
SQL Execute: INTRBASE - select * from employee
```

Trace Disabled | Project1

To use SQL Monitor, simply select the client program you want to inspect. Then set the proper trace options (by using the corresponding speed button or the Options ➢ Trace Options command). The available options are listed in Table 14.1.

TABLE 14.1: The Trace Options of the SQL Monitor

Trace Option	Meaning
Prepared Query Statement	Enables tracing of the SQL statements every time they are prepared.
Executed Query Statement	Traces all the SQL statements sent to the server.
Input Parameters	Shows input parameters as they become available. This is important for testing whether the parameters are correct.
Fetched Data	Shows the data sent by the server (a very slow operation).
Statement Operations	Shows the requests preceding the execution of a SQL statement, such as the allocation, preparation, and parsing of the input.
Connect/Disconnect	Shows the connection and disconnection events. This is an important test when the `KeepConnection` of the `Database` component is set to False, as the client won't maintain the connection with the server but will establish it only as needed (with the side effect of reducing the number of licenses required, in some cases). Looking at the frequency of these events might help you understand whether it is better to keep the connection active or not.
Transactions	Traces the transactions, including those activated automatically by the BDE if you don't use transactions directly.
Blob I/O	Shows the data about BLOB fields.
Miscellaneous	Traces other operations that don't fit any of the above categories.
Vendor Errors	Shows server error messages.
Vendor Calls	Shows client API calls.

SQL Monitor is useful for seeing if the SQL statements sent by the BDE to the server are correct, but it also helps you see how many operations are done behind the scenes. Along with the time-stamp information for each operation, the number of operations can give some clue about your application's speed (although you should remember that the presence of SQL Monitor slows down the connection quite a lot).

In other words, SQL Monitor should be your guide in determining how to speed up your client/server application, using some of the tricks described in this chapter. At the same time, however, it takes a lot of experience and a good understanding of SQL to interpret its output properly.

As an example of the use of SQL Monitor, we can test what happens when we use the `Filter` property of a Table component. In a new project, simply place a Table, a DataSource, and a DBGrid. Select a database and a table (for example, the EMPLOYEE table of IBLocal) and set the `Filtered` property to True and the `Filter` property to `EmpNo>20`. If you now run the program, SQL Monitor will show you that the `select` statement generated by the BDE has a `where` clause corresponding to the filter. You can see this situation in Figure 14.5.

FIGURE 14.5:

(EMPNO > ?) ORDER BY  EMPNO ASC

Trace Enabled    Project1
```

Performance Tuning

Besides using the SQL Monitor (or another monitoring technique) to determine the potential bottlenecks in your applications, you can do several things to speed up your client/server programs. The key element to keep in mind—as I've stressed many times in this chapter—is to reduce the network traffic, by reducing the result sets returned by the server both in the number of records and in the size of each.

Besides a good overall database design and a good Delphi implementation of it, there are many settings you can check. The following tips might come in handy, but they won't help as much as a better design!

- In InterBase, you can set an automatic sweep (or "garbage collection") interval. The operation is also automatically performed when you do a backup. Because a sweep slows down the database, it should not be done too frequently. However, if you never do it, the database will keep track of many leftover deleted records, reducing the overall performance and using extra memory.
- Use indexes on the fields used more often, particularly if you sort the result set on them. Keep in mind, though, that a good RDBMS will add at least temporary indexes for you. Using indexes can speed up queries quite a lot, particularly if the indexed fields are used to join two tables.

Continued on next page

- If you sort a field in descending order, a corresponding descending index might help.
- If you're an expert user, you might examine the *query plan*, the approach used by the server to perform a query, which is displayed (for example) when you use WISQL. The query plan will show you whether the SQL server is using indexes. In some cases, you might need to modify some complex queries to help the query optimizer built into the RDBMS.
- Check the server settings, including its cache, to obtain the best overall performance. The operating system cache on the server computer might help as well. In InterBase, if you want to perform all the updates physically, you can set the Forced Writes option in the Maintenance ➢ Database Properties menu of the InterBase Server Manager.
- Whenever possible, avoid an excessive use of transactions and try to keep them short and focused. Use a local cache instead of transactions (or together with them) to let the client computer do some more work for you, and skip some costly server operations.
- Handle transactions directly, disabling the auto-commit feature of the BDE; to do this, set `SQLPASSTHRU MODE` to `SHARED NOAUTOCOMMIT`. (You can set this and other BDE features described in this list with the BDE Administrator program.)
- If you have no licensing problems, set the `KeepConnection` property of the BDE Database component to True.
- With the BDE, set `TRACE MODE` to `0` when you are not debugging, to avoid having the drivers send trace strings to the debugger and slowing down the operations. Also the other monitoring services should be disabled when you're not debugging the application.
- In the BDE, enable schema caching (set `ENABLE SCHEMA CACHE` to `TRUE`). This setting reduces the time required to open a table, as the client doesn't need to ask for the metadata. You can also use the Delphi `FieldDefs` and `StoreDefs` properties of the Table component to store the metadata directly in the client program.
- With Microsoft and Sybase SQL Servers, try to set the `PACKETSIZE` parameter to a minimum of 4 KB, also modifying the corresponding value on the server. With these servers, also check that the `DRIVER FLAGS` parameter is set to `0`. If it is `2048`, queries will be executed in asynchronous mode and will be much slower.
- With ORACLE, DB/2, and ODBC drivers, try to fine-tune the `ROWSET SIZE` parameter until you obtain the best performance.
- With the InterBase driver, if you don't use explicit transactions, set the `DRIVER FLAGS` parameter to `4096`. This value enables *soft commits*, meaning that after each commit or rollback operation the open cursors won't have to be refreshed.

The dbExpress Library

As I mentioned in Chapter 13, one of the most notable new features of Delphi 6 is the adoption of the dbExpress database access library, a new SQL server access layer introduced by Borland in its Kylix product for Linux, and now with Delphi 6 also for Windows. As I've already provided a general overview of dbExpress in the preceding chapter, let's focus right away on the technical details.

Working with Unidirectional Cursors

The motto of dbExpress could be "fetch but don't cache." The key difference between this library and BDE or ADO is that dbExpress can only execute SQL queries and fetch the results in a *unidirectional cursor*. In "unidirectional" database access, you can move from one record to the next, but you cannot get back to a previous record of the dataset. This is because the library doesn't store the data is has retrieved in a local cache, but only passes it from the database server to the calling application.

Using a unidirectional cursor might sound like a limitation, and it really is! Besides having problems with the navigation, you cannot connect a database grid to a dataset like this. So what is a unidirectional dataset good for?

- You can use a unidirectional dataset for reporting purposes. In a printed report, but also an HTML page or an XML transformation, you move from record to record, produce the output, and that's it. No need to get back to past records and, in general, no interaction of the user with the data. Unidirectional datasets are probably the best option for Web and multitier architectures.
- You can use a unidirectional dataset to feed a local cache, such as the one provided by a ClientDataSet component. At this point, you can connect visual components to the in-memory dataset and operate on it with all the standard techniques, including the use of visual grids. You can freely navigate and edit the data in the in-memory cache, but also control it far better than with the BDE or ADO.

The important thing to notice is that, in these circumstances, avoiding the caching of the database engine actually saves time and memory. The library doesn't have to use extra memory for the cache and doesn't need to waste time storing data, duplicating information. Over the last couple of years, many programmers moved from BDE-based cached updates to the ClientDataSet component, which provides more flexibility in managing the content of the data and update information they keep in memory. However, using a ClientDataSet on top of the BDE (or ADO) exposes you to the risk of having two separate caches, actually wasting a lot of memory.

Another advantage of using the ClientDataSet component is that its cache supports editing operations, and the updates stored in this cache can be applied to the original database server by the DatasetProvider component. This component can generate the proper SQL update statements, and can do so in a more flexible way than the BDE (although ADO is quite powerful in this respect). In general, the provider can also use a dataset for the updates, but this isn't directly possible with the dbExpress dataset components.

Platforms and Databases

A key element of the dbExpress library is its availability for both Windows and Linux, in contrast to all the other database engines available for Delphi (BDE and ADO), which are available only for Windows. Notice, though, that some of the database-specific components, such as InterBase Express, are also available on multiple platforms.

When you use dbExpress, you are provided with a common framework, which is independent from the actual SQL database server you are planning to use. dbExpress comes with drivers for MySQL, InterBase, Oracle, and IBM DB2. These drivers are available as separate DLLs you have to deploy along with your program or as compiled units you can link into the executable file.

NOTE It is actually possible to write custom drivers for the dbExpress architecture. This is documented in details in the paper *dbExpress Draft Specification*, published on the Borland Community Web site. At the time of this writing, this document is at `http://community.borland.com/article/0,1410,22495,00.html`. You'll probably be able to find third-party drivers. For example, there is a free one (available also in Kylix), which bridges dbExpress and ODBC.

The dbExpress Components

The VCL components used to interface the dbExpress library encompass a group of dataset components plus a few ancillary ones. To differentiate these components from other database-access families, the components are prefixed with the letters *SQL*, underlining the fact that they are used for accessing RDBMS servers.

These components include a database connection component, a few dataset components (a generic one, three specific versions for tables, queries, and stored procedures, and one encapsulating a ClientDataSet component), and a monitor utility.

The SQLConnection Component

The `TSQLConnection` class inherits from the `TCustomConnection` component, and handles database connections, the same as its sibling classes (the Database, ADOConnection, and IBConnection components).

TIP

Unlike other component families, in dbExpress the connection is compulsory. In each of the dataset components, you cannot specify directly which database to use, but can only refer to a SQLConnection.

The connection component uses the information available in the drivers.ini and connections.ini files, which are the only two configuration files of dbExpress (these files are saved by default under \Program Files\Common Files\Borland Shared\DBExpress). The first, drivers.ini, lists the available dbExpress drivers, one for each supported database. For each driver, there is a set of default connection parameters. For example, the InterBase section reads as follows:

```
[Interbase]
GetDriverFunc=getSQLDriverINTERBASE
LibraryName=dbexpint.dll
VendorLib=GDS32.DLL
BlobSize=32
CommitRetain=True
Database=database.gdb
Password=masterkey
RoleName=RoleName
TransIsolation=ReadCommited
User_Name=sysdba
WaitOnLocks=True
```

The parameters indicate the dbExpress driver DLL (the LibraryName value), the entry function to use (GetDriverFunc), the vendor client library, and some more specific parameters that depend on the database. If you read the entire drivers.ini file, you'll see that the parameters are really database-specific. I have to say that some of these parameters don't make a lot of sense at the driver level, such as the database to connect to, but the list includes all the available parameters, regardless of their actual usage.

The connections.ini file provides the database specific description. This list resembles the aliases of the BDE, and you can enter multiple connection details for every database driver. The connection describes the physical database you want to connect to. As an example, this is the portion for the default IBLocal definition:

```
[IBLocal]
BlobSize=32
CommitRetain=True
Database=database.gdb
DriverName=Interbase
Password=masterkey
RoleName=RoleName
TransIsolation=ReadCommited
User_Name=sysdba
WaitOnLocks=True
```

As you can see by comparing the two listings, this is a subset of the parameters of the driver. When you create a new connection, the system will copy the default parameters from the driver; you can then edit them for the specific connection—for example, providing a proper database name. Each connection relates to the driver for its key attributes, as indicated by the `DriverName` property.

The important thing to notice is that these initialization files are used only at design time. In fact, when you select a driver or a connection at design time, the values of these files are copied to corresponding properties of the SQLConnection component, as in this example:

```
object SQLConnection1: TSQLConnection
  ConnectionName = 'IBLocal'
  DriverName = 'Interbase'
  GetDriverFunc = 'getSQLDriverINTERBASE'
  LibraryName = 'dbexpint.dll'
  LoginPrompt = False
  Params.Strings = (
    'BlobSize=-1'
    'CommitRetain=False'
    'Database=c:\program files\interbase corp\interbase6\examples\' +
      'database\employee.gdb'
    'DriverName=Interbase'
    'LocaleCode=0x0000'
    'Password=masterkey'
    'RoleName=RoleName'
    'ServerCharSet=ASCII'
    'SQLDialect=1'
    'Interbase TransIsolation=ReadCommited'
    'User_Name=sysdba'
    'WaitOnLocks=True')
  VendorLib = 'GDS32.DLL'
end
```

At run time, your program will rely on the properties to have all the required information, so you don't need to deploy the two INI files along with your programs. In theory, the files will be required if you want to change the `DriverName` or `ConnectionName` properties at run time. However, in case you want to connect your program to a new database, you can set directly the relevant properties.

When you add a new SQLConnection component to an application, you can proceed in different ways. You can set up a driver, using the list of values available for the `DriverName` property, and then select a predefined connection, by selecting one of the values available in the `ConnectionName` property. This second list is filtered according with the driver you've already selected. As an alternative, you can start by selecting directly the `ConnectionName` property, which in this case includes the entire list.

Instead of hooking up an existing connection, you can define a new one (or see the details of the existing connections) by double-clicking the SQLConnection component and launching the dbExpress Connection Editor (Figure 14.6). This editor lists, on the left side, all of the predefined connections, for a specific driver or all of them, and allows you to edit the connection properties using the grid on the right. You can use the toolbar buttons to add, delete, rename, and test connections, and to open the read-only dbExpress Drivers Settings window, shown in Figure 14.7.

FIGURE 14.6:

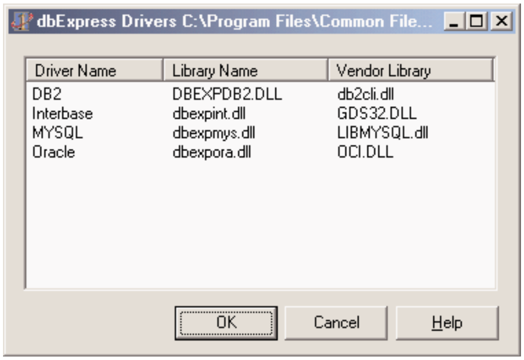
Connection Settings

Key	Value
BlobSize	-1
CommitRetain	False
Database	c:\program files\interbase
DriverName	Interbase
LocaleCode	0x0000
Password	masterkey
RoleName	RoleName
ServerCharSet	ASCII
SQLDialect	1
Interbase TransIsolatio	ReadCommited
User_Name	sysdba

FIGURE 14.7:

The dbExpress Drivers Settings window of the dbExpress Connection Editor



dbExpress Drivers C:\Program Files\Common File...

Driver Name	Library Name	Vendor Library
DB2	DBEXPDB2.DLL	db2cli.dll
Interbase	dbexpint.dll	GDS32.DLL
MYSQL	dbexpmys.dll	LIBMYSQL.dll
Oracle	dbexpora.dll	OCI.DLL

Besides editing the predefined connection settings, the dbExpress Connection Editor allows you also to select a connection for the SQLConnection component. This is what the OK button is for. Notice, in fact, that if you change some of the settings, the data is immediately written to the INI files: clicking the Cancel button doesn't revert your editing!

If you want to define access to a database, editing the connection properties is certainly the suggested approach. This way when you need to access the same database from another application, or another connection within the same application, all you need to do is to select the connection. However, since this operation copies the connection data, notice that updating the connection doesn't automatically refresh the values within other SQLConnection components referring to the same named connection: you have to reselect the connection these other components refer to. In this respect, the predefined connections are very different from the BDE aliases.

What really matters for the SQLConnection component is the value of its properties. Driver and vendor libraries are listed in properties you can freely change at design time (although you'll rarely want to do this), while the database and other database-specific connection settings are specified in the `Params` properties. This is a string list including information such as the database name, the user name and password, and so on. In practice, you could set up a SQL-Connection component by setting up the driver and then assigning the database name directly in the `Params` property, forgetting about the predefined connection. I'm not suggesting this as the best option, but it is certainly a possibility; the predefined connections are handy, but when the data changes, you still have to manually refresh every SQLConnection component.

Actually, to be complete, I have to mention that there is an alternative. You can set the `LoadParamsOnConnect` property to indicate that you want to refresh the component parameters from the initialization files every time you open the connection. In this case, a change in the predefined connections will be reloaded when you open the connection, at either design time or run time. At design time, this provides a handy technique (which has the same effect as reselecting the connection), but using it at run time means you'll also have to deploy the `connections.ini` file, which can be a good idea or an inconvenient one, depending on your deployment environment.

The only property of the SQLConnection component that is not related to the driver and database settings is `LoginPrompt`. Setting it to False allows you to provide a password skipping the login request, both at design time and run time. If this is very handy for development, it can reduce the security of your system. Of course this is also the option you'll want to use for unattended connections, for example on a Web server.

The dbExpress Dataset Components

The dbExpress component's family provides four different dataset components: a generic dataset, a table, a query, and a stored procedure. The latter three components are provided for compatibility with the equivalent BDE components and have similarly named properties. If you don't have to port existing code, you should tend to use the general SQLDataSet component, which can be used to execute a query but also to access a table or a stored procedure.

The first important thing to notice is that all of these datasets inherit from a new special base class, `TCustomSQLDataSet`. This class and its derived classes represent unidirectional datasets, with the key features I've already described. In practice, this means that the browse operations are limited to calling `First` and `Next`, while `Prior`, `Last`, `Locate`, the use of bookmarks, and all other navigational features are disabled.

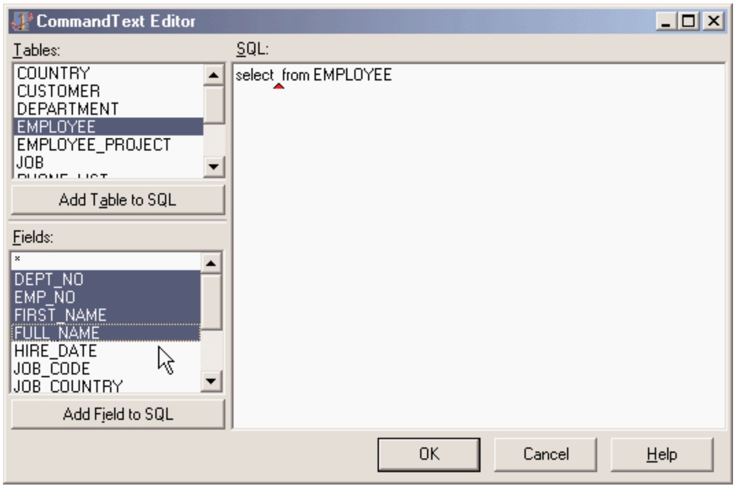
NOTE Technically, some of the moving operations call the `CheckBiDirectional` internal function and eventually raise an exception. `CheckBiDirectional` refers to the public `IsUnidirectional` property of the `TDataSet` class, which you can eventually use in your own code to disable operations that are illegal on unidirectional datasets.

Besides having limited navigational capabilities, these datasets have no editing support, so a lot of methods and events common to other datasets are not available. For example, there is no `AfterEdit` or `BeforePost` event.

As I mentioned earlier, of the four dataset components for dbExpress, the fundamental one is `TSQLDataSet`, which can be used both to retrieve a dataset and to execute a command. The two alternatives are activated by calling the `Open` method (or setting the `Active` property to True) and by calling the `ExecSQL` method.

The SQLDataSet component can retrieve an entire table, or use a SQL query or a stored procedure for reading a dataset or issuing a command. The `CommandType` property determines one of the three access modes. The possible values are ctQuery, ctStoredProc, and ctTable, which determine the value of the `CommandText` property (and also the behavior of the related property editor in the Object Inspector). For a table or stored procedure, the `CommandText` property indicates the name of the related element of the database, and the editor provides a drop-down list with the possible values. For a query, the `CommandText` property stores the text of the SQL command, and the editor provides a little help in building the SQL query (in case it is a select statement). You can see the editor in Figure 14.8.

When you use a table, the component will generate a SQL query for you, as dbExpress targets only SQL databases. The generated query will include all the fields of the table, and if you specify the `SortFieldNames` property, it will include a `sort by` directive.



```
select from EMPLOYEE
```

FIGURE 14.8: The CommandText Editor used by the SQLDataSet component for queries

The three *specific* dataset components offer a similar behavior, but you specify the SQL query in the `SQL` string list property, the stored procedure in the `StoredProcName` property, and the table name in the `TableName` property, as in the three corresponding BDE components.

The SQLClientDataSet Component

The SQLClientDataSet is a combination of three components: the SQLDataSet component, a (hidden) provider, and the ClientDataSet. The idea is to be a helper, as you need only one component instead of three, which must also be connected. However, it doesn't surface all of the properties and events of the underlying components, so in complex situations, it's better to use the various components it stands for. I'll cover this and other variations of the ClientDataSet component later in this chapter, after I discuss the ClientDataSet itself in detail.

The SQLMonitor Component

The final component of the dbExpress group is the SQLMonitor, used to log the requests sent from dbExpress to the database server. This monitor provides capabilities similar to the stand-alone SQL Monitor application, which is bound to the BDE and cannot be used with the dbExpress library (and the analogous IBXMonitor component of the InterBase Express family, as we'll see in the next chapter).

The TimeStamp Field Type

Along with dbExpress, Delphi 6 introduces the `TSQLTimeStampField` field type, mapped to the timestamp data type that many SQL servers have (InterBase included). This data type is now available also in Delphi and is called `TSQLTimeStamp`. A time stamp is a simple record-based representation of a date or time, quite different from the floating-point representation used by the `TDateTime` data type. A time stamp is defined as:

```
TSQLTimeStamp = packed record
  Year : SmallInt;
  Month : Word;
  Day : Word;
  Hour : Word;
  Minute : Word;
  Second : Word;
  Fractions : LongWord;
end;
```

A time stamp field can automatically covert standard date and time values using the `AsDateTime` property (as opposed to the native `AsSQLTimeStamp` property). You can also do custom conversions and further manipulation of time stamps by using the routines provided by the SqlTimSt unit, including functions like `DateTimeToSQLTimeStamp`, `SQLTimeStampToStr`, and `VarSQLTimeStampCreate`.

A Simple dbExpress Demo

After that introduction, let's have a look at an actual demonstration, highlighting the key features of these components and showing how to use the ClientDataSet to provide caching and editing support for the unidirectional datasets. In another example, later on, I'll show you an example of native use of the unidirectional query, with no caching and editing support required.

The standard visual application based on dbExpress uses this series of components:

- The SQLConnection component provides the connection with the database and the proper dbExpress driver.
- The SQLDataSet component, which is hooked to the connection (via the `SQLConnection` property), indicates which SQL query to execute or table to open (using the `CommandType` and `CommandText` properties discussed earlier).
- The DataSetProvider component, connected with the dataset, extracts the data from the SQLDataSet and can generate the proper SQL update statements.

- The ClientDataSet component reads from the data provider and stores all the data (if its PacketRecords property is set to –1) in memory. This component has a lot of extra features and provides the actual data to the application, with full navigation and editing capabilities. You'll need at least to call its ApplyUpdates method to send the actual updates back to the database server (through the provider).
- The DataSource component allows you to surface the data from the ClientDataSet to the visual data-aware controls.

As I mentioned earlier, the picture can be simplified by using the SQLClientDataSet, which replaces the two datasets and the provider. The SQLClientDataSet combines most of the properties of the components it replaces. For a simple example, you'll have to set the DBConnection property for connecting to the proper database, the CommandType and CommandText properties to specify which data to fetch, and the PacketRecords property to indicate how many records to retrieve in each block. You'll also need to call to the ApplyUpdates method to send the actual updates back to the database.

These are the key properties of the core components of the DbxSingle example:

```
object SQLConnection1: TSQLConnection
  ConnectionName = 'IBLocal'
  LoginPrompt = False
end
object SQLClientDataSet1: TSQLClientDataSet
  CommandText = 'EMPLOYEE'
  CommandType = ctTable
  DBConnection = SQLConnection1
end
```

As an alternative, the DbxMulti example uses the entire sequence of components:

```
object SQLConnection1: TSQLConnection
  ConnectionName = 'IBLocal'
  LoginPrompt = False
end
object SQLDataSet1: TSQLDataSet
  SQLConnection = SQLConnection1
  CommandText = 'select * from EMPLOYEE'
end
object DataSetProvider1: TDataSetProvider
  DataSet = SQLDataSet1
end
object ClientDataSet1: TClientDataSet
  ProviderName = 'DataSetProvider1'
end
object DataSource1: TDataSource
  DataSet = ClientDataSet1
end
```

Both examples also have some visual controls: a grid and a toolbar based on the action manager architecture.

Applying Updates

What is important to do in every example based on a local cache, like the one provided by the ClientDataSet and SQLClientDataSet components, is to write the local changes back to the database server. This is typically accomplished by calling the ApplyUpdates method. But when should you call it? You can either keep the changes in the local cache for a while and then apply a bunch of updates at once, or post each change right away. In these two simple examples, I've gone for the latter approach, attaching the following event handler to the AfterPost (fired after an edit or an insert operation) and AfterDelete events of the ClientDataSet components:

```
procedure TForm1.DoUpdate(DataSet: TDataSet);
begin
  // immediately apply local changes to the database
  SQLClientDataSet1.ApplyUpdates(0);
end;
```

If you want to apply all the updates in a single batch, you can either do this when the form is closed or the program ends, or let a user do the update operation by selecting a specific command. We'll explore some of these alternatives when discussing the ClientDataSet component in more detail.

Monitoring the Connection

Another feature, which I've added only to the DbxSingle example, is the monitoring capability offered by the SQLMonitor component. In the example, the component is activated as the program starts.

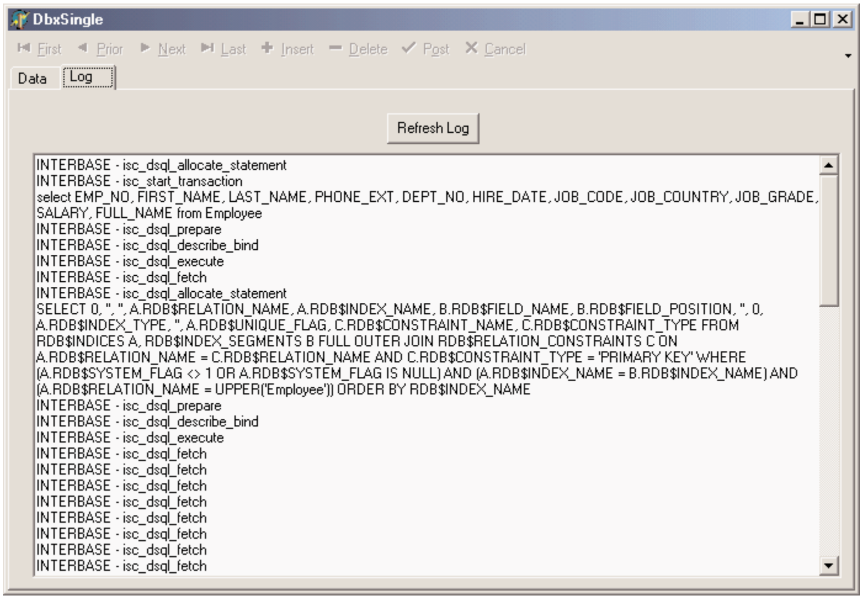
Every time there is a tracing string available, the component fires the OnTrace event to let you choose whether to include the string in the log. If the LogTrace parameter of this event is True (the default value), the component logs the message in the TraceList string list and fires the OnLogTrace event to indicate that a new string has been added to the log.

The component can also automatically store the log into the file indicated by its FileName property, but I haven't used this feature in the example. All I've done is to handle the OnLogTrace event, adding the last message to a memo component with the following code (and the output of Figure 14.9):

```
procedure TForm1.SQLMonitor1LogTrace(Sender: TObject;
  CBInfo: pSQLTRACEDesc);
begin
  MemoLog.Lines.Add (CBInfo.pszTrace);
end;
```

FIGURE 14.9:

A sample log obtained by the SQLMonitor in the DbxSingle example.



```
INTERBASE - isc_dsql_allocate_statement
INTERBASE - isc_start_transaction
select EMP_NO, FIRST_NAME, LAST_NAME, PHONE_EXT, DEPT_NO, HIRE_DATE, JOB_CODE, JOB_COUNTRY, JOB_GRADE,
SALARY, FULL_NAME from Employee
INTERBASE - isc_dsql_prepare
INTERBASE - isc_dsql_describe_bind
INTERBASE - isc_dsql_execute
INTERBASE - isc_dsql_fetch
INTERBASE - isc_dsql_allocate_statement
SELECT 0, '', '', A.RDB$RELATION_NAME, A.RDB$INDEX_NAME, B.RDB$FIELD_NAME, B.RDB$FIELD_POSITION, '', 0,
A.RDB$INDEX_TYPE, '', A.RDB$UNIQUE_FLAG, C.RDB$CONSTRAINT_NAME, C.RDB$CONSTRAINT_TYPE FROM
RDB$INDICES A, RDB$INDEX_SEGMENTS B FULL OUTER JOIN RDB$RELATION_CONSTRAINTS C ON
A.RDB$RELATION_NAME = C.RDB$RELATION_NAME AND C.RDB$CONSTRAINT_TYPE = 'PRIMARY KEY' WHERE
(A.RDB$SYSTEM_FLAG <> 1 OR A.RDB$SYSTEM_FLAG IS NULL) AND (A.RDB$INDEX_NAME = B.RDB$INDEX_NAME) AND
(A.RDB$RELATION_NAME = UPPER('Employee')) ORDER BY RDB$INDEX_NAME
INTERBASE - isc_dsql_prepare
INTERBASE - isc_dsql_describe_bind
INTERBASE - isc_dsql_execute
INTERBASE - isc_dsql_fetch
INTERBASE - isc_dsql_fetch
INTERBASE - isc_dsql_fetch
INTERBASE - isc_dsql_fetch
INTERBASE - isc_dsql_fetch
INTERBASE - isc_dsql_fetch
INTERBASE - isc_dsql_fetch
INTERBASE - isc_dsql_fetch
```

Also, a button allows a user to refresh the memo with the entire content of the trace list:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  MemoLog.Lines := SQLMonitor1.TraceList;
end;
```

Controlling the SQL Update Code

If you run the DbxSingle program and change, for example, the telephone number of an employee, the monitor will log this update operation:

```
update EMPLOYEE  set
  PHONE_EXT = ?
where
  EMP_NO = ? and
  FIRST_NAME = ? and
  LAST_NAME = ? and
  PHONE_EXT = ? and
  HIRE_DATE = ? and
  DEPT_NO = ? and
  JOB_CODE = ? and
  JOB_GRADE = ? and
  JOB_COUNTRY = ? and
  SALARY = ? and
  FULL_NAME = ?
```

The structure of the update statement depends on the UpdateMode property of the SQLClientDataSet component. Trying to use upWhereChanged or upWhereKeyOnly, however, causes an error, as the component is unable to determine which are the key records, and the provider doesn't generate a correct update statement. In fact, it simply tries to update the update the record based on the specific field changed, without including the key field in the where statement:

```
update EMPLOYEE set
  PHONE_EXT = ?
where
  PHONE_EXT = ?
```

The update statement should rather be:

```
update EMPLOYEE set
  PHONE_EXT = ?
where
  EMP_NO = ? and
  PHONE_EXT = ?
```

How can we obtain the proper update call? Considering we cannot directly attach a component like the UpdateSQL (which is a BDE-only component), a simple solution would be to force the inclusion of the key field. This can be accomplished in the ClientDataSet architecture by turning on the pfInKey flag of the ProviderOptions property of the source field.

This can easily be accomplished in the DbxMulti example, after adding persistent fields for the SQLDataSet component, but the problem is that the database library should locate the key fields automatically. In the DbxSingle example, we have no control on the source dataset and its fields, so the only solution is to write the update statements in a totally custom way, with quite some effort.

NOTE We'll be able to discuss this type of problem again as we get into the details of the ClientDataSet component, the Provider, the Resolver, and other technical details later in this chapter and in Chapter 17.

Accessing Database Metadata with *SetSchemaInfo*

All RDBMS systems use special-purpose tables (generally called *system tables*) for storing metadata, such as the list of the tables, their fields, indexes, and constraints, and any other system information. As dbExpress provides a unified API for working with different SQL servers, it provides also a common way for accessing metadata. The TSQLDataSet component has a method, SetSchemaInfo, which fills the dataset with system information. This SetSchemaInfo method has three parameters:

SchemaType indicates the type of information requested and includes stTables, stSysTables, stProcedures, stColumns, and stProcedureParams.

SchemaObject indicates the object you are referring to, such as the name of the table for which you are requesting the columns.

SchemaPattern is a filter, so that you can limit your request to tables, columns, or procedures starting with the given letters. This is very handy if you use prefixes to identify groups of elements.

For example, in the SchemaTest program, a button reads into the dataset all of the tables of the connected database:

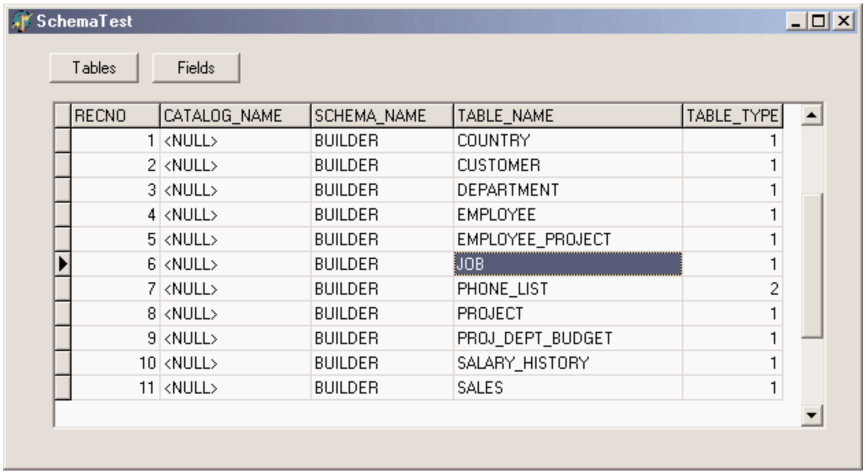
```
ClientDataSet1.Close;
SQLDataSet1.SetSchemaInfo (stTables, '', '');
ClientDataSet1.Open;
```

The program uses the usual group of dataset provider, client dataset and data source component to display the resulting data in a grid, as you can see in Figure 14.10. After you've retrieved the tables, you can select a row of the grid and press the second button to see a list of the fields of this table:

```
SQLDataSet1.SetSchemaInfo (stColumns, ClientDataSet1['Table_Name'], '');
ClientDataSet1.Close;
ClientDataSet1.Open;
```

FIGURE 14.10:

The SchemaTest example allows you to see the tables of a database and the columns of a given table.



RECNO	CATALOG_NAME	SCHEMA_NAME	TABLE_NAME	TABLE_TYPE
1	<NULL>	BUILDER	COUNTRY	1
2	<NULL>	BUILDER	CUSTOMER	1
3	<NULL>	BUILDER	DEPARTMENT	1
4	<NULL>	BUILDER	EMPLOYEE	1
5	<NULL>	BUILDER	EMPLOYEE_PROJECT	1
6	<NULL>	BUILDER	JOB	1
7	<NULL>	BUILDER	PHONE_LIST	2
8	<NULL>	BUILDER	PROJECT	1
9	<NULL>	BUILDER	PROJ_DEPT_BUDGET	1
10	<NULL>	BUILDER	SALARY_HISTORY	1
11	<NULL>	BUILDER	SALES	1

Besides accessing database metadata, dbExpress provides a way to access to its own configuration information, including the installed drivers and the configured connections. The unit DbConnAdmin defines a `TConnectionAdmin` class for this purpose, but the aim of this support is probably limited to dbExpress add-on utilities for developers, as letting end users access multiple databases in a totally dynamic way is not very common.

TIP The DbxExplorer demo included in Delphi 6 shows how to access both dbExpress administration files and schema information. Also check the help file under "The structure of metadata datasets" within the section "Developing database applications."

A Round-Up on dbExpress

After we've delved a little more into the dbExpress architecture and SQL components, I can try to add a few comments about this solution and its alternatives. On the whole, dbExpress provides a much neater architecture, compared to the BDE. In particular, I like it a lot when a database engine does things for me but lets me control what's going on and fine-tune every element. Ready-to-use defaults, such as those provided by the SQLClientDataSet component, are nice, but it is important for me in real-world applications to be able to take full control and write the exact SQL code I want my system to execute.

NOTE Another complaint I have is that I don't really like the architecture used for the specific ClientDataSet components bound to the various technologies (BDE, ADO, dbExpress and so on). In Chapter 19, "COM Programming," I'll discuss an alternate approach. In particular, I dislike the fact that you cannot code for a generic base component, but have to tune your code to the specific version of the ClientDataSet. Moreover, this architecture isn't extensible: you'll have to write a new specific component for each data access class you want to use (or to write). This seems really contrary to the spirit of OOP and to the overall architecture of VCL. My suggestion is simply to avoid using these all-in-one components and get used to dropping the DataSet–Provider–ClientDataSet triad every time you need to (or build a custom compound component for them).

When One-Way Is Enough: Printing Data

We have seen that one of the key elements of the dbExpress library is that it returns unidirectional datasets and that we can use the ClientDataSet component (in one of its incarnations) to store the records in a local cache. Now it is interesting to discuss at least a simple example where a unidirectional dataset is all we need.

This is common in *reporting*, that is, to produce information for each record in sequence without needing any further access to the data. This broad category includes producing printed reports (via a set of reporting components or using the printer directly), sending data to other applications like Microsoft Excel or Word, saving data to files (including HTML and XML formats), and more.

As I don't want to delve into HTML and XML right now, and we still haven't discussed COM-based automation, I'll go ahead with an example of printing—nothing fancy and nothing based on reporting components, but a simple way to produce a draft report on your video and printer. For this reason, I'm going to use Delphi's simplest technique to produce a printout: assigning a file to the printer with the AssignPrn RTL procedure.

The example, called UniPrint, has a unidirectional SQLDataSet component, hooked to an InterBase connection and based on the following SQL statement, which joins the employee table with the department table to display the name of the department where each employee works:

```
select d.DEPARTMENT, e.FULL_NAME, e.JOB_COUNTRY, e.HIRE_DATE
from EMPLOYEE e
inner join DEPARTMENT d on d.DEPT_NO = e.DEPT_NO
```

To handle printing, I've written a somewhat generic routine, requiring as parameters the data to print, a progress bar for status information, the output font, and the maximum format size of each field. The entire routine, listed below, uses file-print support and the graphic objects recall technique, and formats each field in a fixed-size, left-aligned string, to produce a columnar type of report. The call to the Format function has a parametric format string, built dynamically using the size of the field.

Here is the code, which uses three nested try/finally blocks to release all the resources properly:

```
procedure PrintOutDataSet (data: TDataSet;
  progress: TProgressBar; Font: TFont; maxSize: Integer = 30);
var
  PrintFile: TextFile;
  I: Integer;
  sizeStr: string;
  oldFont: TFontRecall;
begin
  // assign the printer to a file
  AssignPrn (PrintFile);
  Rewrite (PrintFile);

  // set the font and keep the original one
  oldFont := TFontRecall.Create (Printer.Canvas.Font);
  try
    Printer.Canvas.Font := Font;
    try
      data.Open;
      try
        // print header (field names) in bold
        Printer.Canvas.Font.Style := [fsBold];
        for I := 0 to data.FieldCount - 1 do
        begin
          sizeStr := IntToStr (min (data.Fields[i].DisplayWidth, maxSize));
          Write (PrintFile, Format ('%-' + sizeStr + 's',
            [data.Fields[i].FieldName]));
        end;
        Writeln (PrintFile);

        // for each record of the dataset
        Printer.Canvas.Font.Style := [];
        while not data.EOF do
        begin
          // print out each field of the record
          for I := 0 to data.FieldCount - 1 do
          begin
            sizeStr := IntToStr (min (data.Fields[i].DisplayWidth, maxSize));
            Write (PrintFile, Format ('%-' + sizeStr + 's',
              [data.Fields[i].AsString]));
          end;
          Writeln (PrintFile);
          // advance ProgressBar
          progress.Position := progress.Position + 1;
          data.Next;
        end;
      finally
        // close the dataset
        data.Close;
      end;
    finally
      // reassign the original printer font
      oldFont.Free;
    end;
  finally
    // close the printer/file
    System.CloseFile (PrintFile);
  end;
end;
```

The program invokes this routine when the Print All button is clicked. The program executes a separate query, which returns the number of records of the employee table to set up the progress bar (the unidirectional dataset, in fact, has no way to know how many records it is going to retrieve until it has reached the last one). Then it sets the output font, possibly using a fixed-width font, and calls the `PrintOutDataSet` routine.

```
procedure TNavigator.PrintAllButtonClick(Sender: TObject);
var
  Font: TFont;
begin
  // set ProgressBar range
  EmplCountData.Open;
  try
```

```
      ProgressBar1.Max := EmplCountData.Fields[0].AsInteger;
    finally
      EmplCountData.Close;
    end;

    Font := TFont.Create;
    try
      Font.Name := 'Courier New';
      Font.Size := 9;
      PrintOutDataSet (EmplData, ProgressBar1, Font);
    finally
      Font.Free;
    end;
  end;
```

ClientDataSet and MyBase

The general idea of a client/server application implies that the computation workload is shared between two separate programs, the RDBMS and a client application. Although it is very hard to strike a precise line between the two sides, it is certainly useful to do operations on the client. Most database engines (BDE, as we've seen in this chapter, and ADO, as we'll see in Chapter 16, "ActiveX Data Objects") can manipulate client-side data stored in a cache. Using the ClientDataSet component, you can do the same regardless of the database engine you are using, which makes your program more flexible, particularly if you want to use dbExpress, which doesn't provide a similar feature natively.

A practical example will underline what I mean: Suppose you've written a SQL query to retrieve a rather large dataset, and a user wants to see the same data in a different order. You can certainly run a new query, with the proper `order by` clause, but this implies sending the same (possibly large) dataset once more from the server to the client. Since the client already has the data in memory, it would be more practical and generally faster to re-sort the data in memory and present the same data to the user with a different ordering.

The ClientDataSet component allows you to do this: Attaching the code to sort the data by assigning a proper field name to the `IndexFieldNames` property. This is often accomplished when the user clicks the field title in a DBGrid component (firing the `OnTitleClick` event):

```
procedure TForm1.DBGrid1TitleClick(Column: TColumn);
begin
  ClientDataSet1.IndexFieldNames := Column.Field.FieldName;
end;
```

TIP Unlike local databases, a ClientDataSet can have dynamic indexes, as they are computed in memory anyway. The component also supports indexes based on a calculated field, specifically an *internally calculated* field, a type of field available only for this dataset. Unlike ordinary calculated fields, which are computed every time the record is used, values of internally calculated fields are kept in memory. This is why indexes consider them as plain fields.

Indexing is not all the ClientDataSet has to offer. When you have an index, you can define groups based on it, possibly with multiple levels of grouping. There is even specific support for determining the position of a record within a group (first, last, or middle position). Over groups or entire tables, you can define aggregates; that is, you can compute the sum or average value of a column for the entire table or the current group on-the-fly. The data doesn't need to be posted to a physical server, because these aggregate operations take place in memory. You can even define new aggregate fields, to which you can directly connect data-aware controls. I'll explore these capabilities in the next section.

Another very interesting area of the ClientDataSet component is its ability to handle the updates log, undoing changes, looking at their list before committing them, and so on. I'll explore this next.

The ClientDataSet component supports many features, only some of which are related to the three-tier architecture (covered in Chapter 17). This component represents a database completely mapped in memory and can also be made persistent to a local file. Borland marketing has introduced the name MyBase to describe this feature of the ClientDataSet component, which was formerly called the briefcase model.

The important thing to keep in mind is that all of these features are available to any client/server and even local applications. The ClientDataSet component, in fact, can get its data from a remote connection, from a local dataset (as you must do with dbExpress), or from a local MyBase file. This is another huge area to explore, so I'll simply show you a couple of examples highlighting key features.

WARNING The use of the ClientDataSet component, in each of its incarnations, requires either the deployment of the `Midas.dll` library or the inclusion in the project of the MidasLib unit (available in compiled format only). The core code of this component, in fact, is not directly part of the library and is not available in source code format. This is unfortunate, as many Delphi developers are accustomed to debugging into the source code and using it as the ultimate reference. It is noteworthy, though, the inclusion in Delphi 6 of the DCU version of the library, obtained from a C-language source code. This allows you to avoid deploying the actual library along with your program.

The Packets and the Cache

The ClientDataSet component reads data in packets made of the number of records indicated by the PacketRecords property. The default value of this property is –1, which means that the provider will pull all the records at once (this is reasonable only for a small dataset). Alternatively, you can set this value to zero to ask the server for only the field descriptors and no actual data or use any positive value to specify an actual number.

If you retrieve only a partial dataset, as you browse past the end of local cache, if FetchOnDemand property is set to True (the default value), the ClientDataSet component will get more records from its source. This same property also controls whether BLOB fields and nested datasets of the current records are fetched automatically (these values might not be already part of the data packet, depending on the value of the Options of the dataset provider).

If you turn off this property, you'll need to manually fetch more records, by calling the GetNextPacket method, until the method returns zero. (You'll call FetchBlobs and FetchDetails for these other elements.)

WARNING Notice, by the way, that before you set a index for the data, you should retrieve the entire dataset (either by going to its last record or by setting the PacketRecords property to –1). Otherwise you'll have an odd index based on partial data.

Filtering

As with any other dataset, you can use the Filter property to specify the inclusion in the dataset of portions of the data the component is bound to. When manipulating a large table, of course, you should use a proper query so that you don't retrieve a large dataset from a SQL server. Filtering up-front in the server should generally be your first choice.

However, local filtering in the ClientDataSet can be quite useful, particularly because the filter expressions you can use are much more extensive than those you can use with other datasets. In particular, you can use the standard comparison and logical operators (`Population > 1000 and Area < 1000`) and arithmetic operators (`Population / Area < 10`), but also string functions (`Substring(Last_Name), 1, 2 = 'Ca'`), date and time functions (`Year (Invoice_Date) = 2002`), and others, including a Like function, wildcards, and an In operator.

These filtering capabilities are fully documented in the VCL Help file. Notice that the documentation was already there for Delphi 5, but most of these features didn't actually work. Now they do.

Grouping and Aggregates

We've already seen that a ClientDataSet can have an index different than the order in which it received the data. Once you've defined an index, you can group the data by that index. In practice, a group is defined as a list of consecutive records (according to the index) for which the value of the indexed field doesn't change. For example, if you have an index by state, all the addresses within that state will fall in the group.

Grouping

The CdsCalcs example has a ClientDataSet component that extracts its data from the Country table of the familiar DBDEMOS database. This operation is performed using a DataSetProvider component to the form, connecting the three components as follows:

```
object Table1: TTable
  Active = True
  DatabaseName = 'DBDEMOS'
  TableName = 'COUNTRY.DB'
end
object DataSetProvider1: TDataSetProvider
  DataSet = Table1
end
object ClientDataSet1: TClientDataSet
  ProviderName = 'DataSetProvider1'
end
```

I could have also used the specific BDEClientDataSet component, as I'll discuss later. Now we can focus on the definition of the group. This is obtained, along with the definition of an index, by specifying a grouping level for the index itself:

```
object ClientDataSet1: TClientDataSet
  IndexDefs = <
    item
      Name = 'ClientDataSet1Index1'
      Fields = 'Continent'
      GroupingLevel = 1
    end>
  IndexName = 'ClientDataSet1Index1'
```

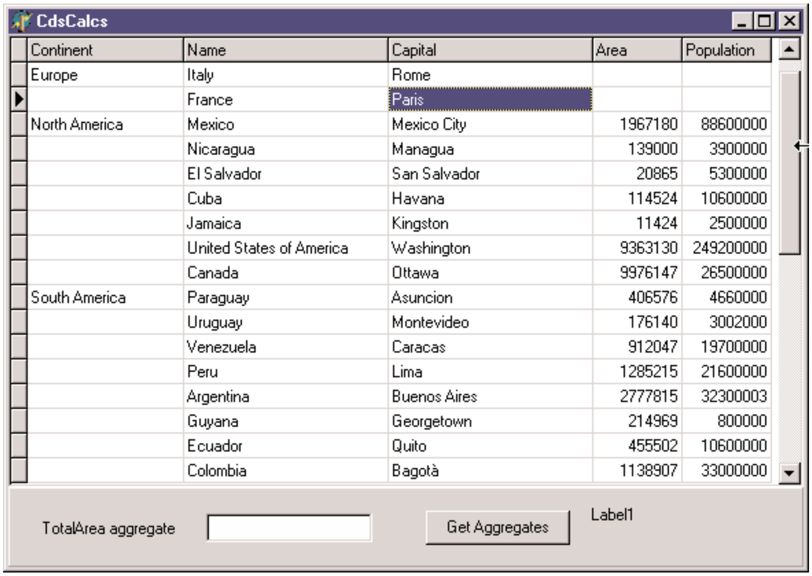
When you have a group active, you can make this obvious to the user by displaying the grouping structure in the DBGrid, as shown in Figure 14.11. Simply handle the `OnGetText` event for the grouped field (the `Continent` field in the example), and show the text only if the record is the first of the group:

```
procedure TForm1.ClientDataSet1ContinentGetText(Sender: TField;
  var Text: String; DisplayText: Boolean);
begin
```

```
    if gbFirst in ClientDataSet1.GetGroupState (1) then
      Text := Sender.AsString
    else
      Text := '';
  end;
```

FIGURE 14.11:

The CdsCalcs example demonstrates that by writing a little code, you can have the DBGrid control visually show the grouping defined in the ClientDataSet.



Continent	Name	Capital	Area	Population
Europe	Italy	Rome		
	France	Paris		
North America	Mexico	Mexico City	1967180	88600000
	Nicaragua	Managua	139000	3900000
	El Salvador	San Salvador	20865	5300000
	Cuba	Havana	114524	10600000
	Jamaica	Kingston	11424	2500000
	United States of America	Washington	9363130	249200000
	Canada	Ottawa	9976147	26500000
South America	Paraguay	Asuncion	406576	4660000
	Uruguay	Montevideo	176140	3002000
	Venezuela	Caracas	912047	19700000
	Peru	Lima	1285215	21600000
	Argentina	Buenos Aires	2777815	32300003
	Guyana	Georgetown	214969	800000
	Ecuador	Quito	455502	10600000
	Colombia	Bagotà	1138907	33000000

Defining Aggregates

Another feature of the ClientDataSet component is support for *aggregates*. An aggregate is a calculated value based on multiple records, such as the sum or the average value of a field for the entire table or a group of records (defined with the grouping logic I've just discussed). Aggregates are *maintained*; that is, they are recalculated immediately if one of the records changes. For example, the total of an invoice can be maintained automatically while the user types in the invoice items.

NOTE Aggregates are maintained incrementally, not by recalculating all the values every time one value changes. Aggregate updates take advantage of the deltas tracked by the ClientDataSet. For example, to update a sum when a field is changed, the ClientDataSet subtracts the old value from the aggregate and adds the new value. Only two calculations are needed, even if there are thousands of rows in that aggregate group. For this reason, aggregate updates are instantaneous.

There are two ways to define aggregates. You can use the Aggregates property of the ClientDataSet, which is a collection, or you can define aggregate fields using the Fields editor. In both cases, you define the aggregate expression, give it a name, and connect it to an index and a grouping level (unless you want to apply it to the entire table). Here is the Aggregates collection of the CdsCalcs example:

```
object ClientDataSet1: TClientDataSet
  Aggregates = <
    item
      Active = True
      AggregateName = 'Count'
      Expression = 'COUNT (NAME)'
      GroupingLevel = 1
      IndexName = 'ClientDataSet1Index1'
      Visible = False
    end
    item
      Active = True
      AggregateName = 'TotalPopulation'
      Expression = 'SUM (POPULATION)'
      Visible = False
    end>
  AggregatesActive = True
```

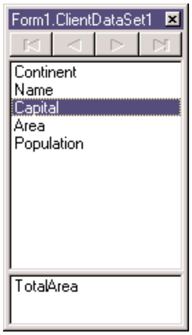
Notice in the last line above that you must activate the support for aggregates, in addition to activating each specific aggregate you want to use. Disabling aggregates is important, because having too many of them can slow down a program. The alternative approach, as I mentioned, is to use the Fields editor, select the New Field command of its shortcut menu, and choose the Aggregate option (available, along with the InternalCalc option, only in a ClientDataSet). This is the definition of an aggregate field:

```
object ClientDataSet1: TClientDataSet
  object ClientDataSet1TotalArea: TAggregateField
    FieldName = 'TotalArea'
    ReadOnly = True
    Visible = True
    Active = True
    DisplayFormat = '###,###,###'
    Expression = 'SUM(AREA)'
    GroupingLevel = 1
    IndexName = 'ClientDataSet1Index1'
  end
```

The aggregate fields are displayed in the Fields editor in a separate group, as you can see in Figure 14.12. The advantage of using an aggregate field, compared to a plain aggregate, is that you can define the display format and hook the field directly to a data-aware control, such as a DBEdit in the CdsCalcs example. Because the aggregate is connected to a group, as soon as you select a record of a different group, the output will be automatically updated. Also, if you change the data, the total will immediately show the new value.

FIGURE 14.12:

The bottom portion of the Fields editor of a ClientDataSet displays aggregate fields.



Form1.ClientDataSet1

Continent
Name
Capital
Area
Population

TotalArea

To use plain aggregates, instead, you have to write a little code, as in the following example (notice that the `Value` of the aggregate is a variant):

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Label1.Caption :=
    'Area: ' + ClientDataSet1TotalArea.DisplayText + #13'Population : '
    + FormatFloat ('###,###,###', ClientDataSet1.Aggregates [1].Value) +
    #13'Number : ' + IntToStr (ClientDataSet1.Aggregates [0].Value);
end;
```

Manipulating Updates

One of the core ideas behind the ClientDataSet component is that it is used as a local cache to collect some input from a user and then send a batch of update requests to the database. The component has both a list of the changes to apply to the database server, stored in the same format used by the ClientDataSet (accessible though the `Delta` property), and a complete updates log that you can manipulate with a few methods (including an Undo capability).

The Status of the Records

The component lets us monitor what's going on within the data packets. The `UpdateStatus` method returns one of the following indicators for the current record:

```
type TUpdateStatus = (usUnmodified, usModified, usInserted, usDeleted);
```

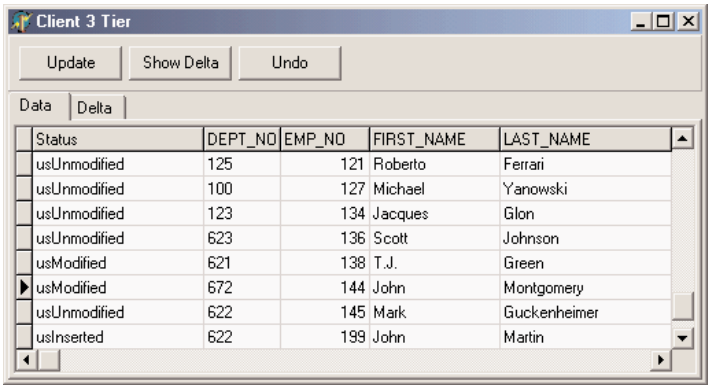
To check the status of every record in the client dataset easily, you can add a string-type calculated field to the dataset (I've called it `ClientDataSet1Status`) and compute its value with the following `OnCalcFields` event handler:

```
procedure TForm1.ClientDataSet1CalcFields(DataSet: TDataSet);
begin
  ClientDataSet1Status.AsString := GetEnumName (TypeInfo(TUpdateStatus),
    Integer (ClientDataSet1.UpdateStatus));
end;
```

This method (based on the RTTI `GetEnumName` function) converts the current value of the `TUpdateStatus` enumeration to a string, with the effect you can see in Figure 14.13.

FIGURE 14.13:

The CdsDelta program displays the status of each record of a ClientDataSet.



Status	DEPT_NO	EMP_NO	FIRST_NAME	LAST_NAME
usUnmodified	125	121	Roberto	Ferrari
usUnmodified	100	127	Michael	Yanowski
usUnmodified	123	134	Jacques	Glon
usUnmodified	623	136	Scott	Johnson
usModified	621	138	T.J.	Green
usModified	672	144	John	Montgomery
usUnmodified	622	145	Mark	Guckenheimer
usInserted	622	199	John	Martin

Accessing the Delta

Beyond examining the status of each record, the best way to understand which changes have occurred in a given ClientDataSet (but haven't been uploaded to the server) is to look at the delta, the list of changes waiting to be applied to the server. This property is defined as follows:

```
property Delta: OleVariant;
```

The format used by the `Delta` property is the same as that used to transmit the data from the client to the server. What we can do, then, is add another ClientDataSet component to an application and connect it to the data in the `Delta` property of the first client dataset:

```
if ClientDataSet1.ChangeCount > 0 then
begin
  ClientDataSet2.Data := ClientDataSet1.Delta;
  ClientDataSet2.Open;
```

In the CdsDelta example, I've added a data module with the two ClientDataSet components and an actual source of data, a SQLDataSet mapped to InterBase's EMPLOYEE demo table. Both client datasets have the extra status calculated field, with a slightly more generic version than the code discussed earlier, because the event handler is shared between them.

TIP

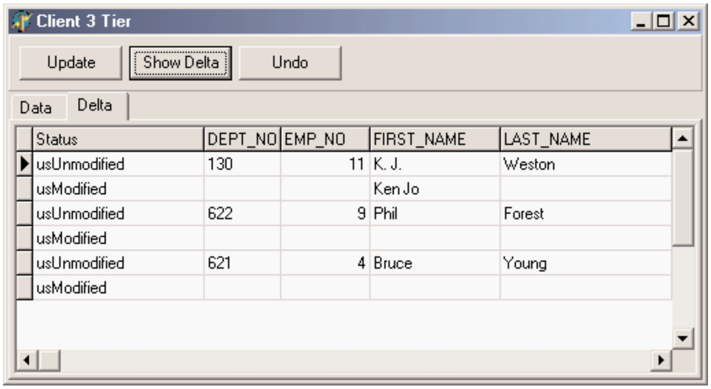
To create persistent fields for the ClientDataSet hooked to the delta (at run time), I've temporarily connected it, at design time, to the same provider of the main ClientDataSet. The structure of the delta, in fact, is the same of the dataset it refers to. After creating the persistent fields, I've removed the connection.

The form of this application has a page control with two pages, each with a DBGrid, one for the actual data and one for the delta. Some code hides or shows the second tab depending on the existence of data in the change log, as returned by the `ChangeCount` method, and updates the delta when the corresponding tab is selected. The core of the code used to handle the delta is very similar to the last code snippet above, and you can study the example source code on the CD to see more details.

You can see the change log of the CdsDelta application in Figure 14.14. Notice that the delta dataset has two entries for each modified record: the original values and the modified fields, unless this is a new or deleted record, as indicated by its status.

FIGURE 14.14:

The CdsDelta example allows you to see the temporary update requests stored in the `Delta` property of the ClientDataSet.



Status	DEPT_NO	EMP_NO	FIRST_NAME	LAST_NAME
usUnmodified	130	11	K. J.	Weston
usModified			Ken Jo	
usUnmodified	622	9	Phil	Forest
usModified				
usUnmodified	621	4	Bruce	Young
usModified				

TIP

You can also filter the delta dataset (or any other ClientDataSet) depending on its update status, using the `StatusFilter` property. This allows you to show new, updated, and deleted records in separate grids or in a grid filtered by selecting an option in a TabControl.

Undo and *SavePoint*

Because the update data is stored in the local memory (in the delta), besides applying the updates and sending them to the application server, we can reject them, removing entries from the delta. The ClientDataSet component has a specific UndoLastChange method to accomplish this. The parameter of this method allows you to *follow* the undo operation (the name of this parameter is FollowChange). This means the client dataset will move to the record that has been restored by the undo operation.

Here is the code connected to the Undo button of the CdsDelta example:

```
procedure TForm1.ButtonUndoClick(Sender: TObject);
begin
  DmCds.cdsEmployee.UndoLastChange (True);
end;
```

An extension of the undo support is the possibility to save a sort of bookmark of the change log position (the current status) and to restore it later by undoing all successive changes. The SavePoint property can be used either to save the number of changes in the log or to reset the log to a past situation. Notice, anyway, that you can only remove records from the change log, not reinsert changes. In other words, the ChangeLog refers to a position in a log, so it can only go back to a position in which there were fewer records! This position is just a number of changes, so if you undo some changes and then do more edits, that number of changes will become meaningless.

Enabling and Disabling Logging

Keeping track of changes makes sense if you need to send the updated data back to a server database. In local applications with data stored to a MyBase file, keeping this log around can become useless and consumes memory. For this reason, you can disable logging altogether with the LogChanges property.

You can also call the MergeChangesLog method to remove all current editing from the change log. This makes sense if the dataset doesn't directly originate by a provider but was built with custom code, or in case you want to add or edit the data programmatically, without having to send it to the back-end database server.

TIP The ClientDataSet in Delphi 6 has a new property, DisableStringTrim, which allows you to keep trailing spaces in field values. In past versions, in fact, string fields were invariably trimmed, which creates trouble with some databases.

Updating the Data

Now that we have a better understanding of what goes on during local updates, we can try to make this program work by sending the local update (stored in the delta) back to the database server. To apply all the updates from a dataset at once, pass -1 to the ApplyUpdates method.

If the provider (or actually the Resolver component inside it) has trouble applying an update, it triggers the OnReconcileError event. This can take place because of a concurrent update by two different people. As we tend to use optimistic locking in client/server applications, this should be regarded as a normal situation.

The OnReconcileError event allows you to modify the Action parameter (passed by reference), which determines how the server should behave:

```
procedure TForm1.ClientDataSet1ReconcileError(DataSet: TClientDataSet;
  E: EReconcileError; UpdateKind: TUpdateKind; var Action: TReconcileAction);
```

This method has three parameters: the client dataset component (in case more than one client application is interacting with the application server), the exception that caused the error (with the error message), and the kind of operation that failed (ukModify, ukInsert, or ukDelete). The return value, which you'll store in the Action parameter, can be any one of the following:

```
type TReconcileAction = (raSkip, raAbort, raMerge, raCorrect, raCancel,
  raRefresh);
```

- The raSkip value specifies that the server should skip the conflicting record, leaving it in the delta (this is the default value).
- The raAbort value tells the server to abort the entire update operation and not even try to apply the remaining changes listed in the delta.
- The raMerge value tells the server to merge the data of the client with the data on the server, applying only the modified fields of this client (and keeping the other fields modified by other clients).
- The raCorrect value tells the server to replace its data with the current client data, overriding all field changes already done by other clients.
- The raCancel value cancels the update request, removing the entry from the delta and restoring the values originally fetched from the database (thus ignoring changes done by other clients).
- The raRefresh value tells the server to dump the updates in the client delta and to replace them with the values currently on the server (thus keeping the changes done by other clients).

If you want to test a collision, you can simply launch two copies of the client application, change the same record in both clients, and then post the updates from both. We'll do this later to generate an error, but let's first see how to handle the OnReconcileError event.

This is actually a simple thing to accomplish, but only because we'll receive a little help. Since building a specific form to handle an OnReconcileError event is very common, Delphi already provides such a form in the Object Repository. Simply go to the Dialogs page and select the Reconcile Error Dialog item. This unit exports a function you can directly use to initialize and display the dialog box, as I've done in the CdsDelta example:

```
procedure TDmCds.cdsEmployeeReconcileError (DataSet: TCustomClientDataSet;
  E: EReconcileError; UpdateKind: TUpdateKind; var Action: TReconcileAction);
begin
  Action := HandleReconcileError(DataSet, UpdateKind, E);
end;
```

WARNING As the source code of the Reconcile Error Dialog unit suggests, you should use the Project Options dialog to remove this form from the list of automatically created forms (if you don't, an error will occur when you compile the project). Of course, you need to do this only if you haven't set up Delphi to skip the automatic form creation.

The `HandleReconcileError` function simply creates the form of the dialog box and shows it, as you can see in the code provided by Borland:

```
function HandleReconcileError(DataSet: TDataSet; UpdateKind: TUpdateKind;
  ReconcileError: EReconcileError): TReconcileAction;
var
  UpdateForm: TReconcileErrorForm;
begin
  UpdateForm := TReconcileErrorForm.CreateForm(DataSet, UpdateKind,
    ReconcileError);
  with UpdateForm do
  try
    if ShowModal = mrOK then
    begin
      Result := TReconcileAction(ActionGroup.Items.Objects[
        ActionGroup.ItemIndex]);
      if Result = raCorrect then
        SetFieldValues(DataSet);
    end
    else
      Result := raAbort;
  finally
    Free;
  end;
end;
```

The Reconc unit, which hosts the Reconcile Error dialog, contains over 350 lines of code, so we can't describe it in detail. However, you should be able to understand the source code by studying it carefully. Alternatively, you can simply use it without caring about how everything works.

The dialog box will appear in case of an error, reporting the requested change that caused the conflict and allowing the user to choose one of the possible `TReconcileAction` values. You can see an example in Figure 14.15.

FIGURE 14.15:

The Reconcile Error dialog provided by Delphi in the Object Repository and used by the CdsDelta example

Field Name	Modified Value	Conflicting Value	Original Value
FIRST_NAME	<Unchanged>	Roberto	Robert
PHONE_EXT	281	289	288

☑ Show conflicting fields only □ Show changed fields only

TIP When you call `ApplyUpdates`, you start a rather complex update sequence, discussed in more detail in Chapter 17 for multitier architectures. In short, the delta is sent to the provider, which fires the `OnUpdateData` event and then receives a `BeforeUpdateRecord` event for every record to update. These are two chances you have to take a look at the changes and force specific operations on the database server.

MyBase (or the Briefcase Model)

The last capability of the ClientDataSet component I want to discuss in this chapter is its support for mapping memory data to local files, building stand-alone applications. The same technique can be applied in multitier applications to use the client program even when you're not physically connected to the application server. In this case, you can save all the data you expect to need in a local file for travel with a laptop (perhaps visiting client sites). You'll use the client program to access the local version of the data, edit the data normally, and when you reconnect, apply all the updates you've performed while disconnected.

To map a ClientDataSet to a local file you only need to set its `FileName` property, which requires an absolute pathname. To build a minimal MyBase program (called MyBase1), all you need is a ClientDataSet component hooked to a file and with a few fields defined (in the `FieldDefs` property):

```
object ClientDataSet1: TClientDataSet
  FileName = 'C:\md6code\14\MyBase1\test'
  FieldDefs = <
    item
      Name = 'one'
      DataType = ftString
      Size = 20
    end
    item
      Name = 'two'
      DataType = ftSmallint
    end>
  StoreDefs = True
end
```

At this point you can use the Create DataSet command of the local menu of the ClientDataSet at design time, or call its `CreateDataSet` method at run time, to physically create the file for the table. As you make changes and close the application, the data will be automatically saved to the file. (You might want to disable the change log, though, to reduce the size of this data.) The dataset, in any case, also has a `SaveToFile` method and a `LoadFromFile` method you can use in your code.

MyBase1, my example program, shown in Figure 14.16, doesn't require any database server or database connection to work. It needs only your own program and the `Midas.dll` file, but you can even get rid of it by including the MidasLib unit in the project. And the program doesn't require any actual Pascal code, either.

FIGURE 14.16:

The MyBase1 example, which saves data directly to a MyBase file

	one	two
	test	1
	marco	2
*	another	3

TIP MyBase generally saves the datasets in XML format, although the internal CDS format is still available. I'll explore this format in detail when I discuss XML in Chapter 23, "XML and SOAP." For the moment, suffice to say this is a text-based format (so it is less space-efficient than the internal format), which can be manipulated programmatically but immediately makes some sense even if you try reading it.

The MyBase support in Delphi 6 also includes the possibility of extracting the XML representation of a memory dataset by using the XMLData property. In Delphi 5, you could obtain the same by saving the ClientDataSet in XML format in a memory stream.

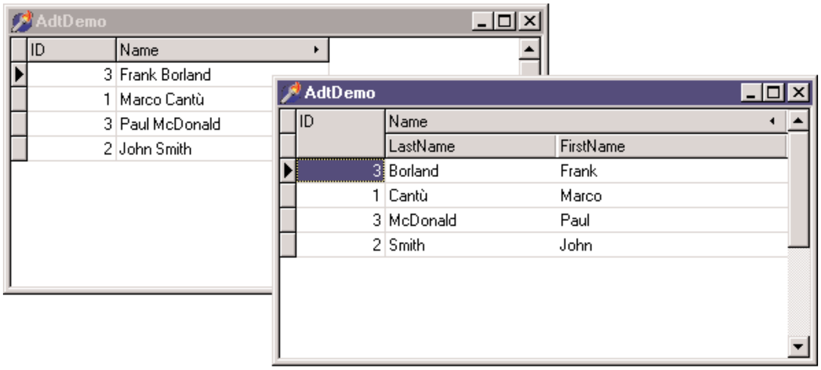
Abstract Data Types in MyBase

The ClientDataSet component supports most data types provided by Delphi, including nested data types and abstract data types, the case I want to investigate with this second MyBase example. In the FieldDefs property editor of a ClientDataSet component you can and select the ftADT value for the DataType property of one of fields. Now move to the ChildDefs property and define the child fields. This is the field definition of the AdtDemo example:

```
FieldDefs = <
  item
    Name = 'ID'
    DataType = ftInteger
  end
  item
    Name = 'Name'
    ChildDefs = <
      item
        Name = 'LastName'
        DataType = ftString
        Size = 20
      end
      item
        Name = 'FirstName'
        DataType = ftString
        Size = 20
      end>
    DataType = ftADT
    Size = 2
  end>
```

At this point, provide the FileName, create the dataset, and you are ready to compile and run the application. If you use a DBGrid to view the resulting dataset, it will allow you to expand or collapse the subfields of the ADT field, as you can see in Figure 14.17. The *condensed* value of the field is defined in the AdtDemo program by handling the OnGetText event of the ADT field:

```
procedure TForm1.ClientDataSet1NameGetText(Sender: TField;
  var Text: String; DisplayText: Boolean);
begin
  Text := ClientDataSet1NameFirstName.AsString + ' ' +
    ClientDataSet1NameLastName.AsString;
end;
```



ID	Name
3	Frank Borland
1	Marco Cantù
3	Paul McDonald
2	John Smith

ID	Name	
	LastName	FirstName
3	Borland	Frank
1	Cantù	Marco
3	McDonald	Paul
2	Smith	John

FIGURE 14.17:

The AdtDemo example shows the support for expanding or collapsing the definition of an ADT field.

Indexing for ADT Fields

We've seen how easily you can set up an index as the user selects the title of a DBGrid. In ADT fields, the situation becomes a little more complex. The AdtDemo program, in fact, uses the `FullName` property of the field (not the `FieldName` property) because of the ADT definition. For the `LastName` child field, in fact, the index should be based on `Name.LastName`, not simply on `LastName`. Also, the ADT field cannot itself be indexed, so if it is selected, the program uses as index the `LastName` subfield. Here is the code:

```
procedure TForm1.DBGrid1TitleClick(Column: TColumn);
begin
  if Column.Field.FullName = 'Name' then
    ClientDataSet1.IndexFieldNames := 'Name.LastName'
  else
    ClientDataSet1.IndexFieldNames := Column.Field.FullName;
end;
```

What's Next?

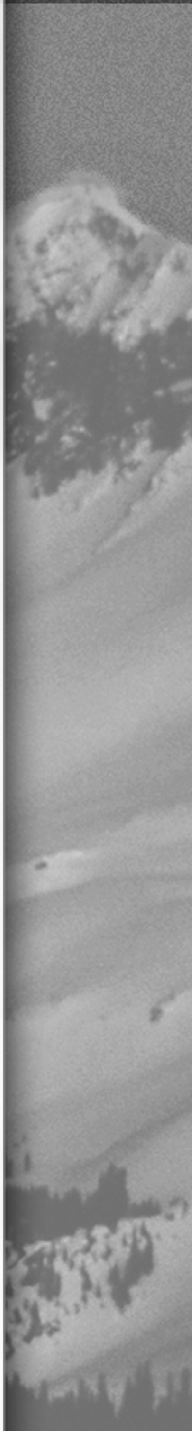
This chapter has presented a somewhat detailed introduction to client/server programming with Delphi. We saw what the key issues are and delved a little into some interesting areas of client/server programming. After a general introduction, I discussed the use of the dbExpress database library Borland is introducing in Delphi 6 and of the ClientDataSet component and MyBase technology.

There is certainly more we can say about client/server programming in Delphi, and in the next chapter I'll discuss some real-world examples, after introducing InterBase and the IBX components. Chapter 16 will then focus on Microsoft's ADO database engine.

CHAPTER 15

InterBase and IBX

- Getting started with InterBase 6
- Server-side programming: views, stored procedures, and triggers
- Using InterBase Express
- Pieces for a real-world example



Client/server programming requires two sides: a client application that you probably want to build with Delphi, and a relational database management system (RDBMS), usually a "SQL server." In this chapter, I focus on one specific SQL server, InterBase. There are many reasons for this choice. InterBase is the SQL server developed by Borland; it is an open source project and can be obtained for free; and it has traditionally been bound with Delphi, which has specific dataset components for it.

For all of these reasons, InterBase should be a good choice for your Delphi client/server development, although there are many other equally powerful alternatives. I'll discuss InterBase from the Delphi perspective, without delving in to its internal architecture. A lot of the information presented also applies to other SQL servers, so even if you've decided not to use InterBase, you might still find it valuable.

Getting Started with InterBase 6

After installing InterBase 6, you'll be able to activate the server from the Windows Start menu, but if you plan on using it frequently, you should install it as a Windows service (of course, only if you have Windows NT/2000, as Windows 9*x*/Me doesn't have support for services). When the server is active, you'll see a corresponding icon in the Tray Icon area of the Windows Taskbar (unless you start it as a service). The menu connected with this icon allows you to see status information (see Figure 15.1) and do some very limited configuration.

FIGURE 15.1:

Inside InterBase

Even though it has a limited market share, InterBase is a very powerful RDBMS. In this section I'll introduce the key technical features of InterBase, without getting into too much detail. This is a book on Delphi programming, in fact. Unfortunately, there is currently very little published about InterBase, although there are some ongoing efforts for an InterBase book and there is a wealth of information in the documentation accompanying the product and on a few Web sites devoted to the product.

InterBase was built from the beginning with a very modern and robust architecture. Its original author, Jim Starkey, invented an architecture for handling concurrency and transactions without imposing physical locks on portions of the tables, something other well-known database servers can hardly do even today. InterBase architecture is called Multi-Generational Architecture (MGA), and it handles concurrent access to the same data by multiple users, who can modify records without affecting what other concurrent users see in the database.

This approach naturally maps to the *Repeatable Read* transaction isolation mode, in which a user within a transaction keeps seeing the same data, regardless of changes done and committed by other users. Technically, the server handles this by maintaining a different version of each accessed record for each open transaction. Even if this approach (also called *versioning*) can lead to larger memory consumption, it avoids almost any physical lock on the tables and makes the system much more robust in case of a crash. Also, MGA pushes toward a very clear programming model—Repeatable Read—which other well-known SQL servers don't even support without losing most of their performance.

If Multi-Generational Architecture is at the heart of InterBase, the server has many other technical advantages:

- A limited footprint, which makes InterBase the ideal candidate for running directly on client computers, including portables. The disk space required by InterBase for a minimal installation is well below 10 MB, and its memory requirements are also incredibly limited.
- Good performance on large amounts of data.
- Availability on many different platforms (including 32-bit Windows, Solaris, and Linux), with totally compatible versions, which makes the server scalable from very small to huge systems without notable differences.
- A very good track record, as InterBase has been in use for 15 years with very few problems.
- A language very close to the SQL standard.

- Advanced programming capabilities, with positional triggers, selectable stored procedures, updateable views, exceptions, events, generators, and more.
- Simple installation and management, with limited administration headaches.

A Short History of InterBase

Jim Starkey wrote InterBase for his own Groton Database Systems company (hence the `.gds` extension still in use for InterBase files). The company was later bought by Ashton-Tate, which was then acquired by Borland. Borland handled InterBase directly for a while, then created an InterBase subsidiary, which was later re-absorbed into the parent company.

Starting with Delphi 1, an evaluation copy of InterBase has been distributed along with the development tool, spreading the database server among developers. Although it doesn't have a large piece of the RDBMS market, which is dominated by a handful of players, InterBase has been chosen by a few very relevant organizations, from Ericsson to the U.S. Department of Defense, from stock exchanges to home banking systems.

More recent events include the announcement of InterBase 6 as an open source database (December 1999), the effective release of source code to the community (July 2000), and the release of the officially certified version of InterBase 6 by Borland (March 2001).

In between these events, there were announcements of the spin-off of a separate company to run the consulting and support business on top of the open source database. Contacts with a group of former InterBase developers and managers (who had left Borland) didn't lead to an agreement, but the group decided to go ahead even without Borland's help and formed IBPhoenix (`www.ibphoenix.com`) with the plan of supporting InterBase users.

At the same time, independent groups of InterBase experts formed the InterBase Developer Initiative (IBDI; `www.interbase2000.org`) and started the Firebird open source project to further extend InterBase. For this reason, SourceForge currently hosts two different versions of the project, InterBase itself run by Borland and the Firebird project run by this independent group. You see that the picture is rather complex, but this certainly isn't a problem for InterBase, as there are currently many organizations pushing it, along with Borland.

IBConsole

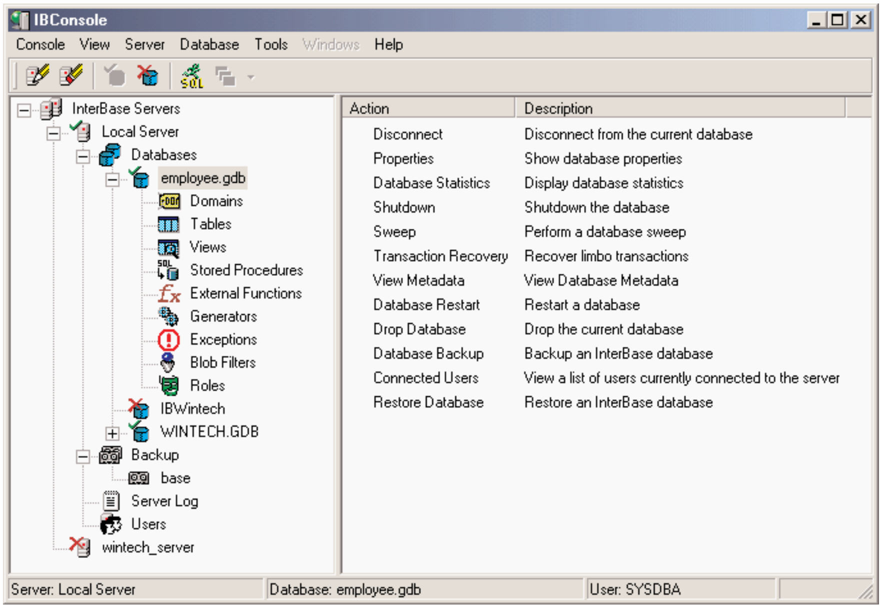
In past versions of InterBase, there were two main tools you could use to interact directly with the program: the Server Manager application, which could be used to administer both a local and a remote server; and Windows Interactive SQL (WISQL). Version 6 includes a much more powerful front-end application, called IBConsole. This is a full-fledged Windows program (built with Delphi) that allows you to administer, configure, test, and query an InterBase server, whether local or remote.

IBConsole is a simple and complete system for managing InterBase servers and their databases. You can use it to look into the details of the database structure, modify it, query the data (which can be useful to develop the queries you want to embed in your program), back up and restore the database, and perform all the other administrative tasks.

As you can see in Figure 15.2, IBConsole allows you to manage multiple servers and databases, all listed in a single, handy configuration tree. You can ask for general information about the database and list its entities (tables, domains, stored procedures, triggers, and everything else), accessing the details of each. You can also create new databases and configure them, back up the files, update the definitions, check what's going on and who is currently connected, and so on.

FIGURE 15.2:

IBConsole allows you to manage, from a single computer, InterBase databases hosted by multiple servers.



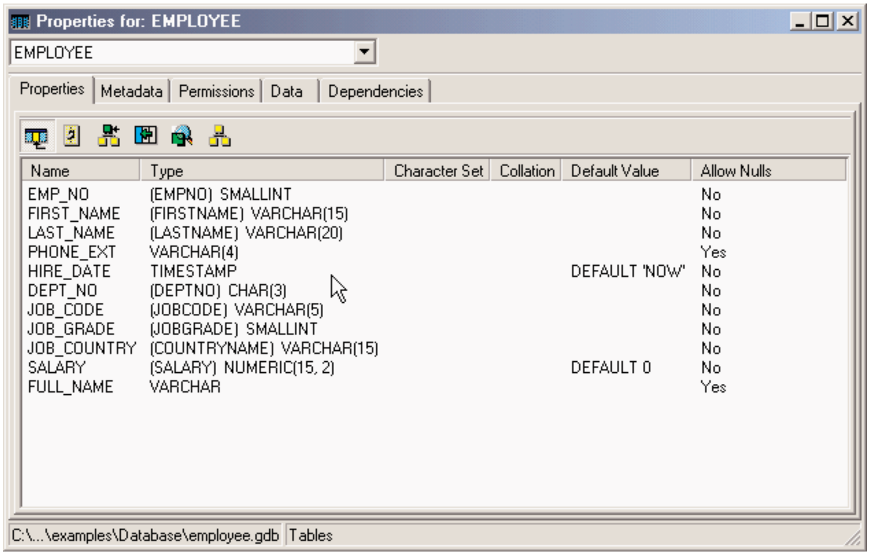
Action	Description
Disconnect	Disconnect from the current database
Properties	Show database properties
Database Statistics	Display database statistics
Shutdown	Shutdown the database
Sweep	Perform a database sweep
Transaction Recovery	Recover limbo transactions
View Metadata	View Database Metadata
Database Restart	Restart a database
Drop Database	Drop the current database
Database Backup	Backup an InterBase database
Connected Users	View a list of users currently connected to the server
Restore Database	Restore an InterBase database

Server: Local Server | Database: employee.gdb | User: SYSDBA

The IBConsole application allows you to open multiple windows to look at detailed information, such as the tables window depicted in Figure 15.3. In this window, you can see lists of the key properties of each table (columns, triggers, constraints, and indexes), see the raw metadata (the SQL definition of the table), access permissions, have a look at the actual data, modify it, and study the dependencies of the table. Similar windows are available for each of the other entities you can define in a database.

FIGURE 15.3:

IBConsole can open separate windows to show you the details of each entity—in this case, a table.



Name	Type	Character Set	Collation	Default Value	Allow Nulls
EMP_NO	(EMPNO) SMALLINT				No
FIRST_NAME	(FIRSTNAME) VARCHAR(15)				No
LAST_NAME	(LASTNAME) VARCHAR(20)				No
PHONE_EXT	VARCHAR(4)				Yes
HIRE_DATE	TIMESTAMP			DEFAULT 'NOW'	No
DEPT_NO	(DEPTNO) CHAR(3)				No
JOB_CODE	(JOBCODE) VARCHAR(5)				No
JOB_GRADE	(JOBGRADE) SMALLINT				No
JOB_COUNTRY	(COUNTRYNAME) VARCHAR(15)				No
SALARY	(SALARY) NUMERIC(15, 2)			DEFAULT 0	No
FULL_NAME	VARCHAR				Yes

Finally, IBConsole embeds an improved version of the original Windows Interactive SQL application (see Figure 15.4). You can directly type a SQL statement in the upper portion of the window (without any actual help from the tool, unfortunately) and then execute the SQL query. As a result, you'll see the data, but also the access *plan* used by the database (which an expert can use to determine the efficiency of the query) and some statistics on the actual operation performed by the server.

This is really a minimal description of IBConsole, which is a rather powerful tool and the only one included by Borland with the server besides command-line tools. IBConsole is probably not the most complete tool in its category, though. Quite a few third-party InterBase management applications are more powerful, although they are not all very stable or user-friendly. Some InterBase tools are shareware programs, while others are totally free. Two examples, out of many, are InterBase Workbench (`www.interbaseworkbench.com`) and IB_WISQL (done with and part of InterBase Objects, `www.ibobjects.com`).

FIGURE 15.4: The Interactive SQL window of IBConsole allows you to try out in advance the queries you plan to include in your Delphi programs.

TIP To find the latest third-party InterBase tools, have a look at `www.interbase2000.org/tools`, which hosts an up-to-date list.

Server-Side Programming

At the beginning of the previous chapter, I underlined the fact that one of the objectives of client/server programming—and one of its problems—is the division of the workload between the computers involved. When you activate SQL statements from the client, the burden falls on the server to do most of the work. However, you should try to use `select` statements that return a large result set, to avoid jamming the network.

Besides accepting DDL and DML requests, most RDBMS servers allow you to create routines directly on the server using the standard SQL commands plus their own server-specific extensions (which are generally not portable). These routines typically come in two forms, stored procedures and triggers.

Stored Procedures

Stored procedures are like the global functions of a Delphi unit and must be explicitly called by the client side. Stored procedures are generally used to define routines for data maintenance, to group sequences of operations you need in different circumstances, or to hold complex `select` statements.

Like Pascal procedures, stored procedures can have one or more typed parameters. Unlike Pascal procedures, they can have more than one return value. As an alternative to returning a value, a stored procedure can also return a result set, the result of an internal `select` statement or a custom fabricated one.

The following is a stored procedure written for InterBase; it receives a date in input and computes the highest salary among the employees hired on that date:

```
create procedure maxsaloftheday(ofday date)
returns (maxsal decimal(8,2)) as
begin
  select max(salary)
  from employee
  where hiredate = :ofday
  into :maxsal;
end
```

Notice the use of the `into` clause, which tells the server to store the result of the `select` statement in the `maxsal` return value. To modify or delete a stored procedure, you can later use the `alter procedure` and `drop procedure` commands.

Looking at this stored procedure, you might wonder what its advantage is compared to the execution of a similar query activated from the client. The difference between the two approaches is not in the result you obtain but in its speed. A stored procedure is compiled on the server in an intermediate and faster notation when it is created, and the server determines at that time the strategy it will use to access the data. By contrast, a query is compiled every time the request is sent to the server. For this reason, a stored procedure can replace a very complex query, provided it doesn't change too often!

From Delphi you can activate a stored procedure returning a result set by using either a Query or a StoredProc component. With a Query, you can use the following SQL code:

```
select *
from MaxSalOfTheDay ('01/01/1990')
```

Triggers (and Generators)

Triggers behave more or less like Delphi events and are automatically activated when a given *event* occurs. Triggers can have specific code or call stored procedures; in both cases, the execution is done completely on the server. Triggers are used to keep data consistent, checking new data in more complex ways than a check constraint allows, and to automate the side effects of some input operations (such as creating a log of previous salary changes when the current salary is modified).

Triggers can be fired by the three basic data update operations: `insert`, `update`, and `delete`. When you create a trigger, you indicate whether it should fire before or after one of these three actions.

As an example of a trigger, we can use a generator to create a unique index in a table. Many tables use a unique index as primary key. InterBase doesn't have an AutoInc field, unlike Paradox and other local databases. Because multiple clients cannot generate unique identifiers, we can rely on the server to do this. Almost all SQL servers offer a counter you can call to ask for a new ID, which you should later use for the table. InterBase calls these automatic counters *generators*, while Oracle calls them *sequences*. Here is the sample InterBase code:

```
create generator cust_no_gen;
...
gen_id (cust_no_gen, 1);
```

The `gen_id` function then extracts the new unique value of the generator passed as first parameter, with the second parameter indicating how much to increase (in this case, by one).

At this point you can add a trigger to a table, an automatic handler for one of the table's events. A trigger is similar to the event handler of the Table component, but you write it in SQL and execute it on the server, not on the client. Here is an example:

```
create trigger set_cust_no for customers
before insert position 0 as
begin
  new.cust_no = gen_id (cust_no_gen, 1);
end
```

This trigger is defined for the Customer table and is activated each time a new record is inserted. The `new` symbol indicates the new record we are inserting. The `position` option indicates the order of execution of multiple triggers connected to the same event. Triggers with the lowest values will be executed first.

Inside a trigger, you can write DML statements that also update other tables, but watch out for updates that end up reactivating the trigger, creating an endless recursion. You can later modify or disable a trigger by calling the `alter trigger` statement or `drop trigger`.

TIP Triggers fire automatically for specified events. If you have to make many changes in the database using batch operations, the presence of a trigger might slow down the process. If the input data has already been checked for consistency, you can temporarily deactivate the trigger. These batch operations are often coded in stored procedures, but stored procedures generally cannot issue DDL statements, like those required for deactivating and reactivating the trigger. In this situation, you can define a view based on a simple `select * from table` command, thus creating an alias for the table. Then you can let the stored procedure do the batch processing on the table and apply the trigger to the view (which should also be used by the client program).

Using InterBase Express

The examples built in the last chapter either still used the BDE or were done with the new dbExpress database engine. Using this server-independent engine could allow you to switch the database server used by your application, although in practice this is often far from simple. You might decide that an application you are building will invariably use a given database server, possibly the internal server of the company you are working for. In this case, you can decide to skip any database engine or library as well and write programs that are tied directly to the API of the specific database server, which will make your program intrinsically nonportable to other SQL servers.

Of course, you won't generally use similar APIs directly, but rather base your development on some native or third-party dataset components, which wrap these APIs and naturally fit into Delphi and the architecture of its class library. An example of such a family of components is InterBase Express (IBX). Applications built using these components should work better and faster (even if only marginally), giving you more control over the specific features of the server. For example, IBX provides you a set of administrative components specifically built for InterBase 6.

NOTE I'll examine the IBX components because they are tied to InterBase (the database server discussed in this chapter) and because that set is the only one available in the standard Delphi installation. Other similar sets of components (for InterBase, Oracle, and other database servers) are equally powerful and well-regarded in the Delphi programmers' community. A good example (and an alternative to IBX) is InterBase Objects, `www.ibobjects.com`.

IBX Dataset Components

The IBX components include custom dataset components and a few others. The dataset components inherit from the base `TDataSet` class, can use all the common Delphi data-aware controls, provide a field editor and all the usual design-time features, and can be used in the Data Module Designer, but they don't require the BDE.

You can actually choose among multiple dataset components. Three datasets of IBX have a role and a set of properties similar to their BDE counterparts:

- IBTable resembles the Table component and allows you to access a single table or view.
- IBQuery resembles the Query component and allows you to execute a SQL query, returning a result set. The IBQuery component can be used together with the IBUpdateSQL component to obtain a live (or editable) dataset.
- IBStoredProc resembles the StoredProc component and allows you to execute a stored procedure.

For new applications, you should generally use the IBDataSet component, which allows you to work with a live result set obtained by executing a `select` query. It basically merges IBQuery with IBUpdateSQL in a single component. The three components above, in fact, are provided mainly for compatibility with Delphi BDE applications.

Many other components in InterBase Express don't belong to the dataset category, but are still used in applications that need to access to a database:

- IBDatabase mimics the BDE Database component and is used to set up the database connection. The BDE also uses the specific Session component to perform some global tasks done by the IBDatabase component.
- IBTransaction allows complete control over transactions. It is important in InterBase to use transactions explicitly and isolate each transaction properly, using the Snapshot isolation level for reports and the Read Committed level for interactive forms. Each dataset explicitly refers to a given transaction, so you can have multiple concurrent transactions against the same database, choosing which datasets take part in which transaction.
- IBSQL lets you execute SQL statements that don't return a dataset (for example, DDL requests, or update and delete statements) without the overhead of a dataset component.
- IBDatabaseInfo is used for querying the database structure and status.
- IBSQLMonitor is used for debugging the system, since the SQL Monitor debugger provided by Delphi is a BDE-specific tool.
- IBEvents receives events posted by the server.

This group of components provides greater control over the database server than you can have with the BDE. For example, having a specific transaction component allows you to manage multiple concurrent transactions over one or multiple databases, as well as a single transaction spanning multiple databases. The IBDatabase component allows you to create databases, test the connection, and generally access system data, something the Database and Session BDE components don't fully provide.

TIP A feature of the IBX datasets that is new in Delphi 6 is the ability to set up the automatic behavior of a generator as a sort of auto-incremental field. This is accomplished by setting the `GeneratorField` property using its specific property editor. An example of this is discussed later in this chapter in the section "Generators and IDs."

IBX Administrative Components

A new page of Delphi 6 Component palette, InterBase Admin, hosts InterBase 6 administrative components. Although your aim is probably not to build a full InterBase console application, including some administrative features (such as backup handling or user monitoring) can make sense in applications meant for power users.

Most of these components have self-explanatory names. They are IBConfigService, IBBackupService, IBRestoreService, IBValidationService, IBStatisticalService, IBLogService, IBSecurityService, IBServerProperties, IBInstall, and IBUninstall. I won't build any advanced examples of the use of these components, as they are more focused towards the development of server management applications than that of client programs. I'll only embed a couple of them in a simple example, later in this chapter.

From BDE to IBX

To demonstrate how simple it can be to move from the use of the BDE to the use of IBX, I've built a trivial application, using the Database Form Wizard (which is strictly bound to the BDE). The application, on the companion CD, is called IbEmp and shows only a few fields of the *usual* Employee table of the corresponding InterBase demo database.

All of the features of the IbEmp example are summarized by the properties of its Query component:

```
object Query1: TQuery
  DatabaseName = 'IBLocal'
  RequestLive = True
  SQL.Strings = (
    'SELECT * '
    'FROM EMPLOYEE')
end
```

I could have extended the structure of this example generated by Delphi, adding a Database component to handle the connection, but I decided this was useless, as my intention was only to port the example to the use of the IBX components. The interesting example, in fact, is IbEmp2, which I started by copying all of the source code files of the version generated by the wizard. (The previous example is available on the companion CD just so you can try this type of porting, as the example by itself is not particularly interesting.)

After replacing the Query component with an IBQuery, I had to add two more components: IBTransaction and IBDatabase. Any IBX application requires at least an instance of each of these two components. You cannot set database connections in a dataset (as you can do with a plain Query), and at least a transaction object is required even to read the result of a query.

Here are the key properties of these components in the IbEmp2 example:

```
object IBTransaction1: TIBTransaction
  Active = False
  DefaultDatabase = IBDatabase1
end
object IBQuery1: TIBQuery
  Database = IBDatabase1
  Transaction = IBTransaction1
  CachedUpdates = False
  SQL.Strings = (
    'SELECT * FROM EMPLOYEE')
end
object IBDatabase1: TIBDatabase
  DatabaseName = 'C:\Program Files\InterBase ' +
    'Corp\InterBase6\examples\Database\employee.gdb'
  Params.Strings = (
    'user_name=SYSDBA'
    'password=masterkey')
  LoginPrompt = False
  IdleTimer = 0
  SQLDialect = 1
  TraceFlags = []
end
```

The changes don't take too much time to perform, and if you are accessing the same database table as in the BDE-based program, you won't need to change the data-aware components at all, but only hook the DataSource component to IBQuery1. Because I'm not using the BDE, I had to type in the pathname of the InterBase database. However, not everyone in the world has the Program Files folder, which depends on the local version of Windows, and of course the InterBase sample data files could have been installed in any other location of the disk. We'll try to solve these problems in the next example.

WARNING Notice that I've embedded the password in the code, a very naïve approach to security. Not only can anyone run the program, but someone could even extract the password by looking at the hexadecimal code of the executable file. I used this approach so I wouldn't need to keep typing in my password while testing a program, but in a real application you should require your users to do so if they care about the security of their data.

Building a Live Query

The IbEmp2 example has a query that doesn't allow editing. To activate editing, you need to use an IBTable component or add to the query an IBUpdateSQL component, even if the query is very simple. Usually the BDE does the behind-the-scenes work that lets you edit the result set of a simple query, but we are not using the BDE now.

The relationship between the IBQuery and IBUpdateSQL components is the same as between the Query and UpdateSQL components. To highlight this, I've taken the main form of the UpdateSql example discussed in the last chapter and ported it to the InterBase Express components, building the UpdSql2 example. I've simply copied the two components from the original example, pasted them into an editor, changed the type of the object, and copied the resulting text into a new form. The properties are so similar that I had only to ignore a couple of missing ones (the `DatabaseName` and the `UpdateMode` properties).

At this point, I simply added an IBDatabase and an IBTransaction component, a data source and a grid, and my program was up and running. The key element of these components, in fact, is their SQL code, which is attached to the `SQL` property of the query and the `ModifySQL`, `DeleteSQL`, and `InsertSQL` properties of the update component.

However, this time I've made the reference to the database a little more flexible. Instead of typing in the database name at design time, I've extracted the `InterBase` folder from the Windows Registry (where Borland saves it while installing the programs). This is the code executed when the program starts:

```
uses
  Registry;

procedure TForm1.FormCreate(Sender: TObject);
var
  Reg: TRegistry;
begin
  Reg := TRegistry.Create;
  try
    Reg.RootKey := HKEY_LOCAL_MACHINE;
    Reg.OpenKey('\Software\Borland\InterBase\CurrentVersion', False);
    IBDatabase1.DatabaseName := Reg.ReadString('RootDirectory') +
      'examples\database\employee.gdb';
    finally
      Reg.CloseKey;
      Reg.Free;
    end;
    EmpDS.DataSet.Open;
  end;
```

The source code actually contains alternate code for using the database installed in the `Data` subfolder of the `Borland Shared` folder, used for Delphi sample databases. Notice also that InterBase 6 places the sample databases in a different subfolder than InterBase 5 did.

NOTE For more information about the Windows Registry and INI files, see the related sidebar in Chapter 10, "The Architecture of Delphi Applications."

The new feature of this example, compared to the last version, is the presence of a transaction component. As I've already said, the InterBase Express components make the use of a transaction component compulsory, explicitly following a requirement of InterBase. Simply adding a couple of buttons to the form to commit or roll back the transaction would be enough, because a transaction starts automatically as you edit any dataset attached to it.

I've also improved the program a little by adding an ActionList component to it. This includes all the standard database actions and adds two custom actions for transaction support, Commit and Rollback. Both actions are enabled when the transaction is active:

```
procedure TForm1.ActionUpdateTransactions(Sender: TObject);
begin
  acCommit.Enabled := IBTransaction1.InTransaction;
  acRollback.Enabled := acCommit.Enabled;
end;
```

When executed, they perform the main operation but also need to reopen the dataset in a new transaction (which can also be done by "retaining" the transaction context). Actually, `CommitRetaining` doesn't reopen a new transaction, but it allows the current transaction to remain open. This way, you can keep using your datasets, which won't be refreshed (so you won't see edits already committed by other users) but will keep showing the data you've modified. This is the code:

```
procedure TForm1.acCommitExecute(Sender: TObject);
begin
  IBTransaction1.CommitRetaining;
end;

procedure TForm1.acRollbackExecute(Sender: TObject);
begin
  IBTransaction1.Rollback;
```

```
    // reopen the dataset in a new transaction
    IBTransaction1.StartTransaction;
    EmpDS.DataSet.Open;
  end;
```

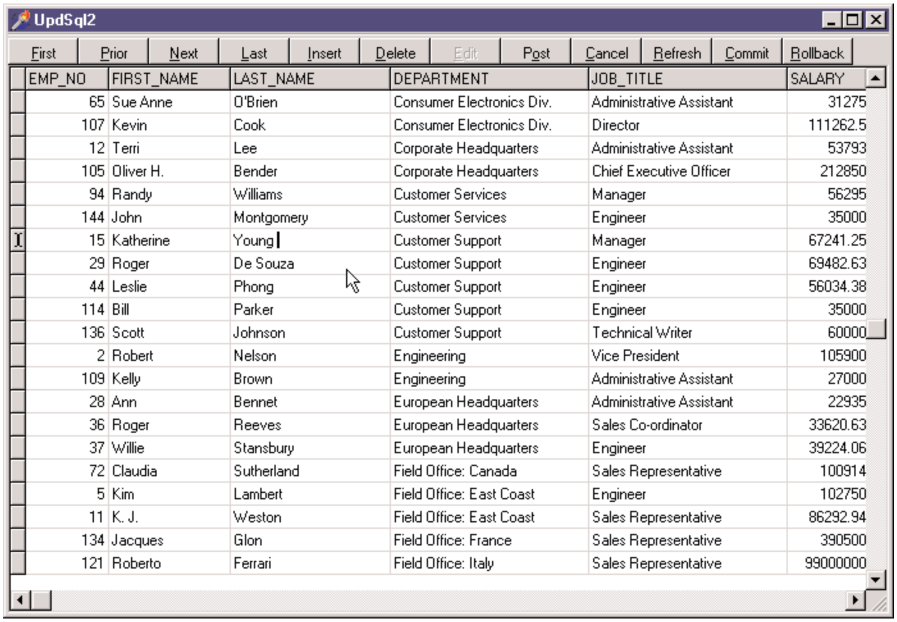
WARNING Be aware that InterBase closes any opened cursors when a transaction ends, which means you have to reopen them and refetch the data even if you haven't made any changes. When committing data, instead, you can ask InterBase to retain the "transaction context"—not to close open datasets—by issuing a `CommitRetaining` command, as mentioned before. The reason for this behavior of InterBase depends on the fact that a transaction corresponds to a snapshot of the data. Once a transaction is finished, you are supposed to read the data again to refetch records that may have been modified by other users. Version 6.0 of InterBase includes also a `RollbackRetaining` command, which I've decided not to use, because in a rollback operation, the program should refresh the dataset data to show the original values on screen, not the updates you've discarded.

The last operation refers to a generic dataset and not a specific one because I'm going to add a second alternate dataset to the program. The actions are connected to a text-only toolbar, as you can see in Figure 15.5. The program opens the dataset at startup and automatically closes the current transaction on exit, after asking the user what to do, with the following `OnClose` event handler:

```
procedure TForm1.FormClose(Sender: TObject; var Action: TCloseAction);
var
  nCode: Word;
begin
  if IBTransaction1.InTransaction then
  begin
    nCode := MessageDlg ('Commit Transaction? (No to rollback)',
      mtConfirmation, mbYesNoCancel, 0);
    case nCode of
      mrYes: IBTransaction1.Commit;
      mrNo: IBTransaction1.Rollback;
      mrCancel: Action := caNone; // don't close
    end;
  end;
end;
```

An alternative to using the IBQuery and IBUpdateSQL components is to use the IBDataSet component, which combines the two. An InterBase dataset, in fact, is a live query with a complete set of SQL statements for all the main operations. The differences between using the two components and the single one are minimal. Using IBQuery and IBUpdateSQL is probably better when porting an existing application based on the two equivalent BDE components, even if porting the program directly to the IBDataSet component doesn't really require a lot of extra work.

FIGURE 15.5: The output of the UpdSql2 example



EMP_NO	FIRST_NAME	LAST_NAME	DEPARTMENT	JOB_TITLE	SALARY
65	Sue Anne	O'Brien	Consumer Electronics Div.	Administrative Assistant	31275
107	Kevin	Cook	Consumer Electronics Div.	Director	111262.5
12	Terri	Lee	Corporate Headquarters	Administrative Assistant	53793
105	Oliver H.	Bender	Corporate Headquarters	Chief Executive Officer	212850
94	Randy	Williams	Customer Services	Manager	56295
144	John	Montgomery	Customer Services	Engineer	35000
15	Katherine	Young	Customer Support	Manager	67241.25
29	Roger	De Souza	Customer Support	Engineer	69482.63
44	Leslie	Phong	Customer Support	Engineer	56034.38
114	Bill	Parker	Customer Support	Engineer	35000
136	Scott	Johnson	Customer Support	Technical Writer	60000
2	Robert	Nelson	Engineering	Vice President	105900
109	Kelly	Brown	Engineering	Administrative Assistant	27000
28	Ann	Bennet	European Headquarters	Administrative Assistant	22935
36	Roger	Reeves	European Headquarters	Sales Co-ordinator	33620.63
37	Willie	Stansbury	European Headquarters	Engineer	39224.06
72	Claudia	Sutherland	Field Office: Canada	Sales Representative	100914
5	Kim	Lambert	Field Office: East Coast	Engineer	102750
11	K. J.	Weston	Field Office: East Coast	Sales Representative	86292.94
134	Jacques	Glon	Field Office: France	Sales Representative	390500
121	Roberto	Ferrari	Field Office: Italy	Sales Representative	99000000

In the UpdSql2 example, I've provided both alternatives, so that you can test the differences yourself. Here is part of the DFM description of the dataset component:

```
object IBDataSet1: TIBDataSet
  Database = IBDatabase1
  Transaction = IBTransaction1
  CachedUpdates = False
  BufferChunks = 32
  DeleteSQL.Strings = (
    'delete from EMPLOYEE'
    'where EMP_NO = :OLD_EMP_NO')
  InsertSQL.Strings = (
    'insert into EMPLOYEE'
    '  (FIRST_NAME, LAST_NAME, SALARY, DEPT_NO, JOB_CODE, JOB_GRADE, ' +
    '  JOB_COUNTRY)'
    'values'
```

```
      '  (:FIRST_NAME, :LAST_NAME, :SALARY, :DEPT_NO, :JOB_CODE, ' +
      '  :JOB_GRADE, :JOB_COUNTRY)')
    SelectSQL.Strings = (...)
    UpdateRecordTypes = [cusUnmodified, cusModified, cusInserted]
    ModifySQL.Strings = (...)
  end
```

If you connect the `IBQuery1` or the `IBDataSet1` components to the data source and run the program, you'll see that the behavior is identical. Not only do the components have a similar effect; the available properties and events are also very similar.

Monitoring InterBase Express

SQL Monitor works by using a hook into the BDE architecture. For this reason, you cannot use it with applications based on the InterBase Express components. Instead, you can simply embed in your application a copy of the IBSQLMonitor component and produce a custom log.

You can even write a more generic monitoring application, as I've done in the IbxMon example. I've placed in its form a monitoring component and a RichEdit control, and written the following handler for the `OnSQL` event:

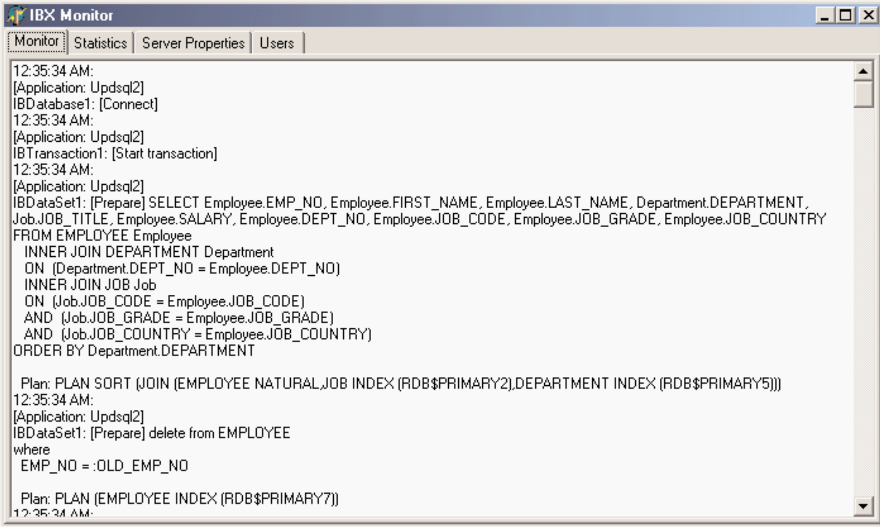
```
procedure TForm1.IBSQLMonitor1SQL(EventText: String);
begin
  if Assigned (RichEdit1) then
    RichEdit1.Lines.Add (TimeToStr (Now) + ': ' + EventText);
end;
```

The `if Assigned` test can be useful when receiving a message during shutdown, and it is required when you add this code directly inside the application you are monitoring.

To receive the messages from other applications (or from the current one), you have to turn on the tracing options of the IBDatabase component. In the UpdSql2 example (discussed earlier, in the section "Building a Live Query"), I turned them all on:

```
object IBDatabase1: TIBDatabase
  ...
  TraceFlags = [tfQPrepare, tfQExecute, tfQFetch, tfError, tfStmt,
                tfConnect, tfTransact, tfBlob, tfService, tfMisc]
```

If you run the two examples at the same time, the output of the IbxMon program will list the details about the UpdSql2 program's interaction with InterBase, as you can see in Figure 15.6.



```
12:35:34 AM:
[Application: Updsql2]
IBDatabase1: [Connect]
12:35:34 AM:
[Application: Updsql2]
IBTransaction1: [Start transaction]
12:35:34 AM:
[Application: Updsql2]
IBDataSet1: [Prepare] SELECT Employee.EMP_NO, Employee.FIRST_NAME, Employee.LAST_NAME, Department.DEPARTMENT,
Job.JOB_TITLE, Employee.SALARY, Employee.DEPT_NO, Employee.JOB_CODE, Employee.JOB_GRADE, Employee.JOB_COUNTRY
FROM EMPLOYEE Employee
   INNER JOIN DEPARTMENT Department
   ON  (Department.DEPT_NO = Employee.DEPT_NO)
   INNER JOIN JOB Job
   ON  (Job.JOB_CODE = Employee.JOB_CODE)
   AND  (Job.JOB_GRADE = Employee.JOB_GRADE)
   AND  (Job.JOB_COUNTRY = Employee.JOB_COUNTRY)
ORDER BY Department.DEPARTMENT

  Plan: PLAN SORT (JOIN (EMPLOYEE NATURAL,JOB INDEX (RDB$PRIMARY2),DEPARTMENT INDEX (RDB$PRIMARY5)))
12:35:34 AM:
[Application: Updsql2]
IBDataSet1: [Prepare] delete from EMPLOYEE
where
  EMP_NO = :OLD_EMP_NO

  Plan: PLAN (EMPLOYEE INDEX (RDB$PRIMARY7))
12:35:34 AM:
```

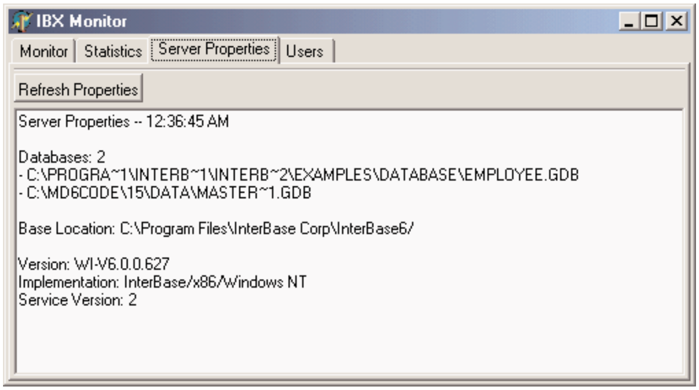
The output of the IbxMon example, based on the IBMonitor component

Getting More System Data

The IbxMon example doesn't only monitor the InterBase connection, but it allows you also to query some settings to the server using the various tabs of its page control. The example embeds a few IBX administrative components, showing server statistics, a few server properties, and all connected users. You can see an example of server properties in Figure 15.7 and the code for extracting the users in the following code fragment.



```
Server Properties -- 12:36:45 AM

Databases: 2
- C:\PROGRA~1\INTERB~1\INTERB~2\EXAMPLES\DATABASE\EMPLOYEE.GDB
- C:\MD6CODE\15\DATA\MASTER~1.GDB

Base Location: C:\Program Files\InterBase Corp\InterBase6/

Version: WI-V6.0.0.627
Implementation: InterBase/x86/Windows NT
Service Version: 2
```

FIGURE 15.7:

The assorted server information displayed by the IbxMon application

```
// grab the users data
IBSecurityService1.DisplayUsers;
// display the name of each user
for i := 0 to IBSecurityService1.UserInfoCount - 1 do
  with IBSecurityService1.UserInfo[i] do
    RichEdit4.Lines.Add (Format ('User: %s, Full Name: %s, Id: %d',
      [UserName, FirstName + ' ' + LastName, UserId]));
```

Real-World Blocks

Up to now, we've discussed specific techniques related to InterBase programming, but we haven't delved into the development of an actual application, with the problems this presents in practice. In the following subsections, I'll discuss a few practical techniques, with no specific order.

Nando Dessena (who knows InterBase much better than I do) and I have used all of these techniques in a seminar discussing the porting of an internal Paradox application to InterBase. The application discussed in that circumstance was much larger and more complex, and I've trimmed it down to only a few tables to make it fit into the space I have for this chapter.

TIP The database discussed in this section is called `mastering.gdb` and is hosted on the companion CD inside the `data` subfolder of the folder for this chapter. You can examine it using InterBase Console, possibly after making a copy to a writable drive so that you can fully interact with it.

Generators and IDs

I've mentioned in the last chapter that I'm quite a fan of an extensive use of IDs to identify the records in each table of a database.

NOTE I even tend to use a single sequence of IDs for an entire system, something often indicated as an Object ID (OID). The advantage is that I can place a series of related objects in different tables, depending on their internal structure, one of the possible approaches for implementing inheritance using relational tables. In such a circumstance, however, the IDs of the two tables must be unique. As you might not know in advance which objects could be used in place of others, adopting a global OID allows more freedom later. The drawback is that, if you have lots of data, using an integer as the ID (that is, having only 4 billion objects) might not be enough. For this reason, InterBase 6 supports 64-bit generators.

How do you generate the unique values for these IDs when multiple clients are running? Keeping a table with a *latest* value is going to create troubles, as multiple concurrent transactions (from different users) will see the same values. If you don't use tables, you can use a database-independent mechanism, including the rather large Windows GUIDs or the so-called high-low technique (the assignment of a base number to each client at startup—the high number—that is combined with a consecutive number—the low number—determined by the client).

Another approach, bound to the database, is the use of internal mechanisms for sequences, indicated with different names in each SQL server. In InterBase they are called *generators*. The characteristic of these sequences is that they operate and are incremented outside of transactions, so that they provide unique numbers even to concurrent users (remember that InterBase forces you to open a transaction even to read data).

We've already seen how to create a generator. Here is the definition for the one in my demo database, followed by the definition of the view you can use to query for a new value:

```
create generator g_master;

create view v_next_id (
  next_id
  ) as
select gen_id(g_master, 1) from rdb$database
;
```

Inside the RWBlocks application, I've added to a data module an IBQuery component (as I don't need it to be an editable dataset) with the following SQL:

```
select next_id from v_next_id;
```

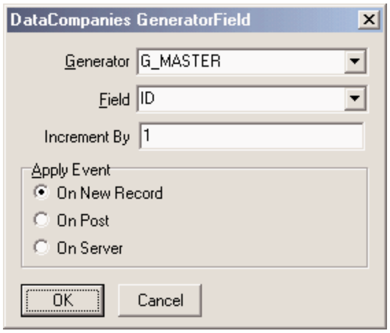
The advantage, compared to using the direct statement, is that this is easier to write and maintain, even if the underlying generator changes (or in case you switch to a different approach behind the scenes). Moreover, in the same data module I've added a function, which returns a new value for the generator:

```
function TDmMain.GetNewId: Integer;
begin
  // return the next value of the generator
  QueryId.Open;
  try
    Result := QueryId.Fields[0].AsInteger;
  finally
    QueryId.Close;
  end;
end;
```

This method can be called in the `AfterInsert` event of any dataset, to fill in the value for the ID:

```
mydataset.FieldByName ('ID').AsInteger := data.GetNewId;
```

As I've mentioned, the IBX datasets in Delphi 6 can be tied directly to a generator, simplifying the overall picture quite a lot. Thanks to the specific property editor (shown in Figure 15.8), in fact, connecting a field of the dataset to the generator becomes trivial.



DataCompanies GeneratorField

Generator: G_MASTER

Field: ID

Increment By: 1

Apply Event

● On New Record

○ On Post

○ On Server

FIGURE 15.8: The editor of the `GeneratorField` property of the IBX datasets in Delphi 6

Notice that both these approaches are much better than the one, based on a server-side trigger, discussed earlier in this chapter. In that case, in fact, the Delphi application didn't know the ID of the record sent to the database and so was unable to refresh it. Not having the record ID (which is also the only key field) on the Delphi side implies it is almost impossible to insert such a value directly inside a DBGrid. If you try, you'll see that the value you insert apparently gets lost right away, only to reappear in case of a full refresh.

Using client-side techniques instead, based on the manual code or the `GeneratorField` property, causes no trouble, as the Delphi application knows the ID, the record key, before posting it, so it can easily place it in a grid and refresh it properly.

Case-Insensitive Searches

An interesting issue with SQL servers in general, not specifically InterBase, has to do with case-insensitive searches. Suppose you don't want to show a large amount of data inside a grid (which is rather a bad idea for a client/server application). You instead choose to let the user type the initial portion of a name and then filter a query on this input, displaying only the smaller resulting record set in a grid. I've done this for a table of companies.

This search by company name is going to be executed quite frequently and will probably take place on a large table. However, if we simply search using the `starting with` or `like` operators, the search will be case sensitive, as in the following SQL statement:

```
select * from companies
where name starting with 'win';
```

To make a case-insensitive search, you can use the `upper` function on both sides of the comparison to test the uppercase values of each string, but a similar query would be very slow, as it won't be based on an index. On the other hand, saving the company names (or any other name) in uppercase letters would be rather silly, because when you have to print out those names, the result will be quite unnatural (even if very common in old information systems).

If we can trade off some disk space and memory for the extra speed, we can use a trick: add an extra field to the table, to store the uppercase value of the company name, using a server-side trigger to generate it and update it. We can then ask the database to maintain an index on the uppercase version of the name, to speed our search operation even further.

In practice, the table definition will look like this:

```
create domain d_uid as integer;
create table companies
(
  id          d_uid not null,
  name        varchar(50),
  tax_code    varchar(16),
  name_upper  varchar(50),
constraint companies_pk primary key (id)
);
```

To copy the uppercase name of each company into the related field, we cannot rely on client-side code, as an inconsistency would cause problems. In a case like this, it is better to use a trigger on the server, so that each time the company name changes, its uppercase version is updated accordingly. Another trigger will be used for the insertion of a new company:

```
create trigger companies_bi for companies
active before insert position 0
as
begin
  new.name_upper = upper(new.name);
end;

create trigger companies_bu for companies
active before update position 0
as
begin
  if (new.name <> old.name) then
    new.name_upper = upper(new.name);
end;
```

Finally, I've added an index to the table with this DDL statement:

```
create index i_companies_name_upper on companies(name_upper);
```

With this structure behind the scenes, we can now select all the companies starting with the text of an edit box (edSearch) by writing the following code in a Delphi application:

```
dm.DataCompanies.Close;
dm.DataCompanies.SelectSQL.Text :=
  'select c.id, c.name, c.tax_code,' +
    '  from companies c ' +
    '  where name_upper starting with ''' +
    UpperCase (edSearch.Text) + '''';
  dm.DataCompanies.Open;
```

TIP Using a prepared parametric query, we might be able to make this code even faster.

As an alternative, we could have created a server-side calculated field in the table definition, but this would have prevented us from having an index on the field, which speeds up our queries considerably:

```
name_upper  varchar(50) computed by (upper(name))
```

Handling Locations and People

You might notice that the table describing companies is quite bare. In fact, it has no company address, nor any contact information. The reason is simple: I want to be able to handle companies that have multiple offices (or locations) and list contact information about multiple employees of those companies.

Every location is bound to a company. Notice, though, that I've decided not to use a location identifier related to the company (such as a progressive location number for each company) but a global ID for all of the locations. This way I can refer to a location ID (let's say, for shipping goods) without having to refer also to the company ID. This is the definition of the table storing company locations:

```
create table locations
(
  id          d_uid not null,
  id_company  d_uid not null,
  address     varchar(40),
  town        varchar(30),
  zip         varchar(10),
  state       varchar(4),
  phone       varchar(15),
  fax         varchar(15),
constraint locations_pk primary key (id),
constraint locations_uc unique (id_company, id)
);

alter table locations add constraint locations_fk_companies
  foreign key (id_company) references companies (id)
  on update no action on delete no action;
```

The final definition of a foreign key relates the `id_company` field of the locations table with the `ID` field of the companies table. The other table lists names and contact information for people at specific company locations. To follow the database normalization rules, I should have added to this table only a reference to the location, as each location relates to a company. However, to make it simpler to change the location of a person within a company and to make my queries much more efficient (avoiding an extra step), I've added to the people table both a reference to the location and to the company.

The table also has another unusual feature: One of the people working for a company can be set as the key contact. This is obtained with a Boolean field (defined with a domain, as the Boolean type is not supported by InterBase) and by adding triggers to the table so that only one employee of each company can have this flag active:

```
create domain d_boolean as char(1)
  default 'F'
  check (value in ('T', 'F')) not null

create table people
(
  id           d_uid not null,
  id_company   d_uid not null,
  id_location  d_uid not null,
  name         varchar(50) not null,
  phone        varchar(15),
  fax          varchar(15),
  email        varchar(50),
  key_contact  d_boolean,
constraint people_pk primary key (id),
constraint people_uc unique (id_company, name)
);

alter table people add constraint people_fk_companies
  foreign key (id_company) references companies (id)
  on update no action on delete cascade;
alter table people add constraint people_fk_locations
  foreign key (id_company, id_location)
  references locations (id_company, id);

create trigger people_ai for people
active after insert position 0
as
begin
  /* if a person is the key contact, remove the
     flag from all others (of the same company) */
  if (new.key_contact = 'T') then
    update people
    set key_contact = 'F'
    where id_company = new.id_company
    and id <> new.id;
end;
```

```
create trigger people_au for people
active after update position 0
as
begin
  /* if a person is the key contact, remove the
     flag from all others (of the same company) */
  if (new.key_contact = 'T' and old.key_contact = 'F') then
    update people
    set key_contact = 'F'
    where id_company = new.id_company
    and id <> new.id;
end;
```

Building a User Interface

The three tables we have discussed so far have a clear master/detail relation. For this reason, the RWBlocks example uses three IBDataSet components for accessing the data, hooking up the two secondary tables to the main one. The code for the master/detail support is that of a standard database example based on queries, so I won't discuss it further (but I suggest you study the source code of the example).

Each of the datasets has a full set of SQL statements, to make the data editable. Whenever you enter a new detail element, the program hooks it to its master tables, as in the two following methods:

```
procedure TDmCompanies.DataLocationsAfterInsert(DataSet: TDataSet);
begin
  // initialize the data of the detail record
  // with a reference to the master record
  DataLocationsID_COMPANY.AsInteger := DataCompaniesID.AsInteger;
end;

procedure TDmCompanies.DataPeopleAfterInsert(DataSet: TDataSet);
begin
  // initialize the data of the detail record
  // with a reference to the master record
  DataPeopleID_COMPANY.AsInteger := DataCompaniesID.AsInteger;
  // the suggested location is the active one, if available
  if not DataLocations.IsEmpty then
    DataPeopleID_LOCATION.AsInteger := DataLocationsID.AsInteger;
  // the first person added becomes the key contact
  // (checks whether the filtered dataset of people is empty)
  DataPeopleKEY_CONTACT.AsBoolean := DataPeople.IsEmpty;
end;
```

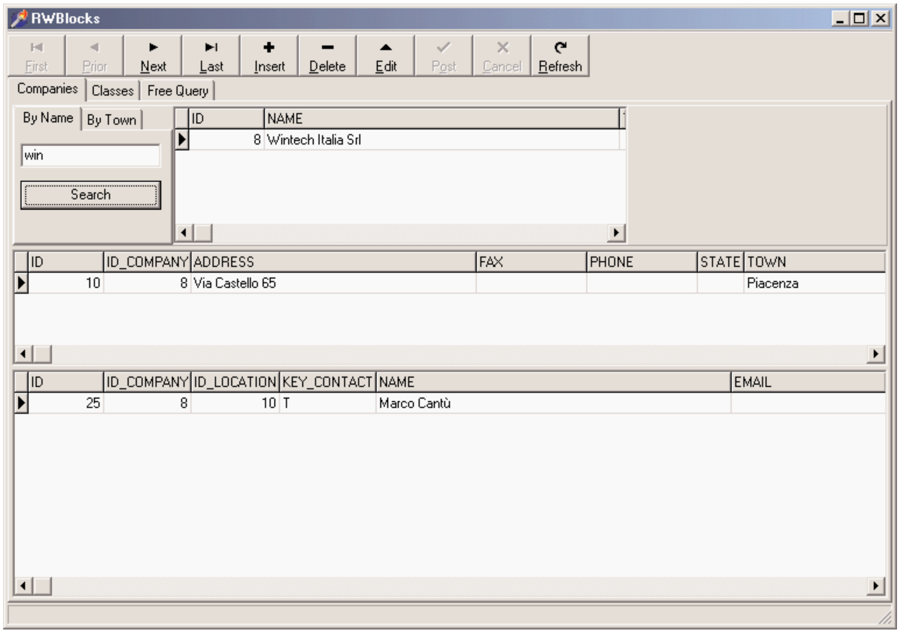
As this code suggests, a data module hosts the dataset components. Actually, the program has a data module for every form (hooked up dynamically, as you can create multiple instances of each form). Each of these data modules has a separate transaction, so that the various operations done in different pages are totally independent. The database connection, instead, is centralized. A main data module hosts the corresponding component, which is referenced by all the datasets. Each of the data modules is created dynamically by the form referring to it, and its value is stored in the dm private field of the form:

```
procedure TFormCompanies.FormCreate(Sender: TObject);
begin
  dm := TDmCompanies.Create (Self);
  dsCompanies.Dataset := dm.DataCompanies;
  dsLocations.Dataset := dm.DataLocations;
  dsPeople.Dataset := dm.DataPeople;
end;
```

This way we can easily create multiple instances of a form, with an instance of the data module connected to each of them. The form connected to the data module has three DBGrid controls, each tied to a data module and one of the corresponding datasets. You can see this form at run time, with some actual data, in Figure 15.9.

FIGURE 15.9:

A form showing companies, office locations, and people (part of the RWBlocks example)



win

ID	NAME
8	Wintech Italia Srl

ID	ID_COMPANY	ADDRESS	FAX	PHONE	STATE	TOWN
10	8	Via Castello 65				Piacenza

ID	ID_COMPANY	ID_LOCATION	KEY_CONTACT	NAME	EMAIL
25	8	10	T	Marco Cantù	

The form is actually hosted by a main form, which in turn is based on a page control, with the other forms embedded. Only the form connected with the first page is created when the program starts. The ShowForm method I've written takes care of parenting the form to the tab sheet of the page control, after removing the form border:

```
procedure TFormMain.FormCreate(Sender: TObject);
begin
  ShortDateFormat := 'dd/mm/yyyy';
  ShowForm (TFormCompanies.Create (self), TabCompanies);
end;

procedure TFormMain.ShowForm (Form: TForm; Tab: TTabSheet);
begin
  Form.BorderStyle := bsNone;
  Form.Align := alClient;
  Form.Parent := Tab;
  Form.Show;
end;
```

The other two pages, instead, are populated at runtime:

```
procedure TFormMain.PageControl1Change(Sender: TObject);
begin
  if PageControl1.ActivePage.ControlCount = 0 then
    if PageControl1.ActivePage = TabFreeQ then
      ShowForm (TFormFreeQuery.Create (self), TabFreeQ)
    else if PageControl1.ActivePage = TabClasses then
      ShowForm (TFormClasses.Create (self), TabClasses);
end;
```

The companies form hosts the search by company name we've already discussed in the last section, plus a search by location. You enter the name of a town and get back a list of companies having an office in that town:

```
procedure TFormCompanies.btnTownClick(Sender: TObject);
begin
  with dm.DataCompanies do
  begin
    Close;
    SelectSQL.Text :=
      'select c.id, c.name, c.tax_code' +
      '  from companies c ' +
      '  where exists (select loc.id from locations loc ' +
      '  where loc.id_company = c.id and upper(loc.town) = ''' +
      UpperCase(edTown.Text) + ''' )';
    Open;
    dm.DataLocations.Open;
    dm.DataPeople.Open;
  end;
end;
```

If you look at the source code of the form, you'll find a lot more code. Some of it is related to closing permission (as a user cannot close the form while there are pending edits not posted to the database), while a good amount relates to the use of the form as a lookup dialog, as described later.

Booking Classes

Another portion of the program and of the database involves booking training classes and courses. (Needless to say, although I built this program as a showcase, it also helps me run my own business.) In the database is a classes table listing all the training courses, each with a title and the planned date. Another table hosts registration by company, including the classes registered for, the ID of the company, and some notes. Finally, a third table has a list of people who've signed up, each hooked to a registration for his or her company, with the amount paid.

The rationale behind this company-based registration is that invoices are sent out to companies, which book the classes for their programmers and can receive specific discounts. This is a case in which the database is a little more normalized, as the people registration doesn't refer directly to a class, but only to the company registration for that class. Here is the definition of the tables involved (I've omitted foreign key constraints and other elements):

```
create table classes
(
  id           d_uid not null,
  description  varchar(50),
  starts_on    timestamp not null,
constraint classes_pk primary key (id)
);
create table classes_reg
(
  id          d_uid not null,
  id_company  d_uid not null,
  id_class    d_uid not null,
  notes       varchar(255),
constraint classes_reg_pk primary key (id),
constraint classes_reg_uc unique (id_company, id_class)
);
create domain d_amount as numeric(15, 2);
create table people_reg
(
  id              d_uid not null,
  id_classes_reg  d_uid not null,
  id_person       d_uid not null,
  amount          d_amount,
constraint people_reg_pk primary key (id)
);
```

The data module for this group of tables uses a master/detail/detail relationship, and has code to set the connection with the active master record when a new detail record is created. Each dataset has a generator field for its ID, and each has the proper `update` and `insert` SQL statements. These statements have been generated by the corresponding component editor using only the ID field to identify existing records and updating only the fields of the original table. In fact, each of the two secondary datasets retrieves data from a lookup table, either the list of companies or the list of people. Finally, I had to edit manually the `RefreshSQL` statements to repeat the proper inner join. Here is an example:

```
object IBClassReg: TIBDataSet
  Database = DmMain.IBDatabase1
  Transaction = IBTransaction1
  AfterInsert = IBClassRegAfterInsert
  DeleteSQL.Strings = (
    'delete from classes_reg'
    'where id = :old_id')
  InsertSQL.Strings = (
    'insert into classes_reg (id, id_class, id_company, notes)'
    'values (:id, :id_class, :id_company, :notes)')
  RefreshSQL.Strings = (
    'select reg.id, reg.id_class, reg.id_company, reg.notes, c.name '
    'from classes_reg reg'
    'join companies c on reg.id_company = c.id'
    'where id = :id')
  SelectSQL.Strings = (
    'select reg.id, reg.id_class, reg.id_company, reg.notes, c.name '
    'from classes_reg reg'
    'join companies c on reg.id_company = c.id'
    'where id_class = :id')
  ModifySQL.Strings = (
    'update classes_reg'
    'set'
    '  id = :id,'
    '  id_class = :id_class,'
    '  id_company = :id_company,'
    '  notes = :notes'
    'where id = :old_id')
  GeneratorField.Field = 'id'
  GeneratorField.Generator = 'g_master'
  DataSource = dsClasses
end
```

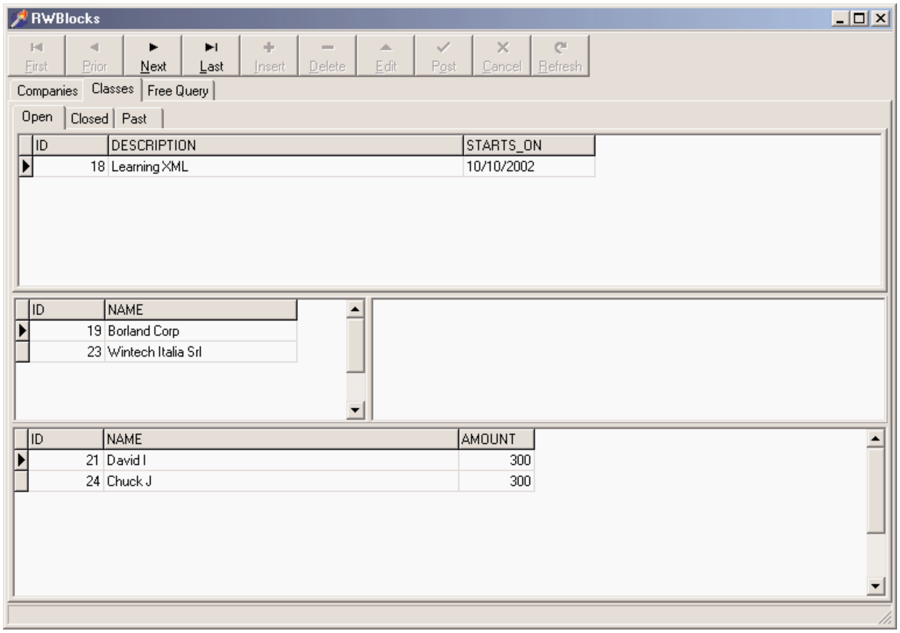
To complete the discussion of `IBClassReg`, here is its only event handler:

```
procedure TDmClasses.IBClassRegAfterInsert(DataSet: TDataSet);
begin
  IBClassReg.FieldByName ('id_class').AsString :=
    IBClasses.FieldByName ('id').AsString;
end;
```

The IBPeopleReg dataset has similar settings, but the IBClasses dataset is simpler, at design time. At run time, the SQL code of this dataset is dynamically modified, using three alternatives to display scheduled classes (whenever the date is after today's date), classes already started or finished in the current year, and classes of past years. A user selects one of the three groups of records for the table with a tab control, which hosts the DBGrid for the main table (see Figure 15.10).

FIGURE 15.10:

The form for class registrations of the RWBlocks example



ID	DESCRIPTION	STARTS_ON
18	Learning XML	10/10/2002

ID	NAME
19	Borland Corp
23	Wintech Italia Srl

ID	NAME	AMOUNT
21	David I	300
24	Chuck J	300

The three alternative SQL statements are created when the program starts, or actually when the class registrations form is created and displayed. The program stores the final portion of the three alternative instructions (the where clause) in a string list, and selects one of the strings when the tab changes:

```
procedure TFormClasses.FormCreate(Sender: TObject);
begin
  dm := TDmClasses.Create (Self);
  // connect the datasets to the data sources
  dsClasses.Dataset := dm.IBClasses;
  dsClassReg.DataSet := dm.IBClassReg;
  dsPeopleReg.DataSet := dm.IBPeopleReg;
  // open the datasets
  dm.IBClasses.Active := True;
  dm.IBClassReg.Active := True;
  dm.IBPeopleReg.Active := True;
  // prepare the SQL for the three tabs
  SqlCommands := TStringList.Create;
  SqlCommands.Add (' where Starts_On > ''now''');
  SqlCommands.Add (' where Starts_On <= ''now'' and ' +
    ' extract (year from Starts_On ) >= extract(year from current_timestamp)');
  SqlCommands.Add (' where extract (year from Starts_On) < ' +
    ' extract(year from current_timestamp)');
end;
procedure TFormClasses.TabChange(Sender: TObject);
begin
  dm.IBClasses.Active := False;
  dm.IBClasses.SelectSQL [1] := SqlCommands [Tab.TabIndex];
  dm.IBClasses.Active := True;
end;
```

Building a Lookup Dialog

The two detail datasets of this class registration form display some lookup fields. Instead of showing the ID of the company that booked the class, for example, it shows the company name. This is obtained with an inner join in the SQL statement and by configuring the DBGrid columns not to display the company ID. In a local application, or one with a limited amount of data, we could have used a lookup field. However, copying the entire lookup dataset locally or opening it for browsing should be limited to tables with about a hundred records at most, embedding some search capabilities.

If you have a large table, like a table of companies, an alternative solution can be to use a secondary dialog box to do the lookup selection. For example, we can choose a company using the form we've already built and taking advantage of its search capabilities. To display this form as a dialog box, the program creates a new instance of it, shows some hidden buttons already there at design time, and lets the user select a company to refer to from the other table.

To simplify the use of this lookup, which can happen multiple times in a large program, I've added to the companies form a class function, having as output parameters the name and ID of the selected company. An initial ID can be passed to the function to determine its initial selection. Here is the complete code of this class function, which creates an object of its class, selects the initial record if requested, shows the dialog box, and finally extracts the return values:

```
class function TFormCompanies.SelectCompany (
  var CompanyName: string; var CompanyId: Integer): Boolean;
var
  FormComp: TFormCompanies;
begin
```

```
    Result := False;
    FormComp := TFormCompanies.Create (Application);
    FormComp.Caption := 'Select Company';
    try
      // activate dialog buttons
      FormComp.btnCancel.Visible := True;
      FormComp.btnOK.Visible := True;
      // select company
      if CompanyId > 0 then
        FormComp.dm.DataCompanies.SelectSQL.Text :=
          'select c.id, c.name, c.tax_code' +
          '   from companies c ' +
          '   where c.id = ' + IntToStr (CompanyId)
      else
        FormComp.dm.DataCompanies.SelectSQL.Text :=
          'select c.id, c.name, c.tax_code' +
          '   from companies c ' +
          '   where name_upper starting with ''a''';
      FormComp.dm.DataCompanies.Open;
      FormComp.dm.DataLocations.Open;
      FormComp.dm.DataPeople.Open;

      if FormComp.ShowModal = mrOK then
      begin
        Result := True;
        CompanyId := FormComp.dm.DataCompanies.FieldByName ('id').AsInteger;
        CompanyName := FormComp.dm.DataCompanies.FieldByName ('name').AsString;
      end;
    finally
      FormComp.Free;
    end;
  end;
```

Another slightly more complex class function (available within the example's source code, but not listed here) allows the selection of a person of a given company to register people for classes. In this case, the form is displayed after disallowing searching another company or changing it.

In both cases, the lookup is triggered by adding an ellipsis button to the column of the DBGrid—for example, the grid column listing the names of companies registered for classes. When this button is pressed, the program calls the class function to display the dialog box and uses its result for updating the hidden ID field and the visible name field:

```
  procedure TFormClasses.DBGridClassRegEditButtonClick(Sender: TObject);
  var
    CompanyName: string;
    CompanyId: Integer;
  begin
    CompanyId := dm.IBClassReg.FieldByName ('id_Company').AsInteger;
    if TFormCompanies.SelectCompany (CompanyName, CompanyId) then
    begin
      dm.IBClassReg.Edit;
      dm.IBClassReg.FieldByName ('Name').AsString := CompanyName;
      dm.IBClassReg.FieldByName ('id_Company').AsInteger := CompanyId;
    end;
  end;
```

Adding a Free Query Form

The final feature of the program is a form where a user can directly type in a SQL statement and run it. As a helper, the form lists in a combo box the available tables of the database, obtained when the form is created by calling:

```
DmMain.IBDatabase1.GetTableNames (ComboTables.Items);
```

Selecting an item of the combo box generates a simple SQL query:

```
MemoSql.Lines.Text := 'select * from ' + ComboTables.Text;
```

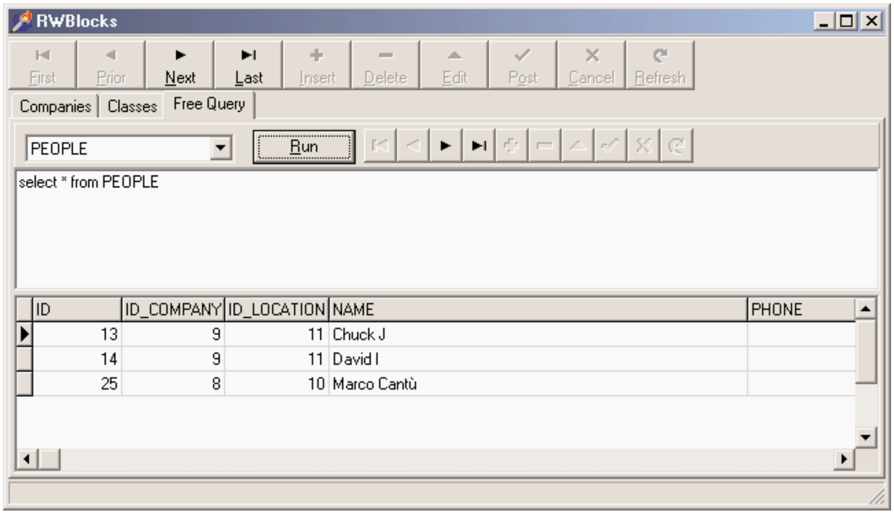
The user, if an expert, can then edit the SQL, possibly introducing restrictive clauses, and then run the query:

```
procedure TFormFreeQuery.ButtonRunClick(Sender: TObject);
begin
  QueryFree.Close;
  QueryFree.SQL := MemoSql.Lines;
  QueryFree.Open;
end;
```

You can see this third form of the RWBlocks program in Figure 15.11. Of course, I'm not suggesting that you add SQL editing to programs intended for all of your users. This feature is intended for power users, maybe programmers. I basically wrote it for myself!

FIGURE 15.11:

The free query form of the RWBlocks example is intended for power users.



```
select * from PEOPLE
```

ID	ID_COMPANY	ID_LOCATION	NAME	PHONE
13	9	11	Chuck J	
14	9	11	David I	
25	8	10	Marco Cantù	

What's Next?

After looking at other, more general, database access technologies Delphi provides (such as the BDE and dbExpress), in this chapter I've introduced the InterBase database and the IBX family of components. The last part of the chapter presented a complete real-world application, discussing a series of general-purpose techniques you can probably apply even to completely different InterBase applications.

Now we are ready to focus on another data access alternative, Microsoft's own ADO technology, which Delphi fully supports with a specific set of dataset components since version 5. In subsequent chapters, we'll continue to explore database development, with multitier architectures and the development of database-oriented Delphi components.

CHAPTER 16

ActiveX Data Objects

- Microsoft Data Access Components (MDAC)
- dbGo
- Data link files
- Getting schema information
- Using the Jet engine
- Transaction processing
- Disconnected and persistent recordsets
- The briefcase model and deploying MDAC

I wish to acknowledge and thank Guy Smith-Ferrier for writing this chapter. Guy is a programmer, author, and speaker. He is the author of several commercial software products and countless internal systems for independent and blue-chip companies alike. He has written many articles for *The Delphi Magazine* and for others on topics beyond Delphi, and he has spoken at numerous conferences in North America and Europe. Guy lives in England with his wife, his son, and his cat.

Since the mid-1980s, database programmers have been on a quest for the "holy grail" of *database independence*. The idea is to use a single API that applications can use to interact with many different sources of data. The use of such an API would release developers from a dependence upon a single database engine and allow them to adapt to the world's changing demands. Vendors have produced many solutions to this goal, the two most notable early solutions being Microsoft's Open Database Connectivity (ODBC) and Borland's Independent Database Application Programming Interface (IDAPI), more commonly known as the Borland Database Engine (BDE).

Microsoft started to replace ODBC with OLE DB in the mid-1990s with the success of COM. However, OLE DB is what Microsoft would class a *system-level* interface and is intended to be used by system-level programmers. It is very large and complex and unforgiving. It makes greater demands on the programmer and requires a higher level of knowledge in return for lower productivity. ActiveX Data Objects (ADO) is a layer on top of OLE DB and is referred to as an *application-level* interface. It is considerably simpler than OLE DB and more forgiving. In short, it is designed for use by application programmers.

ADO has great similarities with the BDE. They are, after all, designed to solve very similar problems. Both support navigation of datasets, manipulation of datasets, transaction processing, and cached updates (called *batch updates* in ADO), so the concepts and issues involved in using ADO are similar to those of the BDE. However, there are also differences. ADO is a more recent technology. This gives it an advantage over the BDE because it is better suited to today's needs and doesn't need to carry so much deadwood around with it. Perhaps more importantly, ADO has a wider interpretation of "data." The BDE is used for accessing "rectangular" data—that is, data in rows and columns. This is ideal for accessing data from databases. ADO can be used for accessing this data but can also be used for accessing non-rectangular data, including directory structures, documents, Web sites, and e-mail.
