Managing consultants is a tricky business. It takes time and dedication to orient them to the company's environment and culture. Their goals and objectives must be explicitly stated in the very beginning, and specific constraints should be placed on them. An organization must clearly define what it is expecting to achieve through their service, its reasonable expectations for completion, and its expectations for an end product. An organization should have a clear and signed statement of work (SOW). It should schedule frequent status meetings and stay on top of the resource allocation and deliverables. Most of the information gathering, risk and gap analysis, and conclusions and recommendations will ultimately be of value throughout the implementation of the project conclusions and recommendations. Indeed, the information will be sustainable for ongoing and future assessments and right-sizing activities. Organizations should keep in mind that consultants will walk away when their job is finished, and the organization and its team will have to implement their recommendations or maintain their implementation.

49.10 Should an Organization Consider Outsourcing Security?

Over the years, my views on outsourcing security have significantly changed. Perhaps it is a natural evolution considering how open the business and IT models are these days. Or perhaps it is the advanced security technology that enables the industry to be simultaneously open and closed to ensure that the company's business imperative is best served. Updated and sound security policies, a solid risk management program, governance and oversight, state of the art security technology, and executive support enable the possibility of outsourcing for consideration.

As with any outsourcing consideration, there are only certain functional candidates for consideration. One perfect security function for outsourcing is firewall management and intrusion detection or intrusion prevention. Outsourcing key security functions and central and critical controls such as identity management is a bad idea. Another candidate for consideration in security outsourcing is key management. If a company is using relatively few SSL certificates for server to serves authentication, it does not make sense to endure the cost to internally initiate a certificate function. However, if the environment is at a high risk and needs stronger authentication and encryption for the entire enterprise, it makes more sense to implement an internal key management system. Many companies are also currently outsourcing infrastructure or server management. In this environment, it is a natural extension to outsourcing anti-virus, spam, and security patch management.

Another area for outsourcing is audit and monitoring or even special ad hoc reviews. Risk assessment, penetration testing, and vulnerability scanning are also candidate functions for outsourcing. Outsourcing should be part of an organization's overall staffing and organization plan consideration. It can be used when a company needs to implement a new and complex technology, to augment staffing, or to add segregation of duties if it is in a highly regulated environment or has a smaller, less technical or operationally oriented team.

Many managed security service providers (MSSPs) have well-established and supported technology and process. They can achieve economies of scale through their customer base and pass on key savings to the organization. Today's security product and vendor environment sees a lot of change and a lot of acquisitions and mergers. Doing the upfront research and benchmarking of the vendor can aid in ensuring that the vendor does not either go out of business totally or become a secondary line of business for a newly acquired owner.

The key to secure outsourcing is to have a good and solid relationship with the vendor and a good contract specifying the vendor's security policies, non-disclosure policies, and a detailed statement of work regarding continuous support, incident management, and other important shared procedures and processes. It is important to have details on who does what and to have solid mutual expectations of both day-to-day processing and longer term strategies. The outsourcing relationship, contract, and statement of work must be very carefully monitored and managed. This is the key to overall success.

49.11 Training

Once an organization has recruited and staffed the security team, it must determine how it will ensure that the team grows and keeps up with the growing changes to the business processes, technology, and the ongoing threats and risks. Once again, the assumption is that there will be some constraints on the training budget and that managers will have to resort to creative resource management. Most organizations budget for a single course or seminar for each person. Some organizations who value high performing teams invest in two courses per year: one in the functional area discipline and one in professional growth. Some organizations will match the employee's own investment and willingness for ongoing learning by splitting the cost and the time commitment.

There are many ways to find free training and many vendors provide free online seminars and host free events. Obviously, there are volumes of information available on the Internet, and most employers are willing to give employees time to incorporate research and reading into the annual training plan. Most organizations also have internal computer-based training available, and the security team should be encouraged to take advantage of these free internal courses.

Finding seasoned and well-trained security professionals in today's market is a challenge. Another alternative is providing in-house security training for existing IT staffers. This works particularly well for other team members currently doing some type of security role such as systems administration, network management, etc.

Organizations should encourage its security team to put together updated and annual individual training plans that include company-provided training opportunities as well as individual personal opportunities. Ongoing Internet research, subscribing to and reading online publications, and membership and involvement in security professional organizations should be part of all team member individual plans. Examples of such organizations included the CSI, Information Systems Security Association (ISSA), Infragard, the Forum of Incident Response and Security Teams, and less formal discussion groups of security professionals associated with individual industry segments. Several security managers said that by participating in this study, they hoped to gain insights on how to improve their information security programs.

To maximize the value of expenditures on external training and events, some central groups require staff members who attend external events to brief others on what they learned. It is also important to upgrade the awareness of the decentralized security team as well as executive management and business teams. For larger organizations, external training firms can be hired to provide canned training materials or design unique training to accommodate the organization's security program.

49.12 Career Paths for Security Professionals and Practitioners

One emerging trend within formalized security organizations is to create career paths for security personnel within the organization. This has an overwhelming and overarching impact to the success of the organization. Using internal security staffing and even augmenting with external training or contractors can help establish and maintain a successful program. This will not only help to grow the internal team, but it will also create job satisfaction, increase retention, and aid in recruiting. The career path should take into consideration both the professional and practitioner aspects of security and ensure that there is a path within each and a combination of the two.

In particular, many organizations are encouraging their staff to become CISSP. The CISSP certification was established by the International Information Systems Security Certification Consortium. The consortium was established as a joint effort of several information security-related organizations, including the ISSA and the CSI to develop a certification program for information security professionals.

The CISSP requires three years of experience plus an undergraduate degree or four years of experience in various security disciplines to sit for the exam. More junior personnel will not seek the CISSP right away, but they will round out their experience with more technical certifications such as SSCP, SANs, Cisco, and Microsoft. The CISSP focuses on high-level security issues at a conceptual level. There are various ways to prepare for the exam that include individual study using a host of preparation guidelines and readings, taking a CISSP one week training course, or using online materials that include pre-tests for practice. According to CertMag's 2005 Salary Survey,

> certified IT professionals believe certification makes them more confident, more productive and more promotable. According to the survey of certified professionals globally, 62.5 percent of respondents have a high level of confidence that certification makes them feel more confident in their work and 57.4 percent enjoy more respect from managers and colleagues thanks to certification. Perhaps most importantly, 51.6 percent of respondents believe being certified leads to a greater demand for their professional services. Respondents felt that certification benefits productivity. Among respondents, 45.6 percent have a high level of confidence that certification increased productivity, and 47.3 percent cited increased problem-solving skills.
>
> Perhaps more important than how certification makes IT professionals feel is how employers feel about certified IT professionals. This year's survey shows slightly less financial support than the same 2004 survey. This year, 45.4 percent of respondents reported paying for their own certification, up from 37.9 percent last year. Last year, 48 percent of employers paid the entire bill, down to 41.7 percent this year. The remaining 12.9 percent of 2005 respondents shared the cost with their employers.

49.13 The Retention Challenge

It is critical to provide staff with state of the art technical tools and training to do its various jobs. A benefit for the information security team is to co-exist with the IT group where there is a natural synergy to other IT functional areas such as development, networking, business process reengineering, etc. Generally, IT professionals earn slightly higher salaries because of the criticality of the function, the constant need to update skills, and the competition for qualified practitioners and professionals. In today's job market, average salaries for security engineers are in the $80k–$100k range while CSOs and CISOs are making from $135k to $180k. These salaries vary across the U.S., depending on geographic location with the east and west coast areas netting higher annual salaries and overall compensation.

Organizations have taken steps to ensure that personnel involved in various aspects of information security programs have the skills and knowledge needed to mitigate risk and implement state of the art security programs. In addition, learning and successful organizations recognized that staff expertise must be frequently updated to keep abreast of ongoing changes in threats, vulnerabilities, software, security techniques, and security monitoring tools. Further, most of the organizations strive to increase the professional stature of their staff in order to gain respect from others in their organizations and attract competent individuals to security-related positions.

There are definitely benefits to maintaining a stable security team with consistent staffing levels. As with most professionals, information security professionals crave recognition in any and all forms. As previously mentioned, the reward comes from ongoing learning and working with evolving state of the art technology, products, and processes. Additionally, time off for training and seminars is a benefit to the overall quality and success of the security team and adds to the professional expertise of the team. Recognition can also vary from a simple pat on the back, an email thank-you, or a more public organization-based reward.

49.14 Attract and Keep Individuals with Technical Skills

Most of the security teams cite maintaining or increasing the technical expertise among their security staff as a major challenge, largely because of the high demand for information technology experts in the job market. In response, many security leaders offer higher salaries and special benefits to attract and keep expert staff. For example, one financial services corporation provides competitive pay based on surveys of industry pay levels and attempts to maintain a challenging work environment. Another organization provides flexible work schedules and telecommuting opportunities that enable most of the staff to work at home one day a week.

All in all, salaries are up for security and information security professionals. In general, information technology has been making its way back up from the dotcom debacle of the late 1990s and early 2000. The security and information security industry and salary market has emerged within this space as one of the leading and most demanding job functions. Because of regulation and legislation, coupled with increased risk in today's business and technology environment, security has risen to the top of the salary range and the job market.

According to a CertMag 2005 Salary Survey, as in 2004, security is bringing in the largest salaries along with storage, Cisco networking, project management, and Java developers. For the first time ever, the survey reported five certification programs all reporting average salaries of more than $100,000. Two programs from the International Information Systems Security Certification Consortium (ISC)2 led the list, the Certified Information Systems Security Management Professional (CISSP–ISSMP) program drawing $116,970 annually and the Certification Systems Security Architecture Professional (CISSP–ISSAP) earning $111,870.

> It's against this backdrop that CertMag's 2005 Salary Survey ranked salaries by specialization. Many of the top job roles from last year are back, but there have been few significant changes. Most notably, information security, which placed fourth last year, vaulted to the top of the heap in 2005. Its practitioners reported that they earn nearly $93,000 a year, compared to $78,910 in 2004. That's a jump of nearly 15 percent in a single year. (Evidently, the buzz around security is much more than just hype.)

49.15 Timing is Everything—Yet Another View

For those individuals who have been in the security profession for a while, they have observed security make its way from the "way back" office to the "front" office within many organizations. Additionally, there is a path for individual contributors who gain stature and status acknowledged professionals with the ability to gain both technical and professional certifications. Over the last decade, security has been elevated, and the Corporate CISO and CSO roles have been created. At some firms, within some verticals, however, the role has begun to lose ground as many companies are cutting back and looking for places to cut senior executive positions. These companies are de-emphasizing the role and its importance within the organization and marginalizing the function. There seems to be fewer opportunities for talented CISOs and CSOs. The organizations where security officers are sustaining their positions and their stature in the organizations are those that are bound by regulatory and legal requirements such as financial services and healthcare. Even these companies who hire CISOs and CSOs to check the compliance box are often looking for a fall guy when there is a problem or issue of non-compliance.

As budgets shrink for security, organizations are asking for strong professional leadership with hands-on expertise. So the CISO role is often shrunk to firewall engineering and other more technical roles. Although a solid CISO will have risen from either business functional roles or technical disciplines, the true value he or she brings to the table is security leadership and an ability to communicate upward, downward, and horizontally across the organization. A key value that a senior security professional brings to the table is a keen sense of the business drivers and underlying process and an overall understanding of how security can enhance the business process and contribute to the organization's bottom line. This person can often measure risk on the fly and adjust the security program accordingly. The same person can effectively communicate security purpose, goals, and values to executive management.

As security gets pushed lower and lower within the organizational structure, senior executives are not given visibility to information security issues on a regular basis. Over time, this results in less and less financial allocation for security projects and sustaining programs. With the continuing increase in risk and vulnerability, security cannot keep pace and be successful without ongoing and even increasing budgets.

The greatest threat is the potential for talented CSOs and CISOs to begin to leave the profession. Fortunately, there is a large pool of talented CISSPs and entrants to the security profession to back fill, but this maturation could take a while and not keep pace to the demand. Many view this as a natural cycle that other professions have faced over time such as Chief Technical Officers (CTOs) and CIOs.

49.16 Future Trends and Directions—Security Convergence

Another currently popular trend is security convergence. Although convergence is being driven by security and audit professional organizations, organizations are embracing it because they can reduce executive and leadership positions as functional areas combine. Executives see this as a cost-saving initiative rather than aligning similar functions to approach security from an end-to-end perspective.

ASIS International identifies security *convergence* as a trend affecting global enterprises. ASIS International defines convergence as, "the identification of security risks and interdependencies between business functions and processes within the enterprise and the development of managed business process solutions to address those risks and interdependencies."

To gain a better understanding of the impact of convergence on global enterprises, the alliance of leading international security organizations, including ASIS International, ISSA, and Information Systems Audit and Control Association (ISACA) retained Booz Allen Hamilton (Booz Allen) to examine this convergence trend within enterprises throughout the United States. Booz Allen solicited responses to web-based surveys on convergence from CSOs, CISOs, and other security professionals. Those security professionals interviewed and surveyed represent U.S.-based global companies with revenues ranging from $1 billion to more than $100 billion. The overall high response rate among senior executives who made up the majority of the interviewees underscores the energy and importance behind this topic. The findings from the surveys and interviews point to several internal and external drivers or imperatives that are forcing convergence to emerge.

- Rapid expansion of the enterprise ecosystem
- Value migration from physical to information-based

- and intangible assets
- New protective technologies, blurring functional boundaries
- New compliance and regulatory regimes
- Continuing pressure to reduce cost

These imperatives are fundamentally altering the security landscape by forcing a change in the role security practitioners play across the value chain of the business. For example, as formal risk discussions become more integrated, cross-functional, and pervasive, the expectation that physical and information security practitioners will generate joint solutions instead of independent views dramatically increases. The study identified a shift from the current state where security practitioners focus on their function to a new state where activities are integrated to improve the value of the business.

This new business of security requires security professionals to reexamine the key operating levers they have available to them. Although these operating levers (e.g., roles and responsibilities, risk management, leadership) are not new, the opportunity to use them in innovative ways may prove so. For example, the surveys and interviews presented clear evidence that as leaders in the business, security professionals need to move from a command and control people model to an empowering and enabling model, and they must develop an enterprise wide view of risk rather than an asset-based view. An analysis of the survey findings clearly shows convergence as a business trend with a great deal of momentum. Delivering on convergence is not just about organizational integration; rather, it is about integrating the security disciplines with the business' mission to deliver shareholder value.[1]

Knowing what distinguishes an effective and winning security team will enable security professionals and enterprise leaders to assemble a variety of security teams in accordance with their unique requirements and risk management program. The placement of the security organization within the company's infrastructure is also a key to success, but it varies from firm to firm. The security team must be empowered and give accountability. Support from executive management is also very important and another key success factor. The security program and the team's roles and responsibilities should be clearly defined and delineated within the organization. The security team should be well-rounded from a skills perspective. The team should have high level skills and depth and breadth in IT, business, and security knowledge. And finally, to ensure success, the team should be led by a seasoned and experienced security professional entitled with a "C" level position or minimally entitled with a vice president title.

50

When Trust Goes Beyond the Border: Moving Your Development Work Offshore

Stephen D. Fried

50.1 Introduction

The convergence of the Internet age and the new global economy has led to an era of unprecedented opportunity and challenges for organizations wishing to compete in the global arena. Traditional brick-and-mortar methods of doing business have given way to global information networks; "virtual companies" (which exist solely in "Internet space" without a unifying physical presence); and every possible combination of business partnership imaginable, ranging from traditional customer–supplier relationships to multi-level outsourcing deals. The impact of this rapid change is that companies have been forced to seek new ways to achieve sustainable profitability in the face of increasing competition from overseas. At the same time, uncertain economic conditions have resulted in extensive cost-cutting efforts and downsizing at many traditionally stable organizations. Opportunities to increase productivity while lowering expenses are cheered equally in the boardroom and on the trading floor.

Nowhere has the impact of this new desire for increased profits and lower costs been felt more than in the software development industry. Over the past 30 years, the model for developing computer software has changed dramatically. In the early days, everything having to do with the use and operation of the computer was performed by a small team dedicated to a particular machine. Hardware maintenance, operations, troubleshooting, and even software development were all performed by the same team.

This was feasible because each machine was unique, often proprietary, and required dedicated support personnel to ensure its continued operation. This model was also extremely costly to maintain.

As computers became more commonplace, the model for software development changed as well. Rather than utilizing teams of hardware and software specialists dedicated to a single machine, special teams of software designers coding for a variety of systems were formed. The key element was that the software developers were all employees of the company that owned the computers, or they were employees of the computer company (for example, IBM) that were permanently stationed on the customer's premises. The advantage of this method was that the company had complete control over the finished software product and could modify and customize it as needed. The negative side to this arrangement was that the cost for developing software was extremely high because employees (or contract workers) would still be paid even if they were not actively working on a project. This was particularly true for companies whose primary competency was not software development or even computer operations. For these companies, maintaining large staffs of software developers drained their resources and their budgets.

Enter the *outsourcer*. The idea behind outsourcing is that the outsourcer can specialize in a particular area—software development, chip manufacturing, personnel management, or financial management, for example—and sell that expertise back to a company for less than the company might spend if it were to perform the task itself. The outsourcing company manages the workforce (and the associated overhead), and the client company defines the particular service levels it expects from the outsourcer. When it works well, it becomes a win–win situation for both sides. The outsourcer can maintain a large development staff and leverage the cost of that staff over many customers. The client company gets skilled development expertise in an area outside its core competency.

50.2 The Business Case for Outsourcing

Historically, most large outsourcing firms have been located in the United States or Europe. From a business perspective, this allows the client company to send its work to a firm in a country with which it is both familiar and comfortable. Unfortunately, labor costs in the United States and many European countries are generally higher than in other regions, and this cost is passed on to the outsourcer's customers. In recent years, however, a new trend has been developing that allows companies to obtain the benefits of outsourcing but reduce the associated labor costs. Many areas of the world have seen a dramatic rise in the technical skill of their indigenous workforce without a corresponding rise in the cost of those skilled workers. Countries such as India, China, Russia, Brazil, Ireland, and the Philippines (to name a few) have emerged as valuable technical resource centers willing to capitalize on the powerful combination of their high-technology skills and low labor costs. Companies in these countries have set up offshore development centers (ODCs) and are enticing U.S. and European companies to reduce their costs, improve their delivery cycles, and increase the quality of their products by outsourcing large parts of their development work to ODCs (a practice also known as *offshoring*).

While this trend has been known (and used) for a long time in manufacturing-based industries, companies in the technology sector have only recently caught on to the trend. Despite the time lag, however, tech companies are quickly catching on. A 2003 survey by *Information Week* showed that 55 percent of banking companies, 30 percent of healthcare companies, 61 percent of information technology companies, and 50 percent of manufacturing companies currently outsource application development or maintenance to ODCs.[1]

This may seem like an ideal position for businesses. After all, utilizing a supplier that offers a high-quality product along with reduced overhead is the best position for a business to be in. However, many government and business leaders are concerned with the rising trend in the use of ODCs, particularly

[1] "Innovation's Really behind the Push for Outsourcing," *Information Week*, October 20, 2003; http://www.informationweek.com/story/showArticle.jhtml?articleID = 15500076.

with regard to the security risks that using ODCs might represent. In fact, a recent CSO online poll indicates that 85 percent of the Chief Security Officers surveyed believe that using offshore developers poses a high security risk.[2] In addition, an *Information Week* research survey indicated that what weighs most heavily on the minds of business-technology executives is the quality of work performed, unexpected costs that arise, and the security of data and physical assets used by the ODC.[3]

Unfortunately, many of these concerns are outweighed by the heavy economic impact and savings that using an ODC can bring to a company. By far, the biggest reason cited by companies for using an ODC is the reduced labor cost involved. For example, Indian workers with five years of experience typically earn between U.S.$25,000 and U.S.$30,000. The salary for the same level of experience could reach $60,000 to $80,000 in the United States. Salaries in other high-technology centers can be even lower; labor costs in Russia can often be 25–40 percent lower than those in India. Many of these countries compound their benefits by having a large, highly technical workforce trained and skilled in the use of the latest technologies. A recent National Public Radio news story indicated that many foreign nationals who came to the United States from India and China during the dot.com boom are now returning to their homelands. The primary reason for this is that the employment outlook there is more stable and, even at the reduced rates these jobs are commanding, the salaries are better, relatively speaking, than other professions in the same country. With potential cost reductions like these, along with the high availability of talent, even the most security-conscious businesses are considering the possibility of offshoring.

50.3 Offshoring Risks

Having established the business advantages of offshore development, a review of some of the major risks of offshoring will help shed light on why this is a growing concern among businesspeople and security professionals. The risks can be categorized into four major areas: services risks, personnel risks, business risks, and legal risks.

50.3.1 Risks Based on Services Performed

The first issue, the type of service offered by the ODC, will play a large part in determining the potential risks that a client company may face. For example, one common type of offshore outsourcing involves companies that move their call center, help desk, and customer service center operations to offshore firms. In this scenario, customers call the company's national (or toll-free) service and support phone number, and the call gets rerouted to a customer service center in India (or the Philippines). Because the information provided to the offshore service center is primarily that which would normally be distributed to the public, the security of personnel and intellectual property is less of a concern here. Perhaps the biggest concern in this situation is a high rate of turnover among the call center staff in many ODC hosting countries. Competition among call center firms can be fierce, and an employee quickly moving from one firm to another for slightly better pay is not uncommon. If this happens too often, the company may find itself facing a lack of employee availability during periods of high call volume. The primary risk here is one of potential customer dissatisfaction and company reputation.

The second most common type of offshore outsourcing is the movement of software or product development efforts to offshore development centers. This practice presents many more security and information risks because a company must transfer a great deal of intellectual property to the ODC to enable the ODC to effectively produce a quality product for its client. Unfortunately, there is very often little control over how that intellectual property is managed or distributed. Once an organization loses effective control over the use and distribution of its intellectual property, a security incident cannot be far behind.

[2] http://www.csoonline.com/poll/results.cfm?poll = 771.

[3] "Companies Thinking about Using Offshore Outsourcing Need to Consider More than Just Cost Savings," *Information Week*, October 20, 2003; http://www.informationweek.com/story/showArticle.jhtml?articleID = 15500032.

It is imperative for the security professional responsible for overseeing the security of an offshore outsourcing relationship to first make the determination as to what type of outsourcing agreement is under consideration. As can be seen from the brief descriptions of the two basic types above, each type has its own unique security considerations—which are widely divergent from each other. Selecting the proper controls is the key to effectively securing the process. Because of the higher risk profile and greater potential for information loss and compromise, for the remainder of this discussion it will be assumed that the client company in question is utilizing the latter of the two types: that of moving development of software or hardware products to an ODC.

50.3.2 Risks from ODC Personnel

The next set of risks comes from the nature of offshore development and the impact that the ODC's personnel will have on the effort. Historically, the risk and threat a company faces from "inside" personnel has been generally considered high, and a great deal of effort has been put into identifying relevant risks and threats and mitigating them to the greatest extent possible. To understand the context in which to discuss the risks of ODC outsourcing, imagine that the knowledgeable insider moves to a company over which the original company has little (or no) security control and which also has high employee turnover. The additional risks begin to become clear.

Next on the list of risks brought on by ODC personnel is the potential for cyber-terrorism, computer crime, and economic espionage. In many ODC development situations, code and products are developed without a great deal of oversight by the client company. The insertion of malicious code into a software project is of real concern. Spyware, backdoors, and other malicious code can easily be inserted into the hundreds of thousands of lines of code that an ODC may deliver to a client. Unless each program is subjected to a rigorous code review, this (malicious) code may never be discovered. The problem is compounded when one considers some of the countries where offshore development is thriving. For example, China has seen tremendous growth in customers outsourcing code development to its local firms. It is also the case that Chinese hackers have been among the most vocal when it comes to their desire and willingness to attack U.S. cyber-targets. This might lead to the supposition that Chinese hacking groups might be looking to infiltrate local ODCs with the aim of inserting malicious code (logic bombs, sniffers, and backdoors) into U.S.-bound software.

50.3.3 Business Risks

When considering the use of ODCs, an organization should consider the risks brought about by the general offshore development business model itself. First, an offshore arrangement brings another level of complexity to the technical and operational environment in which a company operates. There will almost certainly be some level of network connectivity between the client and the ODC, adding to the complexity of the client's network and requiring additional security controls to ensure that only services required by the ODC are accessible on the client's network. In addition, issues such as standard system configurations, system "hardening" standards (whereby systems are specially configured to resist attack), and change management must all be addressed. The degree of compatibility between the two environments can vary, based on the specific nature of the work being performed, but the operating platforms must be sufficiently compatible to be able to interoperate effectively. For example, if the client uses two-factor token authentication to allow employees to gain remote access to its network, the ODC's personnel may need tokens for those that will be accessing the client's network. Alternatively, if either the ODC or the client utilizes a public key infrastructure (PKI) for user authentication or code signatures, the two will need to work together to enable the Certificate Authorities (CAs) on either side to recognize and validate each other's certificates. All this adds complexity to the process, and added complexity can lead to added risk.

Sending a company's development work to an outside company can lead to a loss of control over the development environment, particularly if the outside company is halfway around the globe.

When software and products are developed in-house, the company has wide latitude to control the development process in any way it sees fit. For example, it can enforce quality control standards based on ISO guidelines or create its own guidelines for developing and delivering quality products. But that level of control is often lost when the development process is transferred to an ODC. Unless rigorous standards are established prior to finalizing the agreement, the outsourcer can use whatever quality and process standards it sees fit to develop your product. It may be that their standards are just as rigorous as the client company's standards, and many ODCs are quickly increasing the range of quality and development certifications they possess, but this should not be assumed. Arrangements for strong security controls (change management, code inspection, repeatable builds, separation of development and production environments, and testing plans, for example) should not be assumed. Rather, an agreement as to baseline standards for these areas needs to be explicitly agreed to in advance and specifically stated in any contractual agreement.

The area of intellectual property control is of particular concern to companies choosing to have their products and software developed in foreign countries. The workers employed by the offshore firm must, by definition, be endowed with a great deal of the client's intellectual property in order to perform their work for the client. This may include items such as product plans, trade secrets, customer data, sensitive intellectual property, and competitive research data. Just as an in-house team would need this information, the outsourcer's team will need this to gain an appreciation of, an understanding of, and sufficient background in your methods and technology in order to fulfill the client's requirements. Workers in most U.S. and European companies often have nondisclosure agreements to prevent the disclosure of the intellectual property in their possession to a competitor. ODC workers in many countries do not have any such restrictions; and for those ODCs that do have them with their employees, enforceability of such agreements by clients is often difficult. In addition, most ODCs have many clients, some of which are competitors of each other. This increases the risk that intellectual property held by one team at an ODC (working on a client's project) may find its way to another team at the same outsourcer (working on a competitor's project), particularly if the outsourcer regularly moves staff between projects. Ethical companies will do their best to create internal personnel and procedural boundaries (a so-called "Chinese Wall") that contain information flow between projects and competitors, but that is far from guaranteed.

Just as there may be disparity between the development environments of the two companies, there may also be disparity in the security requirements between the two firms. Each company's security needs are different and they tailor their security processes and standards to meet their individual internal needs. Thus, a client company may have higher expectations for security than the ODC is able to provide. Conversely, many ODCs have implemented their own security requirements, and some of them take physical and information security very seriously, including the use of armed guards, electric fences, backup generators and water supplies, and strong access controls on the facilities. But there may be a large difference between the ODC's notion and the client's notion of appropriate security measures. Questions to consider when evaluating the security controls of a potential outsourcer include:

- Does the ODC perform background checks on all its employees prior to hiring them?
- Do they have strong access controls at their facilities?
- Do they log all system access and review the logs for anomalous behavior?
- Do they have anti-virus controls or intrusion detection systems on their networks?
- Do the ODC systems comply with laws and regulations concerning the security and privacy of individual data?

All these items factor into the overall security of the outsourcer and give a good indication of the priority and importance the outsourcer places on tight security controls. Remember that much of the attraction of the ODC environment is the low cost of production relative to a domestic operation. Any additional security controls that are put into place by the ODC will increase that cost, an increase that will most certainly be passed on to the ODC's customers. The net effect is that offshore outsourcing becomes a less attractive option. If the security standards of the ODC do not match the security expectations of the client, this can lead to an unacceptable risk situation.

Another risk to watch out for is the hidden subcontracting of work from domestic suppliers to offshore outsourcers. In this scenario, a domestic client contracts out part of its operation to a domestic outsourcer. The client believes that doing this mitigates many of the risks of using ODCs. However, unbeknown to the client, the outsourcer subcontracts the work to another firm, perhaps even to an offshore outsourcer. This cycle may repeat itself several times, with the work (and the associated data) changing hands and crossing international borders with each successive round of subcontracting. The net result is that the original client company has no real idea on where its work is being performed, who is performing it, and what operational and security standards are in effect to protect its information and intellectual property. This situation might be applied to all the domestic suppliers for a company. Do its agreements with its suppliers prohibit the supplier from subcontracting the work to offshore concerns? If it does not, does the supplier need to notify the original company that the work is being sent offshore? Most contracts do not require such notification, but the results of such assignments can be risky.

The risks this practice imposes became all too real in 2003 for the University of California San Francisco Medical Center (UCSF). For 20 years, UCSF outsourced its medical records transcription to a local contractor in Sausalito, California, to save costs on this labor-intensive service. It was a simple, low-risk business decision. The transcription of UCSF's records subsequently passed through a chain of three different subcontractors, one of whom used a woman in Pakistan for data entry. In October 2003, the woman felt she was not being properly compensated for her work and threatened to release UCSF's patient medical files on the Internet unless she was paid more. From UCSF's viewpoint, the use of outsourcing the transcription appeared to be a low-risk decision: cost savings, U.S. company, and U.S. legal privacy protection—a win–win situation for all. What UCSF did not anticipate was that the "local" company in Sausalito would subcontract the work to other companies over which UCSF had no contractual agreements or control. Ultimately, UCSF's medical records found their way to Pakistan, where U.S. privacy protection laws are not enforceable. Suddenly, the low-risk outsourcing decision turned into a high-risk game of privacy protection, disclosure, and liability. Although this particular incident was resolved without the disclosure of sensitive medical information, the outcome may just as easily have gone badly for UCSF.[4]

50.3.4 Legal Risks

The final area that introduces risk into the offshore outsourcing equation is the legal protections that may be lost. Anytime international boundaries are crossed, there will be issues concerning the disparity of legal coverage between the two countries. The issue of offshore outsourcing raises this concern even more.

Whereas the United States and many European countries have strong intellectual property and privacy laws protecting the client's information and that of its customers, many of the more popular ODC host countries do not, leading to an inequality in the protections between the two countries. It should not be assumed that the laws protecting the client company in its home country will be enforceable in the outsourcer's country. If the laws of the two countries are not equivalent, the client company can be opening itself up to the risk that the activities performed by the outsourcer, or disclosure of intellectual property or personal information by the outsourcer may not be prosecutable under local laws.

This situation is particularly interesting in the area of privacy law. Many companies are hiring ODCs to handle the processing of medical information, financial records, and other personal information about the client's customers and business partners. Meanwhile, U.S. and European organizations are coming under increasing scrutiny to comply with governance and accountability legislation such as the Safe Harbor Act or the Sarbanes-Oxley Act. Countries where offshore development is on the rise (China, India, and Russia, for example) do not yet have specific data protection laws. In fact, a recent survey

[4] "Pakistani Transcriber Threatens UCSF over Back Pay," http://www.sfgate.com/cgi-bin/article.cgi?file=/c/a/2003/10/22/MNGCO2FN8G1.DTL.

indicated that most Indian firms are unwilling to include compliance with the Safe Harbor Act or Sarbanes-Oxley Act in their outsourcing contracts.

50.4 Mitigating the Risks

Given all the risks discussed in the previous section, it may seem foolhardy to enter into an outsourcing agreement with an ODC. However, as shown previously, the business case for offshore development promises great benefits to the company that can successfully navigate through the risks. This section examines the risk mitigation strategies that can be utilized to minimize the potential risks and to clearly document the roles and responsibilities each party has in the offshoring relationship.

50.4.1 Before the Contract is Signed

The best method for ensuring that security expectations are met is to perform the appropriate due diligence on the ODC and its home country prior to the final selection of an ODC. A little research here goes a long way toward determining if the ODC's environment can be entrusted with a company's secrets and intellectual property.

The first task is to research the country's record on intellectual property protection and privacy. Does the country have specific laws pertaining to privacy, and how well are those laws enforced? Have any cases come up recently where a company has been prosecuted or otherwise cited for violation of privacy provisions? If not, that could be an indication that privacy protection is taken lightly or not covered under appropriate statutes. Likewise, does the country have laws pertaining to the protection of intellectual property? The United States uses trade secret law, copyright and patent laws, and various emerging privacy legislation to protect the intellectual property of U.S. companies. Other countries around the globe may honor some of these laws, but the extent to which they honor them will vary. For example, there are various World Intellectual Property Organization (WIPO) international treaties that cover intellectual property protection, patent and trademark recognition, and the classification of inventions, trademarks, and designs. Many countries recognize and honor the WIPO treaties, but some do not. A potential offshoring client should understand the international treaties that a specific country honors and whether a particular business function (and its associated intellectual property) will be protected in a potential host country.

An examination of the political stability of a country would also be in order. There are many areas of the globe where political instability will affect a company's ability to trust the authority of law to protect its information and its people. Yet, at the same time, many companies are eagerly trying to establish business in these areas, despite the potential risks that business may bring to a company and its employees. The reason for this highlights the significant trade-off between business needs and security needs. There is tremendous short- and long-term business potential in these areas, and companies want to gain a foothold as soon as possible to establish their position for potential long-term growth. Strong research into these factors before finalizing an outsourcing contract would be prudent.

Finally, the approach to security that potential outsourcing companies take is an important indicator of how rigorously they will protect their clients' information and systems. Do they follow international security standards (for example, ISO/IEC 17799), or do they have in-house-developed standards for security? How do those standards compare to those of the client? Are they stronger or more lenient? How security is enforced by the outsourcer and how security incident detection and response are handled will give good insight into how well the client's information will be protected.

50.4.2 Contractual Requirements

Once the decision has been made to begin an offshore development relationship, a contract and associated service level agreements will need to be developed. This is a crucial step in helping to ensure that the ODC provides adequate security coverage to protect your information and intellectual property.

There are several provisions that should be included in any offshore outsourcing contract, and these provisions will help reduce the overall risk that offshore development brings and that were outlined previously.

The first thing to establish as part of an outsourcing contract is the ODC's approach to security, with particular attention paid to how the ODC will keep the client's intellectual property secure and separate from the intellectual property of other clients it may service. Operational areas such as separation of duties, access control requirements, data protection (for example, encryption), logging and audit requirements, physical security standards, and information privacy should be reviewed and compared against the client's own security standards. Any changes to the ODC's security that the client may require should be clearly stated in the contract. Clear contract drafting leaves little (or no) room for misinterpretation once the contract gets underway. It is highly likely that the ODC will charge the client extra to implement these changes, so this is a business decision the client will have to address.

Next, any security policies or standards that the ODC is required to follow when performing work under the contract should be negotiated and included in the contract. In general, an ODC will not provide voluntary security controls unless it is required to do so by contract. For example, if the ODC needs to follow ISO/IEC 17799 standards, or if it is required to abide by a client's own in-house security policies, these should be specifically stated in the contract. The absence of any clear policy standard for the ODC to follow leaves it open to develop or use any security policies it deems *sufficient* (as defined by the ODC)—not necessarily *adequate*, or even *good*, but just sufficient enough to get the work done on time and within budget. A client company should contractually oblige the outsourcer to abide by a higher, and well-documented, security standard.

The area of development quality standards should not be overlooked when developing contractual requirements. Many organizations have process quality criteria that they use in their software and product development efforts. Examples of this would be Common Criteria requirements or the Capability Maturity Model from Carnegie Mellon's Software Engineering Institute. If process quality is an important part of a company's in-house development effort, a potential ODC should be able to live up to the same standards when performing similar services for the same company. This includes the code development process, quality checks, and testing procedures. The ODC should be able to produce documented evidence that such quality process standards exist and should be contractually obligated to follow those standards.

Although outsourcing allows a company to free itself from assigning resources to an area outside its core competency, it does not free the company from the responsibility of overseeing how that process is being performed by the outsourcer. This extends from the initial design phases of any project, through the development and testing phases, and on through the final deployment of the finished product or service. The client company needs to be an active participant in all phases of the development life cycle to ensure that the ODC is living up to the quality and technical ability promises that attracted the client to the ODC. Only through joint oversight of ongoing ODC activities can a client company ensure not only that it is getting what it paid for, but that the finished product is of the form and quality desired. The ODC should be willing to include this joint participation in its contract. An unwillingness to do so might be an indication that the ODC is unable to live up to some of the process and quality standards promised to the client.

Another important aspect of ensuring a high-quality product from a potential ODC is the requirement for overlapping code reviews. The ODC should be required to perform in-depth and comprehensive code reviews on all software it produces. In addition, the client company should perform its own code reviews on the same software. This requirement serves multiple purposes. First, code review by multiple teams increases the likelihood that a larger number of potential problems will be detected in the design and development phases of the project. Second, an independent code review by the client will help ensure that the finished product lives up to the design specifications defined by the client. Finally, from a security standpoint, a code review by the client will help ensure that no malicious code, backdoors, or spyware applications have been inserted into the code by the ODC developers. This code review should be performed at multiple stages of the development process, including a final review of the finished product.

When combined with a strong change management process, this helps ensure that no code changes are made to the product after the code review has taken place. This, of course, requires that the client company has the expertise necessary to check and analyze the code produced by the ODC; but if security and code quality are of great concern for the client, it is a resource well spent.

Moving a company's development effort to an ODC will not free it from the threat that a security incident will affect either the client or the ODC. In fact, moving an in-house effort to an ODC might trigger an increase in security incidents, because lapses in coordination between the two organizations might create holes in the security defenses. If that is the case, the contract with the ODC should specify who is responsible for handling security incidents. This includes the definition of what constitutes an "incident," the process for notifying the appropriate person or group at the client company that an incident has occurred, and the chain of command with respect to investigation and follow-up of incidents. If the client company already has effective incident detection and handling processes, those processes may be simply extended to include activities performed by the ODC. These issues, and the definitions of roles and responsibilities, must be defined in the contract so that when an incident occurs, there is no confusion about the process that should be followed.

To assume that including many of these provisions will ensure that no security incidents occur at the ODC would be a false assumption. Just as no company can absolutely guarantee they will be free from security incidents, no ODC will be able (or willing) to guarantee that they, too, will be incident-free. This should not deter a company from selecting an appropriate ODC, and the suggestions given here will help reduce the potential for risk and mitigate the effect of actualized threats. However, there may come a situation where the number of incidents, or the repeated severity of incidents, cause the client to lose confidence in the ODC's ability to provide a secure environment for the client's information and intellectual property. If that point comes, it is best if the contract with the ODC allows the client to terminate the agreement for a chronic failure to provide adequate security. In most cases, the contract will already have termination provisions for noncompliance or failure to meet performance expectations. Contract termination for security reasons can be added to the existing language or included as a separate article within the contract.

Adequate business continuity and disaster recovery plans are essential to any well-run business, and outsourcing is no different in this regard. Part of the pre-contract investigation should include an inspection of the ODC's business continuity plan (BCP) and disaster recovery (DR) plan to determine if they are adequate for the information that is to be exchanged and the level of service to be performed. When the contract is being drafted, language indicating the required level of BCP/DR planning should be explicitly included. Requirements for regular testing and revision of the BCP/DR plans should also be specified. This ensures that the outsourcer will continue to maintain a secure environment for the client's information in the face of unexpected disturbances in the operational environment. This type of coverage is also essential in areas where political, social, geological disturbances, or military turmoil is an ongoing concern.

The agreement with the ODC should include the protection of intellectual property rights. The work performed by an ODC will be predominately based on the client's intellectual property, but in many cases the ODC will be selected due to some enhanced expertise or technical ability it may have in a given area. The ODC will not want to cede the rights to intellectual property it develops in the course of its work for a client. For this reason, the ownership of intellectual property generated during the course of the ODC's work should be clearly defined in the outsourcing agreement. The ODC may retain intellectual property rights, the client may pay a premium amount for ownership of the IP, or the rights may be jointly held by both companies. Whatever the arrangement, advance agreement on the ownership of these rights will save a great deal of legal expense and litigation time later in the relationship. The contract should also state the limits on the ODC's ability to use intellectual property owned by the client. Clearly, it can be used on the client's projects, but does the outsourcer have the right to use it in any form with its other clients? If it does, must royalties be paid to the client? Again, explicitly defining these provisions in the contract will clearly define the boundaries for use of the intellectual property throughout the life of the agreement and make for a better working relationship with the ODC.

Background checks for outsourced personnel are also an important issue to consider. The first issue client companies should consider is whether they perform background checks on their own internal personnel performing similar work. If they do, they will have a strong case for asking an ODC to live up to a similar standard. If they do not, it may be difficult to convince the ODC that it needs to live up to a higher standard. In either case, performing a thorough and reliable background check on foreign personnel in a foreign country may be problematic at best and extremely difficult to do in practice. If the ODC already performs such checks on its personnel (few currently do), the client should ask to see the results for personnel who will be working on its projects. In addition, the client should meet with the personnel or company performing the background checks to understand the methodology and sources it uses to perform the checks. Whether or not such checks are a deal-breaker with respect to the overall agreement is a business decision that must be determined in the context of the overall outsourcing relationship, but understanding the trustworthiness of the personnel to whom a company's most valuable assets will be entrusted should be important enough to warrant consideration.

Of similar concern are the legal constraints surrounding the ODC's personnel when it comes to protection and disclosure of the client's information. Are ODC personnel required to sign a nondisclosure agreement or intellectual property agreement prior to beginning work on the client's project? Many ODCs sign a blanket agreement that covers all its employees and contractors. If this is the case, what training and education does the ODC provide its employees with respect to its responsibility to uphold those agreements?

Most ODCs will have more than one client at a time. Indeed, much of their profitability comes from their ability to leverage their expertise and resources across many clients at once. The ODCs should be able to provide details on whether their employees work on projects for multiple clients simultaneously or whether they are dedicated to a single client for the duration of a project. The latter is preferable, although it may raise costs, as it lowers the risk that information from one client will leak into the possession (or products) of another client. This sort of exclusivity on the part of the ODC employees might increase the cost of the project, as the ODC will not be able to leverage the cost of those personnel across several projects, but the increase in security protection may be worth the additional cost.

Regular formal audits of the outsourcing process are essential. Whereas the on-site reviews, code inspections, and incident follow-ups provide good insight into the effectiveness of the ODC's business and security processes, a formal audit can establish documented baselines and improvements or deficiencies in the actual work product of the ODC. This includes not only financial and quality audits, but also reviews of the security mechanisms in place, their effectiveness, and any security control weaknesses that might be present in the ODC's environment. Timely remediation of audit findings, coupled with regular follow-up audits, can ensure that the ODC is meeting the client's expectations with respect to security and information protection. The client may also seek the right to conduct penetration tests on the ODC's environment. The contract with the ODC should also allow the client to see the results of other audits that have been performed on the environment in which the client will be operating. This includes any internal audit reports and findings, BS-7799 certification reviews, or SAS 70 reports.

Finally, the contract should specify that the ODC should provide around-the-clock access control and physical security for both the ODC's physical premises and the development areas that will be used in performing work for the client. If there are any physical security requirements that the ODC must provide, this should be specified as well. This includes such items as gates or walls surrounding the facility and the use of guard services to restrict access to the premises. In addition, if the guard forces need special training based on the type of work the client requires or any special protection the client needs, the client should be prepared to provide specialized training to handle those needs. For example, if the client expects guards to search briefcases and handbags of employees leaving the premises to check for intellectual property theft, the client should be prepared to train the guards to understand what a USB thumb drive is and how it is used.

Remember that security often crosses boundaries between the physical realm and the cyber realm. The ODC needs to adequately match its security efforts in both realms.

50.4.3 Connectivity Issues

Nearly all offshore development partnerships require some sort of information exchange between the client and the ODC. This ranges from simple CD-ROM exchanges of data to full, high-speed dedicated network lines. The type of connectivity required will be dictated by the information flow requirements of the project, but different types of connectivity carry different types of risks and available protections.

In situations where basic one-way transfer of information is all that is needed, a simple transfer of data to physical media (for example, a CD-ROM or DVD-ROM) may be the best method of information transfer. A large amount of data can be transported at very low cost (the cost of the media plus an international shipping charge) and security is relatively strong (most commercial carriers are bonded and rarely lose a package). The contents of the disks can be encrypted for extra protection if required. This solution works best in situations where the transfer of information is infrequent or when connectivity issues arise.

If more consistent data transfer is required, or if the data volume is large enough, the client and ODC might consider the use of a dedicated leased line or VPN-based Internet connection. Even if the connection between the two companies is leased from local phone companies, the use of VPN over the connection will ensure that the data transferred over that line is safe from prying eyes as it travels through potentially “hostile” territory. If dedicated connectivity is required, the use of strong access controls on both ends of the connection will enforce a policy of *least privilege* (whereby access to resources is denied unless specifically permitted). In addition, all systems that are accessed through the dedicated connection should have a vulnerability scan performed on them, and any adverse findings should be corrected prior to the initiation of the connection. These systems should also be kept up-to-date with respect to the latest anti-virus updates and operating system and application software patches. These systems will be accessed by networks and users outside the control of the client company. The utmost care should be taken to reduce the risk of intentional or inadvertent compromise as much as possible. Finally, if a leased line or VPN connection is established between the client and the outsourcer, rerouting e-mail traffic between the two companies to use that connection should be considered, rather than transporting potentially sensitive information over Internet e-mail.

If large-volume data transfer is desired, but the companies involved do not want to go through the expense or complexity of setting up a leased line, the use of a DMZ-based file server or FTP drop might prove useful. This has a lower cost to set up than a leased line. However, as an Internet-facing server, this system must be hardened against potential attack. If the system is compromised and an attacker can extract its contents, the client’s intellectual property will be in the possession of the attacker. The use of encryption to protect sensitive information on such systems will mitigate some of these concerns.

50.4.4 Ongoing Concerns

Once the contract has been signed and the relationship begins in earnest, many client companies back away from active involvement with the ODC, keeping them at arm’s length while the ODC performs its work. This is the wrong approach to maintaining an effective and productive outsource relationship. Regular and continuous interaction with the ODC, from both the client’s business unit and security team, is essential to ensure that the ODC is providing the type and level of service that has been agreed upon, as well as providing the security environment that is required by the client’s standards, policies, and outsourcing contract.

Regular progress meetings are essential to this effort. Joint architecture and infrastructure reviews should be performed on a regular basis. The client should also follow up on all security logs and reports provided by the ODC. Much of this can be performed remotely to save on travel expense and time, but regular on-site visits go a long way toward establishing the importance the client places on the security mechanisms the ODC has put in place. These on-site reviews should examine continued maintenance of the physical security of the facility, access control into the work areas utilized for the client’s projects, physical and logical protection of the client’s intellectual property and proprietary information, and discussions of any security incidents that have occurred.

The client can also use these visits as security training and awareness exchanges between the client and the ODC. The client can introduce the ODC to any changes in security policies or methodologies that the client has implemented in its own organization. The ODC, in turn, can educate the client on security incidents that it has experienced and review improvements in security that it has learned or developed from an outsourcing perspective. This type of exchange can greatly improve the trust the two organizations have in each other, as well as improve the overall security the ODC uses for the client's work area. Overall, a strong partnership in an offshore outsourcing relationship creates a much more secure environment.

50.5 Achieving Acceptable Risk

By far, the biggest benefit pushing companies to use offshore development centers emanates from the large potential cost savings the company can realize. These savings can be realized by the company itself as profit or passed on to customers in the form of lower prices for the company's goods and services. Unfortunately, many of the security measures that have been discussed thus far will cause either the outsourcer or the client to incur additional cost to implement and maintain. How much that cost is increased (and who ultimately pays for it) will vary, depending on the type of work the ODC is performing, the level and quality of the ODC's existing security infrastructure, and the level of security the client requires. The reality is that if all the aforementioned security controls, contractual obligations, and process requirements need to be put into place by an ODC, the incremental cost can be quite substantial, reducing the overall cost savings to the client and, in turn, reducing the overall attractiveness of the offshore development strategy.

Additionally, a company may need to weigh nonfinancial risks when considering a possible offshore development agreement. Along with the rise of offshore development has come a parallel awareness of the risks that arrangement may bring. Many companies, particularly those in service industries, are having difficulty justifying the aforementioned risks of information disclosure and privacy concerns to their customers. Some companies such as Hewitt, a global HR outsourcing and consulting firm, have chosen what they feel is an acceptable middle ground. Hewitt has opened its own processing center in India and staffed it with local employees. For Hewitt, this model allowed it to gain the cost savings of a less-expensive labor force while still retaining tight control over the flow and protection of its corporate and customer information, which includes HR and medical records for its client companies.

Ultimately, the senior management of the business needs to make an informed decision as to how much security is adequate, how much is currently available, and how much the company is willing to enforce (or forego) in order to realize a reasonable business return on the endeavor. In many ways this is similar to classic risk assessment methodology. When this analysis takes place, it is the responsibility of the client's security management to understand the business need for the outsourcing, have an appreciation of the business benefits that the outsourcing will bring, and help the business' leadership make an informed risk management and risk acceptance decision in order to advance both the business and security needs as much as possible.

50.6 Conclusion

Offshore development is a trend that is not going away. In fact, its use will be increasing more and more each year. While the occasional company might shy away from offshore outsourcing because the security risk is too high, for many companies the overriding business benefits to be realized often far outweigh the potential security risks that the company (or the outsourcer) might face. By applying solid risk assessment, risk mitigation, and risk management principles to the arrangement, clearly understanding the business goals of the effort, defining the security requirements and expectations of both the client and the outsourcer, and by close and regular monitoring of the ODC environment, an effective, productive, and profitable offshore development project can bring large benefits to the company that can successfully handle all these elements.

51

Maintaining Information Security during Downsizing

Thomas J. Bray

Today, companies of every size are relying on Internet and other network connections to support their business. For each of those businesses, information and network security have become increasingly important. Yet, achieving a security level that will adequately protect a business is a difficult task because information security is a multifaceted undertaking. A successful information security program is a continuous improvement project involving people, processes, and technology, all working in unison.

Companies are especially vulnerable to security breaches when significant changes occur, such as a reduction in workforce. Mischievous individuals and thieves thrive on chaos. Companies need even more diligence in their security effort when executing a reduction in workforce initiative. Security is an essential element of the downsizing effort.

51.1 Even in Good Times

In good times, organizations quickly and easily supply new employees with access to the computer and network systems they need to perform their jobs. A new employee is a valuable asset that must be made productive as soon as possible. Computer and network administrators are under pressure to create accounts quickly for the new hires. In many instances, employees may have more access than they truly need. The justification for this, however misguided, is that "it speeds up the process."

When an employee leaves the company, especially when the departure occurs on good terms, server and network administrators tend to proceed more slowly. Unfortunately, the same lack of urgency exists when an employee departure is not on good terms or a reduction in the workforce occurs.

51.2 Disgruntled Employees

Preparing for the backlash of a disgruntled employee is vital during an employee layoff. Horror stories already exist, including one about an ex-employee who triggered computer viruses that resulted in the deletion of sales commission records. In another company, an ex-employee used his dial-up access to the company network to copy a propriety software program worth millions of dollars. An article in *Business Week* sounded an alarm of concern.[1]

The biggest threat to a company's information assets can be the trusted insiders. This is one of the first concepts learned by information security professionals, a concept substantiated on several occasions by surveys conducted by the Computer Security Institute (CSI) and the Federal Bureau of Investigation (FBI).

The market research firm Digital Research conducted a survey for security software developer Camelot and *eWeek* magazine. They found that, "Insiders pose the greatest computer security threat. Disgruntled insiders and accounts held by former employees are a greater computer security threat to U.S. companies than outside hackers." Out of 548 survey respondents, 43 percent indicated that security breaches were caused by user accounts being left open after employees had left the company.[2]

51.3 Yeah, Right. What Are the Cases?

In many cases of ex-employees doing harm to their former employers, the extent of the problem is difficult to quantify. Some companies do not initially detect many of the incidents, and others prefer to handle the incidents outside the legal system. A small percentage of incidents have gone through the legal system and, in some cases, the laws were upheld. Each time this occurs, it strengthens support for the implementation of information security best practices. Although many states have computer crime laws, there is still only a small percentage of case law.

51.3.1 Example Incident: *The Boston Globe*, by Stephanie Stoughton, Globe Staff, 6/19/2001[3]

> Ex-tech worker gets jail term in hacking. A New Hampshire man who broke into his former employer's computer network, deleted hundreds of files, and shipped fake e-mails to clients was sentenced yesterday to six months in federal prison. U.S. District Judge Joseph DiClerico also ordered Patrick McKenna, 28, to pay $13,614.11 in restitution to Bricsnet's offices in Portsmouth, N.H. Following McKenna's release from prison, he will be under supervision for two years.

51.4 High-Tech Measures

51.4.1 E-Mail

E-mail is one of the most powerful business tools in use today. It can also be a source of communications abuse and information leakage during a downsizing effort. The retention or destruction of stored e-mail messages of ex-employees must also be considered.

[1] http://www.businessweek.com/bwdaily/dnflash/jun2001/nf20010626_024.htm

[2] http://www.usatoday.com/life/cyber/tech/2001-06-20-insider-hacker-threat.htm; http://www.zdnet.com/zdnn/stories/news/0,4586,2777325,00.html; http://www.cnn.com/2001/TECH/Internet/06/20/security.reut/index.html

[3] http://www.boston.com/dailyglobe2/170/business/Ex_tech_worker_gets_jail_term_in_ hacking+.shtml

51.4.2 Abuse

Do not allow former employees to keep e-mail or remote access privileges in an attempt to ease the pain of losing their jobs or help in their job searches. The exposure here is the possibility of misrepresentation and inappropriate or damaging messages being received by employees, clients, or business partners. If the company wants to provide e-mail as a courtesy service to exiting employees, the company should use a third party to provide these services. Using a third party will prevent employees from using existing group lists and addresses from their address books, thus limiting the number of recipients of their messages.

Employees who know they are to be terminated typically use e-mail to move documents outside the organization. The company's termination strategy should include a method for minimizing the impact of confidential information escaping via the e-mail system. E-mail content filters and file-size limitations can help mitigate the volume of knowledge and intellectual capital that leaves the organization via e-mail.

51.4.3 Leakage

E-mail groups are very effective when periodic communication to a specific team is needed. The management of the e-mail group lists is a job that requires diligence. If ex-employees remain on e-mail group lists, they will continue to receive company insider information. This is another reason the company should not let former employees keep company e-mail accounts active as a courtesy service.

51.4.4 Storage

E-mail messages of ex-employees are stored on the desktop system and the backup disk or tapes of the e-mail server. The disposal of these documents should follow the company's procedure for e-mail document retention. In the absence of an e-mail document retention policy, the downsizing team should develop a process for determining which e-mail messages and attachments will be retained and which will be destroyed.

51.5 Low-Tech Measures

The fact that information security is largely a people issue is demonstrated during a reduction in force initiative. It is the business people working hand in hand with the people staffing the technical and physical security controls who will ensure that the company is less vulnerable to security breaches during this very disruptive time in the company.

51.5.1 Document Destruction

As people exit the company during a downsizing effort, mounds of paper will be thrown in the trash or placed in the recycling bin. Ensuring that confidential paper documents are properly disposed of is important in reducing information leaks to unwanted sources.

After one company's downsizing effort, I combed through their trash and recycling bins. During this exercise, I found in the trash several copies of the internal company memo from the CEO that explained the downsizing plan. The document was labeled "*Company Confidential—Not for Distribution Outside of the Company.*" This document would have been valuable to the news media or a competitor.

All companies have documents that are confidential to the business; however, most companies do not have a document classification policy. Such a policy would define the classification designations, such as:

- Internal Use Only
- Confidential
- Customer Confidential
- Highly Restricted

Each of these classifications has corresponding handling instructions defining the care to be taken when storing or routing the documents. Such handling instructions would include destroying documents by shredding them when they are no longer needed.

Many organizations have also been entrusted with confidential documents of business partners and suppliers. The company has a custodial responsibility for these third-party documents. Sorting through paper documents that are confidential to the company or business partners and seeing that they are properly destroyed is essential to the information protection objective.

51.6 Security Awareness

Security awareness is a training effort designed to raise the security consciousness of employees (see Exhibit 51.1). The employees who remain with the organization after the downsizing effort must be persuaded to rally around the company's security goals and heightened security posture. Providing the remaining team of employees with the knowledge required to protect the company's vital information

EXHIBIT 51.1 Checklist of Security Actions During Reduction in Workforce Effort

General

- Assemble a team to define the process for eliminating all computer and network access of downsized employees. The team should include representation from Human Resources, Legal, Audit, and Information Security.
- Ensure that the process requires managers to notify the employees responsible for Information Security and the Human Resources department at the same time.
- Educate remaining employees about Information Security company policy or best practices.
- Change passwords of all employees, especially employees with security administrative privileges.
- Check the computer and laptop inventory list and ensure that downsized employees return all computer equipment that was issued to them as employees.
- Be current with your software licenses—ex-employees have been known to report companies to the Software Piracy Association.

Senior Managers

- Explain the need for the downsizing.
- Persuade key personnel that they are vital to the business.
- Resist the temptation to allow downsized officers, senior managers, or any employees to keep e-mail and remote access privileges to ease the pain or help in their job search. If the company wants to provide courtesy services to exiting employees, the company should use a third party to provide these services, not the company's resources.

Server Administrators, Network Administrators, and Security Administrators

- Identify all instances of employee access:
  - – Scan access control systems for IDs or accounts of downsized employees.
  - – Scan remote access systems for IDs or accounts of downsized employees.
  - – Call business partners and vendors for employee authorizations.
- Consult with departing employee management:
  - – Determine who will take on the exiting employee's access.
  - – Determine who will take control of exiting employee's files.

E-mail System Administrators

- Identify all instances of employee access:
  - – Scan the e-mail systems for IDs or accounts of downsized employees.
- Forward inbound e-mail messages sent to an ex-employees' e-mail account to their manager.
- Create a professional process for responding to individuals who have sent e-mails to ex-employees, with special emphasis on the mail messages from customers requiring special care.
- Remove ex-employees from e-mail group lists.

Managers of Exiting Employees.

- Determine who will take on the access for the exiting employees.
- Determine who will take control of exiting employee computer files.
- Sort through exiting employee paper files for documents that are confidential or sensitive to the business.

Prepare for the Worst

- Develop a list of likely worst-case scenarios.
- Develop actions that will be taken when worst-case scenarios occur.

assets is paramount. Employees should leave the security training with a mission to be security-aware as they perform their daily work. Some of the topics to be covered in the security awareness sessions include:

- Recognizing social engineering scenarios
- Speaking with the press
- Keeping computer and network access credentials, such as passwords, confidential
- Changing keys and combinations
- Encouraging system administrators and security administrators to be vigilant when reviewing system and security logs for suspicious activity
- Combining heightened computer and network security alertness with heightened physical security alertness

51.7 Conclusion

Information security involves people, processes, and technical controls. Information security requires attention to detail and vigilance because it is a continuous improvement project. This becomes especially important when companies embark on a downsizing project.

Companies should always be mindful that achieving 100 percent security is impossible. Mitigating risk to levels that are acceptable to the business is the most effective methodology for protecting the company's information assets and the network systems.

Businesses need to involve all employees in the security effort to have an effective security program. Security is most effective when it is integrated into the company culture. This is why security awareness training is so important.

Technology plays a crucial role in security once the policies and processes have been defined to ensure that people properly manage the technological controls being deployed. A poorly configured firewall provides a false sense of security. This is why proper management of security technologies provides for a better information protection program.

52

The Business Case for Information Security: Selling Management on the Protection of Vital Secrets and Products

Sanford Sherizen

If the world was rational and individuals as well as organizations always operated on that basis, this chapter would not have to be written. After all, who can argue with the need for protecting vital secrets and products? Why would senior managers not understand the need for spending adequate funds and other resources to protect their own bottom line? Why not secure information as it flows throughout the corporation and sometimes around the world?

Unfortunately, rationality is not something that one can safely assume when it comes to the field of information security. Therefore, this chapter is not only required, but it needs to be presented as a bilingual document, that is, written in a way that reveals strategies by which senior managers as well as information security professionals can maximize their specific interests.

This chapter is based on over 20 years of experience in the field of information security, with a special concentration on consulting with senior- and middle-level managers. The suggestions are based on successful projects and, if followed, can help other information security professionals achieve successful results with their management.

52.1 The State of Information Security

Improving information security for an organization is a bit like an individual deciding to lose weight, to exercise, or to stopping smoking. Great expectations. Public declarations of good intentions. A projected starting date in the near future. And then the realization that this is a constant activity, never to end and never to be resolved without effort.

Why is it that there are so many computer crime and abuse problems at the same time that an increasing number of senior executives are declaring that information security is an absolute requirement in their organizations? This question is especially perplexing when one considers the great strides that have been made in the field of information security in allowing greater protection of assets. While the skill levels of the perpetrators have increased and the complexity of technology today leaves many exposures, one of the central issues for today's information security professional is nontechnical in nature. More and more, a challenge that many in the field face is how to inform, convince, influence, or in some other way "sell" their senior management on the need for improving information security practices.

This chapter looks at the information security-senior executive dialogue, offering the reasons why such exchanges often do not work well and suggesting ways to make this a successful discussion.

52.2 Senior Management Views of Information Security

Information security practitioners need to understand two basic issues regarding their senior management. The first is that computer crime is only one of the many more immediate risks that executives face today. The second is that thinking and speaking in managerial terms is a key to even gaining their attention in order to present a business case for improvements.

To the average senior executive, information security may seem relatively easy—simply do not allow anyone who should not see certain information to see that information. Use the computer as a lock against those who would misuse their computer use. Use all of that money that has been given for information technology to come up with the entirely safe computer. Stop talking about risks and vulnerabilities and solve the problem. In other words, information security may be so complex that only simple answers can be applied from the nonpractitioner's level.

Among all the risks that a manager must respond to, computer crime seems to fall into the sky-is-falling category. The lack of major problems with the Y2K issue has raised questions in some managerial and other circles as to whether the entire crisis was manufactured by the media and technical companies. Even given the extensive media coverage of major incidents, such as the Yahoo, etc. distributed denial-of-service attack, the attention of managers is quickly diverted as they move on to other, "more important issues." To managers, who are faced with making the expected profits for each quarter, information security is a maybe type of event. Even when computer crime happens in a particular organization, managers are given few risk figures that can indicate how much improvement in information security (X) will lead to how much prevention of crime (Y).

With certain notable exceptions, there are fundamental differences and perceptions between information security practitioners and senior executives. For example, how can information security professionals provide the type of cost-justification or return-on-investment (ROI) figures given the current limited types of tools? A risk analysis or similar approach to estimating risks, vulnerabilities, exposures, countermeasures, etc. is just not sufficient to convince a senior manager to accept large allocations of resources.

The most fundamental difference, however, is that senior executives now are the Chief Information Security Manager (or Chief Corporate Cop) of their organizations. What that quite literally means is that the executives—rather than the information security manager or the IS manager—now have legal and fiduciary responsibilities to provide adequate resources and support for information protection.

Liabilities are now a given fact of life for senior executives. Of particular importance, among the extensive variety of liability situations found in an advanced economy, is the adequacy of information protection. The adequacy of managerial response to information security challenges can be legally measured in terms of due care, due diligence, and similar measures that indicate what would be considered as a sufficient effort to protect their organization's informational assets. Unfortunately, as discussed, senior executives often do not know that they have this responsibility, or are unwilling to take the necessary steps to meet this responsibility. The responsibility for information security is owned by senior management, whether they want it or not and whether they understand its importance or not.

52.3 Information Security Views of Senior Management

Just as there are misperceptions of information security, so information security practitioners often suffer from their misperceptions of management. At times, it is as if there are two quite different and quite unconnected views of the world.

In a study done several years ago, CEOs were asked how important information security was to their organization and whether they provided what they felt was adequate assistance to that activity. The results showed an overwhelming vote for the importance of information security as well as the majority of these executives providing sufficient resources. However, when the IS, audit, and information security managers were asked about their executives' views of security, they indicated that there was a large gap between rhetoric and reality. Information security was often mentioned, but the resources provided and the support given to information security programs often fell below necessary levels.

One of the often-stated laments of information security practitioners is how difficult it is to be truly heard by their executives. Information security can only work when senior management supports it, and that support can only occur when they can be convinced of the importance of information protection. Such support is required because, by the nature of its work, information security is a political activity that crosses departmental lines, chains of command, and even national boundaries.

Information security professionals must become more managerial in outlook, speech, and perspectives. What that means is that it is no longer sufficient to stress the technical aspects of information protection. Rather, the stress needs to be placed on how the information security function protects senior executives from major legal and public relations liabilities. Further, information security is an essential aspect of managing organizations today. Just as information is a strategic asset, so information protection is a strategic requirement. In essence, information security provides many contributions to an organization. The case to be made to management is the business case for information security.

52.4 The Many Positive Roles of Information Security

While people may realize that they play many roles in their work, it is worthwhile listing which of those roles apply to "selling information security." This discussion allows the information security practitioner to determine which of the work-related activities that he or she is involved in has implications for convincing senior management of the importance of that work and the need for senior management to provide sufficient resources in order to maximize the protection span of control.

One of the most important roles to learn is how to become an information security "marketeer." Marketing, selling, and translating technical, business, and legal concepts into "managerialese" is a necessary skill for the field of information security today. What are you marketing or selling? You are clarifying for management that not only do you provide information protection but, at the same time, also provide such other valuable services as:

1. *Compliance enforcer and advisor.* As IT has grown in importance, so have the legalities that have to be met in order to be in compliance with laws and regulations. Legal considerations are ever-present today. This could include the discovery of a department using unauthorized copies of programs; internal employee theft that becomes public knowledge and creates opportunity for shareholder suits; a penetration from the outside that is used as a launching pad to attack other organizations, thus creating the possibility of a downstream liability issue; or any of the myriad ways that organizations get into legal problems.
   - **Benefit to management**. A major role of the information security professional is to assist management in making sure that the organization is in compliance with the law.

2. *Business enabler and company differentiator.* E-commerce has changed the entire nature of how organizations offer goods and services. The business enabler role of information security is to provide an organization with information security as a value-added way of providing ease of purchase as well as security and privacy of customer activities. Security has rapidly become the way by which organizations can provide customers with safe purchasing while offering the many advantages of E-commerce.
   - **Benefit to management**. Security becomes a way of differentiating organizations in a commercial setting by providing "free safety" in addition to the particular goods and services offered by other corporations. "Free safety" offers additional means of customer satisfaction, encouraging the perception of secure Web-based activities.
3. *Total quality management contributor.* Quality of products and services is related to information security in a quite direct fashion. The confidentiality, integrity, and availability of information that one seeks to provide allow an organization to provide customer service that is protected, personal, and convenient.
   - **Benefit to management**. By combining proper controls over processes, machines, and personnel, an organization is able to meet the often contradictory requirements of production as well as protection. Information security makes E-commerce possible, particularly in terms of the perceptions of customers that such purchasing is safe and reliable.
4. "*Peopleware*" *controller.* Peopleware is not the hardware or software of IT. It involves the human elements of the human-machine interface. Information security as well as the audit function serve as key functions in controlling the unauthorized behavior of people. Employees, customers, and clients need to be controlled in their use of technology and information. The need-to-know and separation-of-duties concepts become of particular importance in the complex world of E-commerce. Peopleware are the elements of the control structure that allow certain access and usage as well as disallow what have been defined as unauthorized activities.
   - **Benefit to management**. Managerial policies are translated into information security policies, programs, and practices. Authorized usage is structured, unauthorized usage is detected, and a variety of access control and similar measures offer protections over sensitive informational assets.

The many roles of information security are of clear benefit to commercial and governmental institutions. Yet, these critical contributions to managing complex technical environments tend not to be considered when managers view the need for information security. As a result, one of the most important roles of information security practitioners is to translate these contributions into a business case for the protection of vital information.

52.5 Making the Business Case for Information Security

While there are many different ways to make the business case and many ways to "sell" information security, the emphasis of this section is on the Common Body of Knowledge (CBK) and similar sources of explication or desired results. These are a highly important source of professional knowledge that can assist in informing senior executives regarding the importance of information security.

CBK, as well as other standards and requirements (such as the Common Criteria and the British Standards 7799), are milestones in the growth of the professional field of information security. These compendia of the best ways to evaluate security professionals as well as the adequacy of their organizations serve many purposes in working with senior management.

They offer information security professionals the ability to objectively recommend recognized outside templates for security improvements to their own organizations. These external bodies contain expert opinion and user feedback regarding information protection. Because they are international in scope, they offer a multinational company the ability to provide a multinational overview of security.

Further, these enunciations of information security serve as a means of measuring the adequacy of an organization's information security program and efforts. In reality, they serve as an indication of "good practices" and "state of knowledge" needed in today's IT environments. They also provide legal authorities with ways to measure or evaluate what are considered as appropriate, necessary, or useful for organizations in protecting information. A "good-faith effort" to secure information, a term used in the U.S. Federal Sentencing Guidelines, becomes an essential legal indicator of an organization's level of effort, concern, and adequacy of security programs. Being measured against these standards and being found lax may cost an organization millions of dollars in penalties as well as other serious personal and organizational punishments. (For further information on the U.S. Sentencing Guidelines as they relate to information security, see the author's publication on the topic at http://www.computercrimestop.com).

52.6 Meeting the Information Security Challenge

The many challenges of information security are technical, organizational, political, legal, and physical. For the information security professional, these challenges require new skills and new orientations. To be successful in "selling" information security to senior executives, information security practitioners should consider testing themselves on how well they are approaching these decision makers.

One way to do such a self-evaluation is based on a set of questions used in forensic reviews of computer and other crimes. Investigators are interested in determining whether a particular person has motive, opportunity, and means (MOM). In an interesting twist, this same list of factors can be helpful in determining whether information security practitioners are seeking out the many ways to get the attention of their senior executives.

1. *Motivation*. Determine what motivates executives in their decisions. Understand the key concepts and terms they use. Establish a benefits approach to information security, stressing the advantages of securing information rather than emphasizing the risks and vulnerabilities. Find out what "marketeering" means in your organization, including what are the best messages, best media, and best communicators needed for this effort.
2. *Opportunity*. Ask what opportunities are available, or can be made, to meet with, be heard by, or gain access to senior executives. Create openings as a means to stress the safe computing message. Opportunities may mean presenting summaries of the current computer crime incidents in memos to management. An opportunity can be created when managers are asked for a statement to be used in user awareness training. Establish an Information Security Task Force, composed of representatives from many units, including management. This could be a useful vehicle for sending information security messages upward. Find out the auditor's perspectives on controls to see how these may reinforce the messages.
3. *Means*. The last factor is means. Create ways to get the message heard by management. Meeting may be direct or indirect. Gather clippings of current computer crime cases, particularly those found in organizations or industries similar to one's own. Do a literature review of leading business, administrative, and industry publications, pulling out articles on computer crime problems and solutions. Work with an organization's attorneys in gathering information on the changing legal requirements around IT and security.

52.7 Conclusion

In the "good old days" of information security, security was relatively easy. Only skilled data processing people had the capability to operate in their environment. That, plus physical barriers, limited the type and number of people who could commit computer crimes.

Today's information security picture is far more complicated. The environment requires information security professionals to supplement their technical skills with a variety of "soft skills" such as managing, communicating, and stressing the business reasons for security objectives. The successful information security practitioner will learn these additional skills in order to be heard in the on-rush of challenges facing senior executives.

The technical challenges will certainly not go away. However, it is clear that the roles of information security will increase and the requirements to gain the acceptance of senior management will become more important.

53

How to Work with a Managed Security Service Provider

Laurie Hill McQuillan

Throughout history, the best way to keep information secure has been to hide it from those without a need to know. Before there was written language, the practice of information security arose when humans used euphemisms or code words to refer to communications they wanted to protect. With the advent of the computer in modern times, information was often protected by its placement on mainframes locked in fortified rooms, accessible only to those who were trusted employees and capable of communicating in esoteric programming languages.

The growth of networks and the Internet have made hiding sensitive information much more difficult. Where it was once sufficient to provide a key to those with a need to know, now any user with access to the Internet potentially has access to every node on the network and every piece of data sent through it. So while technology has enabled huge gains in connectivity and communication, it has also complicated the ability of networked organizations to protect their sensitive information from hackers, disgruntled employees, and other threats. Faced with a lack of resources, a need to recover from an attack, or little understanding of secure technology, organizations are looking for creative and effective ways to protect the information and networks on which their success depends.

53.1 Outsourcing Defined

One way of protecting networks and information is to hire someone with security expertise that is not available in-house. Outsourcing is an arrangement whereby one business hires another to perform tasks it cannot (or does not want to) perform for itself. In the context of information security, outsourcing means that the organization turns over responsibility for its information or assets security to professional security managers. In the words of one IT manager, outsourcing "represents the possibility of recovering from the awkward position of trying to accomplish an impossible task with limited resources."[1] This promising possibility is embodied in a new segment of the information security market called managed system security providers (MSSPs), which has arisen to provide organizations with an alternative to investing in their own systems security.

53.2 Industry Perspective

With the exception of a few large companies that have offered security services for many years, providing outsourced security is a relatively new phenomenon. Until the late 1990s, no company described itself exclusively as a provider of security services; while in 2001, several hundred service and product providers are listed in MSSP directories. One company has estimated that companies spent $140 million on security services in 1999; and by 2001, managed security firms had secured almost $1 billion in venture capital.[2] Another has predicted that the demand for third-party security services will exceed $17.2 billion by the end of 2004.[3]

The security products and services industry can be segmented in a number of different ways. One view is to look at the way in which the outsourced service relates to the security program supported. These services include performance of short-term or one-time tasks (such as risk assessments, policy development, and architecture planning); mid-term (including integration of functions into an existing security program); and long-range (such as ongoing management and monitoring of security devices or incidents). By far, the majority of MSSPs fall into the third category and seek to establish ongoing and long-term relationships with their customers.

A second type of market segmentation is based on the type of information protected or on the target customer base. Some security services focus on particular vertical markets such as the financial industry, the government, or the defense industry. Others focus on particular devices and technologies, such as virtual private networks or firewalls, and provide implementation and ongoing support services. Still others offer combinations of services or partnerships with vendors and other providers outside their immediate expertise.

The outsourcing of security services is not only growing in the United States or the English-speaking world, either in terms of organizations that choose to outsource their security or those that provide the outsourced services. Although many U.S. MSSP companies have international branches, MSSP directories turn up as many Far Eastern and European companies as American or British. In fact, these global companies grow because they understand the local requirements of their customer base. This is particularly evident in Europe, where International Security Standard (ISO) 17799 has gained acceptance much more rapidly than in the United States, providing guidance for good security practices to both client and vendor organizations. This, in turn, has contributed to a reduction in the risk of experiencing some of the outsourcing performance issues described below.

53.2.1 Future Prospective

Many MSSPs were formed during the dot.com boom of the mid-1990s in conjunction with the rapid growth of E-commerce and the Internet. Initially, dot.com companies preferred to focus on their core businesses but neglected to secure that business, providing quick opportunity for those who understood newly evolving security requirements. Later, as the boom turned to bust, dot.coms took their expertise in security and new technology and evolved themselves into MSSPs.

However, as this chapter is being written in early 2002, while the number of MSSPs is growing, a rapid consolidation and fallout among MSSPs is taking place—particularly among those that never achieved financial stability or a strong market niche. Some analysts "expect this proliferation to continue, but vendors over the next year will be sharply culled by funding limits, acquisition, and channel limits.

Over the next three years, we expect consolidation in this space, first by vendors attempting multi-function aggregation, then by resellers through channel aggregation."[4]

53.3 Outsourcing from the Corporate Perspective

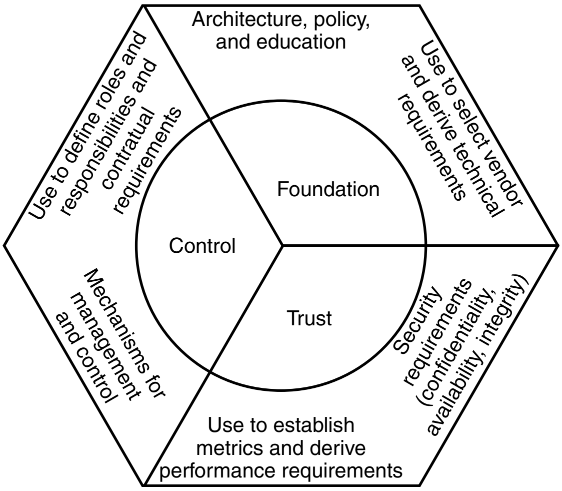
On the surface, the practice of outsourcing appears to run contrary to the ancient tenet of hiding information from those without a need to know. If the use of networks and the Internet has become central to the corporate business model, then exposing that model to an outside entity would seem inimical to good security practice. So why, then, would any organization want to undertake an outsourcing arrangement?

53.3.1 Relationship to the Life Cycle

The answer to this question lies in the pace at which the networked world has evolved. It is rare to read a discussion of the growth of the Internet without seeing the word *exponential* used to describe the rate of expansion. But while this exponential growth has led to rapid integration of the Internet with corporate business models, businesses have moved more slowly to protect the information—due to lack of knowledge, to immature security technology, or to a misplaced confidence in a vendor's ability to provide secure IT products. Most automated organizations have 20 or more years of experience with IT management and operations, and their IT departments know how to build systems and integrate them. What they have not known and have been slow to learn is how to secure them, because the traditional IT security model has been to hide secret information; and in a networked world, it is no longer possible to do that easily.

One of the most commonly cited security models is that documented by Glen Bruce and Rob Dempsey.[5] This model defines three components: foundation, control, and trust. The foundation layer includes security policy and principles, criteria and standards, and the education and training systems. The trust layer includes the environment's security, availability, and performance characteristics. The control layer includes the mechanisms used to manage and control each of the required components.

In deciding whether to outsource its security and in planning for a successful outsourcing arrangement, this model can serve as a useful reference for ensuring that all aspects of security are considered in the requirements. As shown in Exhibit 53.1, each of the model's components can drive aspects of the arrangement.



Architecture, policy, and education
Use to select vendor and derive technical requirements
Security requirements (confidentiality, availability, integrity)
Use to establish metrics and derive performance requirements
Mechanisms for management and control
Use to define roles and responsibilities and contratual requirements
Foundation
Control
Trust

EXHIBIT 53.1 Using a security model to derive requirements.

53.4 The Four Phases of an Outsourcing Arrangement

Phase 1 of an outsourcing arrangement begins when an organization perceives a business problem—in the case of IT, this is often a vulnerability or threat that the organization cannot address. The organization then decides that an outside entity may be better equipped to solve the problem than the organization's own staff. The reasons why this decision is made will be discussed below; but once the decision is made, the organization must put an infrastructure in place to manage the arrangement. In Phase 2, a provider of services is selected and hired. In Phase 3, the arrangement must be monitored and managed to ensure that the desired benefits are being realized. And finally, in Phase 4, the arrangement comes to an end, and the organization must ensure a smooth and nondisruptive transition out.

53.4.1 Phase 1: Identify the Need and Prepare to Outsource

It is axiomatic that no project can be successful unless the requirements are well defined and the expectations of all participants are clearly articulated. In the case of a security outsourcing project, if the decision to bring in an outside concern is made under pressure during a security breach, this is especially true. In fact, one of the biggest reasons many outsourcing projects fail is that the business does not understand what lies behind the decision to outsource or why it is believed that the work cannot (or should not) be done in-house. Those organizations that make the decision to outsource after careful consideration, and who plan carefully to avoid its potential pitfalls, will benefit most from the decision to outsource.

The goal of Phase 1 is to articulate (in writing if possible) the reasons for the decision to outsource. As will be discussed below, this means spelling out the products or services to be acquired, the advantages expected, the legal and business risks inherent in the decision, and the steps to be taken to minimize those risks.

53.4.1.1 Consider Strategic Reasons to Outsource

Many of the reasons to outsource can be considered strategic in nature. These promise advantages beyond a solution to the immediate need and allow the organization to seek long-term or strategic advantages to the business as a whole:

- Free up resources to be used for other mission-critical purposes.
- Maintain flexibility of operations by allowing peak requirements to be met while avoiding the cost of hiring new staff.
- Accelerate process improvement by bringing in subject matter expertise to train corporate staff or to teach by example.
- Obtain current technology or capability that would otherwise have to be hired or acquired by retraining, both at a potentially high cost.
- Avoid infrastructure obsolescence by giving the responsibility for technical currency to someone else.
- Overcome strategic stumbling blocks by bringing in third-party objectivity.
- Control operating costs or turn fixed costs into variable ones through the use of predictable fees, because presumably an MSSP has superior performance and lower cost structure.
- Enhance organizational effectiveness by focusing on what is known best, leaving more difficult security tasks to someone else.
- Acquire innovative ideas from experts in the field.

Organizations that outsource for strategic reasons should be cautious. The decision to refocus on strategic objectives is a good one, but turning to an outside organization for assistance with key strategic security functions is not. If security is an inherent part of the company's corporate mission, and strategic management of this function is not working, the company might consider whether outsourcing is going to correct those issues. The problems may be deeper than a vendor can fix.

53.4.1.2 Consider Tactical Reasons

The tactical reasons for outsourcing security functions are those that deal with day-to-day functions and issues. When the organization is looking for a short-term benefit, an immediate response to a specific issue, or improvement in a specific aspect of its operations, these tactical advantages of outsourcing are attractive:

- Reduce response times when dealing with security incidents.
- Improve customer service to those being supported.
- Allow IT staff to focus on day-to-day or routine support work.
- Avoid an extensive capital outlay by obviating the need to invest in new equipment such as firewalls, servers, or intrusion detection devices.
- Meet short-term staffing needs by bringing in staff that is not needed on a full-time basis.
- Solve a specific problem for which existing staff does not have the expertise to address.

While the tactical decision to outsource might promise quick or more focused results, this does not necessarily mean that the outsourcing arrangement must be short-term. Many successful long-term outsourcing arrangements are viewed as just one part of a successful information security program, or are selected for a combination of strategic and technical reasons.

53.4.1.3 Anticipate Potential Problems

The prospect of seeing these advantages in place can be seductive to an organization that is troubled by a business problem. But for every potential benefit, there is a potential pitfall as well. During Phase 1, after the decision to outsource is made, the organization must put in place an infrastructure to manage that arrangement. This requires fully understanding (and taking steps to avoid) the many problems that can arise with outsourcing contracts:

- Exceeding expected costs, either because the vendor failed to disclose them in advance or because the organization did not anticipate them
- Experiencing contract issues that lead to difficulties in managing the arrangement or to legal disputes
- Losing control of basic business resources and processes that now belong to someone else
- Failing to maintain mechanisms for effective provider management
- Losing in-house expertise to the provider
- Suffering degradation of service if the provider cannot perform adequately
- Discovering conflicts of interest between the organization and the outsourcer
- Disclosing confidential data to an outside entity that may not have a strong incentive to protect it
- Experiencing declines in productivity and morale from staff who believe they are no longer important to the business or that they do not have control of resources
- Becoming dependent on inadequate technology if the vendor does not maintain technical currency
- Becoming a "hostage" to the provider who now controls key resources

53.4.1.4 Document Requirements and Expectations

As discussed above, the goal of Phase 1 is to fully understand why the decision to outsource is made, to justify the rationale for the decision, and to ensure that the arrangement's risks are minimized. Minimizing this risk is best accomplished through careful preparation for the outsourced arrangement.

Thus, the organization's security requirements must be clearly defined and documented. In the best situation, this will include a comprehensive security policy that has been communicated and agreed to throughout the organization. However, companies that are beginning to implement a security program may be hiring expertise to help with first steps and consequently do not have such a policy. In these cases, the security requirements should be defined in business terms. This includes a description of the information or assets to be protected, their level of sensitivity, their relationship to the core business, and the requirement for maintaining the confidentiality, availability, and integrity of each.

One of the most common issues that surfaces from outsourcing arrangements is financial, wherein costs may not be fully understood or unanticipated costs arise after the fact. It is important that the organization understand the potential costs of the arrangement, which include a complete understanding of the internal costs before the outsourcing contract is established. A cost/benefit analysis should be performed and should include a calculation of return on investment. As with any cost/benefit analysis, there may be costs and benefits that are not quantifiable in financial terms, and these should be considered and included as well. These may include additional overhead in terms of staffing, financial obligations, and management requirements.

Outsourcing will add new risks to the corporate environment and may exacerbate existing risks. Many organizations that outsource perform a complete risk analysis before undertaking the arrangement, including a description of residual risk expected after the outsourcing project begins. Such an analysis can be invaluable during the process of preparing the formal specification, because it will point to the inclusion of requirements for ameliorating these risks. Because risk can be avoided or reduced by the implementation of risk management strategies, a full understanding of residual risk will also aid in managing the vendor's performance once the work begins; and it will suggest areas where management must pay stronger attention in assessing the project's success.

53.4.1.5 Prepare the Organization

To ensure the success of the outsourcing arrangement, the organization should be sure that it can manage the provider's work effectively. This requires internal corporate knowledge of the work or service outsourced. Even if this knowledge is not deeply technical—if, for example, the business is networking its services for the first time—the outsourcing organization must understand the business value of the work or service and how it supports the corporate mission. This includes an understanding of the internal cost structure because without this understanding, the financial value of the outsourcing arrangement cannot be assessed.

53.4.1.6 Assign Organizational Roles

As with any corporate venture, management and staff acceptance are important in ensuring the success of the outsourcing project. This can best be accomplished by involving all affected corporate staff in the decision-making process from the outset, and by ensuring that everyone is in agreement with, or is willing to support, the decision to go ahead.

With general support for the arrangement, the organization should articulate clearly each affected party's role in working with the vendor. Executives and management-level staff who are ultimately responsible for the success of the arrangement must be supportive and must communicate the importance of the project's success throughout the organization. System owners and content providers must be helped to view the vendor as an IT partner and must not feel their ownership threatened by the assistance of an outside entity. These individuals should be given the responsibility for establishing the project's metrics and desired outcome because they are in the best position to understand what the organization's information requirements are.

The organization's IT staff is in the best position to gauge the vendor's technical ability and should be given a role in bringing the vendor up to speed on the technical requirements that must be met. The IT staff also should be encouraged to view the vendor as a partner in providing IT services to the organization's customers. And finally, if there are internal security employees, they should be responsible

for establishing security policies and procedures to be followed by the vendor throughout the term of the contract.

The most important part of establishing organizational parameters is to assign accountability for the project's success. Although the vendor will be held accountable for the effectiveness of its work, the outsourcing organization should not give away accountability for management success. Where to lodge this accountability in the corporate structure is a decision that will vary based on the organization and its requirements, but the chances for success will be greatly enhanced by ensuring that those responsible for managing the effort are also directly accountable for its results.

A useful summary of organizational responsibilities for the outsourcing arrangement is shown in Exhibit 53.2, which illustrates the level of management control for various activities.[6]

53.4.1.7 Prepare a Specification and RFP

If the foregoing steps have been completed correctly, the process of documenting requirements and preparing a specification should be a simple formality. A well-written request for proposals (RFP) will include a complete and thorough description of the organizational, technical, management, and performance requirements and of the products and services to be provided by the vendor. Every corporate expectation that was articulated during the exploration stage should be covered by a performance requirement in the RFP. And the expected metrics that will be used to assess the vendor's performance should be included in a service level agreement (SLA). The SLA can be a separate document, but it should be legally incorporated into the resulting contract.

The RFP and resulting contract should specify the provisions for the use of hardware and software that are part of the outsourcing arrangements. This might include, for example, the type of software that is acceptable or its placement, so that the provider does not modify the client's technical infrastructure or remove assets from the customer premises without advance approval. Some MSSPs want to install their own hardware or software at the customer site; others prefer to use customer-owned technical resources; and still others perform on their own premises using their own resources. Regardless, the contract should spell out the provisions for ownership of all resources that support the arrangement and for the eventual return of any assets whose control or possession are outsourced. If there is intellectual property involved, as might be the case in a custom-developed security solution, the contract should also specify how the licensing of the property works and who will retain ownership of it at the end of the arrangement.

During the specification process, the organization should have determined what contractual provisions it will apply for nonperformance or substandard performance. The SLA contract should clearly define items considered to be performance infractions or errors, including requirements for correction of errors. This includes any financial or nonfinancial penalties for noncompliance or failure to perform.

The contract may not be restricted to technical requirements and contractual terms but may also consider human resources and business management issues. Some of the requirements that might be included govern access to vendor staff by the customer, and vice versa, and provisions for day-to-day management of the staff performing the work. In addition, requirements for written deliverables, regular reports, etc. should be specified in advance.

The final section of the RFP and contract should govern the end of the outsourcing arrangement and provisions for terminating the relationship with the vendor. The terms that govern the transition out should be designed to reduce exit barriers for both the vendor and the client, particularly because these terms may need to be invoked during a dispute or otherwise in less-than-optimal circumstances. One key provision will be to require that the vendor cooperates fully with any vendor that succeeds it in performance of the work.

53.4.1.8 Specify Financial Terms and Pricing

Some of the basic financial considerations for the RFP are to request that the vendor provide evidence that its pricing and terms are competitive and provide an acceptable cost/benefit business case. The RFP should request that the vendor propose incentives and penalties based on performance and warrant the work it performs.

The specific cost and pricing sections of the specification depend on the nature of the work outsourced. Historically, many outsourcing contracts were priced in terms of unit prices for units provided, and may have been measured by staff (such as hourly rates for various skill levels), resources (such as workstations supported), or events (such as calls answered). The unit prices may have been fixed or varied based on rates of consumption, may have included guaranteed levels of consumption, and may have been calculated based on cost or on target profits.

However, these types of arrangements have become less common over the past few years. The cost-per-unit model tends to cause the selling organization to try to increase the units sold, driving up the quantity consumed by the customer regardless of the benefit to the customer. By the same token, this causes the customer to seek alternative arrangements with lower unit costs; and at some point the two competing requirements diverge enough that the arrangement must end.

So it has become more popular to craft contracts that tie costs to expected results and provide incentives for both vendor and customer to perform according to expectations. Some arrangements provide increased revenue to the vendor each time a threshold of performance is met; others are tied to customer satisfaction measures; and still others provide for gain-sharing wherein the customer and vendor share in any savings from reduction in customer costs. Whichever model is used, both vendor and customer are given incentives to perform according to the requirements to be met by each.

53.4.1.9 Anticipate Legal Issues

The RFP and resulting contract should spell out clear requirements for liability and culpability. For example, if the MSSP is providing security alert and intrusion detection services, who is responsible in the event of a security breach? No vendor can provide a 100 percent guarantee that such breaches will not occur, and organizations should be wary of anyone who makes such a claim. However, it is reasonable to expect that the vendor can prevent predefined, known, and quantified events from occurring. If there is damage to the client's infrastructure, who is responsible for paying the cost of recovery? By considering these questions carefully, the client organization can use the possibility of breaches to provide incentives for the vendor to perform well.

In any contractual arrangement, the client is responsible for performing due diligence. The RFP and contract should spell out the standards of care that will be followed, and it will assign accountability for technical and management due diligence. This includes the requirements to maintain the confidentiality of protected information and for nondisclosure of sensitive, confidential, and secret information.

There may be legislative and regulatory issues that impact the outsourcing arrangement, and both the client and vendor should be aware of these. Organizations should be wary of outsourcing responsibilities for which it is legally responsible, unless it can legally assign these responsibilities to another party.

In fact, outsourcing such services may be prohibited by regulation or law, particularly for government entities. Existing protections may not be automatically carried over in an outsourced environment. For example, certain requirements for compliance with the Privacy Act or the Freedom of Information Act may not apply to employees of an MSSP or service provider.

Preparing a good RFP for security services is no different than preparing any RFP. The proposing vendors should be obligated to respond with clear, measurable responses to every requirement, including, if possible, client references demonstrating successful prior performance.

53.4.2 Phase 2: Select a Provider

During Phase 1, the organization defined the scope of work and the services to be outsourced. The RFP and specification were created, and the organization must now evaluate the proposals received and select a vendor. The process of selecting a vendor includes determining the appropriate characteristics of an outsourcing supplier, choosing a suitable vendor, and negotiating requirements and contractual terms.

53.4.2.1 Determine Vendor Characteristics

Among the most common security services outsourced are those that include installation, management, or maintenance of equipment and services for intrusion detection, perimeter scanning, VPNs and firewalls, and anti-virus and content protection. These arrangements, if successfully acquired and managed, tend to be long-term and ongoing in nature. However, shorter-term outsourcing arrangements might include testing and deployment of new technologies, such as encryption services and PKI in particular, because it is often difficult and expensive to hire expertise in these arenas. Hiring an outside provider to do one-time or short-term tasks such as security assessments, policy development and implementation, or audit, enforcement, and compliance monitoring is also becoming popular.

One factor to consider during the selection process is the breadth of services offered by the prospective provider. Some vendors have expertise in a single product or service that can bring superior performance and focus, although this can also mean that the vendor has not been able to expand beyond a small core offering. Other vendors sell a product or set of products, then provide ongoing support and monitoring of the offering. This, too, can mean superior performance due to focus on a small set of offerings; but the potential drawback is that the customer becomes hostage to a single technology and is later unable to change vendors. One relatively new phenomenon in the MSSP market is to hire a vendor-neutral service broker who can perform an independent assessment of requirements and recommend the best providers.

There are a number of terms that have become synonymous with outsourcing or that describe various aspects of the arrangement. *Insourcing* is the opposite of outsourcing, referring to the decision to manage services in-house. The term *midsourcing* refers to a decision to outsource a specific selection of services. *Smartsourcing* is used to mean a well-managed outsourcing (or insourcing) project and is sometimes used by vendors to refer to their set of offerings.

53.4.2.2 Choose a Vendor

Given that the MSSP market is relatively new and immature, organizations must pay particular attention to due diligence during the selection process, and should select a vendor that not only has expertise in the services to be performed but also shows financial, technical, and management stability. There should be evidence of an appropriate level of investment in the infrastructure necessary to support the service. In addition to assessing the ability of the vendor to perform well, the organization should consider less tangible factors that might indicate the degree to which the vendor can act as a business partner. Some of these characteristics are:

- *Business culture and management processes*. Does the vendor share the corporate values of the client? Does it agree with the way in which projects are managed? Will staff members be able to work successfully with the vendor's staff?
- *Security methods and policies*. Will the vendor disclose what these are? Are these similar to or compatible with the customer's?

- *Security infrastructure, tools, and technology.* Do these demonstrate the vendor's commitment to maintaining a secure environment? Do they reflect the sophistication expected of the vendor?
- *Staff skills, knowledge, and turnover.* Is turnover low? Does the staff appear confident and knowledgeable? Does the offered set of skills meet or exceed what the vendor has promised?
- *Financial and business viability.* How long has the vendor provided these services? Does the vendor have sufficient funding to remain in the business for at least two years?
- *Insurance and legal history.* Have there been prior claims against the vendor?

53.4.2.3 Negotiate the Arrangement

With a well-written specification, the negotiation process will be simple because expectations and requirements are spelled out in the contract and can be fully understood by all parties. The specific legal aspects of the arrangement will depend on the client's industry or core business, and they may be governed by regulation (for example, in the case of government and many financial entities). It is important to establish in advance whether the contract will include subcontractors, and if so, to include them in any final negotiations prior to signing a contract. This will avoid the potential inability to hold subcontractors as accountable for performance as their prime contractor.

Negotiation of pricing, delivery terms, and warranties should also be governed by the specification; and the organization should ensure that the terms and conditions of the specification are carried over to the resulting contract.

53.4.3 Phase 3: Manage the Arrangement

Once a provider has been selected and a contract is signed, the SLA will govern the management of the vendor. If the SLA was not included in the specification, it should be documented before the contract is signed and included in the final contract.

53.4.3.1 Address Performance Factors

For every service or resource being outsourced, the SLA should address the following factors:

- The expectations for successful service delivery (service levels)
- Escalation procedures
- Business impact of failure to meet service levels
- Turnaround times for delivery
- Service availability, such as for after-hours
- Methods for measurement and monitoring of performance

53.4.3.2 Use Metrics

To be able to manage the vendor effectively, the customer must be able to measure compliance with contractual terms and the results and benefits of the provider's work. The SLA should set a baseline for all items to be measured during the contract term. These will by necessity depend on which services are provided. For example, a vendor that is providing intrusion detection services might be assessed in part by the number of intrusions repelled as documented in IDS logs.

To motivate the vendor to behave appropriately, the organization must measure the right things—that is, results over which the provider has control. However, care should be taken to ensure that the vendor cannot directly influence the outcome of the collection process. In the example above, the logs should be monitored to ensure that they are not modified manually, or backup copies should be turned over to the client on a regular basis.

The SLA metrics should be reasonable in that they can be easily measured without introducing a burdensome data collection requirement. The frequency of measurement and audits should be established in advance, as should the expectations for how the vendor will respond to security issues and whether the vendor will participate in disaster recovery planning and rehearsals. Even if the provider is responsible for monitoring of equipment such as firewalls or intrusion detection devices, the organization may want to retain control of the incident response process, particularly if the possibility of future legal action exists. In these cases, the client may specify that the provider is to identify, but not act on, suspected security incidents. Thus, they may ask the provider for recommendations but may manage or staff the response process itself. Other organizations distinguish between internal and external threats or intrusions to avoid the possibility that an outside organization has to respond to incidents caused by the client's own employees.

53.4.3.3 Monitor Performance

Once the contract is in place and the SLA is active, managing the ongoing relationship with the service provider becomes the same as managing any other contractual arrangement. The provider is responsible for performing the work to specifications, and the client is responsible for monitoring performance and managing the contract.

Monitoring and reviewing the outsourced functions are critically important. Although the accountability for success of the arrangement remains with the client organization, the responsibility for monitoring can be a joint responsibility; or it can be done by an independent group inside or outside the organization.

Throughout the life of the contract, there should be clear single points of contact identified by the client and the vendor; and both should fully understand and support provisions for coordinating emergency response during a security breach or disaster.

53.4.4 Phase 4: Transition Out

In an ideal world, the outsourcing arrangement will continue with both parties to their mutual satisfaction. In fact, the client organization should include provisions in the contract for renewal, for technical refresh, and for adjustment of terms and conditions as the need arises. However, an ideal world rarely exists, and most arrangements end sooner or later. It is important to define in advance (in the contract and SLA) the terms that will govern the parties if the client decides to bring the work in-house or to use another contractor, along with provisions for penalties should either party not comply.

Should the arrangement end, the organization should continue to monitor vendor performance during the transition out. The following tasks should be completed to the satisfaction of both vendor and client:

- All property is returned to its original owner (with reasonable allowance for wear and tear).
- Documentation is fully maintained and up-to-date.
- Outstanding work is complete and documented.
- Data owned by each party is returned, along with documented settings for security controls. This includes backup copies.
- If there is to be staff turnover, the hiring organization has completed the hiring process.
- Requirements for confidentiality and nondisclosure continue to be followed.
- If legally required, the parties are released from any indemnities, warranties, etc.

53.5 Conclusion

The growth of the MSSP market clearly demonstrates that outsourcing of security services can be a successful venture both for the client and the vendor. While the market is undergoing some consolidation and refocusing as this chapter is being written, in the ultimate analysis, outsourcing security services is not much different than outsourcing any other IT service, and the IT outsourcing industry is established and mature. The lessons learned from one clearly apply to the other, and it is clear that organizations that

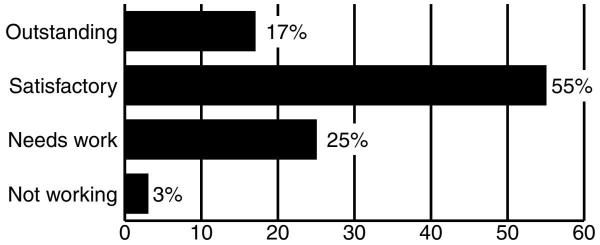

EXHIBIT 53.3 Customer satisfaction with security outsourcing.

choose to outsource are in fact applying those lessons. In fact, as Exhibit 53.3 shows, the majority of companies that outsource their security describe their level of satisfaction as outstanding or satisfactory.[7]

Outsourcing the security of an organization's information assets may be the antithesis of the ancient "security through obscurity" model. However, in today's networked world, with solid planning in advance, a sound rationale, and good due diligence and management, any organization can outsource its security with satisfaction and success.

Considerations for Outsourcing Security

Michael J. Corby

Outsourcing computer operations is not a new concept. Since the 1960s, companies have been in the business of providing computer operations support for a fee. The risks and challenges of providing a reliable, confidential, and responsive data center operation have increased, leaving many organizations to consider retaining an outside organization to manage the data center in a way that the risks associated with these challenges are minimized.

Let me say at the onset that there is no one solution for all environments. Each organization must decide for itself whether to build and staff its own IT security operation or hire an organization to do it for them. This discussion will help clarify the factors most often used in making the decision of whether outsourcing security is a good move for your organization.

54.1 History of Outsourcing IT Functions

54.1.1 Data Center Operations

Computer facilities have been traditionally very expensive undertakings. The equipment alone often cost millions of dollars, and the room to house the computer equipment required extensive and expensive special preparation. For that reason, many companies in the 1960s and 1970s seriously considered the ability to provide the functions of an IT (or EDP) department without the expense of building the computer room, hiring computer operators, and, of course, acquiring the equipment. Computer service bureaus and shared facilities sprang up to service the banking, insurance, manufacturing, and service industries. Through shared costs, these outsourced facilities were able to offer cost savings to their customers and also turn a pretty fancy profit in the process.

In almost all cases, the reasons for justifying the outsourcing decision were based on financial factors. Many organizations viewed the regular monthly costs associated with the outsource contract far more acceptable than the need to justify and depreciate a major capital expense.

In addition to the financial reasons for outsourcing, many organizations also saw the opportunity to off-load the risk of having to replace equipment and software long before it had been fully depreciated due to increasing volume, software and hardware enhancements, and training requirements for operators, system programmers, and other support staff.

The technical landscape at the time was changing rapidly; there was an aura of special knowledge that was shared by those who knew how to manage the technology, and that knowledge was shared with only a few individuals outside the "inner circle."

Organizations that offered this service were grouped according to their market. That market was dictated by the size, location, or support needs of the customer:

- Size was measured in the number of transactions per hour or per day, the quantity of records stored in various databases, and the size and frequency of printed reports.
- Location was important because in the pre-data communications era, the facility often accepted transactions delivered by courier in paper batches and delivered reports directly to the customer in paper form. To take advantage of the power of automating the business process, quick turnaround was a big factor.
- The provider's depth of expertise and special areas of competence were also a factor for many organizations. Banks wanted to deal with a service that knew the banking industry, its regulations, need for detailed audits, and intense control procedures. Application software products that were designed for specific industries were factors in deciding which service could support those industries. In most instances, the software most often used for a particular industry could be found running in a particular hardware environment. Services were oriented around IBM, Digital, Hewlett-Packard, NCR, Burroughs, Wang, and other brands of computer equipment. Along with the hardware type came the technical expertise to operate, maintain, and diagnose problems in that environment. Few services would be able to support multiple brands of hardware.

Of course, selecting a data center service was a time-consuming and emotional process. The expense was still quite a major financial factor, and there was the added risk of putting the organization's competitive edge and customer relations in the hands of a third party. Consumers and businesses cowered when they were told that their delivery was postponed or that their payment was not credited because of a computer problem. Nobody wanted to be forced to go through a file conversion process and learn how to deal with a new organization any more than necessary. The ability to provide a consistent and highly responsive "look and feel" to the end customer was important, and the vendor's perceived reliability and long-term capabilities to perform in this area were crucial factors in deciding which service and organization would be chosen.

54.1.2 Contracting Issues

There were very few contracting issues in the early days of outsourced data center operations. Remember that almost all applications involved batch processing and paper exchange. Occasionally, limited file inquiry was provided, but price was the basis for most contract decisions.

If the reports could be delivered within hours or maybe within the same day, the service was acceptable. If there were errors or problems noted in the results, the obligation of the service was to rerun the process.

Computer processing has always been bathed in the expectation of confidentiality. Organizations recognized the importance of keeping their customer lists, employee ranks, financial operations, and sales information confidential; and contracts were respectful of that factor. If any violations of this expectation of confidentiality occurred in those days, they were isolated incidents that were dealt with privately, probably in the courts.

Whether processing occurred in a contracted facility or in-house, expectations that there would be an independent oversight or audit process were the same. EDP auditors focused on the operational behavior of servicer-designed specific procedures, and the expectations were usually clearly communicated. Disaster recovery planning, document storage, tape and disk archival procedures, and software maintenance procedures were reviewed and expected to meet generally accepted practices. Overall, the performance targets were communicated, contracts were structured based on meeting those targets, companies were fairly satisfied with the level of performance they were getting for their money, and they had the benefit of not dealing with the technology changes or the huge capital costs associated with their IT operations.

54.1.3 Control of Strategic Initiatives

The dividing line of whether an organization elected to acquire services of a managed data center operation or do it in-house was the control of their strategic initiatives. For most regulated businesses, the operations were not permitted to get too creative. The most aggressive organizations generally did not use the data center operations as an integral component of their strategy. Those who did deploy new or creative computer processing initiatives generally did not outsource that part of their operation to a shared service.

54.2 Network Operations

The decision to outsource network operations came later in the evolution of the data center. The change from a batch, paper processing orientation to an online, electronically linked operation brought about many of the same decisions that organizations faced years before when deciding to "build or buy" their computer facilities.

The scene began to change when organizations decided to look into the cost, technology, and risk involved with network operations. New metrics of success were part of this concept. Gone was the almost single focus on cost as the basis of a decision to outsource or develop an inside data communication facility. Reliability, culminating in the concept we now know as *continuous availability*, became the biggest reason to hire a data communications servicer. The success of the business often came to depend on the success of the data communications facility. Imagine the effect on today's banking environment if ATMs had a very low reliability, were fraught with security problems, or theft of cash or data. We frequently forget how different our personal banking was in the period before the proliferation of ATMs. A generation of young adults has been transformed by the direct ability to communicate electronically with a bank—much in the same way, years ago, that credit cards opened up a new relationship between consumers and retailers.

The qualification expected of the network operations provider was also very different from the batch-processing counterpart. Because the ability to work extra hours to catch up when things fell behind was gone, new expectations had to be set for successful network operators. Failures to provide the service were clearly and immediately obvious to the organization and its clients. Several areas of technical qualification were established.

One of the biggest questions used to gauge qualified vendors was bandwidth. How much data could be transmitted to and through the facility? This was reviewed on both a micro and macro domain. From the micro perspective, the question was, "How fast could data be sent over the network to the other end?" The higher the speed, the higher the cost. On a larger scale, what was the capacity of the network provider to transfer data over the 24-hour period? This included downtime, retransmissions, and recovery. This demand gave rise to the 24/7 operation, where staples of a sound operation like daily backups and software upgrades were considered impediments to the totally available network.

From this demand came the design and proliferation of the dual processor and totally redundant systems. Front-end processors and network controllers were designed to be failsafe. If anything happened to any of the components, a second copy of that component was ready to take over. For the most advanced network service provider, this included dual data processing systems at the back end executing every transaction twice, sometimes in different data centers, to achieve total redundancy.

Late delivery and slow delivery became unacceptable failures and would be a prime cause for seeking a new network service provider.

After the technical capability of the hardware/software architecture was considered, the competence of the staff directing the facility was considered. How smart, how qualified, how experienced were the people that ran and directed the network provider? Did the people understand the mission of the organization, and could they appreciate the need for a solid and reliable operation? Could they upgrade operating systems with total confidence? Could they implement software fixes and patches to assure data integrity and security? Could they properly interface with the applications software developers without requiring additional people in the organization duplicating their design and research capabilities?

In addition to pushing bits through the wires, the network service provider took on the role of the front-end manager of the organization's strategy. Competence was a huge factor in building the level of trust that executives demanded.

Along with this swing toward the strategic issues, organizations became very concerned about long-term viability. Often, huge companies were the only ones that could demonstrate this longevity promise. The mainframe vendor, global communications companies, and large well-funded network servicers were the most successful at offering these services universally. As the commerce version of the globe began to shrink, the most viable of these were the ones that could offer services in any country, any culture, at any time. The data communications world became a nonstop, "the store never closes" operation.

54.2.1 Contracting Issues

With this new demand for qualified providers with global reach came new demands for contracts that would reflect the growing importance of this outsourcing decision to the lifeblood of the organization.

Quality-of-service expectations were explicitly defined and put into contracts. Response time would be measured in seconds or even milliseconds. Uptime was measured in the number of nines in the percentage that would be guaranteed. Two nines, or 99 percent was not good enough. Four nines (99.99 percent) or even five nines (99.999 percent) became the common expectation of availability.

A new emphasis developed regarding the extent to which data would be kept confidential. Questions were asked and a response expected in the contract regarding the access to the data while in transit. Private line networks were expected for most data communications facilities because of the perceived vulnerability of public telecommunications facilities. In some high-sensitivity areas, the concept of encryption was requested. Modems were developed that would encrypt data while in transit. Software tools were designed to help ensure unauthorized people would not be able to see the data sent.

Independent auditors reviewed data communications facilities periodically. This review expanded to include a picture of the data communications operation over time using logs and transaction monitors. Management of the data communication provider was frequently retained by the organization so it could attest to the data integrity and confidentiality issues that were part of the new expectations levied by the external regulators, reviewers, and investors. If the executives were required to increase security and reduce response time to maintain a competitive edge, the data communications manager was expected to place the demand on the outsourced provider.

54.2.2 Control of Strategic Initiatives

As the need to integrate this technical ability becomes more important to the overall organization mission, more and more companies opted to retain their own data communications management. Nobody other than the communications carriers and utilities actually started hanging wires on poles;

but data communications devices were bought and managed by employees, not contractors. Alternatives to public networks were considered; microwave, laser, and satellite communications were evaluated in an effort to make sure that the growth plan was not derailed by the dependence on outside organizations.

The daily operating cost of this communications capability was large; but in comparison to the computer room equipment and software, the capital outlay was small. With the right people directing the data communications area, there was less need for outsourced data communications facilities as a stand-alone service. In many cases it was rolled into an existing managed data center; but in probably just as many instances, the managed data center sat at the end of the internally controlled data communications facility. The ability to deliver reliable communications to customers, constituents, providers, and partners was considered a key strategy of many forward-thinking organizations.

54.3 Application Development

While the data center operations and data communications outsourcing industries have been fairly easy to isolate and identify, the application development outsourcing business is more subtle. First, there are usually many different application software initiatives going on concurrently within any large organization. Each of them has a different corporate mission, each with different metrics for success, and each with a very different user focus. Software customer relationship management is very different from software for human resources management, manufacturing planning, investment management, or general accounting.

In addition, outsourced application development can be carried out by general software development professionals, by software vendors, or by targeted software enhancement firms. Take, for instance, the well-known IBM manufacturing product Mapics®. Many companies that acquired the software contracted directly with IBM to provide enhancements; many others employed the services of software development organizations specifically oriented toward Mapics enhancements, while some simply added their Mapics product to the list of products supported or enhanced by their general application design and development servicer.

Despite the difficulty in viewing the clear picture of application development outsourcing, the justification was always quite clear. Design and development of new software, or features to be added to software packages, required skills that differed greatly from general data center or communications operations. Often, hiring the people with those skills was expensive and posed the added challenge in that designers were motivated by new creative design projects. Many companies did not want to pay the salary of good design and development professionals, train and orient them, and give them a one- or two-year design project that they would simply add to their resume when they went shopping for their next job.

By outsourcing the application development, organizations could employ business and project managers who had long careers doing many things related to application work on a variety of platforms and for a variety of business functions—and simply roll the coding or database expertise in and out as needed.

In many instances, also, outsourced applications developers were used for another type of activity—routine software maintenance. Good designers hate mundane program maintenance and start looking for new employment if forced to do too much of it. People who are motivated by the quick response and variety of tasks that can be juggled at the same time are well suited to maintenance tasks, but are often less enthusiastic about trying to work on creative designs and user-interactive activities where total immersion is preferred. Outsourcing the maintenance function is a great way to avoid the career dilemma posed by these conflicting needs. Y2K gave the maintenance programmers a whole new universe of opportunities to demonstrate their values. Aside from that once-in-a-millennium opportunity, program language conversions, operation system upgrades, and new software releases are a constant source of engagements for application maintenance organizations.

Qualifications for this type of service were fairly easy to determine. Knowledge of the hardware platform, programming language, and related applications were key factors in selecting an application development firm. Beyond those specifics, a key factor in selecting an application developer was in the actual experience with the specific application in question. A financial systems analyst or programmer was designated to work on financial systems; a manufacturing specialist on manufacturing systems, and so on.

Word quickly spread about which organizations were the application and program development leaders. Companies opened offices across the United States and around the world offering contract application services. Inexpensive labor was available for some programming tasks if contracted through international job shops, but the majority of application development outsourcing took place close to the organization that needed the work done.

Often, to ensure proper qualifications, programming tests were given to the application coders. Certifications and test-based credentials support extensive experience and intimate language knowledge. Both methods are cited as meritorious in determining the credentials of the technical development staff assigned to the contract.

Along with the measurable criteria of syntax knowledge, a key ingredient was the maintainability of the results. Often, one of the great fears was that the program code was so obscure that only the actual developer could maintain the result. This is not a good thing. The flexibility to absorb the application development at the time the initial development is completed or when the contract expires is a significant factor in selecting a provider. To ensure code maintainability, standards are developed and code reviews are frequently undertaken by the hiring organization.

Perhaps the most complicated part of the agreement is the process by which errors, omissions, and problems are resolved. Often, differences of opinion, interpretations of what is required, and the definition of things like "acceptable response time" and "suitable performance" were subject to debate and dispute. The chief way this factor was considered was in contacting reference clients. It probably goes to say that no application development organization registered 100 percent satisfaction with 100 percent of its customers 100 percent of the time. Providing the right reference account that gives a true representation of the experience, particularly in the application area evaluated, is a critical credential.

54.3.1 Contracting Issues

Application development outsourcing contracts generally took on two forms: pay by product or pay by production.

- Pay by product is basically the fixed-price contract; that is, hiring a developer to develop the product and, upon acceptance, paying a certain agreed amount. There are obvious derivations of this concept: phased payments, payment upon acceptance of work completed at each of several checkpoints—for example, payment upon approval of design concept, code completion, code unit testing, system integration testing, user documentation acceptance, or a determined number of cycles of production operation. This was done to avoid the huge balloon payment at the end of the project, a factor that crushed the cash flow of the provider and crippled the ability of the organization to develop workable budgets.
- Pay by production is the time-and-materials method. The expectation is that the provider works a prearranged schedule and, periodically, the hours worked are invoiced and paid. The presumption is that hours worked are productive and that the project scope is fixed. Failure of either of these factors most often results in projects that never end or exceed their budgets by huge amounts.

The control against either of these types of projects running amok is qualified approval oversight and audit. Project managers who can determine progress and assess completion targets are generally part of the organization's review team. In many instances, a third party is retained to advise the organization's management of the status of the developers and to recommend changes to the project or the relationship if necessary.

54.3.2 Control of Strategic Initiatives

Clearly the most sensitive aspect of outsourced service is the degree to which the developer is invited into the *inner sanctum* of the customer's strategic planning. Obviously, some projects such as Y2K upgrades, software upgrades, and platform conversions do not require anyone sitting in an executive strategy session; but they can offer a glimpse into the specifics of product pricing, engineering, investment strategy, and employee/partner compensation that are quite private. Almost always, application development contracts are accompanied by assurances of confidentiality and nondisclosure, with stiff penalties for violation.

54.4 Outsourcing Security

The history of the various components of outsourcing plays an important part in defining the security outsourcing business issue and how it is addressed by those seeking or providing the service. In many ways, outsourced security service is like a combination of the hardware operation, communications, and application development counterparts, all together. *Outsourced* is the general term; *managed security services* or MSS is the industry name for the operational component of an organization's total data facility, but viewed solely from the security perspective. As in any broad-reaching component, the best place to start is with a scope definition.

54.4.1 Defining the Security Component to be Outsourced

Outsourcing security can be a vast undertaking. To delineate each of the components, security outsourcing can be divided into six specific areas or domains:

1. Policy development
2. Training and awareness
3. Security administration
4. Security operations
5. Network operations
6. Incident response

Each area represents a significant opportunity to improve security, in increasing order of complexity. Let us look at each of these domains and define them a bit further.

54.4.1.1 Security Policies

These are the underpinning of an organization's entire security profile. Poorly developed policies, or policies that are not kept current with the technology, are a waste of time and space. Often, policies can work against the organization in that they invite unscrupulous employees or outsiders to violate the intent of the policy and to do so with impunity. The policies must be designed from the perspectives of legal awareness, effective communications skills, and confirmed acceptance on the part of those invited to use the secured facility (remember: unless the organization intends to invite the world to enjoy the benefits of the facility—like a Web site—it is restricted and thereby should be operated as a secured facility).

The unique skills needed to develop policies that can withstand the challenges of these perspectives are frequently a good reason to contract with an outside organization to develop and maintain the policies. Being an outside provider, however, does not lessen the obligation to intimately connect each policy with the internal organization. Buying the book of policies is not sufficient. They must present and define an organization's philosophy regarding the security of the facility and data assets. Policies that are strict about the protection of data on a computer should not be excessively lax regarding the same data in printed form. Similarly, a personal Web browsing policy should reflect the same organization's policy regarding personal telephone calls, etc. Good policy developers know this.

Policies cannot put the company in a position of inviting legal action but must be clearly worded to protect its interests. Personal privacy is a good thing, but using company assets for personal tasks and sending correspondence that is attributed to the organization are clear reasons to allow some level of supervisory review or periodic usage auditing. Again, good policy developers know this.

Finally, policies must be clearly communicated, remain *apropos*, carry with them appropriate means for reporting and handling violations, and for being updated and replaced. Printed policy books are replaced with intranet-based, easily updated policies that can be adapted to meet new security demands and rapidly sent to all subject parties. Policy developers need to display a good command of the technology in all its forms—data communication, printed booklets, posters, memos, video graphics, and nontraditional means of bringing the policy to its intended audience's attention. Even hot air balloons and skywriting are fair game if they accomplish the intent of getting the policy across. Failure to know the security policy cannot be a defense for violating it. Selecting a security policy developer must take all of these factors into consideration.

54.4.1.2 Training and Awareness

Training and awareness are also frequently assigned to an outside servicer. Some organizations establish guidelines for the amount and type of training an employee or partner should receive. This can take the form of attending lectures, seminars, and conferences; reading books; enrolling in classes at local educational facilities; or taking correspondence courses. Some organizations will hire educators to provide specific training in a specific subject matter. This can be done using standard course material good for anyone, or it can be a custom-designed session targeted specifically to the particular security needs of the organization.

The most frequent topics of general education that anyone can attend are security awareness, asset protection, data classification, and recently, business ethics. Anyone at any level is usually responsible to some degree for ensuring that his or her work habits and general knowledge are within the guidance provided by this type of education. Usually conducted by the human resources department at orientation, upon promotion, or periodically, the objective is to make sure that everyone knows the baseline of security expectations. Each attendee will be expected to learn what everyone in the organization must do to provide for a secure operation. It should be clearly obvious what constitutes unacceptable behavior to anyone who successfully attends such training.

Often, the provider of this service has a list of several dozen standard points that are made in an entertaining and informative manner, with a few custom points where the organization's name or business mission is plugged into the presentation; but it is often 90 percent boilerplate.

Selecting an education provider for this type of training is generally based on their creative entertainment value—holding the student's attention—and the way in which students register their acknowledgment that they have heard and understood their obligations. Some use the standard signed acknowledgment form; some even go so far as to administer a digitally signed test. Either is perfectly acceptable but should fit the corporate culture and general tenor.

Some additional requirements are often specified in selecting a training vendor to deal with technical specifics. Usually some sort of hands-on facility is required to ensure that the students know the information and can demonstrate their knowledge in a real scenario. Most often, this education will require a test for mastery or even a supervised training assignment. Providers of this type of education will often provide these services in their own training center where equipment is configured and can be monitored to meet the needs of the requesting organization.

Either in the general or specific areas, organizations that outsource their security education generally elect to do a bit of both on an annual basis with scheduled events and an expected level of participation. Evaluation of the educator is by way of performance feedback forms that are completed by all attendees. Some advanced organizations will also provide metrics to show that the education has rendered the desired results—for example, fewer password resets, lost files, or system crashes.

54.4.1.3 Security Administration

Outsourcing security administration begins to get a bit more complicated. Whereas security policies and security education are both essential elements of a security foundation, security administration is part of the ongoing security "face" that an organization puts on every minute of every day and requires a higher level of expectations and credentials than the other domains.

First, let us identify what the security administrator is expected to do. In general terms, security administration is the routine adds, changes, and deletes that go along with authorized account administration. This can include verification of identity and creation of a subsequent authentication method. This can be a password, token, or even a biometric pattern of some sort. Once this authentication has been developed, it needs to be maintained. That means password resets, token replacement, and biometric alternative (this last one gets a bit tricky, or messy, or both).

Another significant responsibility of the security administrator is the assignment of approved authorization levels. Read, write, create, execute, delete, share, and other authorizations can be assigned to objects from the computer that can be addressed down to the data item if the organization's authorization schema reaches that level. In most instances, the tools to do this are provided to the administrator, but occasionally there is a need to devise and manage the authority assignment in whatever platform and at whatever level is required by the organization.

A major responsibility of security administrators that is often overlooked is reporting their activities. If a security policy is to be deemed effective, the workload should diminish over time if the population of users remains constant. I once worked with an organization that had outsourced the security administration function and paid a fee based on the number of transactions handled. Interestingly, there was an increasing frequency of reassignment of authorizations, password resets, and adds, changes, and deletes as time went on. The rate of increase was double the rate of user population expansion. We soon discovered that the number of user IDs mushroomed to two or three times the total number of employees in the company. What is wrong with that picture? Nothing if you are the provider, but a lot if you are the contracting organization.

The final crucial responsibility of the security administrator is making sure that the procedures designed to assure data confidentiality, availability, and integrity are carried out according to plan. Backup logs, incident reports, and other operational elements—although not exactly part of most administrators' responsibilities—are to be monitored by the administrator, with violations or exceptions reported to the appropriate person.

54.4.1.4 Security Operations

The security operations domain has become another recent growth area in terms of outsourced security services. Physical security was traditionally separate from data security or computer security. Each had its own set of credentials and its own objectives. Hiring a company that has a well-established physical security reputation does not qualify them as a good data security or computer security operations provider. As has been said, "Guns, guards, and dogs do not make a good data security policy;" but recently they have been called upon to help. The ability to track the location of people with access cards and even facial recognition has started to blend into the data and operational end of security so that physical security is vastly enhanced and even tightly coupled with security technology.

Many organizations, particularly since September 11, have started to employ security operations specialists to assess and minimize the threat of physical access and damage in many of the same terms that used to be reserved only for data access and computer log-in authentication.

Traditional security operations such as security software installation and monitoring (remember ACF2, RACF, Top Secret, and others), disaster recovery and data archival (Comdisco, Sunguard, Iron Mountain, and others), and a whole list of application-oriented control and assurance programs and procedures have not gone away. Skills are still required in these areas, but the whole secure operations area has been expanded to include protection of the tangible assets as well as the data assets. Watch this area for more developments, including the ability to use the GPS location of the input device, together with the location of the person as an additional factor in transaction authentication.

54.4.1.5 Network Operations

The most recent articles on outsourcing security have looked at the security of the network operations as the most highly vulnerable and therefore the most sensitive of the security domains. Indeed, much work has been done in this area, and industry analysts are falling over themselves to assess and evaluate the vendors that can provide a managed security operation center, or SOC.

It is important to define the difference between a *network* operation center (NOC) and a *security* operation center (SOC). The difference can be easily explained with an analogy. The NOC is like a pipe that carries and routes data traffic to where it needs to go. The pipe must be wide enough in diameter to ensure that the data is not significantly impeded in its flow. The SOC, on the other hand, is not like the pipe but rather like a window in the pipe. It does not need to carry the data, but it must be placed at a point where the data flowing through the pipe can be carefully observed. Unlike the NOC, which is a constraint if not *wide* enough, the SOC will not be able to observe the data flow carefully enough if it is not *fast* enough.

Network operations have changed from the earlier counterparts described previously in terms of the tools and components that are used for function. Screens are larger and flatter. Software is more graphically oriented. Hardware is quicker and provides more control than earlier generations of the NOC, but the basic function is the same.

Security operation centers, however, are totally new. In their role of maintaining a close watch on data traffic, significant new software developments have been introduced to stay ahead of the volume. This software architecture generally takes two forms: data compression and pattern matching.

- *Data compression* usually involves stripping out all the inert traffic (which is usually well over 90 percent) and presenting the data that appears to be *interesting* to the operator. The operator then decides if the interesting data is problematic or indicative of a security violation or intrusion attempt, or whether it is simply a new form of routine inert activity such as the connection of a new server or the introduction of a new user.
- *Pattern matching* (also known as data modeling) is a bit more complex and much more interesting. In this method, the data is fit to known patterns of how intrusion attempts are frequently constructed. For example, there may be a series of pings, several other probing commands, followed by a brief period of analysis, and then the attempt to use the data obtained to gain access or cause denial of service. In its ideal state, this method can actually predict intrusions before they occur and give the operator or security manager a chance to take evasive action.

Most MSS providers offer data compression, but the ones that have developed a comprehensive pattern-matching technique have more to offer in that they can occasionally predict and prevent intrusions—whereas the data compression services can, at best, inform when an intrusion occurs.

Questions to ask when selecting an MSS provider include first determining if they are providing a NOC or SOC architecture (the pipe or the window). Second, determine if they compress data or pattern match. Third, review very carefully the qualifications of the people who monitor the security. In some cases they are simply a beeper service. ("Hello, Security Officer? You've been hacked. Have a nice day. Goodbye.") Other providers have well-trained incident response professionals who can describe how you can take evasive action or redesign the network architecture to prevent future occurrences.

There are several cost justifications for outsourcing security operations:

- The cost of the data compression and modeling tools is shared among several clients.
- The facility is available 24/7 and can be staffed with the best people at the most vulnerable time of day (nights, weekends, and holidays).
- The expensive technical skills that are difficult to keep motivated for a single network are highly motivated when put in a position of constant activity. This job has been equated to that of a military fighter pilot: 23 h and 50 min of total boredom followed by 10 min of sheer terror. The best operators thrive on the terror and are good at it.

- Patterns can be analyzed over a wide range of address spaces representing many different clients. This allows some advanced warning on disruptions that spread (like viruses and worms), and also can be effective in finding the source of the disruption (perpetrator).

54.4.2 Incident Response

The last area of outsourced security involves the response to an incident. A perfectly legitimate and popular strategy is that every organization will at some time experience an incident. The ones that successfully respond will consider that incident a minor event. The ones that fail to respond or respond incorrectly can experience a disaster. Incident response involves four specialties:

1. Intrusion detection
2. Employee misuse
3. Crime and fraud
4. Disaster recovery

54.4.2.1 Intrusion Detection

Best depicted by the previous description of the SOC, intrusion detection involves the identification and isolation of an intrusion attempt. This can be either from the outside, or, in the case of server-based probes, can identify attempts by authorized users to go to places they are not authorized to access. This includes placing sensors (these can be certain firewalls, routers, or IDSs) at various points in the network and having those sensors report activity to a central monitoring place. Some of these devices perform a simple form of data compression and can even issue an e-mail or dial a wireless pager when a situation occurs that requires attention.

54.4.2.2 Employee Misuse

Many attempts to discover employee abuse have been tried over the last several years, especially since the universal acceptance of Internet access as a staple of desktop appliances. Employees have been playing “cat and mouse” with employers over the use of the Internet search capabilities for personal research, viewing pornography, gift shopping, participation in unapproved chat rooms, etc. Employers attempt to monitor their use or prevent such use with filters and firewalls, and employees find new, creative ways to circumvent the restriction. In the United States, this is a game with huge legal consequences. Employees claim that their privacy has been violated; employers claim the employee is wasting company resources and decreasing their effectiveness. Many legal battles have been waged over this issue.

Outsourcing the monitoring of employee misuse ensures that independently defined measures are used across the board for all employees in all areas and at all levels. Using proper techniques for evidence collection and corroboration, the potential for successfully trimming misuse and dismissal or punishment of offenders can be more readily ensured.

54.4.2.3 Crime and Fraud

The ultimate misuse is the commission of a crime or fraud using the organization’s systems and facilities. Unless there is already a significant legal group tuned in to prosecuting this type of abuse, almost always the forensic analysis and evidence preparation are left to an outside team of experts. Successfully identifying and prosecuting or seeking retribution from these individuals depends very heavily on the skills of the first responder to the situation.

Professionals trained in data recovery, forensic analysis, legal interviewing techniques, and collaboration with local law enforcement and judiciary are crucial to achieving success by outsourcing this component.

54.4.2.4 Disaster Recovery

Finally, one of the oldest security specialties is in the area of disaster recovery. The proliferation of backup data centers, records archival facilities, and site recovery experts have made this task easier; but most still find it highly beneficial to retain outside services in several areas:

- *Recovery plan development*: including transfer and training of the organization’s recovery team
- *Recovery plan test*: usually periodic with reports to the executives and, optionally, the independent auditors or regulators
- *Recovery site preparation*: retained in advance but deployed when needed to ensure that the backup facility is fully capable of accepting the operation and, equally important, that the restored original site can resume operation as quickly as possible

All of these functions require special skills for which most organizations cannot justify full-time employment, so outsourcing these services makes good business sense. In many cases, the cost of this service can be recovered in reduced business interruption insurance premiums. Look for a provider that meets insurance company specifications for a risk class reduction.

54.4.3 Establishing the Qualifications of the Provider

For all these different types of security providers, there is no one standard measure of their qualifications. Buyers will need to fall back on standard ways to determine their vendor of choice. Here are a few important questions to ask that may help:

- What are the skills and training plan of the people actually providing the service?
- Is the facility certified under a quality or standards-based program (ISO 9000/17799, BS7799, NIST Common Criteria, HIPAA, EU Safe Harbors, etc.)?
- Is the organization large enough or backed by enough capital to sustain operation for the duration of the contract?
- How secure is the monitoring facility (for MSS providers)? If anyone can walk through it, be concerned.
- Is there a redundant monitoring facility? Redundant is different from a follow-the-sun or backup site in that there is essentially no downtime experienced if the primary monitoring site is unavailable.
- Are there SLAs (service level agreements) that are acceptable to the mission of the organization? Can they be raised or lowered for an appropriate price adjustment?
- Can the provider do all of the required services with its own resources, or must the provider obtain third-party subcontractor agreements for some components of the plan?
- Can the provider prove that its methodology works with either client testimonial or anecdotal case studies?

54.4.4 Protecting Intellectual Property

Companies in the security outsourcing business all have a primary objective of being a critical element of an organization’s trust initiative. To achieve that objective, strategic information may very likely be included in the security administration, operation, or response domains. Protecting an organization’s intellectual property is essential in successfully providing those services. Review the methods that help preserve the restricted and confidential data from disclosure or discovery.

In the case of incident response, a preferred contracting method is to have a pre-agreed contract between the investigator team and the organization’s attorney to conduct investigations. That way, the response can begin immediately when an event occurs without protracted negotiation, and any data collected during the investigation (i.e., password policies, intrusion or misuse monitoring methods) are protected by attorney-client privilege from subpoena and disclosure in open court.

54.4.5 Contracting Issues

Contracts for security services can be as different as night is to day. Usually when dealing with security services, providers have developed standard terms and conditions and contract prototypes that make sure they do not commit to more risk than they can control. In most cases there is some "wiggle room" to insert specific expectations, but because the potential for misunderstanding is high, I suggest supplementing the standard contract with an easy-to-read memo of understanding that defines in as clear a language as possible what is included and what is excluded in the agreement. Often, this clear intent can take precedence over "legalese" in the event of a serious misunderstanding or error that could lead to legal action.

Attorneys are often comfortable with one style of writing; technicians are comfortable with another. Neither is understandable to most business managers. Make sure that all three groups are in agreement as to what is going to be done at what price.

Most activities involve payment for services rendered, either time and materials (with an optional maximum), or a fixed periodic amount (in the case of MSS).

Occasionally there may be special conditions. For example, a prepaid retainer is a great way to ensure that incident response services are deployed immediately when needed. "Next plane out" timing is a good measure of immediacy for incident response teams that may need to travel to reach the site. Obviously, a provider with a broad geographic reach will be able to reach any given site more easily than the organization with only a local presence. Expect a higher rate for court testimony, immediate incident response, and evidence collection.

54.4.6 Quality of Service Level Agreements

The key to a successfully managed security agreement lies in negotiating a reasonable service level agreement. Response time is one measure. Several companies will give an expected measure of operational improvement, such as fewer password resets, reduced downtime, etc. Try to work out an agreeable set of QoS factors and tie a financial or an additional time penalty for response outside acceptable parameters. Be prudent and accept what is attainable, and do not try to make the provider responsible for more than it can control. Aggressively driving a deal past acceptable criteria will result in no contract or a contract with a servicer that may fail to thrive.

54.4.7 Retained Responsibilities

Despite what domain of service is selected or the breadth of activities that are to be performed, there are certain cautions regarding the elements that should be held within the organization if at all possible.

54.4.7.1 Management

The first of these is management. Remember that management is responsible for presenting and determining the culture of the organization. Internal and external expectations of performance are almost always carried forth by management style, measurement, and communications, both formal and informal. Risk of losing that culture or identity is considerably increased if the management responsibility for any of the outsourced functions is not retained by someone in the organization ultimately accountable for their performance. If success is based on presenting a trusted image to partners, customers, and employees, help to ensure that success by maintaining close control over the management style and responsibility of the services that are acquired.

54.4.7.2 Operations

Outsourcing security is not outsourcing business operation. There are many companies that can help run the business, including operating the data center, the financial operations, legal, shipping, etc. The same company that provides the operational support should not, as a rule, provide the security of that operation. Keep the old *separation of duties* principle in effect. People other than those who perform the operations should be selected to provide the security direction or security response.

54.4.7.3 Audit and Oversight

Finally, applying the same principle, invite and encourage frequent audit and evaluation activities. Outsourced services should always be viewed like a yoyo. Whenever necessary, an easy pull on the string should be all that is necessary to bring them back into range for a check and a possible redirection. Outsourcing security or any other business service should not be treated as a "sign the contract and forget it" project.

54.4.7.4 Building an Escape Clause

But what if all this is done and it still looks like we made a mistake? Easy. If possible, build in an escape clause in the outsource contract that allows for a change in scope, direction, or implementation. If these changes (within reason) cannot be accommodated, most professional organizations will allow for an escape from the contract. Setup and equipment charges may be incurred, but those would typically be small compared to the lost time and expense involved in misunderstanding or hiring the wrong service. No security service organization wants a reference client that had to be dragged, kicking and screaming, through a contract simply because the name is on the line when everyone can agree that the service does not fit.

54.5 The Future of Outsourced Security

54.5.1 Industries Most Likely to Outsource

The first category of industries most likely to outsource security is represented by those companies whose key assets are the access to reliable data or information service. Financial institutions, especially banks, securities brokers, and insurance, health, or property claims operations, are traditional buyers of security services.

Recent developments in privacy have added healthcare providers and associated industries to that list. Hospitals, medical care providers, pharmaceuticals, and health-centered industries have a new need for protecting the privacy of personal health information. Reporting on the success of that protection is often a new concept that neither meets the existing operation nor justifies the full-time expense. HIPAA compliance will likely initiate a rise in the need for security (privacy) compliance providers.

The third category of industry that frequently requires outsourced security is the set of industries that cannot suffer any downtime or show any compromise of security. Railroads, cargo ships, and air traffic control are obvious examples of the types of industries where continuous availability is a crucial element for success. They may outsource the network operation or periodic review of their response and recovery plan. Internet retailers that process transactions with credit cards or against credit accounts fit into this category. Release of credit card data, or access to or changes made to purchasing history, is often fatal to continued successful operation.

The final category of industry that may need security services are those industries that have as a basis of their success an extraordinary level of trust in the confidentiality of their data. Taken to the extreme, this can include military or national defense organizations. More routinely, this would include technology research, legal, marketing, and other industries that would suffer severe image loss if it were revealed that their security was compromised or otherwise rendered ineffectual.

54.5.2 Measurements of Success

I once worked on a fairly complex application project that could easily have suffered from "scope creep." To offset this risk, we encouraged the user to continually ask the team, "How do we know we are done?" This simple question can help identify quite clearly what the expectations are for the security service, and how success is measured. What comes to my mind is the selection of the three milestones of project success: "scope, time, and cost—pick two out of three." A similar principle applies to measuring the success of security services. They are providing a savings of risk, cost, or effort. Pick two out of three. It is impractical to expect that everything can be completely solved at a low cost with total confidence. Security servicers operate along the same principles. They can explain how you can experience success, but only in two out of three areas. Either they save money, reduce risk, or take on the complexity of securing the enterprise. Only rarely can they do all three. Most can address two of these measures, but it lies to the buying organization to determine which of these are the two most important.

54.5.3 Response of MSS (Managed Security Service) Providers to New World Priorities

After September 11, 2001, the security world moved substantially. What was secure was no longer secure. What was important was no longer important. The world focused on the risk of personal safety and physical security and anticipated the corresponding loss of privacy and confidentiality. In the United States, the constitutional guarantee of freedom was challenged by the collective need for personal safety, and previously guaranteed rights were brought into question.

The security providers have started to address physical safety issues in a new light. What was previously deferred to the physical security people is now accepted as part of the holistic approach to risk reduction and trust. Look for an integration of traditional physical security concepts to be enhanced with new technologies like digital facial imaging, integrated with logical security components. New authentication methods will reliably validate "who did what where," not only when something was done on a certain device.

Look also for an increase in the sophistication of pattern matching for intrusion management services. Data compression can tell you faster that something has happened, but sophisticated modeling will soon be able to predict with good reliability that an event is forming in enough time to take appropriate defensive action.

We will soon look back on today as the primitive era of security management.

54.5.4 Response of the MSS Buyers to New World Priorities

The servicers are in business to respond quickly to new priorities, but managed security service buyers will also respond to emerging priorities. Creative solutions are nice, but practicality demands that enhanced security be able to prove itself in terms of financial viability.

I believe we will see a new emphasis on risk management and image enhancements. Organizations have taken a new tack on the meaning of *trust* in their industries. Whether it is confidentiality, accuracy, or reliability, the new mantra of business success is the ability to depend on the service or product that is promised. Security in all its forms is key to delivering on that promise.

54.6 Summary and Conclusions

Outsourced security, or managed security services (MSS), will continue to command the spotlight. Providers of these services will be successful if they can translate technology into real business metrics. Buyers of that service will be successful if they focus on the measurement of the defined objectives that managed services can provide. Avoid the attraction offered simply by a recognized name and get down to real specifics.

Based on several old and tried methods, there are new opportunities to effectively use and build on the skills and economies of scale offered by competent MSS providers. Organizations can refocus on what made them viable or successful in the first place: products and services that can be trusted to deliver on the promise of business success.

55

The Ethical and Legal Concerns of Spyware

Janice C. Sipior
Burke T. Ward
Georgina R. Roselli

Spyware is regarded as the largest threat to Internet users since spam, yet most users do not even know spyware is on their personal computers (PCs). Spyware (a.k.a. adware, foistware, malware, pestware, scumware, sneakware, snoopware, and trespassware) includes "[a]ny software that covertly gathers user information through the user's Internet connection without his or her knowledge, usually for advertising purposes" (FTC, 2004b). The definition is so broad that it may cover software that is beneficial and benign or software that has poorly written, inefficient code (FTC, 2004c). The Center for Democracy and Technology, a policy research group, has proposed that software that hijacks Web traffic, tracks Internet users without their knowledge and consent, and is not easily removable should be considered spyware.

"Spyware appears to be a new and rapidly growing practice that poses a risk of serious harm to consumers" (FTC, 2004a). An estimated 7,000 spyware programs run on millions of corporate and personal computers. A study in May 2003 reported that 91 percent of home PCs are infected with spyware (Richmond 2004). Gartner Research estimates that over 20 million people have installed spyware applications on their PCs. According to Microsoft, spyware is responsible for half of all PC crashes. Spyware complaints are the most common reason for consumers to contact Dell Tech Support Services (Urbach and Kibel, 2004), with about 20 percent of calls related to spyware or viruses, up from 2 percent for the previous 18 months.

The increasing prevalence of spyware is not unlike the unintended use of cookies, a Web-tracking and information-gathering technique for obtaining personal information from Web users, often without their knowledge. While information concerning user characteristics and preferences collected via cookies may be used beneficially to improve product and service offerings to consumers, the surreptitious nature of its acquisition coupled with no indication of its intended use can raise ethical issues regarding the acceptability of privacy invasions in Web use. However, the consequences of spyware can be more severe. For industry sectors that are subject to data collection laws, such as the Health Insurance Portability and Accountability Act and Sarbanes–Oxley Act, spyware can unwittingly result in noncompliance. Section

404 of Sarbanes–Oxley requires publicly held companies to annually evaluate their financial reporting controls and procedures. The security and privacy of proprietary information and systems cannot be guaranteed should stealth spyware arrive.

This article examines the controversy surrounding spyware. First, the types of spyware are overviewed. The ethical and legal concerns of spyware, including trespass, privacy invasion, surreptitious data collection, direct marketing, and hijacking, are then discussed. Finally, the various methods of battling spyware, including approaches by individual users, organizations, and U.S. Government oversight, legislation, and litigation, are addressed.

55.1 Types of Spyware

Spyware has been variously categorized on the basis of the activities it performs. EarthLink (an Internet service provider) and Webroot Software, Inc. (an anti-spyware software maker) audited over 4 million PCs in 2004 and found 116.5 million instances of spyware, averaging 25 instances of spyware per PC. As shown in Exhibit 55.1, over 90 million (78 percent) of these items were adware cookies. Excluding cookies, the average instance of spyware per PC is nearly 5.

55.1.1 Adware Cookies

Adware cookies are files containing information about a user's Web site interaction, which can be exchanged between the Web site, the user's hard drive, and back. Originally intended for innocuous purposes such as keeping track of items in an online shopping cart, simplifying the log-in process, and providing users with customized information based on stated interests, cookies can be used to create a profile of a user's online behavior without that user's knowledge or consent.

55.1.2 Adware

Adware is used for direct marketing on the Web, with or without user consent. By monitoring users' Web browsing or by using detailed target market profiles, adware delivers specific advertisements and offerings, customized for individual users as they browse the Web. These advertisements can take the form of pop-up or pop-under ads, Web banners, redirected Web pages, and spam e-mail. An example of a redirected homepage and default search engine is presented in Exhibit 55.2. This example results from visiting a known spyware site such as www.yahoogamez.com. (Do not visit this site!) The get_http (HyperText Transfer Protocol) command returns the HyperText Markup Language (HTML) of the Web site whose address is 209.50.251.182, which is an Internet Protocol (IP) address rather than a hostname. The HTML from this site is downloaded. Within this HTML are commands that redirect the homepage and the default search engine of the user's browser.

EXHIBIT 55.1 Earthlink's 2004 Spyware Audit

	Number of Instances of Spyware Found				
Type of Spyware	1st Quarter	2nd Quarter	3rd Quarter	4th Quarter	Total (%)
Adware	3,558,595	7,887,557	5,978,018	6,971,086	24,395,256 (21%)
Adware cookies	14,799,874	27,868,767	22,327,112	25,598,803	90,594,556 (78%)
System monitors	122,553	210,256	154,878	272,211	759,898 (<1%)
Trojans	130,322	236,639	148,214	254,155	769,330 (<1%)
Total	18,611,344	36,203,219	28,608,222	33,096,225	116,519,040

55.1.3 Trojan Horses

A malicious form of spyware named for the Trojan horse from Greek history, a Remote Administration Trojan (RAT), or Trojan, can take control of a user's computer by installing itself with a download and taking directions from other computers it contacts via the Internet. Trojans can turn a PC into a spam proxy without user knowledge or use Microsoft Outlook e-mail as if it were a browser to allow for a torrent of pop-up ads. Trojans can also be designed to steal data or damage computer files.

55.1.4 System Monitors

This form of spyware, also referred to as keystroke loggers, surreptitiously collects data from user–computer interaction, both locally and online. User keystrokes and mouse-clicks can be recorded while shopping or banking on the Web and locally while using software such as spreadsheets or videogames. This data can be transmitted back to the spyware installer, shared with other businesses such as marketers, or sold to data consolidators.

55.2 The Ethical and Legal Concerns of Spyware

The controversy surrounding spyware results from ethical and legal concerns associated with its distribution and capabilities. The issues, including trespass, privacy invasion, surreptitious data collection, direct marketing, and hijacking, are discussed below.

55.2.1 Trespass

Spyware usually arrives uninvited from file-sharing services as hidden components bundled with desired downloads such as screen savers, music-swapping software, or other freeware of shareware but can also be included with purchased software. Spyware can masquerade as a legitimate plug-in needed to launch a certain program or pose as a browser help object, such as a toolbar. Users may unwittingly consent and accept spyware by agreeing to, but not thoroughly reading, the license presented when installing such software. Spyware can also be distributed in a variety of stealth ways. For example, a "drive-by download" starts a download process when a user visits a Web site or clicks on a Web ad. In peer-to-peer networks, spyware can hide in group directories and spread itself through infestation of the directories on a user's PC. Users can also be tricked into installing spyware. A message box might appear saying, "To install this program, click 'No'," prompting a user to unknowingly click for installation. Spyware can also covertly install other spyware programs as part of an "auto-update" component. This creates new security vulnerabilities by including capabilities to automatically download and install additional programs.

The idea of others installing software, undetected, on an individual's hard drive may be offensive. Once installed, spyware utilizes the user's own resources, potentially without the user's knowledge and express permission. Spyware's monitoring or controlling of PC use can significantly slow the performance of basic tasks such as opening programs or saving files. Random error messages, pop-up ads, or a surprise homepage may appear when opening the browser. New and unexpected toolbars or icons may appear on the user's desktop. Common keys, such as tab, may no longer function. The transmission of user information gathered by spyware uses valuable bandwidth and threatens the security of computers and the integrity of online communications. Even with the use of anti-spyware software, removal can be difficult. Knowledge of how to manipulate the Windows registry is required for persistent spyware. Diagnosing compromised system performance and removing spyware places a substantial burden on users or corporate support departments.

Uninvited stealth spyware is particularly insidious and could arguably be considered trespassing. Users should be able to maintain control over their own computer resources and Internet connection. They should not be disallowed from using their own computer as they personally desire and should have the ability to remove, for any reason and at any time, unwanted programs. Applying common law, this unauthorized invasion is called trespass to chattels (i.e., personal property). This is a legal remedy for an individual, not a governmental remedy that protects society generally. Governmental remedies, such as actions by the Federal Trade Commission (FTC), are discussed later, in the section addressing U.S. legislation.

According to the Restatement (Second) of Torts, §217, a trespass to chattel can be committed by intentionally:

- Dispossessing another of the chattel, or
- Using or intermeddling with a chattel in the possession of another.

Although not yet applied in any legal action, it is arguable that a computer user is dispossessed, not physically of course, but at least constructively, by the uninvited spyware when the operation of the PC is impaired through hijacking, crashing, or disruption of performance. At a minimum, the spyware installer is using and intermeddling with the user's possession through unauthorized data collection, control of his browser, Web page redirection, search engine substitution, pop-up ads, and hijacking. Possession is defined in §216 as "physical control … with the intent to exercise such control on his own behalf, or on behalf of another." Spyware clearly interferes with control and therefore should be subject to legal action.

If the unauthorized installation of spyware is actionable as a trespass to chattel, the installer should be liable to the injured party. The Restatement at §218 states that "[O]ne who commits a trespass to a chattel is subject to liability to the possessor of the chattel if, but only if,

- He dispossesses the other of the chattel, or
- The chattel is impaired as to its condition, quality, or value, or
- The possessor is deprived of the use of the chattel for a substantial time, or
- Bodily harm is caused to the possessor, or harm is caused to some person or thing in which the possessor has a legally protected interest."

Depending on the characteristics and purpose of the spyware, at least one, and possibly all, of these consequences will be present.

55.2.2 Privacy Invasion

Privacy is one of the major concerns raised by spyware. The privacy concern is based mainly on the potential for intrusions into a user's computer resources for surreptitious data collection, dissemination of an individual's private information, and uninvited direct marketing. Spyware "install[s] itself without your permission, run[s] without your permission, and use[s] your computer without your permission" (Baker, 2003). Without having knowingly provided permission for the installation of spyware, the user is likely to see spyware as a violation of privacy.

Is the user's privacy legally protected? There is no definitive answer. The full extent of privacy rights within the United States remains unclear. Recognition of privacy rights within the United States did not occur until the late 1800s (Warren and Brandeis, 1890). Almost a half century ago, privacy was recognized as, in part, a spiritual issue, the unprivileged invasion of which is an affront to individuality and human dignity (Bloustein, 1964). Are the actions of spyware such an unethical affront to individual human dignity, to be afforded legal protection? Currently, privacy protection in the United States is an incomplete but complex amalgam of federal and state constitutions, statutes, and regulations. The scope of privacy protection provided by each legal source varies. Therefore, the reasonableness of a user's expectation of privacy differs depending on whether the claim is made under constitutional, common, or statutory law. The resolution of the issue will ultimately require either federal legislation or a seminal legal case in which the user's reasonable expectation of privacy is determined.

55.2.3 Surreptitious Data Collection

Spyware, such as system monitors, can surreptitiously capture personal information stored or typed into a PC. Hard drives can be scanned to obtain information from a user's files and application programs such as e-mail, word processors, and games. User keystrokes and mouse-clicks can be recorded during both Internet access and local PC use, in playing videogames for example. Information obtained, such as user behavior, financial data, credit card numbers, passwords, and ID-tagged downloads, can be transmitted to the spyware installer and partners for marketing or fraudulent purposes. These sites can "phish" for data from user inputs while surfing, banking, and making purchases, or promote pornography, gambling, or fraudulent schemes. An investment broker recently lost $540,000 after he installed spyware disguised as a phony market analysis program that transmitted his account information to hackers. Other sinister uses may evolve, such as capturing and transmitting Word and Excel documents to steal corporate secrets or recording telephone conversations when a suitable modem is attached to the PC.

Spyware uses novel approaches to collect data, such as adware cookies. Avoiding Web sites that place cookies on your hard drive, however, does not eliminate them. Spam e-mail can contain cookies that are read by the originating server and matched to the user's e-mail address. The information gathered by cookies can beneficially increase convenience in the online shopping experience and allow for personalized marketing strategies to be employed. However, without informed consent for specific information collection, cookies can be viewed as "a self-serving act of capitalist voyeurism" (Stead and Gilbert, 2001).

Another novel form of spyware is the "Backdoor Santa," a stand-alone program that gathers user information. A popular example of this spyware is a novelty cursor representing a seasonal icon or the likeness of Dilbert or a Peanuts character. Using a Globally Unique IDentifier (GUID), issued when the program is downloaded, the provider's servers are contacted to record logs of cursor impressions, the identity of referrers, Internet Protocol (IP) addresses, and system information, all without user awareness. The date collected by the provider is given to paying clients to inform them of how many individual users have customized cursors obtained from specific sites.

Ethically, spyware installers have an obligation to users to obtain informed consent for the collection and use of personal information. However, in the commercially competitive environment of E-commerce, information gathering may be undertaken without user's knowledge or permission. The mere awareness, on the part of an end user, of the existence of spyware may impart an eerie feeling during computer use. The knowledge that someone, somewhere, may be tracking every mouse-click and every keystroke can be unsetting. Even if users were aware of all the data collected about them, they would still have little idea of how that data is used, by whom, and the resulting direct marketing that can result. Perhaps users having comprehense information about what date is being collected, when and for what purpose, and what impact such activities can have on computer performance, as well as being presented with the opportunity to grant permission, could remove the stealth reputation of these activities.

55.2.4 Direct Marketing

Adware serving networks pay software companies to include spyware with their legitimate software such as games, utilities, and music/video players for the purpose of gathering user preferences, characteristics, and online behavior. Using programs installed on the user's computer, this user information is sent to the advertiser that serves the targeted ad. Such marketing activity is expected to continue to increase, raising concerns about its acceptability. The Direct Marketing Association (DMA) projects a growth rate in interactive media expenditures of 18.9 percent annually, reaching US $5.0 billion in 2006. Adware can be used beneficially to improve product and service offering to consumers. For example, a determination of what advertisements a Web site visitor has already seen can be made so that only new ads are presented during future visits. Such tracking allows for a personalized screening capability, thus reducing information overload. A user's online usage and interests can also be used to determine what other sites are visited, thereby allowing identification of potential affiliate Web sites. Such use seems rather innocuous and perhaps even desirable; however, if used to promote pornography, gambling, or fraudulent schemes, adware becomes a questionable medium. Further contributing to the unacceptability of adware is the practice of browser hijacking, disallowing the user control of his own browser. The user should receive adequate notice of and permission for the installation of spyware (with the capability to uninstall it) for the explicit purpose of exchanging user information for the benefits of adware. Although adware applications are usually disclosed in the End User Licensing Agreement (EULA) of the software it accompanies and can be uninstalled from the user's system, such disclosures may not be read. Without explicit user permission, the user is likely to object to and be offended by the delivery of adware.

55.2.5 Hijacking

Spyware, such as Trojan horses, can persistently disallow user control over his computing resources, precluding his use of the system and compromising system security. Most users are not aware of the depth of penetration into their systems. The browser's homepage, default search engine, bookmarks, and toolbars can be changed to persistently present a competitor's Web site or a look-alike site. Mistyped URLs can be redirected to pornographic sites and pop-up advertising can be presented. Web sites may be launched without any action on the part of the user. Dialers can use a telephone modem to dial into a service, such as a pornographic 900 number, for which the user is then billed. System settings can be modified. For example, the auto signature can be reset; uninstall features can be disabled or bypassed; and anti-virus, anti-spyware, and farewell software can be modified. McAfee, an intrusion prevention software provider, first detected a homepage hijacking program is July 2002. As of July 2004, there were more than 150 hijacker spyware programs (Gomes, 2004). Hijacking is particularly offensive due to its persistent nature.

55.3 Battling Spyware

The approaches to reduce unwanted spyware include individual user vigilance, organizational initiatives, U.S. Federal Trade Commission (FTC) oversight, legislation, and litigation, as shown in Exhibit 55.3 None of these approaches alone has been effective. Rather, battling spyware requires a combination of these approaches.

55.3.1 Individual User Vigilance

Individual users can undertake some defense against spyware through vigilance in interacting with the Internet and properly managing their computing resources. First and foremost, a user needs to be vigilant in downloading files. Before installing any software, a user should carefully read the EULA. Ethically, any spyware bundled with the download should be disclosed in this “clickwrap” agreement. There may be an opt-out option to avoid downloading spyware, but this does not occur frequently. If a pop-up window

2. Claria Corporation (formerly Gator) multidistrict litigation case
3. WhenU.com’s multiple cases

appears to ask the user, “Do you want to install this software?” the user should avoid clicking no, which may result in unwanted installation. Rather, the user should close the window with the “X” window closer or press Alt and F4. Another safeguard is to check for disclosures about downloads by searching for the name of the software followed by “spyware” using a search engine. Do not install software without knowing exactly what it is.

Users can take additional actions to reduce the potential for spyware. Avoid peer-to-peer networks, which offer downloads containing spyware because of revenues generated from advertising with which it is packaged, and visit only known Web sites to minimize drive-by downloads. Remember that Web links on Web sites, within pop-up windows, or in e-mails can be masked to look like legitimate links. Do not use instant messengers or shopping or search helpers. Software for purchase, such as videogames, may also contain spyware to capture user behavior to support ad placement and pricing within the software. Run a virus check on unfamiliar files. Update operating system and Web browser software to obtain patches to close holes in the system that spyware could exploit. Set the browser security setting to Medium or High to detect download attempts. Turn off the PC when not in use.

55.3.2 Organizational Initiatives

Organizations cannot rely on individual user vigilence as a defense against spyware. Organizations should thoroughly educate users about the types and risks of spyware through spyware awareness training and create user policies that minimize the occurrence of spyware corruption. More importantly, organizations should pursue technological approaches to reduce spyware. Additionally, the Windows Hosts file or the Proxy Automatic Configuration (PAC) file in the browser can be used to block access to Web sites known for spyware.

55.3.2.1 Employee Education and Organizational Policies

Employees need to understand that their downloading and Web-surfing habits can lead to an increased amount of spyware infestation. PC and Internet use policies should explicitly forbid visitation of Web sites known for placing spyware, such as those promoting pirated software, gambling, and pornography. Employees should be encouraged to report unwitting or accidental visits resulting from typos or clicking on the wrong links, for example, with an assurance that they will not be reprimanded for such mistakes. Additionally, organizational policy should prohibit peer-to-peer file sharing and downloading freeware or shareware. Further, PC use by anyone other than the employee, such as family members and other unauthorized users, should be disallowed. Finally, organizations should consider requiring the use of alternative Internet browsers and instruct users on appropriate browser settings. Alternatives to Microsoft’s Internet Explorer (IE), the standard Internet browser, are currently more secure due, in part, to the fact that these alternate browsers are smaller targets for malware authors. Alternatives such as Mozilla’s Firefox are competent browsers that are free to users.

55.3.2.2 Technological Approaches

Technological approaches directed toward eradicating spyware include setting operating system and browser features to block Web sites and installing security software. Additionally, organizations are encouraged to utilize server-based applications, as they are less susceptible to attack, and to keep operating system software up-to-date.

55.3.2.2.1 Hosts File and Proxy Automatic Configuration File

The Hosts file within operating systems such as Windows, Linux, or UNIX, and the Proxy Automatic Configuration (PAC) file within browsers such as IE, Firefox, and Netscape Navigator, are two alternatives available to IP network administrators. To use either of these approaches, a list of Web sites, or even Web pages, to not visit must be created. The Hosts file or the PAC file is then edited to include the list, thereby blocking access to Web sites known for spyware. The Windows Hosts file, for example, is found under c:\windows\system32\drivers\etc and has no extension. This text file is used to associate host names with IP addresses. Any network program on the organization’s system consults this file to determine the IP address that corresponds to a host name. When a Web address, called a domain name, is typed into a browser, the browser first checks the Hosts file. The central Domain Name System (DNS) server is then contacted to look up the numeric equivalent of the Web address, the IP address, necessary to locate the Web site to be displayed. If the Hosts file contains an IP address for the domain name to be visited, the browser never contacts the DNS to find the number. The Hosts file can be edited in Notepad to enter or update a list of known spyware sites and redirect them to 127.0.0.1 (which is the IP address the computer uses to refer to itself, the local host). This will effectively block any requests made to undesirable sites because the domain name of such Web sites will point to the local host. Hosts files can only block entire Web sites, while PAC files can block addresses of individual Web pages within a site. The user is thus afforded greater control over what is blocked. A Web site with desirable content may also serve ads via individual Web pages, which can selectively be blocked. The PAC file is written in JavaScript, introduced with Netscape Navigator 2.0 in 1996 (LoVerso 2004). The browser evaluates a JavaScript function for every URL (i.e., Web page) to be displayed. Like the Hosts file, the JavaScript function in the PAC file blocks access by redirecting the requested Web page to the local host.

55.3.2.2.2 Security Software

Security software solutions include anti-spyware software, firewalls, and spyware blockers. A recent, concentrated effort on the part of software makers is bringing a proliferation of anti-spyware initiatives for the corporate world to market. The market for anti-spyware software is still small, with $10 to $15 million in sales, compared to the $2.2 billion anti-virus software industry. Effective anti-spyware software should identify the spyware threat, as well as provide an informative explanation of the nature and severity of the detected threat, and allow the user to decide what to remove. To date, no anti-spyware utility can provide an impenetrable defense. Attracted to the potential to generate advertising revenue, professional programmers continue to refine spyware to make it difficult to identify and remove. Therefore, at least two anti-spyware tools should be used, as the first may not detect something that another tool does. Further, every network or PC that accesses the Internet should have its own firewall to block unauthorized access and provide an alert if spyware, sending out information, is already resident. Defensive spyware blocker software can also detect and stop spyware before it is installed.

Anti-spyware software vendors face many gray areas as they attempt to eradicate adware and potentially unwanted programs (PUPs). For example, McAfee's VirusScan 8.0 will detect PUPs on a computer, including adware programs, but will only delete them if the PUP is in direct opposition to the terms stated and agreed to in its EULA. If the user had given consent to download the adware, when all functions of the software were accurately represented, eradication of the program by McAfee becomes more difficult.

PestPatrol Corporate Edition, owned by Computer Associates, has a central management console that lets administrators scan desktops for spyware, quarantine infected systems, and cleanse them. Zone Labs, Symantec, and Cisco plan to release anti-spyware programs for enterprise systems. By the end of 2005, firewall, anti-virus protection, and behavior-based protection will be available in one integrated software package.

55.3.3 Government Oversight and Legislation

The U.S. government has recently begun to investigate the effects and legitimacy of spyware, with the FTC leading the charge. While legislation has been proposed at the federal level in the Senate and House of Representatives, some states have already imposed regulations. Spyware has not yet caused widespread public outcry because most users are unaware that their systems have been compromised.

55.3.3.1 Federal Trade Commission Oversight

The FTC has stated that "spyware appears to be a new and rapidly growing practice that poses a risk of serious harm to the consumers." Furthermore, the FTC feels that government response "will be focused and effective" (FTC, 2004c). The FTC currently has legal authority to take action, both civilly and criminally, against spyware installers. Civil action would be brought under the Federal Trade Commission Act §5 to regulate "*unfair or deceptive acts or practices*." Criminal action would be brought under the Computer Fraud and Abuse Act to provide remedies against whoever "knowingly and with intent to defraud, accesses a protected computer without authorization, or exceeds authorized access, and by means of such conduct furthers the intended fraud and obtains anything of value." The FTC conceded that if the spyware infiltration continues, there could be "loss in consumer confidence in the Internet as a medium of communication and commerce" (FTC, 2004c).

The FTC is endorsing the use of self-regulatory measures, as opposed to the introduction of regulating legislation, through a series of workshops and hearings. lndustry and consumer and privacy advocates have met to address the online privacy and security issues of spyware and to encourage and facilitate industry leaders to develop and implement effective self-regulatory programs. Additionally, a variety of education and civil enforcement initiatives have been undertaken to reduce the negative effects of personal information disclosure, such as identity theft, violations of privacy promises, and breaches of customer databases.

In response, companies whose spyware is installed with free software have improved methods for disclosure and removal. According to Urbach and Kibel (2004), most reputable and responsible technology providers feel that adherence to the following five principles is crucial for all adware providers and those who take advantage of their services:

1. Clear and prominent notification must be presented to the user prior to downloads or data collection. Additionally, the EULA should contains such notification.
2. The user has the opportunity to accept the terms of the application for both access to the user's PC and to any communications between a user's PC and the Internet.
3. Easy removal procedures to uninstall any unwanted applications should be provided.
4. Branding of pop-up windows should be clear so there is no confusion regarding the source of the ad.
5. Internet businesses should adhere to all applicable laws and best business practices.

55.3.3.2 U.S. Federal Legislation Introduced during the l08th Session of Congress

The U.S. Congress has begun to study and debate various initiatives to address concerns associated with spyware. At the time of writing, a number of legislative proposals were pending in Congress. Each is discussed below and presented in Exhibit 55.3 (see III.B).

The Safeguard Against Privacy Invasions Act (H.R. 2929) was introduced in the U.S. House of Representatives on July 23, 2003. The bill directs the FTC to prohibit the transmission of spyware to a computer system used by a financial institution or the federal government by means of the Internet. The bill requires conspicuous notification of the installation of spyware. Furthermore, it requires the FTC to establish requirements for the transmission of an application through affirmative action on the part of the user. Also, the spyware installer would need to disclose valid identification. Violators could be fined up to $3 million. On October 5, 2004, the House voted to pass the bill and referred it to the U.S. Senate.

The Internet Spyware (I-SPY) Prevention Act of 2004 (H.R. 4661) was introduced in the House on June 23, 2004. This bill amends the federal criminal code to prohibit intentionally accessing a protected computer without authorization to install spyware to transmit personal information with the intent to defraud or injure an individual or cause damage to a protected computer. Penalties of up to five years in prison for certain crimes committed with spyware are included. In addition, $10 million would be provided annually to the Justice Department for enforcement. The House voted to pass this bill on October 7, 2004, and referred it to the Senate.

The Software Principles Yielding Better Levels of Consumer Knowledge (SPYBLOCK) Act (S. 2145) was introduced in the Senate on February 27,2004. This bill addresses the use of spyware on computers systems used in interstate or foreign commerce and communication. It makes the installation of spyware unlawful unless the user has received notice and granted consent and there are software uninstall procedures that meet requirements set forth. The notice to the user must be clearly displayed on the screen until the user either agrees or denies consent to install and a separate disclosure concerning information collection, advertising, distributed computing, and settings modifications must be featured. Interestingly, the bill does not attempt to define spyware: Instead, the bill applies to "any computer program at all that does not comply with its notice, choice, and uninstall requirements" while making exceptions for technologies such as cookies, preinstalled software, e-mail, and instant messaging (Urbach and Kibel, 2004). At the time of writing, the bill was pending in the Senate.

The Piracy Deterrence and Education Act of 2004 (H.R. 4077), introduced in the House on March 31, 2004, touts the dangerous activity on publicly accessible peer-to-peer file-sharing services. It stresses that appropriate measures to protect consumers should be considered. Similarly, the FTC has already warned the public not to use file-sharing programs, due to the inherent risks associated with such activity. This bill was passed by the House on September 29, 2004, and referred to the Senate.

55.3.3.3 State Legislation

On March 23, 2004, the governor of Utah signed the nation's first anti-spyware legislation. The Spyware Control Act prohibits the installation of software without the user's consent, including programs that send personal information. Under this law, only businesses are given the right to sue. This has resulted in the view that the Utah law was drafted to protect businesses and not the privacy of individual consumers. Spyware is indeed a major concern for businesses. If customer information is stolen from a firm's system, that firm may be liable under data protection regulations; however, legislation has yet to be enforced. At the time of writing, litigation from the adware firm WhenU.com has resulted in a preliminary injunction against it.

In California, the governor signed into law the SB 1436 Consumer Protection Against Computer Spyware Act on September 28, 2004. Effective January 1, 2005, this law prohibits the installation of software that deceptively modifies settings, including a user's homepage, default search page, or bookmarks, unless notice is given. Further, it prohibits intentionally deceptive means of collecting personally identifiable information through keystroke-logging, tracking Web surfing or extracting information from a user's hard drive. A consumer can seek damages of $1,000, plus attorney fees, per violation. At the time of writing, Iowa, New York, and Virginia were considering anti-spyware measures.

55.3.3.4 Possible Roadblocks to Legislation

Passage of legislation has been slow because broad legislation could prohibit legitimate practices and stifle innovation. Protecting consumers' concerns must be carefully balanced against the beneficial use of spyware as a legitimate marketing tool. Interactively capturing behavioral measures provides marketers with greater insight and precision, compared to traditional media, to improve product offerings and target advertisements to receptive consumers. Furthermore, definitions may be ineffective upon becoming law because innovation occurs so quickly, while the passage of legislation is a slower process. The Direct marketing Association has compared the efforts to regulate spyware to those of spam, in that in the absence of effective enforcement, the legislation itself is toothless and may cause harm to legitimate businesses.

55.3.4 Federal Litigating

In the first spyware case brought by the FTC, *Federal Trade Commission, Plaintiff, v Seismic Entertainment Productions, Inc., SmartBot.net, Inc., and Sanford Wallace*, on October 12, 2004, the defendants were charged with unfair acts or practices in violation of section 5(a) of the FTC Act, 15 U.S.C. §45(a), which outlaws "unfair or deceptive acts or practices in or affecting commerce." The FTC alleges that these defendants engaged in an unfair and deceptive practice by downloading spyware onto the computers of consumers without advance notice or permission. This spyware hijacked consumers' homepages and search engines, presented a torrent of pop-up ads, and installed adware and other software programs to capture consumers', Web-surfing behavior. Further the spyware may cause computers to malfunction, slow down, or even crash. As a result, consumers were compelled to either purchase the $30 anti-spyware software sold by the defendants, for which they received a commission, or spend substantial time and money to fix their computers. At the time of writing, the FTC asked a U.S. District Court to issue an order preventing the defendants, from installing spyware and foregoing their proceeds.

Leaving unresolved the question of the legality of pop-up adware, a series of legal cases have been settled out of court by Claria corporation, formerly known as Gator. As many as 13 cases were consolidate into one multidistrict case. A lawsuit brought by retail florist Teleflora, filed in April 2004, is still pending. Claria was sued for copyright and trademark violations by Hertz, L. L. Bean, Quicken Loans, six Continents, Tiger Direct, UPS, *The Washington Post*, Well Fargo, and others for presenting competing ads to appear atop or under the plaintiff's sites. Claria's advertisements are included with free downloads from peer-to-peer applications such us KaZaa. Once downloaded, pop-up and pop-under ads appear when user surf or visit specific sites. The terms of the settlements were not disclosed.

The legality of pop-up adware could still be determined through lawsuits. WhenU.com, a competitor of Claria, has also been sued by numerous corporations, including 1-800-Contacts, Quicken Loans, U-Haul, and Wells Fargo. Unlike Claria, WhenU.com was not able to consolidate its cases. In September of 2003, a federal court in Virginia granted WhenU.com's motion for summary judgment against U-Haul, the plaintiff. The court stated that WhenU.com did not commit copyright infringement nor did they infringe on the trademarks of U-Haul. Moreover, the pop-up advertisements, although annoying, were permissible because end users consented to installation in the EULA. U-Haul has appealed the ruling. In November of 2003, a federal court in Michigan denied a motion for summary judgment by the plaintiff Wells Fargo, concurring with the reasoning in the U-Haul ruling. Conversely, in December 2003, a New York federal court granted 1-800-Contacts' motion for a preliminary injunction to prevent WhenU.com from serving ads until resolution. The court also found there was trademark infringement. The court maintained that WhenU.com deceptively used the trademark of the plaintiff to trigger a WhenU.com application to serve an ad. WhenU.com is appealing this ruling.

55.4 Conclusion

The ethical and legal concerns associated with spyware call for a response. The form of that response will ultimately be determined by users, organizations, and government action through their assessment of the ease and effectiveness of the various approaches to battling spyware. Do the various software tools currently available satisfy users by allowing them to enjoy the use of their own computing resources, while affording protection against concerns raised? Will industry self-regulation be effective? Will user protests ultimately be so strong as to lead to legal legislation? While the concerns associated with the presence of spyware are clear, legislating spyware is difficult because the definition of spyware is vague. Some spyware installers have contended they have been unfairly targeted. A balance must be found between the legitimate interests of spyware installers, who have obtained the informed consent of users who accept advertisements or other marketing devices in exchange for free software, and users who are unwitting targets. Currently, there is no widespread awareness or understanding on the part of users as to the existence of spyware, its effects, and what remedies are available to defend against its installation or removal. As the prevalence of spyware continues to increase, the views of users regarding the acceptability of spyware will ultimately drive the resolution of concerns.

56
Ethics and the Internet

Micki Krause

The research for this chapter was done entirely on the Internet. The Net is a powerful tool. This author dearly hopes that the value of its offerings is not obviated by those who would treat the medium in an inappropriate and unethical manner.

Ethics: Social values; a code of right and wrong

56.1 Introduction

The ethical nature of the Internet has been likened to "a restroom in a downtown bus station," where the lowest of the low congregate and nothing good ever happens. This manifestation of antisocial behavior can be attributed to one or more of the following:

- The relative anonymity of those who use the Net
- The lack of regulation in cyberspace
- The fact that one can masquerade as another on the Internet
- The fact that one can fulfill a fantasy or assume a different persona on the net, thereby eliminating the social obligation to be accountable for one's own actions

Whatever the reason, the Internet, also known as the "Wild West" or the "untamed frontier," is absent of law and therefore is a natural playground for illicit, illegal, and unethical behavior.

In the ensuing pages, we will explore the types of behavior demonstrated in cyberspace, discuss how regulation is being introduced and by whom, and illustrate the practices that businesses have adopted in order to minimize their liability and encourage their employees to use the Net in an appropriate manner.

56.2 The Growth of the Internet

When the Internet was born approximately 30 years ago it was a medium used by the government and assorted academicians, primarily to perform and share research. The user community was small and mostly self-regulated. Thus, although a useful tool, the Internet was not considered “mission-critical,” as it is today. Moreover, the requirements for availability and reliability were not as much a consideration then as they are now, because Internet usage has grown exponentially since the late 1980s.

The increasing opportunities for productivity, efficiency and world-wide communications brought additional users in droves. Thus, it was headline news when a computer worm, introduced into the Internet by Robert Morris, Jr., in 1988, infected thousands of Net-connected computers and brought the Internet to its knees.

In the early 1990s, with the advent of commercial applications and the World Wide Web (WWW), a graphical user interface for Internet information, the number of Internet users soared. Sources such as the *Industry Standard*, “The Newsmagazine of the Internet Economy,” published the latest Nielsen Media Research Commerce Net study in late 1998, which reported the United States Internet population at 70.5 million (out of a total population of 196.5 million).

Today, the Internet is a utility, analogous to the electric company, and “dotcom” is a household expression. The spectrum of Internet users extends from the kindergarten classroom to senior citizenry, although the Gen-X generation, users in their 20s, are the fastest adopters of Net technology (see Exhibit 56.1).

Because of its popularity, the reliability and availability of the Internet are critical operational considerations, and activities that threaten these attributes, e.g., spamming, spoofing, hacking and the like, have grave impacts on its user community.

56.3 Unethical Activity Defined

Spamming, in electronic terminology, means electronic garbage. Sending unsolicited junk electronic mail, for example, such as an advertisement, to one user or many users via a distribution list, is considered spamming.

One of the most publicized spamming incidents occurred in 1994, when two attorneys (Laurence Carter and Martha Siegel) from Arizona, flooded the cyber waves, especially the Usenet newsgroups[1], with solicitations to the immigrant communities of the United States to assist them in the green card lottery process to gain citizenship. Carter and Siegel saw the spamming as “an ideal, low-cost and perfectly legitimate way to target people likely to be potential clients” (*Washington Post*, 1994). Many Usenet newsgroup users, however, saw things differently. The lawyers’ actions resulted in quite an uproar among the Internet communities primarily because the Internet has had a long tradition of noncommercialism since its founding. The attorneys had already been ousted from the American Immigration Lawyers’ Association for past sins, and eventually they lost their licenses to practice law.

EXHIBIT 56.1 GenX Internet Use

A Higher Percentage of Gen-Xers Use the Web…	
	Used the Web in the past 6 months
Generation X	61%
Total U.S. Adults	49%
… More regularly…	
	Use the Web regularly
Generation X	82%
Baby boomers	52%
… Because it’s the most important medium	
	Most important media
Internet	55%
Television	39%

Source: *From The Industry Standard*, M.J. Thompson, July 10, 1998.

[1] Usenet newsgroups are limited communities of Net users who congregate online to discuss specific topics.

There have been several other spams since the green card lottery, some claiming "MAKE MONEY FAST," others claiming "THE END OF THE WORLD IS NEAR." There have also been hundreds, if not thousands, of electronic chain letters making the Internet rounds. The power of the Internet is the ease with which users can forward data, including chain letters. More information about spamming occurrences can be found on the Net in the Usenet newsgroup (alt.folklore.urban).

Unsolicited Internet e-mail has become so widespread that lawmakers have begun to propose sending it a misdemeanor. Texas is one of 18 states considering legislation that would make spamming illegal. In February 1999, Virginia became the fourth state to pass an antispamming law. The Virginia law makes it a misdemeanor for a spammer to use a false online identity to send mass mailings, as many do. The maximum penalty would be a $500 fine. However, if the spam is deemed malicious and results in damages to the victim in excess of $2500 (e.g., if the spam causes unavailability of computer service), the crime would be a felony, punishable by up to five years in prison. As with the Virginia law, California law allows for the jailing of spammers. Laws in Washington and Nevada impose civil fines.

This legislation has not been popular with everyone, however, and has led organizations such as the American Civil Liberties Union (ACLU), to complain about its unconstitutionality and threat to free speech and the First Amendment.

Like spamming, threatening electronic mail messages have become pervasive in the Internet space. Many of these messages are not taken as seriously as the one that was sent by a high school student from New Jersey, who made a death threat against President Clinton in an electronic mail message in early 1999. Using a school computer that provided an option to communicate with a contingent of the U.S. government, the student rapidly became the subject of a Secret Service investigation.

Similarly, in late 1998, a former investment banker was convicted on eight counts of aggravated harassment when he masqueraded as another employee and sent allegedly false and misleading Internet e-mail messages to top executives of his former firm.

Increasingly, businesses are establishing policy to inhibit employees from using company resources to perform unethical behavior on the Internet. In an early 1999 case, a California firm agreed to pay a former employee over $100,000 after she received harassing messages on the firm's electronic bulletin board, even though the company reported the incident to authorities and launched an internal investigation. The case is a not-so-subtle reminder that businesses are accountable for the actions of their employees, even actions performed on electronic networks.

Businesses have taken a stern position on employees surfing the Web, sending inappropriate messages, and downloading pornographic materials from the Internet. This is due to a negative impact on productivity, as well as the legal view that companies are liable for the actions of their employees. Many companies have established policies for appropriate use and monitoring of computers and computing resources, as well as etiquette on the Internet, or "Netiquette."

These policies are enhancements to the Internet Advisory Board's (Request for Comment) RFC 1087, "Internet Ethics," January 1989, which proposed that access to and use of the Internet is a privilege and should be treated as such by all users of the system. The IAB strongly endorsed the view of the Division Advisory Panel of the National Science Foundation Division of Network Communications Research and Infrastructure. That view is paraphrased below.

Any activity is characterized as unethical and unacceptable that purposely:

- Seeks to gain unauthorized access to the resources of the Internet
- Disrupts the intended use of the Internet
- Wastes resources (people, capacity, computers) through such actions
- Destroys the integrity of computer-based information
- Compromises the privacy of users
- Involves negligence in the conduct of Internet-wide experiments[2]

[2] *Source*: RFC 1087, "Ethics and Internet," Internet Advisory Board, January 1989.

A sample "Appropriate Use of the Internet" policy is attached as Appendix A. Appendix B contains the partial contents of RFC 1855, "Netiquette Guidelines," a product of the Responsible Use of the Network (RUN) Working Group of the Internet Engineering Task Force (IETF).

In another twist on Internet electronic mail activity, in April 1999 Intel Corporation sued a former employee for doing a mass e-mailing to its 30,000 employees, criticizing the company over workers' compensation benefits. Intel claims the e-mail was an assault and form of trespass, as well as an improper use of its internal computer resources. The former employee contends that his e-mail messages are protected by the First Amendment. "Neither Intel nor I can claim any part of the Internet as our own private system as long as we are hooked up to this international network of computers," said Ken Hamidi in an e-mail to *Los Angeles Times* reporters. The case was not settled as of this writing ("Ruling is Due on Mass E-mail Campaign Against Intel," Greg Miller, *Los Angeles Times*, April 19, 1999).

Using electronic media to stalk another person is known as "cyber stalking." This activity is becoming more prevalent, and the law has seen fit to intercede by adding computers and electronic devices to existing stalking legislation. In the first case of cyber stalking in California, a Los Angeles resident, accused of using his computer to harass a woman who rejected his romantic advances, is the first to be charged under a new cyber stalking law that went into effect in 1998. The man was accused of forging postings on the Internet, on America Online (AOL), and other Internet services, so that the messages appeared to come from the victim. The message provided the woman's address and other identifying information, which resulted in at least six men visiting her home uninvited. The man was charged with one count of stalking, three counts of solicitation to commit sexual assault, and one count of unauthorized access to computers.

In another instance where electronic activity has been added to existing law, the legislation for gambling has been updated to include Internet gambling. According to recent estimates, Internet-based gambling and gaming has grown from about a $500 million-a-year industry in the late 1990s, to what some estimate could become a $10 billion-a-year enterprise by 2000. Currently, all 50 states regulate in-person gambling in some manner. Many conjecture that the impetus for the regulation of electronic gambling is financial, not ethical or legal.

56.4 Privacy on the Internet

For many years, American citizens have expressed fears of invasion of privacy, ever since they realized that their personal information is being stored on computer databases by government agencies and commercial entities. However, it is just of late that Americans are realizing that logging on to the Internet and using the World Wide Web threatens their privacy as well. Last year, the Center for Democracy and Technology (CDT), a Washington, D.C. advocacy group, reported that only one third of federal agencies tell visitors to their Web sites what information is being collected about them.

AT&T Labs conducted a study early last year, in which they discovered that Americans are willing to surrender their e-mail address online, but not much more than that. The study said that users are reluctant to provide other personal information, such as a phone number or credit card number.

The utilization of technology offers the opportunity for companies to collect specific items of information. For example, Microsoft Corporation inserts tracking numbers into its Word program documents. Microsoft's Internet Explorer informs Web sites when a user bookmarks them by choosing the "Favorites" option in the browser. In 1998, the Social Security Administration came very close to putting a site on line that would let anyone find out another person's earnings and other personal information. This flies in the face of the 1974 Privacy Act, which states that every agency must record "only such information about an individual as is relevant and necessary to accomplish a purpose of the agency required to be accomplished by statute or by executive order of the President."

There is a battle raging between privacy advocates and private industry aligned with the U.S. government. Privacy advocates relate the serious concern for the hands-off approach and lack of privacy legislation, claiming that citizens are being violated. Conversely, the federal government and private businesses, such as American Online, defend current attempts to rely on self-regulation and other less government-intrusive means of regulating privacy, for example, the adoption of privacy policies. These policies, which state intent for the protection of consumer privacy, are deployed to raise consumer confidence and increase digital trust. The CDT has urged the federal government to post privacy policies on each site's home page, such as is shown in Exhibit 56.2 from the Health and Human Services Web site from the National Institute of Health (www.nih.gov).

HHS Web Privacy Notice

(as of April 13, 1999)

Thank you for visiting the Department of Health and Human Services Web site and reviewing our Privacy Policy. Our Privacy Policy for visits to www.hhs.gov is clear:

We will collect no personal information about you when you visit our Web site unless you choose to provide that information to us.

Here is how we handle information about your visit to our Web site:

56.4.1 Information Collected and Stored Automatically

If you do nothing during your visit but browse through the website, read pages, or download information, we will gather and store certain information about your visit automatically. This information does not identify you personally. We automatically collect and store only the following information about your visit:

- The Internet domain (for example, "xcompany.com" if you use a private Internet access account, or "yourschool.edu" if you connect from a university's domain), and IP address (an IP address is a number that is automatically assigned to your computer whenever you are surfing the Web) from which you access our Web site
- The type of browser and operating system used to access our site
- The date and time you access our site
- The pages you visit
- If you linked to our Web site from another Web site, the address of that Web site

We use this information to help us make our site more useful to visitors—to learn about the number of visitors to our site and the types of technology our visitors use. We do not track or record information about individuals and their visits.

56.4.2 Links to Other Sites

Our Web site has links to other federal agencies and to private organizations. Once you link to another site, it is that site's privacy policy that controls what it collects about you.

EXHIBIT 56.2

Information Collected when You Send Us an E-mail Message

When inquiries are e-mailed to us, we again store the text of your message and e-mail address information, so that we can answer the question that was sent in, and send the answer back to the e-mail address provided. If enough questions or comments come in that are the same, the question may be added to our Question and Answer section, or the suggestions are used to guide the design of our Web site.

We do not retain the messages with identifiable information or the e-mail addresses for more than 10 days after responding unless your communication requires further inquiry. If you send us an e-mail message in which you ask us to do something that requires further inquiry on our part, there are a few things you should know.

The material you submit may be seen by various people in our Department, who may use it to look into the matter you have inquired about. If we do retain it, it is protected by the Privacy Act of 1974, which restricts our use of it, but permits certain disclosures.

Also, e-mail is not necessarily secure against interception. If your communication is very sensitive, or includes personal information, you might want to send it by postal mail instead.

56.5 Anonymity on the Internet

Besides a lack of privacy, the Internet promulgates a lack of identity. Users of the Internet are virtual, meaning that they are not speaking with, interacting with, or responding to others, at least not face to face. They sit behind their computer terminals in the comfort of their own home, office, or school. This anonymity makes it easy to masquerade as another, since there is no way of proving or disproving who you are or who you say you are.

Moreover, this anonymity lends itself to the venue of Internet chat rooms. Chat rooms are places on the Net where people congregate and discuss topics common to the group, such as sports, recreation, or sexuality. Many chat rooms provide support to persons looking for answers to questions on health, bereavement, or disease and, in this manner, can be very beneficial to society.

Conversely, chat rooms can be likened to sleazy bars, where malcontents go seeking prey. There have been too many occurrences of too-good-to-be-true investments that have turned out to be fraudulent. Too many representatives of the dregs of society lurk on the net, targeting the elderly or the innocent, or those who, for some unknown reason, make easy marks.

A recent *New Yorker* magazine ran a cartoon showing a dog sitting at a computer desk, the caption reading "On the Internet, no one knows if you're a dog." Although the cartoon is humorous, the instances where child molesters have accosted their victims by way of the Internet are very serious. Too many times, miscreants have struck up electronic conversations with innocent victims, masquerading as innocents themselves, only to lead them to meet in person with dire results. Unfortunately, electronic behavior mimics conduct that has always occurred over phone lines, through the postal service, and in person. The Internet only provides an additional locale for intentionally malicious and antisocial behavior. We can only hope that advanced technology, as with telephonic caller ID, will assist law enforcement in tracking anonymous Internet "bad guys."

Attempts at self-regulation have not been as successful as advertised, and many question whether the industry can police itself. Meanwhile, there are those within the legal and judicial systems that feel more laws are the only true answer to limiting unethical and illegal activities on the Internet. How it will all play out is far from known at this point in time. The right to freedom of speech and expression has often been at odds with censorship. It is ironic, for example, that debates abound on the massive amounts of pornography available on the Internet, and yet, in early 1999, the entire transcript of the President Clinton impeachment hearings was published on the Net, complete with sordid details of the Monica Lewinsky affair.

56.6 Internet and the Law

The Communications Decency Act of 1996 was signed into law by President Clinton in early 1996 and has been challenged by civil libertarian organizations ever since. In 1997, the United States Supreme Court declared the law's ban on indecent Internet speech unconstitutional.

The Childrens' Internet Protect Act (S.97, January 1999), introduced before a recent Congress, requires "the installation and use by schools and libraries of a technology for filtering or blocking material on the Internet on computers with Internet access to be eligible to receive or retain universal service assistance."

56.7 Monitoring the Web

Additionally, many commercial businesses have seen the opportunity to manufacture software products that will provide parents the ability to control their home computers. Products such as Crayon Crawler, FamilyConnect, and KidsGate are available to provide parents with control over what Internet sites their children can access, although products like WebSense, SurfControl and Webroot are being implemented by companies that choose to limit the sites their employees can access.

56.8 Summary

Technology is a double-edged sword, consistently presenting us with benefits and disadvantages. The Internet is no different. The Net is a powerful tool, providing the ability for global communications in a heartbeat; sharing information without boundaries; a platform for illicit and unethical shenanigans.

This chapter has explored the types of behavior demonstrated in cyberspace, antisocial behavior, which has led to many discussions about whether or not this activity can be inhibited by self-regulation or the introduction of tougher laws. Although we do not know how the controversy will end, we know it will be an interesting future in cyberspace.

Appendix A
"Appropriate Use and Monitoring of Computing Resources"

Policy

The Company telecommunications systems, computer networks, and electronic mail systems are to be used only for business purposes and only by authorized personnel. All data generated with or on the Company's business resources are the property of the Company; and may be used by the Company without limitation; and may not be copyrighted, patented, leased, or sold by individuals or otherwise used for personal gain.

Electronic mail and voice mail, including pagers and cellular telephones, are not to be used to create any offensive or disruptive messages. The Company does not tolerate discrimination, harassment, or other offensive messages and images relating to, among other things, gender, race, color, religion, national origin, age, sexual orientation, or disability.

The Company reserves the right and will exercise the right to review, monitor, intercept, access, and disclose any business or personal messages sent or received on Company systems. This may happen at any time, with or without notice.

It is the Company's goal to respect individual privacy, while at the same time maintaining a safe and secure workplace. However, employees should have no expectation of privacy with respect to any Company computer or communication resources. Materials that appear on computer, electronic mail, voice mail, facsimile and the like, belong to the Company. Periodically, your use of the Company's systems may be monitored.

The use of passwords is intended to safeguard Company information, and does not guarantee personal confidentiality.

Violations of company policies detected through such monitoring can lead to corrective action, up to and including discharge.

Netiquette

RFC 1855
Netiquette Guidelines

Status of this Memo

This memo provides information for the Internet community. This memo does not specify an Internet standard of any kind. Distribution of this memo is unlimited.

Abstract

This document provides a minimum set of guidelines for Network Etiquette (Netiquette) which organizations may take and adapt for their own use. As such, it is deliberately written in a bulleted format to make adaptation easier and to make any particular item easy (or easier) to find. It also functions as a minimum set of guidelines for individuals, both users and administrators. This memo is the product of the Responsible Use of the Network (RUN) Working Group of the IETF.

1.0 Introduction

In the past, the population of people using the Internet had "grown up" with the Internet, were technically minded, and understood the nature of the transport and the protocols. Today, the community of Internet users includes people who are new to the environment. These "newbies" are unfamiliar with the culture and do not need to know about transport and protocols. To bring these new users into the Internet culture quickly, this Guide offers a minimum set of behaviors which organizations and individuals may take and adapt for their own use. Individuals should be aware that no matter who supplies their Internet access, be it an Internet Service Provider through a private account, or a student account at a University, or an account through a corporation, that those organizations have regulations about ownership of mail and files, about what is proper to post or send, and how to present yourself. Be sure to check with the local authority for specific guidelines.

We have organized this material into three sections: One-to-one communication, which includes mail and talk; One-to-many communications, which includes mailing lists and NetNews; and Information Services, which includes ftp, WWW, Wais, Gopher, MUDs and MOOs. Finally, we have a Selected Bibliography, which may be used for reference.

2.0 One-to-One Communication (Electronic Mail, Talk)

We define one-to-one communications as those in which a person is communicating with another person as if face-to-face: a dialog. In general, rules of common courtesy for interaction with people should be in force for any situation and on the Internet it is doubly important where, for example, body language and tone of voice must be inferred. For more information on Netiquette for communicating via electronic mail and talk, check references [1,23,25,27] in the Selected Bibliography.

2.1 User Guidelines

2.1.1 For Mail:

- Unless you have your own Internet access through an Internet provider, be sure to check with your employer about ownership of electronic mail. Laws about the ownership of electronic mail vary from place to place.
- Unless you are using an encryption device (hardware or software), you should assume that mail on the Internet is not secure. Never put in a mail message anything you would not put on a postcard.
- Respect the copyright on material that you reproduce. Almost every country has copyright laws.
- If you are forwarding or reposting a message you have received, do not change the wording. If the message was a personal message to you and you are reposting to a group, you should ask permission first. You may shorten the message and quote only relevant parts, but be sure you give proper attribution.

- Never send chain letters via electronic mail. Chain letters are forbidden on the Internet. Your network privileges will be revoked. Notify your local system administrator if your ever receive one.
- A good rule of thumb: Be conservative in what you send and liberal in what you receive. You should not send heated messages (we call these "flames") even if you are provoked. On the other hand, you should not be surprised if you get flamed and it is prudent not to respond to flames.
- In general, it is a good idea to at least check all your mail subjects before responding to a message. Sometimes a person who asks you for help (or clarification) will send another message which effectively says "Never Mind." Also make sure that any message you respond to was directed to you. You might be cc:ed rather than the primary recipient.
- Make things easy for the recipient. Many mailers strip header information which includes your return address. To ensure that people know who you are, be sure to include a line or two at the end of your message with contact information. You can create this file ahead of time and add it to the end of your messages. (Some mailers do this automatically.) In Internet parlance, this is known as a ".sig" or "signature" file. Your.sig file takes the place of your business card. (And you can have more than one to apply in different circumstances.)
- Be careful when addressing mail. There are addresses which may go to a group but the address looks like it is just one person. Know to whom you are sending.
- Watch "CCs" when replying. Do not continue to include people if the messages have become a two-way conversation.
- In general, most people who use the Internet do not have time to answer general questions about the Internet and its workings. Do not send unsolicited mail asking for information to people whose names you might have seen in RFCs or on mailing lists.
- Remember that people with whom you communicate are located across the globe. If you send a message to which you want an immediate response, the person receiving it might be at home asleep when it arrives. Give them a chance to wake up, come to work, and log in before assuming the mail didn't arrive or that they do not care.
- Verify all addresses before initiating long or personal discourse. It is also a good practice to include the word "long" in the subject header so the recipient knows the message will take time to read and respond to. Over 100 lines is considered "long".
- Know whom to contact for help. Usually you will have resources close at hand. Check locally for people who can help you with software and system problems. Also, know whom to go to if you receive anything questionable or illegal. Most sites also have "Postmaster" aliased to a knowledgeable user, so you can send mail to this address to get help with mail.
- Remember that the recipient is a human being whose culture, language, and humor have different points of reference from your own. Remember that date formats, measurements, and idioms may not travel well. Be especially careful with sarcasm.
- Use mixed case. UPPER CASE LOOKS AS IF YOU ARE SHOUTING.
- Use symbols for emphasis. That *is* what I meant. Use underscores for underlining. _War and Peace_ is my favorite book.
- Use smileys to indicate tone of voice, but use them sparingly.:-) is an example of a smiley (Look sideways). Do not assume that the inclusion of a smiley will make the recipient happy with what you say or wipe out an otherwise insulting comment.
- Wait overnight to send emotional responses to messages. If you have really strong feelings about a subject, indicate it via FLAME ON/OFF enclosures. For example:
  FLAME ON

  This type of argument is not worth the bandwidth it takes to send it. It is illogical and poorly reasoned. The rest of the world agrees with me.

- FLAME OFF
- Do not include control characters or non-ASCII attachments in messages unless they are MIME attachments or unless your mailer encodes these. If you send encoded messages make sure the recipient can decode them.
- Be brief without being overly terse. When replying to a message, include enough original material to be understood but no more. It is extremely bad form to simply reply to a message by including all the previous message: edit out all the irrelevant material.
- Limit line length to fewer than 65 characters and end a line with a carriage return.
- Mail should have a subject heading which reflects the content of the message.
- If you include a signature keep it short. Rule of thumb is no longer than four lines. Remember that many people pay for connectivity by the minute, and the longer your message is, the more they pay.
- Just as mail (today) may not be private, mail (and news) are (today) subject to forgery and spoofing of various degrees of detectability. Apply common sense "reality checks" before assuming a message is valid.
- If you think the importance of a message justifies it, immediately reply briefly to an e-mail message to let the sender know you got it, even if you will send a longer reply later.
- "Reasonable" expectations for conduct via e-mail depend on your relationship to a person and the context of the communication. Norms learned in a particular e-mail environment may not apply in general to your e-mail communication with people across the Internet. Be careful with slang or local acronyms.
- The cost of delivering an e-mail message is, on the average, paid about equally by the sender and the recipient (or their organizations). This is unlike other media such as physical mail, telephone, TV, or radio. Sending someone mail may also cost them in other specific ways like network bandwidth, disk space or CPU usage. This is a fundamental economic reason why unsolicited e-mail advertising is unwelcome (and is forbidden in many contexts).
- Know how large a message you are sending. Including large files such as Postscript files or programs may make your message so large that it cannot be delivered or at least consumes excessive resources. A good rule of thumb would be not to send a file larger than 50 kb. Consider file transfer as an alternative, or cutting the file into smaller chunks and sending each as a separate message.
- Do not send large amounts of unsolicited information to people.
- If your mail system allows you to forward mail, beware the dreaded forwarding loop. Be sure you have not set up forwarding on several hosts so that a message sent to you gets into an endless loop from one computer to the next to the next.

Selected Bibliography

This bibliography was used to gather most of the information in the sections above as well as for general reference. Items not specifically found in these works were gathered from the IETF-RUN Working Group's experience.

57 Computer Ethics

Peter S. Tippett

The computer security professional needs both to understand and to influence the behavior of everyday computer users. Traditionally, security managers have concentrated on building security into the system hardware and software, on developing procedures, and on educating end users about procedures and acceptable behavior. Now, the computer professional must also help develop the meaning of ethical computing and help influence computer end users to adopt notions of ethical computing into their everyday behavior.

57.1 Fundamental Changes to Society

Computer technology has changed the practical meaning of many important, even fundamental, human and societal concepts. Although most computer professionals would agree that computers change nothing about human ethics, computer and information technologies have caused and will pose many new problems. Indeed, computers have changed the nature and scope of accessing and manipulating information and communications. As a result, computers and computer communications will significantly change the nature and scope of many of the concepts most basic to society. The changes will be as pervasive and all encompassing as the changes accompanying earlier shifts from a society dependent on hunters and gatherers to one that was more agrarian to an industrial society.

Charlie Chaplin once observed, “The progress of science is far ahead of man's ethical behavior.” The rapid changes that computing technology and the digital revolution have brought and will bring are at least as profound as the changes prompted by the industrial revolution. This time, however, the transformation will be compressed into a much shorter time frame.

It will not be known for several generations whether the societal changes that follow from the digital revolution will be as fundamental as those caused by the combination of easy transportation, pervasive and near-instantaneous news, and inexpensive worldwide communication brought on by the industrial and radio revolutions. However, there is little doubt that the digital age is already causing significant changes in ways that are not yet fully appreciated.

Some of those changes are bad. For example, combining the known costs of the apparent unethical and illegal uses of computer and information technology—factors such as telephone and PBX fraud, computer viruses, and digital piracy—amounts to several billion dollars annually. When these obvious problems are combined with the kinds of computing behavior that society does not yet fully comprehend as unethical and that society has not yet labeled illegal or antisocial, it is clear that a great computer ethics void exists.

57.2 No Sandbox Training

By the time children are six years old, they learn that eating grasshoppers and worms is socially unacceptable. Of course, six-year-olds would not say it quite that way. To express society's wishes, children say something more like: "Eeewwww!, Yich! Johnny, you are not going to eat that worm are you?"

As it turns out, medical science shows that there is nothing physically dangerous or wrong with eating worms or grasshoppers. Eating them would not normally make people sick or otherwise cause physical harm. But children quickly learn at the gut level to abhor this kind of behavior—along with a whole raft of other behavior. What is more, no obvious rule exists that leads to this gut-feeling behavior. No laws, church doctrine, school curriculum, or parental guides specifically address the issue of eating worms and grasshoppers. Yet, even without structured rules or codes, society clearly gives a consistent message about this. Adults take the concept as being so fundamental that it is called common sense.

By the time children reach the age of ten, they have a pretty clear idea of what is right and wrong, and what is acceptable and unacceptable. These distinctions are learned from parents, siblings, extended families, neighbors, acquaintances, and schools, as well as from rituals like holiday celebrations and from radio, television, music, magazines, and many other influences.

Unfortunately, the same cannot be said for being taught what kind of computing behavior is repugnant. Parents, teachers, neighbors, acquaintances, rituals, and other parts of society simply have not been able to provide influence or insight based on generations of experience. Information technology is so new that these people and institutions simply have no experience to draw on. The would-be teachers are as much in the dark as those who need to be taught.

A whole generation of computer and information system users exists. This generation is more than one hundred million strong and growing. Soon information system users will include nearly every literate individual on earth. Members of this new generation have not yet had their sandbox training. Computer and information users, computer security professionals included, are simply winging it.

Computer users are less likely to know the full consequences of many of their actions than they would be if they could lean on the collective family, group, and societal experiences for guidance. Since society has not yet established much of what will become common sense for computing, individuals must actively think about what makes sense and what does not. To decide whether a given action makes sense, users must take into account whether the action would be right not only for themselves personally but also for their peers, businesses, families, extended families, communities, and society as a whole. Computer users must also consider short-term, mid-term, and long-term ramifications of each of the potential actions as they apply to each of these groups. Since no individual can conceivably take all of this into consideration before performing a given action, human beings need to rely on guides such as habit, rules, ritual, and peer pressure. People need to understand without thinking about it, and for that, someone needs to develop and disseminate ethics for the computer generation.

Computer security professionals must lead the way in educating the digital society about policies and procedures and behavior that clearly can be discerned as right or wrong. The education process involves defining those issues that will become gut feelings, common sense, and acceptable etiquette of the whole society of end users. Computer professionals need to help develop and disseminate the rituals, celebrations, habits, and beliefs for users.

In other words, they are the pivotal people responsible for both defining computer ethics and disseminating their understanding to the computer-using public.

57.3 Common Fallacies of The Computer Generation

The lack of early, computer-oriented, childhood rearing and conditioning has led to several pervasive fallacies that generally (and loosely) apply to nearly all computer and digital information users. The generation of computer users includes those from 7 to 70 years old who use computing and other information technologies. Like all fallacies, some people are heavily influenced by them, and some are less so. There are clearly more fallacies than those described here, but these are probably the most important. Most ethical problems that surface in discussions show roots in one or more of these fallacies.

57.3.1 The Computer Game Fallacy

Computer games like solitaire and game computers like those made by Nintendo and Sega do not generally let the user cheat. So it is hardly surprising for computer users to think, at least subliminally, that computers in general will prevent them from cheating and, by extension, from otherwise doing wrong.

This fallacy also probably has roots in the very binary nature of computers. Programmers in particular are used to the precise nature that all instructions must have before a program will work. An error in syntax, a misplaced comma, improper capitalization, and transposed characters in a program will almost certainly prevent it from compiling or running correctly once compiled. Even non-programming computer users are introduced to the powerful message that everything about computers is exact and that the computer will not allow even the tiniest transgression. DOS commands, batch file commands, configuration parameters, macro commands, spreadsheet formulas, and even file names used for word processing must have precisely the right format and syntax, or they will not work.

To most users, computers seem entirely black and white—sometimes frustratingly so. By extension, what people do with computers seems to take on a black-and-white quality. But what users often misunderstand while using computers is that although the computer operates with a very strict set of inviolable rules, most of what people do with computers is just as gray as all other human interactions.

It is a common defense for malicious hackers to say something like "If they didn't want people to break into their computer at the [defense contractor], they should have used better security." Eric Corley, the publisher of the hacker's *2,600 Magazine,* testified at hearings for the House Telecommunications and Finance Subcommittee (June 1993) that he and others like him were providing a service to computer and telecommunication system operators when they explored computer systems, found faults and weaknesses in the security systems, and then published how to break these systems in his magazine. He even had the audacity while testifying before Congress to use his handle, Emanuel Goldstein (a character from the book *1984),* never mentioning that his real name was Eric Corley.

He, and others like him, were effectively saying "If you don't want me to break in, make it impossible to do so. If there is a way to get around your security, then I should get around it in order to expose the problem."

These malicious hackers would never consider jumping over the four-foot fence into their neighbor's backyard, entering the kitchen through an open kitchen window, sitting in the living room, reading the mail, making a few phone calls, watching television, and leaving. They would not brag or publish that their neighbor's home was not secure enough, that they found a problem or loophole, or that it was permissible to go in because it was possible to do so. However, using a computer to perform analogous activities makes perfect sense to them.

The computer game fallacy also affects the rest of the members of the computer-user generation in ways that are a good deal more subtle. The computer provides a powerful one-way mirror behind which people can hide. Computer uses can be voyeurs without being caught. And if what is being done is not permissible, the thinking is that the system would somehow prevent them from doing it.

57.3.2 The Law-Abiding Citizen Fallacy

Recognizing that computers can't prevent everything that would be wrong, many users understand that laws will provide some guidance. But many (perhaps most) users sometimes confuse what is legal, which defines the minimum standard about which all can be justly judged, with what is reasonable behavior, which clearly calls for individual judgment. Sarah Gordon, one of the leaders of the worldwide hobbyist network FidoNet said, "In most places, it is legal to pluck the feathers off of a live bird, but that doesn't make it right to do it."

Similarly, people confuse things that they have a right to do with things that are right to do. Computer virus writers do this all the time. They say: "The First Amendment gives me the constitutional right to write anything I want, including computer viruses. Since computer viruses are an expression, and a form of writing, the constitution also protects the distribution of them, the talking about them, and the promotion of them as free speech."

Some people clearly take their First Amendment rights too far. Mark Lud-wig has written two how-to books on creating computer viruses. He also writes a quarterly newsletter on the finer details of computer virus authors and runs a computer virus exchange bulletin board with thousands of computer viruses for the user's downloading pleasure. The bulletin board includes source code, source analysis, and tool kits to create nasty features like stealthing, encryption, and polymorphism. He even distributes a computer virus CD with thousands of computer viruses, a source code, and some commentary.

Nearly anyone living in the United States would agree that in most of the western world, people have the right to write almost anything they want. However, they also have the responsibility to consider the ramifications of their actions and to behave accordingly. Some speech, of course, is not protected by the constitution—like yelling "fire" in a crowded theater or telling someone with a gun to shoot a person. One would hope that writing viruses will become nonprotected speech in the future. But for now, society has not decided whether virus writing, distribution, and promotion should be violently abhorred or tolerated as one of the costs of other freedoms.

57.3.3 The Shatterproof Fallacy

How many times have computer novices been told "Don't worry, the worst you can do with your computer is accidentally erase or mess up a file—and even if you do that, you can probably get it back. You can't really hurt anything."

Although computers are tools, they are tools that can harm. Yet most users are totally oblivious to the fact that they have actually hurt someone else through actions on their computer. Using electronic-mail on the Internet to denigrate someone constitutes malicious chastisement of someone in public. In the nondigital world, people can be sued for libel for these kinds of actions; but on the Internet, users find it convenient to not be held responsible for their words.

Forwarding E-mail without at least the implied permission of all of its authors often leads to harm or embarrassment of participants who thought they were conferring privately. Using E-mail to stalk someone, to send unwanted mail or junk mail, and to send sexual innuendoes or other material that is not appreciated by the recipient all constitute harmful use of computers.

Software piracy is another way in which computer users can hurt people. Those people are not only programmers and struggling software companies but also end users who must pay artificially high prices for the software and systems they buy and the stockholders and owners of successful companies who deserve a fair return on their investment.

It is astonishing that a computer user would defend the writing of computer viruses. Typically, the user says, “My virus is not a malicious one. It does not cause any harm. It is a benign virus. The only reason I wrote it was to satisfy my intellectual curiosity and to see how it would spread.” Such users truly miss out on the ramifications of their actions. Viruses, by definition, travel from computer to computer without the knowledge or permission of the computer’s owner or operator.

Viruses are just like other kinds of contaminants (e.g., contaminants in a lake) except that they grow (replicate) much like a cancer. Computer users cannot know they have a virus unless they specifically test their computers or diskettes for it. If the neighbor of a user discovers a virus, then the user is obliged to test his or her system and diskettes for it and so are the thousand or so other neighbors that the user and the user’s neighbors have collectively.

The hidden costs of computer viruses are enormous. Even if an experienced person with the right tools needs only 10 minutes to get rid of a virus—and even if the virus infects only 4 or 5 computers and only 10 or 20 floppy disks in a site (these are about the right numbers for a computer virus incident in a site of 1,000 computers), then the people at the site are obliged to check all 1,000 computers and an average of 35,000 diskettes (35 active diskettes per computer) to find out just which five computers are infected.

As of early 1995, there were demonstrably more than a thousand people actively writing, creating, or intentionally modifying the more than 6,000 computer viruses that currently exist—and at least as many people knowingly participated in spreading them. Most of these people were ignorant of the precise consequences of their actions.

In 1993, there was a minor scandal in the IRS when clerical IRS employees were discovered pulling computerized tax returns of movie stars, politicians, and their neighbors—just for the fun of it. What is the harm? The harm is to the privacy of taxpayers and to the trust in the system, which is immeasurably damaged in the minds of U.S. citizens. More than 350 IRS employees were directly implicated in this scandal. When such large numbers of people do not understand the ethical problem, then the problem is not an isolated one. It is emblematic of a broad ethical problem that is rooted in widely held fallacies.

The shatterproof fallacy is the pervasive feeling that what a person does with a computer could hurt at most a few files on the machine. It stems from the computer generation’s frequent inability to consider the ramifications of the things we do with computers before we do them.

57.3.4 The Candy-from-a-Baby Fallacy

Guns and poison make killing easy (i.e., it can be done from a distance with no strength or fight) but not necessarily right. Poisoning the water supply is quite easy, but it is beyond the gut-level acceptability of even the most bizarre schizophrenic.

Software piracy and plagiarism are incredibly easy using a computer. Computers excel at copying things, and nearly every computer user is guilty of software piracy. But just because it is easy does not mean that it is right.

Studies by the Software Publisher’s Association (SPA) and Business Software Alliance (BSA) show that software piracy is a multibillion dollar problem in the world today—clearly a huge problem.

By law and by any semblance of intellectual property held both in Western societies and most of the rest of the world, copying a program for use without paying for it is theft. It is no different than shoplifting or being a stowaway on an airliner, and an average user would never consider stealing a box of software from a computer store’s display case or stowing away on a flight because the plane had empty seats.

57.3.5 The Hacker’s Fallacy

The single most widely held piece of The Hacker’s Ethic is “As long as the motivation for doing something is to learn and not to otherwise gain or make a profit, then doing it is acceptable.” This is actually quite a strong, respected, and widely held ethos among people who call themselves non-malicious hackers.

To be a hacker, a person's primary goal must be to learn for the sake of learning—just to find out what happens if one does a certain thing at a particular time under a specific condition (Emmanuel Goldstein, *2,600 Magazine,* Spring 1994). Consider the hack on Tonya Harding (the Olympic ice skater who allegedly arranged to have her archrival, Nancy Kerrigan, beaten with a bat). During the Lillehammer Olympics, three U.S. newspaper reporters, with the *Detroit Free Press, San Jose Mercury News,* and *The New York Times,* discovered that the athletes' E-mail user IDs were, in fact, the same as the ID numbers on the backs of their backstage passes. The reporters also discovered that the default passwords for the Olympic Internet mail system were simple derivatives of the athlete's birthdays. Reporters used this information to gain access to Tonya Harding's E-mail account and discovered that she had 68 messages. They claim not to have read any of them. They claim that no harm was done, nothing was published, no privacy was exploited. As it happens, these journalists were widely criticized for their actions. But the fact is, a group of savvy, intelligent people thought that information technology changed the ground rules.

57.3.6 The Free Information Fallacy

There is a common notion that information wants to be free, as though it had a mind of its own. The fallacy probably stems from the fact that once created in digital form, information is very easy to copy and tends to get distributed widely. The fallacy totally misses the point that the wide distribution is at the whim of people who copy and disseminate data and people who allow this to happen.

57.4 Action Plan

The following procedures can help security managers encourage ethical use of the computer within their organizations:

- Developing a corporate guide to computer ethics for the organization.
- Developing a computer ethics policy to supplement the computer security policy.
- Adding information about computer ethics to the employee handbook.
- Finding out whether the organization has a business ethics policy, and expanding it to include computer ethics.
- Learning more about computer ethics and spreading what is learned.
- Helping to foster awareness of computer ethics by participating in the computer ethics campaign.
- Making sure the organization has an E-mail privacy policy.
- Making sure employees know what the E-mail policy is.

Exhibit 57.1 through Exhibit 57.6 contain sample codes of ethics for end users that can help security managers develop ethics policies and procedures.

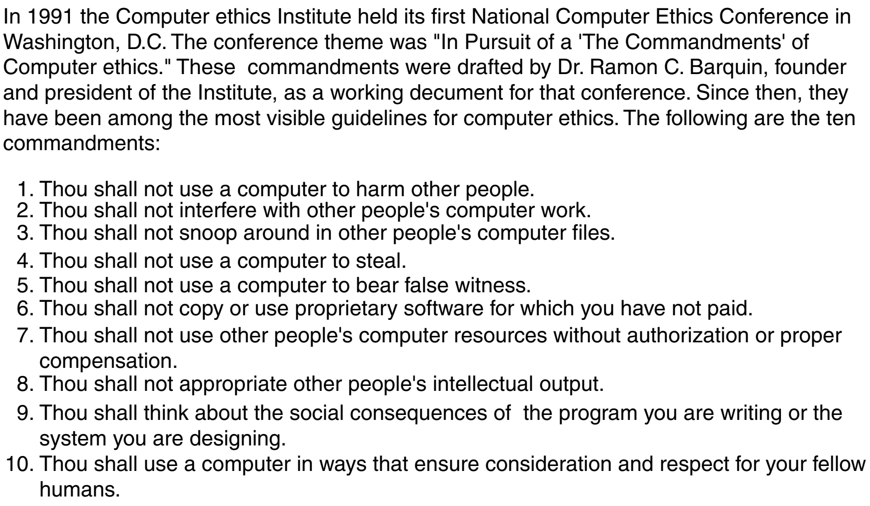
57.5 Resources

The following resources are useful for developing computer-related ethics codes and policies.

57.5.1 Computer Ethics Institute

The Computer Ethics Institute is a non-profit organization concerned with advancing the development of computers and information technologies within ethical frameworks. Its constituency includes people in business, the religious communities, education, public policy, and computer professions. Its purpose includes the following:

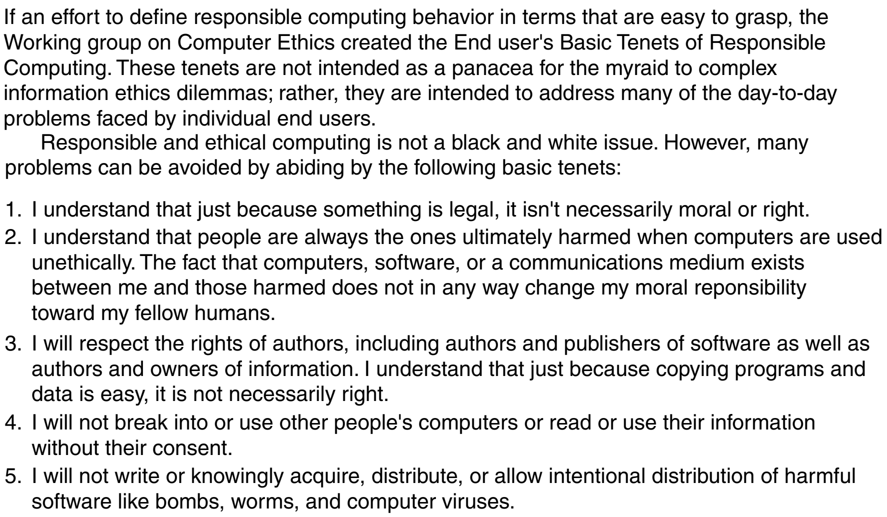
- The dissemination of computer ethics information.
- Policy analysis and critique.



In 1991 the Computer ethics Institute held its first National Computer Ethics Conference in Washington, D.C. The conference theme was "In Pursuit of a 'The Commandments' of Computer ethics." These commandments were drafted by Dr. Ramon C. Barquin, founder and president of the Institute, as a working decument for that conference. Since then, they have been among the most visible guidelines for computer ethics. The following are the ten commandments:

1. Thou shall not use a computer to harm other people.
2. Thou shall not interfere with other people's computer work.
3. Thou shall not snoop around in other people's computer files.
4. Thou shall not use a computer to steal.
5. Thou shall not use a computer to bear false witness.
6. Thou shall not copy or use proprietary software for which you have not paid.
7. Thou shall not use other people's computer resources without authorization or proper compensation.
8. Thou shall not appropriate other people's intellectual output.
9. Thou shall think about the social consequences of the program you are writing or the system you are designing.
10. Thou shall use a computer in ways that ensure consideration and respect for your fellow humans.

EXHIBIT 57.1 The ten commandments of computer ethics.

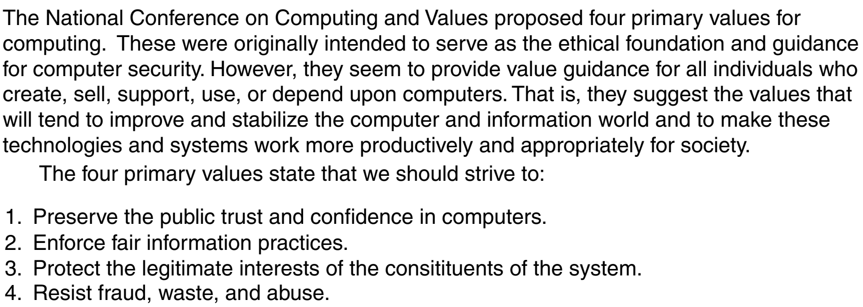


If an effort to define responsible computing behavior in terms that are easy to grasp, the Working group on Computer Ethics created the End user's Basic Tenets of Responsible Computing. These tenets are not intended as a panacea for the myraid to complex information ethics dilemmas; rather, they are intended to address many of the day-to-day problems faced by individual end users.

Responsible and ethical computing is not a black and white issue. However, many problems can be avoided by abiding by the following basic tenets:

1. I understand that just because something is legal, it isn't necessarily moral or right.
2. I understand that people are always the ones ultimately harmed when computers are used unethically. The fact that computers, software, or a communications medium exists between me and those harmed does not in any way change my moral reponsibility toward my fellow humans.
3. I will respect the rights of authors, including authors and publishers of software as well as authors and owners of information. I understand that just because copying programs and data is easy, it is not necessarily right.
4. I will not break into or use other people's computers or read or use their information without their consent.
5. I will not write or knowingly acquire, distribute, or allow intentional distribution of harmful software like bombs, worms, and computer viruses.

EXHIBIT 57.2 The end user's basic tenets of responsible computing.

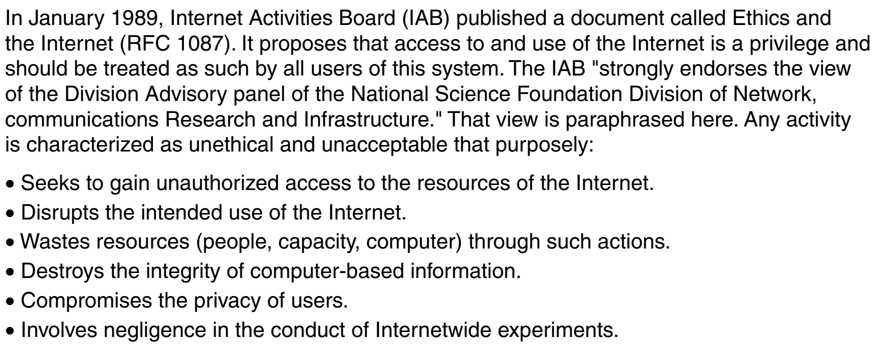


The National Conference on Computing and Values proposed four primary values for computing. These were originally intended to serve as the ethical foundation and guidance for computer security. However, they seem to provide value guidance for all individuals who create, sell, support, use, or depend upon computers. That is, they suggest the values that will tend to improve and stabilize the computer and information world and to make these technologies and systems work more productively and appropriately for society.

The four primary values state that we should strive to:

1. Preserve the public trust and confidence in computers.
2. Enforce fair information practices.
3. Protect the legitimate interests of the consitituents of the system.
4. Resist fraud, waste, and abuse.

EXHIBIT 57.3 Four primary values.



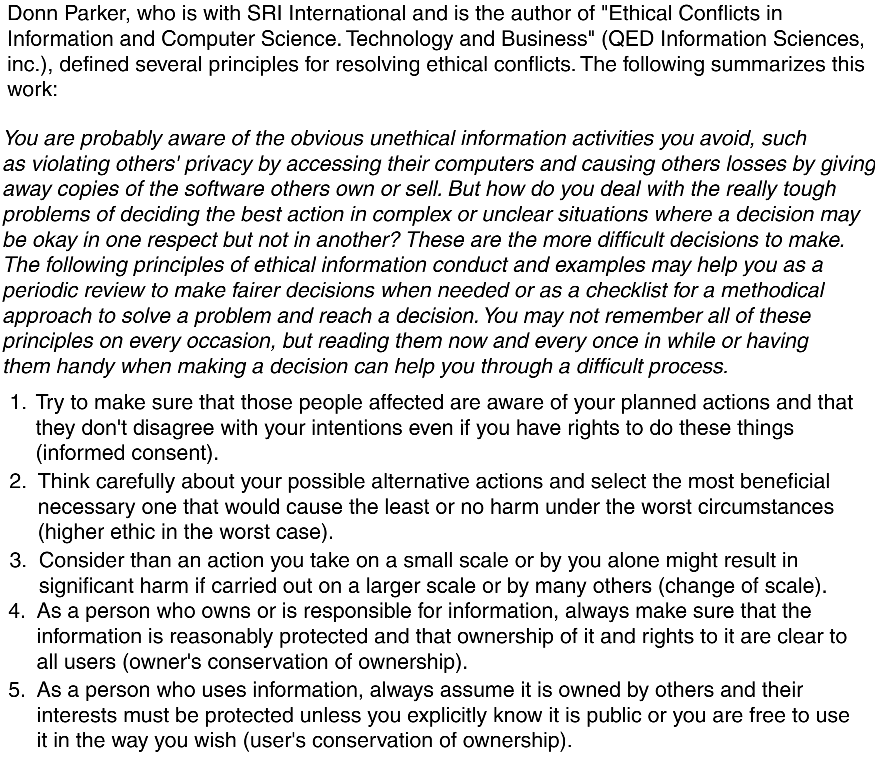
In January 1989, Internet Activities Board (IAB) published a document called Ethics and the Internet (RFC 1087). It proposes that access to and use of the Internet is a privilege and should be treated as such by all users of this system. The IAB "strongly endorses the view of the Division Advisory panel of the National Science Foundation Division of Network, communications Research and Infrastructure." That view is paraphrased here. Any activity is characterized as unethical and unacceptable that purposely:

- Seeks to gain unauthorized access to the resources of the Internet.
- Disrupts the intended use of the Internet.
- Wastes resources (people, capacity, computer) through such actions.
- Destroys the integrity of computer-based information.
- Compromises the privacy of users.
- Involves negligence in the conduct of Internetwide experiments.

EXHIBIT 57.4 Unacceptable internet activities.

- The recognition and critical examination of ethics in the use of computer technology.
- The promotion of identifying and applying ethical principles for the development and use of computer technologies.

In 1991 the Computer Ethics Institute held its first National Computer Ethics Conference in Washington, O.C. The conference theme was "In Pursuit of a 'Ten Commandments' of Computer Ethics." These commandments were drafted by Dr. Ramon C. Barquin, founder and president of the Institute, as a working document for that conference. Since then, they have been among the most visible guidelines for computer ethics. The following are the ten commandments:

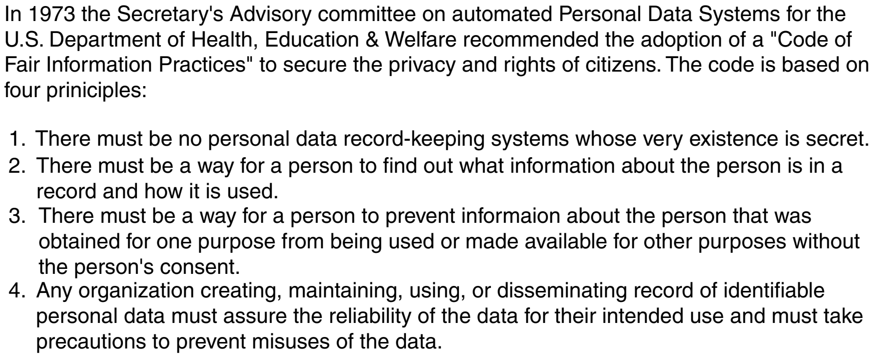


Donn Parker, who is with SRI International and is the author of "Ethical Conflicts in Information and Computer Science. Technology and Business" (QED Information Sciences, inc.), defined several principles for resolving ethical conflicts. The following summarizes this work:

You are probably aware of the obvious unethical information activities you avoid, such as violating others' privacy by accessing their computers and causing others losses by giving away copies of the software others own or sell. But how do you deal with the really tough problems of deciding the best action in complex or unclear situations where a decision may be okay in one respect but not in another? These are the more difficult decisions to make. The following principles of ethical information conduct and examples may help you as a periodic review to make fairer decisions when needed or as a checklist for a methodical approach to solve a problem and reach a decision. You may not remember all of these principles on every occasion, but reading them now and every once in while or having them handy when making a decision can help you through a difficult process.

1. Try to make sure that those people affected are aware of your planned actions and that they don't disagree with your intentions even if you have rights to do these things (informed consent).
2. Think carefully about your possible alternative actions and select the most beneficial necessary one that would cause the least or no harm under the worst circumstances (higher ethic in the worst case).
3. Consider than an action you take on a small scale or by you alone might result in significant harm if carried out on a larger scale or by many others (change of scale).
4. As a person who owns or is responsible for information, always make sure that the information is reasonably protected and that ownership of it and rights to it are clear to all users (owner's conservation of ownership).
5. As a person who uses information, always assume it is owned by others and their interests must be protected unless you explicitly know it is public or you are free to use it in the way you wish (user's conservation of ownership).

EXHIBIT 57.5 Considerations for conduct.



In 1973 the Secretary's Advisory committee on automated Personal Data Systems for the U.S. Department of Health, Education & Welfare recommended the adoption of a "Code of Fair Information Practices" to secure the privacy and rights of citizens. The code is based on four priniciples:

1. There must be no personal data record-keeping systems whose very existence is secret.
2. There must be a way for a person to find out what information about the person is in a record and how it is used.
3. There must be a way for a person to prevent informaion about the person that was obtained for one purpose from being used or made available for other purposes without the person's consent.
4. Any organization creating, maintaining, using, or disseminating record of identifiable personal data must assure the reliability of the data for their intended use and must take precautions to prevent misuses of the data.

EXHIBIT 57.6 The code of fair information practices.

In an effort to define responsible computing behavior in terms that are easy to grasp, the Working Group on Computer Ethics created the End User's Basic Tenets of Responsible Computing. These tenets are not intended as a panacea for the myriad of complex information ethics dilemmas; rather, they are intended to address many of the day-to-day problems faced by individual end users.

Responsible and ethical computing is not a black and white issue. However, many problems can be avoided by abiding by the following basic tenets:

The National Conference on Computing and Values proposed four primary values for computing. These were originally intended to serve as the ethical foundation and guidance for computer security. In 1973 the Secretary's Advisory Committee on Automated Personal Data Systems for the U.S. Department of Health, Education & Welfare recommended the adoption of a "Code of Fair Information Practices" to secure the privacy and rights of citizens. The Code is based on four principles:

To meet these purposes, the Computer Ethics Institute conducts seminars, convocations, and the annual National Computer Ethics Conference. The Institute also supports the publication of proceedings and the development and publication of other research. In addition, the Institute participates in projects with other groups with similar interests. The following are ways to contact the institute:

Dr. Patrick F. Sullivan
Executive Director
Computer Ethics Institute
P.O. Box 42672
Washington, D.C. 20015
Voice and fax: 301-469-0615
psullivan@brook.edu

57.5.2 Internet Listserve:cei-1@listserv.american.edu

This is a listserv on the Internet hosted by American University in Washington, D.C., on behalf of the Computer Ethics Institute. Electronic mail sent to this address is automatically forwarded to others interested in computer ethics and in activities surrounding the Computer Ethics Institute. To join the list, a person should send E-mail to:

listserv@american.edu

The subject field should be left blank. The message itself should say:

subscribe cei-1 <yourname>

The sender will receive postings to the list by E-mail (using the return address from the E-mail site used to send the request).

57.5.3 The National Computer Ethics and Responsibilities Campaign (NCERC)

The NCERC is a campaign jointly run by the Computer Ethics Institute and the National Computer Security Association. Its goal is to foster computer ethics awareness and education. The campaign does this by making tools and other resources available for people who want to hold events, campaigns, awareness programs, seminars, and conferences or to write or communicate about computer ethics.

The NCERC itself does not subscribe to or support a particular set of guidelines or a particular viewpoint on computer ethics. Rather, the Campaign is a nonpartisan initiative intended to foster increased understanding of the ethical and moral issues peculiar to the use and abuse of information technologies.

The initial phase of the NCERC was sponsored by a diverse group of organizations, including (alphabetically) The Atterbury Foundation, The Boston Computer Society, The Business Software Alliance, CompuServe, The Computer Ethics Institute, Computer Professionals for Social Responsibility, Merrill Lynch, Monsanto, The National Computer Security Association, Software Creations BBS, The Software Publisher's Association, Symantec Corporation, and Ziff-Davis Publishing. The principal sponsor of the NCERC is the Computer Ethics Institute.

Other information about the campaign is available on CompuServe (GO CETHICS), where a repository of computer privacy, ethics and similar tools, codes, texts, and other materials are kept.

57.5.4 Computer Ethics Resource Guide

The Resource Guide to Computer Ethics is available for $12. (Send check or credit card number and signature to: NCERC, 10 S. Courthouse Ave., Carlisle, PA, 17013, or call 717-240-0430 and leave credit card information as a voice message.) The guide is meant as a resource for those who wish to do something to increase the awareness of and discussion about computer ethics in their workplaces, schools, universities, user groups, bulletin boards, and other areas.

57.5.5 The National Computer Security Association

The National Computer Security Association (NCSA) provides information and services involving security, reliability, and ethics. NCSA offers information on the following security-related areas: training, testing, research, product certification, underground reconnaissance, help desk, and consulting services. This information is delivered through publications, conferences, forums, and seminars—in both traditional and electronic formats. NCSA manages a CompuServe forum (CIS: GO NCSA) that hosts private online training and seminars in addition to public forums and libraries addressing hundreds of issues concerning information and communications security, computer ethics, and privacy.

The information about computer ethics that is not well suited to electronic distribution can generally be obtained through NCSA's InfoSecurity Resource Catalog, which provides one-stop-shopping for a wide variety of books, guides, training, and tools. (NCSA: 10 S. Courthouse Ave., Carlisle, PA, 17013, 717-258-1816).

57.6 Summary

Computer and information technologies have created many new ethical problems. Compounding these problems is the fact that computer users often do not know the full consequences of their behavior.

Several common fallacies cloud the meaning of ethical computing. For example, many computer users confuse behavior that they have a right to perform with behavior that is right to perform and fail to consider the ramifications of their actions. Another fallacy that is widely held by hackers is that as long as the motivation is to learn and not otherwise profit, any action using a computer is acceptable.

It is up to the system managers to destroy these fallacies and to lead the way in educating end users about policies and procedures and behavior that can clearly be discerned as right or Fwrong.

A Look at RFID Security

Ben Rothke

Radio-frequency identification (RFID) is one of the most exciting technologies of the past decade. It has revolutionized everything from warehouses to factory floors, and trucking to distribution centers. But history has shown us that with every technological innovation, there are corresponding information security risks. Far too often, those risks are only dealt with well after the technology has been deployed, as opposed to during the architecture and development stage.

The function of this article is to provide a basic overview to the security issues involved with RFID technology. This is meant to be a starting point on the reader's journey into this new and existing technology, and is not a comprehensive overview of the topic.

58.1 Introduction

RFID is the ability to identify physical objects through a radio interface. Usually, an RFID is a tag that holds a small amount of unique data, or a serial number or other unique attribute of the item. This data can be read from a distance, and no physical contact or line of sight is necessary. Exhibit 58.1 describes the general model of how an RFID infrastructure operates.

RFID is used in everything from proximity to toll collection (EZ Pass) to consumer goods (ExxonMobil SpeedPass), safety (LoJack), and much more (Exhibit 58.2). With each passing quarter, more and more items are finding RFID tags embedded within them. Ari Juels, Principal Research Scientist at RSA Laboratories sees a future where our world will be composed of billions of ant-sized, five-cent computers, namely RFID tags.

RFID works by having a transceiver or reader obtain data from the RFID tag that is on an object. A database is used to correlate the ID information to the physical object on which the RFID tag resides.

The tags themselves are powered either in a passive or active manner. Passive power means that all of the power comes from the reader's signal, and that the tags are inactive unless a reader activates them. These are generally cheaper and smaller, but have a much shorter range. EZpass is an example of a passive RFID powered device.

Passive tags operate in the UHF band (915 MHz in North America) and can typically be read within the range of 10 m or more in free space, but the range diminishes when tags are attached to everyday objects.

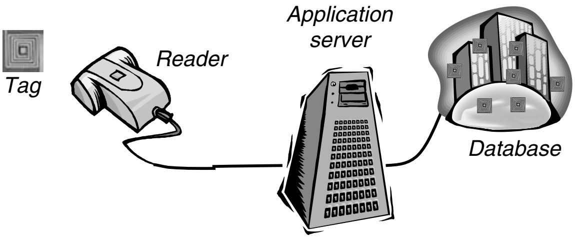

EXHIBIT 58.1 General model of how an RFID infrastructure operates. (From Juels, A. 2005. *RFID Security and Privacy: A Research Survey*. RSA Laboratories, Bedford, MA.)

Four primary frequency bands have been allocated for RFID use:

- Low frequency (125/134 kHz): most commonly used for access control and asset tracking
- Mid-frequency (13.56 MHz): used where medium data rate and read ranges are required
- Ultra-high-frequency (850–950 MHz and 2.4–2.5 GHz): offers the longest read ranges and high reading speeds
- Microwave (2.45 and 5.8 GHz)

Active power means that the tag has an on-board battery power source and can record sensor readings or perform calculations in the absence of a reader. These have much longer read ranges, but are also much more expensive. LoJack is an example of an active RFID powered device.

EXHIBIT 58.2 Examples of RFID Already in Use

Automobile lock and key anti-theft systems	Newer vehicles are coming equipped with highly encrypted RFID systems
	Utilizing a tag in the key and one or more readers in the ignition, these systems have already been shown to deter theft
Credit and debit cards	Recently, two major credit card companies have introduced cards that contain an RFID tag
	This allows holders the option of flashing their card before a reader at the point of sale. Pilot studies have shown this method is 53% faster than swiping a card's magnetic strip. It also reduces wear and tear on the card
Electronic toll collecting	Most states have adopted RFID technology to expedite highway toll collection by attaching devices such as an EZ Pass to vehicles, eliminating the need for drivers to stop and pay
Employee ID cards	Government agencies and private companies have long used RFID-enabled ID cards as a reliable means of authenticating an employee's identity and granting access to secure facilities
Library books	Many libraries have embedded RFID chips in their books to allow more effective inventory management and self-checkout
	The system helps librarians identify when a book is misplaced on the shelf and further frees them to perform more varied work such as interacting with patrons
Livestock	One of the first widespread applications of RFID, tags are used to streamline farm management and isolate diseased livestock to prevent potential epidemics
Mass transit cards	Cities around the world now use RFID technology in contact-less metro cards that speed commuters through turnstiles. Vendors are partnering with transit authorities to enable commuters to use these smart cards instead of cash to purchase items such as coffee and newspapers
Pallet tracking	Retail chains worldwide have implemented RFID systems to track pallets and containers of goods along the supply chain from factory to store shelf. The result is reduced theft and other forms of product shrinkage, lower warehousing costs, and more efficient inventory management

Source: From American Electronics Association, http://aeanet.org.

RFID can be thought of as a barcode on steroids. Consumers are used to seeing barcodes on a myriad of consumer devices. But the problem is that barcodes lack significant amounts of advanced functionality. The following table compares the basic attributes of barcodes and RFID tags:

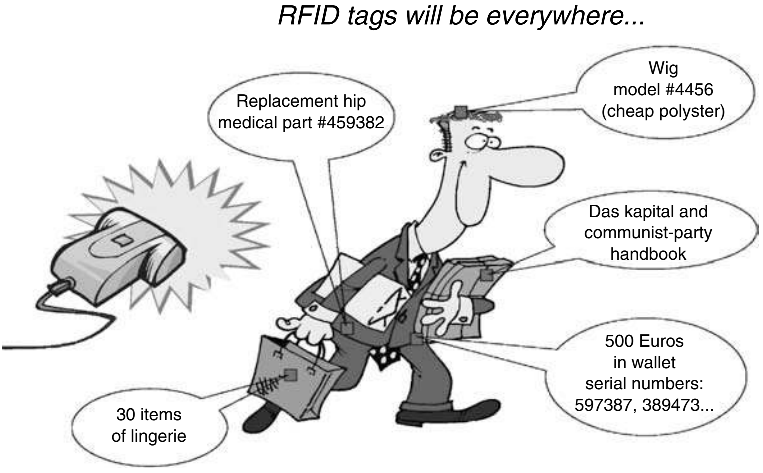
Barcode	RFID
Static data: single product type	Dynamic data, bicycle serial #58291958
Single object type	Unique identifiers. This permits very fine grained and accurate control over the specific product
	Ability to have a full history for every item
Requires line of sight: readers must be looking directly at the barcode	Reading by radio contact—the reader can be anywhere within range. The security danger is that it can be read from a distance, through clothes, wallets, backpacks, purses, etc., without the user's knowledge or consent, by anybody with the appropriate device reader
Requires much closer read range	May be read at a range of up to several meters. But ultimately is dependant on its operational frequency and environment

The benefits of RFID are innumerable. Yet with those benefits come significant security and privacy risks. RFID tags can be used to obviate security and privacy. The cartoon in Exhibit 58.3 is an example of the ultimate privacy risks with RFID. The future will likely see significant amounts of RFID technologies that will obviate many of the most blatant security and privacy risks.

Obviously, it is up to the consumer to ensure that they employ these technologies wherever possible. But history has shown that while consumers have screamed about security and privacy, when push comes to shove, they are often far too indolent when it comes to putting security and privacy controls in place.

58.2 RFID Security and Privacy Issues

One of the biggest security issues with RFID is that for the most part, it is not being deployed with comprehensive security. RFID is similar to wireless networks that far too many of them are deployed without serious thoughts to information security.



RFID tags will be everywhere...
Replacement hip medical part #459382
Wig model #4456 (cheap polyster)
Das kapital and communist-party handbook
500 Euros in wallet serial numbers: 597387, 389473...
30 items of lingerie

EXHIBIT 58.3 An example of the ultimate privacy risks with RFID. The future will likely see significant amounts of RFID technologies that will obviate many of the most blatant security and privacy risks. (From Juels, A. 2004. *RFID: Security and Privacy for Five-Cent Computers*, RSA Laboratories, Bedford, MA.)

Although many organizations have embedded RFID tags in their products, many have not given thought to the fact that adversaries may try to reprogram the tag. Reprogrammability should be a huge concern for those organizations.

The problem is that RFID used maliciously can be used to track people. It can link them with their identity when they would prefer to be anonymous. Some of those security and privacy risks include:

- Personal privacy: briefcases and luggage can be scanned for its contents, medication, reading material, etc.
- Location: people can be scanned for their specific location.
- Corporate espionage: tracking the inventory and orders of one's competition.
- Eavesdropping: leaking of personal information (medical prescriptions, brand of underwear, etc.), location tracking, etc.
- Spoofing: fooling automated checkout into thinking that a product was still on a shelf, rewriting or replacing tags on expensive items with spoofed data from cheaper items.
- Denial-of-service: sabotage, attack against the RFID infrastructure, wipe-out inventory data, signal jamming

Although the security and privacy issues of RFID are real, the problem is that much of the press has written about it within the confines of a doomsday scenario. Simson Garfinkel (2005) notes that "news reports on RFID privacy rarely point out that the technology has already been massively deployed throughout the U.S. and much of the industrialized world." In November, 2003, Mario Rivas, executive vice president for communications at Philips Semiconductors, said that Phillips had shipped more than a billion RFID devices worldwide. Mark Roberti, editor of *RFID Journal*, estimates that between 20 and 50 million Americans carry an RFID chip in their pocket every day—either in the form of a proximity card for entering buildings and garages or in an automobile key with an "immobilizer" chip molded into the key's plastic handle.

Garfinkle also notes that some privacy activists see RFID's widespread and unrestricted deployment as a kind of doomsday scenario in which corporate and governent interests can pervasively track individuals—paving the way for a technototalitarian state in which each person's movements, associates, and casual acquaintances are carefully monitored and recorded in futuristic data centers.

One of the leading crusaders here is Katherine Albrecht, director of Consumers Against Supermarket Privacy Invasion and Numbering (CASPIAN). Albrecht variously calls RFID tags "spy chips" and "tracking devices" and she organized a Benetton boycott that forced the company to officially repudiate any RFID testing plans.

Even though much of the media and consumer hysteria against RFID is based on misperception, this is still a significant problem for those organizations that want to deploy it.

A similar example of such consumer hysteria is when the Piggly Wiggly grocery chain attempted to deploy a fingerprint-based retail authentication system in 2005. During the testing, the assistant IT Director stated that he did not appreciate how emotionally intense some of the opposition was until he visited a store and saw a 70-year-old woman literally throw a Bible at an employee trying to enroll people in the program. The customer told him that "God was going to rain hellfire on him and that he was promoting the devil's work" The store manager took it to mean that the customer was not interested in enrolling in the biometric system.

In a similar vein, noted privacy and security expert Simson Garfinkel created the RFID Bill of Rights that attempts to create a framework for enabling consumers to regain control of how their personal RFID data is used. Garfinkel (2002) writes that the likely proliferation of these devices has spurred him to come up with this RFID Bill of Rights. Specifically, consumers should have:

- The right to know whether products contain RFID tags
- The right to have RFID tags removed or deactivated when you purchase products
- The right to use RFID-enabled services without RFID tags

- The right to access an RFID tag's stored data
- The right to know when, where and why the tags are being read

Ultimately, the use of biometrics at Piggly Wiggly showed that consumer and end-user resistance can be significant. With that, education and awareness are critical issues in accelerating any new technology acceptance. The bottom line: Consumer and end-user resistance can sink even the best technology. Be prepared.

58.3 Securing RFID

Organizations that want to secure their RFID infrastructure should approach it the same way that they would secure a standard network or Internet infrastructure. By and large, RFID and non-RFID networks have the same security issues.

It has been observed that organizations with effective information security practices in place will also use them when deploying RFID.

Securing RFID tags from eavesdropping is one of the biggest concerns with this nascent technology. Although this level of security is possible, to date, securing basic RFID tags presents somewhat of a monetary and technological considerable challenge.

For enterprises, eavesdropping on RFID is a real and significant threat. It can be a highly effective form of corporate or military espionage, since the RFID readers are able to broadcast their tag data up to hundreds of yards away.

Shielding these radio emissions is possible, but that effectively negates much of their primary use. One of a few approaches that are in use to overcome the eavesdropping issue is silent tree-walking, which was developed at MIT. Silent tree-walking involves a modification to the basic reading protocol for RFID tags that eliminates reader broadcast of tag data.

Another, albeit proprietary technique was developed by RSA and involves the use of pseudonyms. In this security system, tags carry multiple identifiers, and emit different identifiers at different times. Thus the appearance of a tag is changeable. Legitimate readers are capable of recognizing different identifiers belonging to a single RFID tag. An eavesdropper, however, is not. Pseudonyms can prevent an adversary from unauthorized tracking of RFID-tagged objects.

58.4 Conclusions

RFID is most definitely a technology whose time has come. Only by understanding the many security and privacy issues can this vital technology be deployed in a manner that truly supports its mission.

New Emerging Information Security Technologies and Solutions

Tara Chand

59.1 Introduction

News items come out on a regular basis related to information security. For instance, how hackers get the better of it as well as the never ending security bulletins and patches to the information security products are examples. A large number of security experts are engaged and working for security companies as well as the companies that use these information security products to attend to this situation. These experts are facing an evolving struggle in their attempts to find the hacker. One of the largest obstacles in front of information security experts is in determining if the weakness is in the system or if it is the people or the process that are to blame.

When the FBI cannot keep its systems secure (February 14, 2005, Newsweek) with the most sophisticated firewall and when it cannot determine how or what has happened, it is clear to many that the war on security is being lost. After having had the umpteenth update of the firewall that has not worked, the security experts wish people were more security aware and better trained, and experts push for better laws to punish hackers.

In his September, 2004 keynote speech, "The End of the Internet as We Have Known It," William Hugh Murray, executive consultant to Tru Secure Corporation, paints a bleak picture that validates the notion that the war on security is being lost.

In recent speeches, Hal Tipton, a member of the ISSA Hall of Fame, claims that the systems are getting more complex and the security "sky is still falling" compared to 10 years ago.

Security is a complex, multidimensional subject. Security affects businesses differently, but it affects all businesses. The businesses most vulnerable are those that are in the financial services industry such as credit cards companies, banks, insurance companies, and those that store personal data such as government agencies, merchants, and employers.

Besides the ten domains of the common body of knowledge (CBK), information security has many other dimensions. One of these dimensions involves a hacker with different degrees of skill, education, motivation, organization, and malevolent intent who is located in any part of the world. The hacker is constantly on the prowl and looking for a weakness in a system's security.

Another dimension involves a financial institution that is loaded with items ranging from hard currency to personal data that can be converted to money on the open market. Of course, there is also the added dimension of the financial institution or bank customer whose money or data everyone is after as financial institutions attempt to offer additional services and hackers attempt to steal information.

All three dimensions have very different objectives and different yardsticks. Thwarting the hacker while keeping the financial institution and customer satisfied is a daunting challenge in this age of security. One may have a security solution that is good only until a hacker works around it. The solution may be so cumbersome to use that the customers do not want to use it on a consistent basis, or it is too cost prohibitive for banks to deploy it.

There is no total perfect solution to any given situation or problem. Experts conveniently state this bit of wisdom in terms of probability. As an illustration, a commercial plane is perfectly safe if its safety features have been demonstrated to the Federal Aviation Administration (FAA) with the analysis that the probability of a crash and the loss of life are less than 1 in 11 billion. The same concept holds true for security, and this is stated in terms of an acceptable or residual risk.

Therefore, Information Technology (IT) and its dependence on information security is a continuously and rapidly changing discipline. Information security has been built on some fundamental assumptions and principles that are not working well in this rapidly changing security landscape and are essentially breaking down.

One of the fundamental assumptions is that extra or enhanced security equates to extra cost for the businesses and extra hoops for the employee or the customer. This leads to greater complexity for systems that leads to greater vulnerabilities. Those engaged in information security enterprise businesses are creating ever more complex solutions. Intrusion detection systems (IDS) or Intrusion Prevention Systems (IPS) are examples of that solution. The notion that people are and would be integral parts of any security system is almost lost. This will always be the weakest link. With this assumption, businesses are struggling to determine the true measure and cost of security and how it can be paid. The Information Security and Risk Management domain of the CBK does not provide sufficient solutions to this problem.

The premise behind current information security is based on the following principles:

1. Authentication, defined in terms of weak or strong authentication, is determined by factors of authentication, such as password (what you know), tokens (what you have), and biometrics (what you are). Each mechanism has its own issues of cost, reliability, and security.

2. Firewall for network access security that is usually implemented close to the border routers of a network, but the abilities of a firewall are limited to access control list-based filtering on the IP addresses that can be made up.
3. Traffic analysis inside a network as part of using IDS or IPS; transmission security by encryption such as public key infrastructure (PKI) and secure socket layer (SSL); data-at-rest security by key-based encryption of files in storage servers.
4. Filtering for hidden threats by host-based applications with predetermined signatures, similar to filters for viruses and worms.

The current security technologies and practices based on these principles have demonstrated severe shortcomings that have become clear to experts as well as the general public. These principles of security and current technologies based on them are being incrementally refined and are providing a diminishing return for security.

Given this landscape of information security, new security concepts and technologies are needed to address information security in the modern age that will also stand the test of time.

New information security technologies are addressed in five different areas of: authentication, global Internet security, encryption, identity data security, and e-commerce security. E-commerce security represents payment or transaction based security.

59.2 New Information Security Technologies

59.2.1 Authentication

Under this topic, five different technologies are described. The first is a technology that provides strong authentication without tokens and long passwords and is best suited for the online banking environment. The second is for authenticating the bank server before authenticating the user to the server. The third is for multifactor authentication where a single user action and single system interface provides more security than three factors of authentication. The fourth is for password storage and retrieval (PSR) technology that solves the problem of safely saving and retrieving complex passwords without relying on memory, paper, and file records. The fifth provides packet-level authentication at the border router of a network.

59.2.2 New Remote User Authentication Service™

59.2.2.1 Introduction

In October, 2005, the Federal Financial Institutions Examination Council (FFIEC) released new guidelines, *Authentication in an Internet Banking Environment*, that call on banks to upgrade current single-factor authentication processes—typically based on user names and passwords—with a stronger, second form of authentication by the end of 2006.

The FFIEC guideline is a result of letters that the author wrote to the SEC and members of Congress early in 2005. New Remote User Authentication Service (NRUAS™) satisfies the FFIEC guidelines and was primarily developed for a large customer base such as one found in a financial institution.

New Remote User Authentication Service delivers strong authentication by a unique combination of existing long held and proven security concepts. First, NRUAS eliminates the use of long passwords. Second, it does not have security tokens.

Current strong remote-user-authentication security solutions use complex passwords, security tokens, and biometrics. These are logistically complex, costly, difficult to scale up, and not user-friendly.

These problems point to a need for new strong remote user authentication security technologies. New Remote User Authentication Service technology solution stands apart from the industry as being able to provide strong remote user authentication without complex passwords, security tokens, biometric sensors, and sample databases.

New Remote User Authentication Service does not inherit the weaknesses and limitations that are well-known and well-publicized such as the password, security tokens, and biometrics.

New Remote User Authentication Service is a strong authentication service that is highly scalable, easy to implement, user-friendly, and cost-effective by many orders of magnitude for the reasons described herein.

The bank customer is told to have long, random passwords that are difficult to crack and also difficult to create and remember. Customers may be additionally burdened with a security token to implement a two-factor strong authentication as well as performing other cumbersome steps. These are not viable security solutions when dealing with a large customer base, such as that of a financial institution that delivers online financial services. New Remote User Authentication Service works without long passwords and security tokens, and it provides a two-factor strong authentication as required by FFIEC guidelines.

New Remote User Authentication Service uses technologies already in widespread use to be able to provide two-factor strong authentication without long passwords and security tokens. New Remote User Authentication Service uses Call Origination Call Back (COCB) and digital tone multi frequency-personal identification number (DTMF–PIN) as the two factors of authentication leading to strong authentication. COCB factor of authentication is based on Telco Screen technology that can determine or trace a call's origin. The caller ID from a phone is not reliable because, in some instances, the caller has the ability to create his own caller ID. Therefore, when a call is received, assurance on the call origin cannot be assumed. Telco Screen technology solves that problem.

59.2.2.2 Telco Screen™ Technology

A call that originates from a cell phone has distinct attributes and signatures. One of these distinctions is that the cellular telephone company determines the caller ID and not the caller. A cellular telephone company does that by the subscriber identity module (SIM), and it then checks the account status, records the call status, and maps the SIM to the caller ID that is forwarded as the call's origin from the cellular telephone company. One example of call status is based on the destination number called, such as flagging the call mobile to mobile (M2M) when the destination is a number from a certain class such as a specific company's mobile number. The technology to be able to differentiate different types of call origination (CO) is called Telco Screen™.

The Telco Screen technology leverages these distinctions to create two distinct and separate paths of call processing. For example, the call path from an unknown call origin is processed by interactive voice response (IVR) Script A, and calls from known call origins such as from cellular telephone company are processed by IVR Script B by an IVR System. IVR Script A requires a call-back (CB) feature to pre-registered numbers. The CB is to a number that the caller selects in real time at the time of CO. IVR Script B requires only CO without the need to have a CB. Given the wide use and availability of cell phones, it is assumed that path A will be rarely used, but it does allow flexibility when the cell phone is not available to be used.

Therefore, COCB™ acts as the first factor of authentication. The second factor of authentication is a numeric PIN entered in the phone that is delivered as multifrequency tones to the IVR system. Hence, this factor is called DTMF–PIN™. Thus NRUAS is able to provide two-factor authentication without long passwords and physical tokens.

Another unique aspect of NRUAS is its use of a just-in-time delivery of a one-time-use and limited-time-use numeric pass key, freeing the bank customer from ever having to create, remember, and use long passwords. If the NRUAS system by either CO or COCB and DTMF–PIN is successful in authenticating the caller, the NRUAS system then generates a short Random Pass Key (RPK™) and voice-delivers it to the caller with a time limit when it would work. For example, the RPK may be ACY39 that is good for 60 seconds for one-time use.

The RPK has the attributes of being short and fast because it is usually a four to six digit alphanumeric code that is good for seconds or minutes. However, NRUAS enables the RPK to be customized to the needs of its users and the system they are logging in to by customizing the length of RPK, the time it is good for (minutes, hours, or days), and from which of a remote person's phones the COCB factor can work.

Because no one size fits all, if a user has a good memory, he can call NRUAS less frequently and receive and memorize a longer RPK that may be good for a number of days for multiple use. This level of flexibility may be implemented at the individual level based on the security policy of the business.

The caller on a login window uses their primary phone number as user ID and uses the newly received RPK as the password. The business's existing authentication system identifies the caller and authenticates the caller using the RPK and then allows access to the authorized application server.

Phones, specifically cell phones, are the most widely used infrastructure. In digital phones, the control information and voice channel are encrypted and are not subject to cloning or eavesdropping. The phone used in NRUAS is not a security device in the sense of the security token because no formulas are executing within it. Therefore, losing a phone is not like losing a security token. Cellular phone companies generate the cell-phone caller ID, not the phone itself, by mapping the Subscriber Identity Module (SIM) or device MAC to an account number and its status and then to the caller ID.

Some users may prefer RPK delivery by short messaging system (SMS). However, SMS uses a data packet store-and-forward network like the Internet and may be subject to hacking. Therefore, NRUAS prefers real-time voice delivery to ensure a remote person is in the loop. Each authenticated call generates a new RPK and can be obtained anytime from anywhere.

The existing authentication systems of a bank remain independent from the NRUAS system. That means there is no change to the login screen process that a user sees and uses, and there is no change in the bank's authentication system. For example, in the login webpage, the bank user enters his primary caller ID or his existing user ID. In the password fields, the bank user enters the RPK received from the NRUAS system. New Remote User Authentication Service uses the most widely used existing login user interface of any authentication system.

New Remote User Authentication Service system requires two simple interfaces to the bank's authentication system. One interface is for account maintenance to add or delete new users by replicating their caller IDs in the NRUAS directory or database. The second interface is the RPK that is used for authentication that is fetched by the bank's authentication server from the NRUAS system in real time for each instance users log in. New Remote User Authentication Service system exclusively maintains the random creation, delivery, and time or use based deletion of RPK from its directory.

Decoupling the NRUAS system from the bank's existing authentication system in the manner described above enables a cost-effective NRUAS implementation. The NRUAS system does not touch or use any employee or customer data. The IVR server that is part of the Telco Screen does not store any code or data. New Remote User Authentication Service can be incrementally deployed to work within existing systems with virtually zero training costs.

Telco Screen, implemented in the telephone company, prevents DoS attacks on the IVR server. For these reasons, NRUAS deployment is cost effective by many orders of magnitude compared to security-token-based systems.

The NRUAS implementation embodies systems engineering and security principles such as separation of systems, compartmentalization of data, and need-to-know. This makes the NRUAS implementation clean, robust, secure, and economical. A cellular telephone makes an ideal component of the NRUAS strong authentication service for many reasons. Cell phones are a personal item in the physical control of the owner. The telephone number associated with a cellular telephone uniquely identifies the owner because the telephone company has verified the owner's identity, and it provides caller ID that cannot be tampered with, altered, or blocked by a user because the caller ID is provided by the telephone company computer systems. Cell phones are owned by many people because of their convenience and affordable pricing. In some respects, a cellular phone is superior to a card because a cellular phone has a minimal risk of theft because the telephone company can trace the location of a cellular phone.

The computer systems have different security needs and the users have different preferences. For a successful technology service, all of the affected parties must be kept reasonably satisfied. There are many implementations of the NRUAS remote user-authentication service. The flexible features of NRUAS are as follows:

- The NRUAS access service can be gradually phased in without any system downtime and customer education.

- During a transition or a training period, the NRUAS access control function in the authentication server can be programmed to accept either the traditional password or the RPK of the NRUAS strong authentication. This would enable those who prefer to use the password to continue to use the password and those who prefer to use the NRUAS access service to use this service during this transition period.
- For those who may continue to use the password, they may still use the NRUAS access service on those occasions when they have forgotten the password.
- In one version of the NRUAS security service, as illustrated in Exhibit 59.1, the individual business has an IVR equipped authentication server. In another version, as illustrated in Exhibit 59.2, a central IVR equipped authentication server is used that connects on a virtual private network (VPN) to the business's authentication server.

59.2.2.3 Online Banking Application

Online banking is the most common service that would benefit from NRUAS strong remote user authentication and is described here in more detail.

A customer connects to the bank server and receives a login page. The customer has a cellular telephone number of 707-399-4333 and calls 1-800-111-3434. The bank system asks for a PIN, and the customer enters a PIN of 1249. It could be the same PIN used for an ATM card or anything else. The NRUAS authentication function in the bank computer system identifies and verifies the customer by caller ID and PIN, and it creates a passkey of 7073994333-4345 where the first number is the cell telephone number and the last four digits are a random number created for this customer for this transaction (see Exhibit 59.3).

The NRUAS authentication function communicates the passkey of 7073994333-4345 to the access-control function of the bank's authentication server. The NRUAS authentication function also voice-delivers the passkey to the customer. Because the customer already knows the telephone number, there is no need to communicate that part of the passkey. Therefore, the voice response may be "plus 4345."

On the login page, the customer enters the passkey as 7073994333-4345. The bank identifies the customer by the telephone number 707-399-4333 and verifies the customer by the random code (RC) of 4345, granting access once or for a limited time (see Exhibit 59.4 and Exhibit 59.5).

59.2.2.4 How Banks and Their Customers Benefit from Strong Authentication

The new authentication technology enables the bank customer to:

1. Not have to have a password to remember and safeguard.
2. Not have to use a social security number as user ID to access the account.

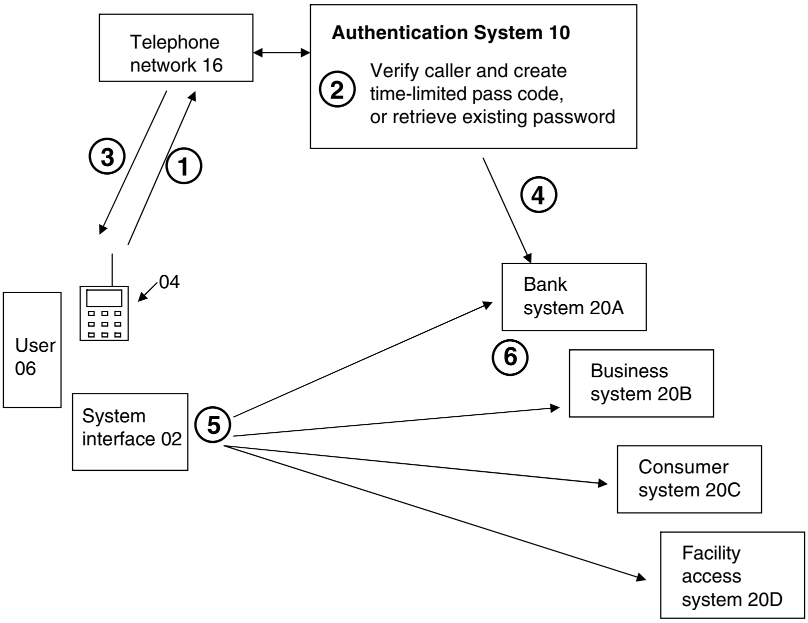

EXHIBIT 59.2 In this version of the NRUAS security service, a central IVR equipped authentication server is used that connects on a VPN to the business's authentication server.

3. Not need additional resources as the bank customer already has a cell phone or home phone with unique phone numbers.
4. Not have to learn a new procedure as the bank customer is already familiar with using an 800 number call to a bank and getting an automated voice response.

To the bank, NRUAS provides:

1. Not having to implement a new system other than the NRUAS authentication function software in its existing bank computer system.

59.2.2.5 Different Implementations of NRUAS

This strong user-authentication technology works equally well at the ATM terminal in retrieving a transient PIN. It also works well where a bank customer would use his existing password but has forgotten it. He can instantly get a transient passkey and use it See Exhibit 59.4.

As illustrated in Exhibit 59.2, the NRUAS may be implemented in a centralized service based architecture where with a one centralized NRUAS authentication system may serve a large number of smaller banks and businesses, who would pay for NRUAS authentication on a use basis. As illustrated in Exhibit 59.3, large banks or other large businesses may implement their own NRUAS architeture.

59.2.3 Reverse Authority Authentication System™: A Solution for Phishing

59.2.3.1 Introduction

IT enables many new and creative methods that may be used to spoof a secure Web page from a bank server. Each and every part of a Web page can be faked. The customer then has no idea if the Web page he is about to enter his personal online banking identity data onto originate from the bank server or from a fraudulent page. For this security issue, the industry has coined the term *phishing* to imply fishing for and stealing online bank customer identity. The industry has seen phishing scams grow and become increasingly sophisticated to the extent that the industry formed an anti-phishing organization (http://www.antiphishing.org) to measure the scope of the problem.

To counter this security menace, reverse-authentication technology was developed. Reverse-authentication technology is based on the premise that individuals will not be comfortable entering personal data on a Web page without an assurance that it has not been spoofed.

The Reverse Authority Authentication System (RAAS™) concept is illustrated in Exhibit 59.6. In Step A, RAAS allows the customer to create or receive a RAAS code by calling a RAAS system. What an RAAS code is exactly is described below. In Step B, a customer connects to an institution's secure server, in step C, the RAAS code then appears on the page that is used for login. The presence of the RAAS code assures the customer that the login web page had not been spoofed and did originate from the requested online bank server.

The RAAS code can take the form of a simple alphanumeric such as KAP457 or a phrase such as *clear ocean*, or even symbols such as a smiley face and crescent. The customer can create the RAAS code

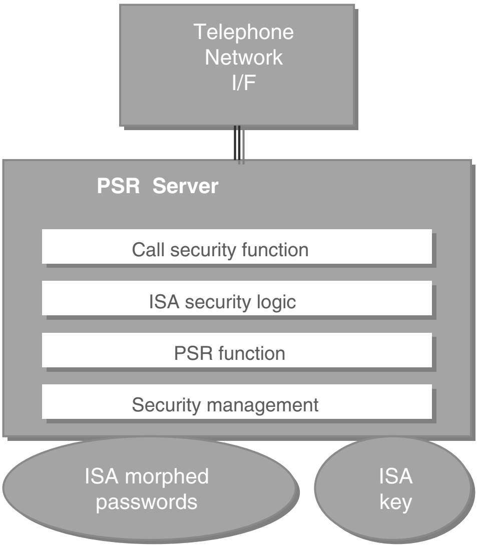

EXHIBIT 59.6 Reverse Authority Authentication System (RAAS™) code.

anytime from anywhere by calling a private number via a phone that has a caller ID associated with it to the RAAS system.

The RAAS system may randomly generate the RAAS code. Alternatively, the RAAS code may be created by the customer and merely deposited in the RAAS system by the customer.

After the RAAS code is obtained, it can be good for any length of time, such as up to one year. However, it can be regenerated to a new replacement code whenever the customer desires. The RAAS code is anchored in the RAAS system by the caller ID of the phone. The caller ID is simply used as a reference. It does not matter which caller ID it is, and no account need be established.

59.2.3.2 How RAAS Works

As had been described when the user connects to a secure server, the RAAS code appears as a graphic file in the corner of the login page to assure the customer that indeed this login page is not as a result of phishing or spoofing. The RAAS system process described below in steps A, B, and C, is seamless and relies on existing technologies. The RAAS process is mostly transparent to the customer, until the Web page with the RAAS code image appears to verify the authenticity of the bank server.

Step A. The customer may make a bank secure server connection from any personal computer (PC), a personal one or one in the library. A RAAS agent in the PC is automatically activated and opens a window to receive from the customer a caller-ID-secret-number combination and connects to the RAAS system. The RAAS system matches the information, saves the PC's internet protocol (IP) return address, creates a time stamp (TS), and responds with an OK advisory to the RAAS agent in the PC. The RAAS agent then exits and allows the PC's secure server connection proceed as usual.

Step B. Bank server's RAAS application, on receiving a connection request from the customer's PC, forms a query to the RAAS system with its own server authentication data and the customer's IP return route address. The RAAS system authenticates the bank server, and then reverse matches the customer IP route address to find a caller ID record and checks for the TS. If the caller-ID record that corresponds to the IP route address is found, the RAAS system creates a one-time/limited-time-use RAAS code image file address and sends that image link address to the bank server.

Step C. The bank server embeds the image link in the login Web page and sends it to the PC of the customer in response to the secure server connection request. The PC's browser fetches the image from the RAAS system and displays it to the user as a part of the login Web page. The RAAS system times out on one image fetch or on time stamp expiry of TS and deletes the image. The browser deletes the login page after the login is performed. Therefore, the RAAS code image is not stored anywhere, except in the RAAS system for a fraction of a second.

59.2.3.3 RAAS Implementation

The RAAS implementation is not only cost effective but is also logistically easy to implement. The customer PC requires a RAAS agent, which can be delivered by the bank or may become part of the browser or operating system. The customer only needs to create or receive an RAAS code from the RAAS server via a phone call with an associated caller ID. The RAAS agent is only activated on connections to a list of secure servers such as those belonging to online banks and not for all secure server connections.

The bank secure server requires an RAAS interface agent and an account with the RAAS system. The RAAS system may be an independent system and may be owned by a bank, independent company, or a consortium of banks. Very large institutions may choose to maintain their own RAAS servers.

59.2.3.4 Who Pays for the RAAS System

Those who benefit from the RAAS system pay for it. An RAAS system is a fixed cost and handles a large number of customers. Scaling an RAAS server drives down the costs as more and more users are added and may average 50 cents per customer per month, or about $5/year. Recapture or justification of these costs can be easily obtained through fraud and theft reduction. In addition, the customer may be charged a fee for the RAAS code by billing it to their phone account.

59.2.3.5 Quad-Factor™: Multifactor Authentication

The industry is used to implementing three different factors with three different mechanisms, both for the system as well as the remote user, such as entry of a password in a login window, carrying of a physical token with either a soft interface via changing numbers that need to be entered in the login window or a hard interface by inserting the token in the network device, or use of a biometric sensor. In addition, each of these factors have their own issues of reliability, security, and logistics that have been well documented and are well known to information-security practitioners.

In an ideal security world, one would want or desire all three factors, but that would increase both the system and logistics costs, as well as create a time-consuming number of steps for the remote user.

Quad-Factor (QF™) is one of those emerging authentication technologies. Quad-Factor technology provides four factors of authentication without having separate factors to deal with. Hence, one single user action, with one single device like a security card and one single system interface would be able to provide two to four dynamically adjustable factors of authentication. The QF technology eliminates the login window, password, traditional use of tokens, and biometrics by embedding all of them in one user action and one device in a way that reduces cost, logistical complexity, and system complexity, yet provides security that can be achieved by using all three traditional factors of authentication. The fourth factor in addition to the three factors is location, where an embedded GPS chip in the QF card would allow the card to be authenticated from only certain locations.

59.2.3.6 Password Storage and Retrieval™ Technology and Application

Simple passwords are easy to crack. Therefore, business professionals and IT workers are required to create and use long and complex passwords that are difficult to remember.

A recent poll from SearchSecurity.com found that 77% of respondents had six or more passwords to remember for their jobs. About 23% had five or fewer passwords. But 20% had 15 or more passwords for their jobs. More than 200 took part in the online survey. Having many passwords is part of being an IT professional or "part of the wretched way the world is," said Jon Callas, chief technology officer and founder of PGP Corp. and a SearchSecurity.com site expert.

Saving passwords in paper slips or in a file, even if encrypted, is a security risk. From both the inside and the outside, a weak password presents an unacceptable security risk. Enforcing long, complex, and changing passwords creates additional security risks while attempting to solve one security risk.

In some password applications, such as those for embedded systems such as routers, etc., NRUAS, as described earlier, is not applicable. Hence, Password Storage and Retrieval (PSR)™ was developed for this specific application.

59.2.3.7 Password Storage and Retrieval

Password Storage and Retrieval reduces and eliminates risk at a far lower cost than any other acceptable control mechanism. PSR™ is an anytime, anywhere, on-demand technology. PSR technology provides a risk-managed, cost-effective solution for this security risk and reduces IT costs by reducing help desk requirements for password maintenance and resets (see Exhibit 59.7).

In PSR, the authentication server stores existing passwords using shredding/aliasing technology, enabling each to be re-recreated on demand, just in time, and voice-delivered to the user. The shredding/aliasing technology is described later in this chapter. PSR is described with reference to the Exhibit 59.7:

- PSR server: a standard server interfaced with the telephone network.
- Call security function: receives calls from only mobile phones and using caller ID and a six-digit PIN verifies the caller.
- Intelligent Shredding and Aliasing (ISA) security logic: for password storage—receives tone entries from mobile's keypad and in real time intelligently shreds each password and randomly aliases each digit. ISA-security-morphed passwords are then stored in one database, and the ISA-generated random key is stored in another database server.

EXHIBIT 59.7 Password Storage and Retrieval (PSR) architecture.

- PSR function: for password retrieval—re-creates anytime, anywhere, on-demand, an employee's specific password by reversing the ISA logic. The password is voice-delivered to the verified caller and then deleted.
- Security management function: maintains caller IDs and PINs and implements password maintenance policy.

These are the information-security risk-management issues, issues for which PSR technology application provides a risk-managed solution. PSR™ is a cost-effective security-risk mitigation technology service that also reduces IT costs. Large companies implement their own PSR server. Others may share a PSR server and pay a nominal annual fee per employee.

59.2.3.8 Router-Based Authentication System™

The source identification of a data packet, in the form of an IP address, can be altered and set at any value by the source computer. A border router/firewall relies on the source identification to be effective in discarding packets as defined in the access control list. IDS deployed within the network sniff packets after they have entered the network. The Router-Based Authentication System (RBAS™) technology secures a data network by positively authenticating the source of each packet entering a network and discarding other packets. Router-Based Authentication System provides network security with packet authentication signatures that enables the source of each packet to be authenticated by a dynamic signature in the header of each packet.

The security of data networks has surfaced as a critical national issue. The RBAS technology, by consolidating the firewall, login, and intrusion detection/prevention functions into one RBAS system that is deployed in the network in place of the router/firewalls, will provide security at a lower cost. In addition, the RBAS technology provides security in an area for which no security existed before – that is two-factor source authentication for each data packet entering a secure network.

Router-Based Authentication System security technology will enable each packet received by a data network to be authenticated by a dynamic signature. It will also enable the businesses to improve the security of their network at a lower cost by consolidating the functions of login, firewall and intrusions detection systems into a RBAS technology adapted border router or router internal to a data network.

The header of the incoming data packets contains the source-computer IP address, the destination-computer IP address, and the destination computer port. IP denotes a unique address of every computer on a network and the port denotes the connection to a specific application of the computer.

The identification of the source of a packet is in the form of an IP address, and is created and can be altered to be any value by the source computer. Therefore, the destination computer cannot truly know where the packet came from or which computer it originated from. This is how spurious and harm-causing data packets are sent to a computer over which the destination computer has no control, because it cannot really authenticate the source of the data packet.

A business's network servers are protected by a border router, which also hosts a firewall. The firewall checks and filters each incoming data packet, based on an access-control list programmed in the firewall.

The access-control list identifies the source and destination IP addresses as well as destination computer port addresses. The firewall rejects packets based on the source-computer IP address, destination-computer IP address, and the destination computer port address that are listed in the access-control list.

In addition to the protection using a border router/firewall to filter out data packets as described above, current technology uses a user ID and password for session authentication. However, a password is only one factor and is therefore considered a weak form of authentication, by information security experts because this form of authentication can be easily compromised.

Because there is no certainty that the sender of these data packets is who they say they are, the current state of the technology may allow entry of data packets into a network that are harmful to a destination computer.

The industry solution to this state of weakness in protecting a network from harm has been to build an IDS. The IDS is a software function that is deployed on a server inside the network to monitors or "sniff" all data packets traveling in the network. The IDS copies all data packets in the network and applies rule- and signature-based logic to detect threat scenarios and alert the system managers that an attack may be taking place.

In the IDS approach, the data packets that cause harm have already entered the network despite the border router/firewall and user authentication using with a password. The IDS is a complex approach and does not work all of the time, thereby creating many false alarms. It is so complex that many businesses have outsourced the monitoring of the IDS, thus also creating an issue of confidentiality of data.

The development of an IDS by the information security industry is a testimony to the problem that the firewall method for screening the content of incoming data packets is not sufficient to protect a network from harm.

The RBAS technology is applicable to controlled access content data networks and would enable data packets entering a network to be positively authenticated before they are allowed to enter a network. Thus, RBAS enables the data network to be more secure against this kind of threat and is believed to be a superior technology compared to the use of firewalls, password authentication, and IDS.

59.2.3.9 Description of RBAS Network Security Technology

The card/token-based strong (two-factor) source authentication in current systems for network security is costly, has operational security and logistical issues, and, therefore, is not widely used by businesses. Therefore, businesses are using only a one-factor (password) authentication for establishing security of a session.

The innovative RBAS security enables two-factor source authentication of each data packet at a lower cost. Router-Based Authentication System takes advantage of the existing public network infrastructure and thus avoids the infrastructure cost of maintaining card-dependent security systems. The source authentication is performed via a two-factor authentication that leverages the public voice telephone using caller ID features and a PIN.

The RBAS implementation has:

- The router/firewall equipped with an interactive voice–response (IVR) system, a database that maintains the cellular telephone numbers and PINs of authorized users, and a function that verifies each session user via the caller ID and PIN and generates and voice-delivers a four-digit random numeral to the user.
- A client software function that displays the 800 number of the router/firewall IVR, accepts the cellular number plus the random numeral for login, and embeds the cellular number plus random numeral in the option field of each packet header.
- As added optional security features, the random numeral may be modulated and thus will be different for each packet, creating a dynamic source signature for each packet. Furthermore, another security feature allows the user to pre-select the length of the session in minutes; this would enable the router to disable packet traffic from this user at the expiry of the session time.

EXHIBIT 59.8 Router-Based Authentication System (RBAS) and Current Network Security Technology Comparison

	Feature		
Security Technology	Function	Security Features	Operation Logistics
Intrusion detection systems (IDS)	Sniffs all data packets inside a network, compute packet statistical data	Detect attacks based on pattern of data packets	Requires (1) selection of network location for IDS placement, (2) IDS sniffer software logic, (3) threat signatures and comparison logic (4) and an alerting mechanism to the security manager to investigate unusual packet traffic
Firewall	Check each packet header. Discard packets that are not approved	Filters all incoming data packets entering a network based on access control lists	Requires defining access control lists by specifying source internet protocol (IP) and destination IP to screen each packet by its source and destination IP addresses
Password login	Used for session authentication by user ID and password	Does not allow access without the entry of correct password	Requires creation and maintenance of a password infrastructure
RBAS	Filters all incoming data packets based on a dynamic signature in each packet header	Discard packets without authenticated signature from the source	Requires (1) an IVR System in the router/firewall, (2) a cell telephone data base, (3) and a RBAS function that checks dynamic signatures for each incoming packet before routing

Router-Based Authentication System enables a robust and cost-effective network security solution compared to the current prevalent network security technologies. Exhibit 59.8 provides a comparison of the RBAS network security compared to the current security technologies of firewalls, IDS and the login using a password.

The RBAS can be implemented in both the border routers and the major internal to the network routers. As the Exhibit 59.8 comparison illustrates, the RBAS has the potential to replace firewalls, password infrastructure, and the IDS systems and their costs, and still provide a comparable or better network security.

With reference to Exhibit 59.9, the dynamic packet authentication signature (DPAS) system for network security has a packet authentication function (PAF) in a router/firewall and a client security function (CSF) in a client.

PAF includes: (1) an IVR system with the ability to receive a telephone call and verify the caller by comparing with pre-stored caller ID and a PIN, (2) a DPAS function to generate a random passkey, voice-deliver it to the caller, and save in the system, where the DPAS rejects packets from the client that do not have the cell number plus passkey embedded in option field of the header of the packet.

CSF in the client includes (1) a display of an authentication screen that displays an 800 number to the IVR of the router/firewall and enables entry of the cell number plus passkey, and (2) a function that inserts the cell number plus passkey in each data packet. As an additional security feature the passkey for each packet can be modulated to be different for each packet, providing a dynamic signature for each packet.

The preferred embodiment uses cellular phones to call the IVR of the router/firewall. The current caller-ID technology provided by the telephone companies uniquely identifies a cell phone owner and is used to verify the caller to the router system.

The RBAS security system serves the businesses by eliminating the risk of having data packets whose source cannot be authenticated come in to the network. This eliminates the risk of being a target for hackers.

The RBAS using the PAF and the CSF performs the following six steps:

1. Step 1: A border router server to a business data network, adapted with RBAS, pre-stores a database with the client's cellular telephone number and PIN.
2. Step 2: A user desiring a data interface connection to the business invokes a security software function in the client, which displays an authentication screen, displaying an 800 number and an entry field for the passkey.

EXHIBIT 59.10 User interface for mail implementation of packet source validation architecture system (PSVAS).

3. Step 3: The user calls the 800 number and enters the PIN. Optionally, he or she also enters a numeral that specifies in minutes the length of the session desired. The border router receives the call from the user, verifies the caller ID in the database. The router then generates a random numeric passkey and delivers it to the user and saves these in the border router database anchored by caller ID.
4. Step 4: The User enters in the authentication screen a passkey made up of the caller ID and just-received random passkey and clicks the "connect" button.
5. Step 5: The connect-button click initiates a session to the border router, the button link having pre-stored the link URL. The security software function embeds a passkey in the option data fields of each data packet sent to the border router. The connect-button activates a function to (a) save the passkey of the caller ID and the random passkey, (b) initiate a TCP/IP, telnet/FTP session, (c) modulate the passkey based on predefined parametric logic (the parameters are from the passkey), and (d) embeds the modulated passkey in the option fields of data packets being sent to the server.
6. Step 6: PAF rejects all packets without option data. PAF verifies the option data against the IVR database. If the option data field match the caller ID and passkey in the IVR database, then the server forwards the packet to the data network; otherwise, it sends a page to the client for unauthorized traffic.

As added optional security features, the random numeral may be modulated and thus will be different for each packet, and the user can pre-select the length of the session in minutes. The pass code modulation scheme is described as follows: The CSF logic embeds the cell number plus passkey in each packet header. The CSF logic may modulate the passkey for each header. The PAF filters packets based on the modulated passkey.

59.3 New Infosec Technologies, Part II

59.3.1 Packet Source Validation Architecture System™—Global Network Security

PSVAS provides global Internet security by validating the source of all packets by improvement in the global computer network structure. PSVAS would enhance Internet security and potentially guard against all of these types of threats. The innovation, named *packet source validation architecture system* (PSVAS), validates the sources of data packets entering the network. PSVA rejects and does not route those data packets that are not source-validated.

Packet source validation architecture (PSVA) system has a set of key servers (KSs), adapted major routers, and a CSF in the sending and receiving clients. The PSVA system enables the source of each data packet to be validated by the major routers with the help of the KSs. Not being able to validate the source of data packets is a fundamental security weakness of the Internet. Because there is no certainty that the sender of these data packets is who it says it is, the current Internet infrastructure may allow entry of data packets into a network that are harmful to a destination computer. The harm that may be caused to the destination computer may take any number of forms, such as deletion of files, crashes of the system, the system being made unavailable for some time to the users, theft of data files, and many other known and as yet unknown types of harm.

The PSVA system provides enhanced network access security by providing a solution to the fundamental weakness of the Internet architecture: the inability to authenticate the source of the packets entering the data packet. These security enhancements should discourage the senders from transmitting harm-causing data over the Internet.

The PSVA system will solve major shortcomings of Internet security and thus help make the Internet more secure and robust. The cost of improvements will be recovered from a fee via the ISPs or by surcharging telephone calls to the KSs.

Data packets are the basic transport mechanism underlying the Internet. When the packets are routed over the network of routers, each successive router checks the destination IP address in the header to determine the best routing path and delivers the packet to the destination computer. The routers, by design, never check the data part of a packet and are limited by their design to find the destination IP address and find the best routing path.

Therefore, the routers that are the basic transport mechanism of the Internet have no underlying mechanism to be able to validate the source of the data packet. The identification of the source of a packet is in the form of an IP address. This IP address is created and can be changed or altered to be set at any value by the source computer. Therefore, the destination computer cannot truly know where the packet came from or which computer it originated from.

This security weakness is exploited in many different ways by all types of hackers and people intent on causing harm. E-mails are used as a means to distribute many types of viruses, worms, and other forms of mischief such as phishing and spamming. That is the reason various types of worms, virus and other mischief can enter and circulate on the global network from anywhere in the world.

The current security technologies leave it entirely up to the destination computer to screen the incoming data packets. To accomplish this purpose, current technologies provide various types of firewalls and intrusion detection and intrusion prevention systems that operate at the packet level. Other security technologies, such as virus checkers and application-specific proxy firewalls operate at the file level. Yet another security technology of remote user authentication, via user ID and password, operates at the session level.

The entire information security industry is geared towards providing better and improved forms of these tools to protect the destination computer from data packets that may be harmful to the destination computer. This approach to security leaves the sender of harm-causing data packets to keep trying to send harm-causing packets and the businesses to defend themselves from such attacks and intrusions on a continual basis. This explains why, over the years, there has been such a large proliferation in different types of threats in the form of harm-causing packets that are sent via servers or e-mail servers. As soon as the destination computers implement a defense mechanism against a known type of threat, the senders employ different techniques to defeat that defense by creating a new type and variety of harm-causing packets.

Using this inherent weakness, new vulnerabilities are discovered and exploited on a regular basis. For example, in a recent news story, titled “New Virus Snarls Thousand of Computers” by Anick Jesdanun dated May 03, 2004, he says “Unlike most outbreaks, the Sasser worm does not require users to activate it by clicking on an e-mail attachment. Sasser is known as a network work because it can automatically scan the Internet for computers with the security flaw and send a copy of itself there.”

This innovation is an improvement in the global computer network structure that would enhance security and potentially guard against all of these types of threats. The innovation, named PSVAS, validates the sources of data packets entering the network. PSVA rejects those data packets that are not source validated. The innovation includes packet level authentication for all incoming data packets from a source computer before routing them to the destination computer.

There are two distinct applications of PSVAS. First, the application validates the source of all data packets that are sent over the Internet. The second application validates the source of all e-mail data packets. For the first application, the PSVA system has a set of KSs, adapted major routers, and a CSF in the sending and receiving clients. The PSVA system enables the source of each data packet to be validated by the major routers with the help of the KSs.

For the e-mail security applications, the PSVA system has a set of KSs and adapted mail servers. The PSVA system enables either the sending mail clients or the sending servers to insert a source-validation code in the header of outgoing packets and the destination mail servers can validate the code with reference to the KSs.

59.3.2 Description of PSVAS

Computing devices called *routers* are the basic transport mechanism of the Internet. Routers route data packets from the sending computer to the destination computer using an IP address in the header part of each packet. The routers have no underlying mechanism that would validate the source of the data packet. This innovation provides a solution to this inherent weakness of the Internet.

The PSVA system is used to validate the source of the data packet in such a manner that the source of the data packet remains hidden and is revealed only to a law enforcement agency. Thus, the PSVA system provides a system of checks and balances that does not hinder the ability of people to communicate freely. But at the same time, if a person sends a data packet that causes harm that is identified in a list of approved harms by a rule making agency, then the sender of the data packet can be found and prosecuted by law enforcement.

The Internet is international in scope and has widespread users. Therefore, the PSVA system of this invention is also international in scope and can be used by anyone, anywhere.

The PSVA system leverages another global network with wide accessibility and an extremely large number of users, believed to be as large or even larger than the users of the Internet. That global network is the telephone network, including both the mobile cellular phones that integrate with this network, as well as the existing landline network.

With the cost efficiency and easy availability of mobile phones, they are now used by the masses, in both the developed world and the third-world countries. In a recent news report on the manufacturers in Telecom Industry, titled "Global mobile phone market explodes in first quarter: study", dated April 29, 2004, it notes that it is estimated that 586 million mobile phones will be sold in 2004 worldwide. An important feature of the global telephone network is that it is widely available and widely used, as this statistic demonstrates.

Another important feature of the telephone network is the caller ID feature. The caller ID feature enables a party being called to know the number from which the call originated. That is true for both the landlines as well as the mobile phones. While the landlines are fixed to a location, the mobile phones are movable and are in the custody of an individual owner. This difference does not affect the caller-ID features of the telephone network and this feature may be used as a means for a remote identification as described below.

Each mobile phone, as part of their manufacturing process has a built-in device identification number, sometimes called the *electronic serial number* (ESN). Each phone, when it is given to a customer, is personalized to that customer by a SIM card. The SIM card has a number that embeds an encryption key and a set of numbers that personalize the device to an individual owner. The SIM card is inserted in the mobile device. In addition to the device ID and the SIM card, identification in the form of a telephone number is assigned to the phone and the customer. The telephone number maps to the device ID and the SIM and is only maintained in the databases of the telephone network; it is not embedded in the mobile phone. When a mobile phone is used to make a connection, it sends the ESN and the SIM data and uses the encryption to encrypt the communication. The telephone network, when it receives a communication from the mobile phone, associates the ESN and the SIM data within its database and uses the prestored database information to verify the device, the SIM, and the encryption key and then associate the communication with a telephone number. When the network switches the connection to the destination telephone number, it forwards the telephone number as an encoded signal on the line so that the receiving telephone, if equipped with caller-ID circuitry, can decode the number being called from and display it on the receiver phone.

Because each mobile phone has three unique sets of numbers associated with it (a device ID, a SIM, and a telephone number) that are used by the telephone network for verification, security, and accounting functions, the caller ID acts as a form of a national identification mechanism without doing anything more. The telephone companies, in addition to assigning a telephone number, may also assign an account ID. The telephone number is now portable, enabling a customer to keep the same number when changing telephone companies.

These powerful identification and security abilities of the telephone network are leveraged to provide PSVA for validating the source of the data packets entering the global network.

Some information security experts have the opinion that the caller-ID feature of a telephone network is a weak form of identification because (1) anyone can make a phone call from another's phone, when the phone is stolen, lost, or given away, and (2) somehow the personnel of the telephone company can be deceived or duped or bribed to make the caller ID ineffective as a foolproof identification mechanism. For example, an identity thief may open a telephone account in someone else's name.

However, the telephone network is part of an important national communication infrastructure that is vital to the nation. Therefore, the telephone companies expend adequate resources to maintain the integrity, availability, and security of the network. Specifically, mobile phones contain a feature where the telephone company knows the cellular location where the call originated. In the future, more precise location information as part of the 911 emergency system will also be provided in mobile phones. The PSVA adds additional layers of security in a call security function, which are described later. In spite of the caller-ID weaknesses, the caller-ID feature of mobile telephones with the call security function would provide adequate security in knowing where a call originated and would help law enforcement and the telephone companies to investigate fraudulent practices.

59.3.3 Packet Source Validation Architecture System

The PSVA system is used as a system of checks and balances for enhanced Internet security. The PSVA system of checks and balances includes: (1) a system means to insert a source-validation code in the header of the packets entering the Internet, (2) a system means wherein the source-validation code does not identify the source of the packets to anyone except to a law enforcement agency, (3) a system means to transport such a packet from the sending computer to the destination computer over the existing global computer network, (4) a means for packet-receiving clients to forward the validation code therein to law enforcement agencies, when an identified type of harm is detected in the data of the received packets.

For the first application, the PSVA system is made up of (1) a distributed set of KSs and (2) an adaptation of the major routers of the Internet. For the second application, the PSVA system, when restricted to the e-mail security, is made up of (1) a distributed set of KSs and (2) an adaptation of the e-mail servers. This later application is flexible in scope and implementation in that all e-mail servers do not need to be adapted at the same time.

59.3.3.1 E-mail Application of PSVAS

E-mail application can be incrementally developed and deployed. A simplified illustration of the operation of the PSVA system that is restricted to the e-mail security is described here with reference to Exhibit 59.10 and Exhibit 59.11, which are one diagram but illustrated on separate sheets due to the size of the diagram.

At step A1, as in Exhibit 59.10, a sender of e-mail, having a sending mail client screen 82A, when it has outgoing messages as indicated by outgoing folder 84B, and then activates the send/receive function 84A, of the mail client, on these two events, activates a mail security function 88, which displays a mail security function window 86.

At step A2, as in Exhibit 59.11, a sender of e-mail, a person acting for them self or for an entity, using his/her mobile phone 12, using mobile network 14, calls a KS 76. The specific KS 76 to be called is identified by a special telephone number within that area code of the telephone, for a specific country code.

At step B, as in Exhibit 59.11, the KS 76 performs a call security function 18 and then using key function 20, generates a RC 78D that is limited in length. The code 78D may be a four- to six-digit numeric. It may also be alphanumeric. The key function 20 voice-delivers the RC 78D to the caller 12, and records data for this call in a key server database (KSDB) 78. The data recorded in the KSDB 78 may include: caller ID 78A, date and TS of the call 78B, cell location 78C, RC 78D, and an encrypted validation code (EVC) 78E. Encrypting the caller ID 78A and the RC 78D with the RC 78D itself as the encryption key makes the EVC 78E. The EVC 78E thus hides both the caller ID and the RC.

At step C1, as in Exhibit 59.10, the caller then enters this RC 78D, along with the country code 25A, and the cell telephone number 78A in the mail security function window 86 and activates it by OK, which activates a mail-sending CSF 88, in an adapted mail client 70A, as in Exhibit 59.11.

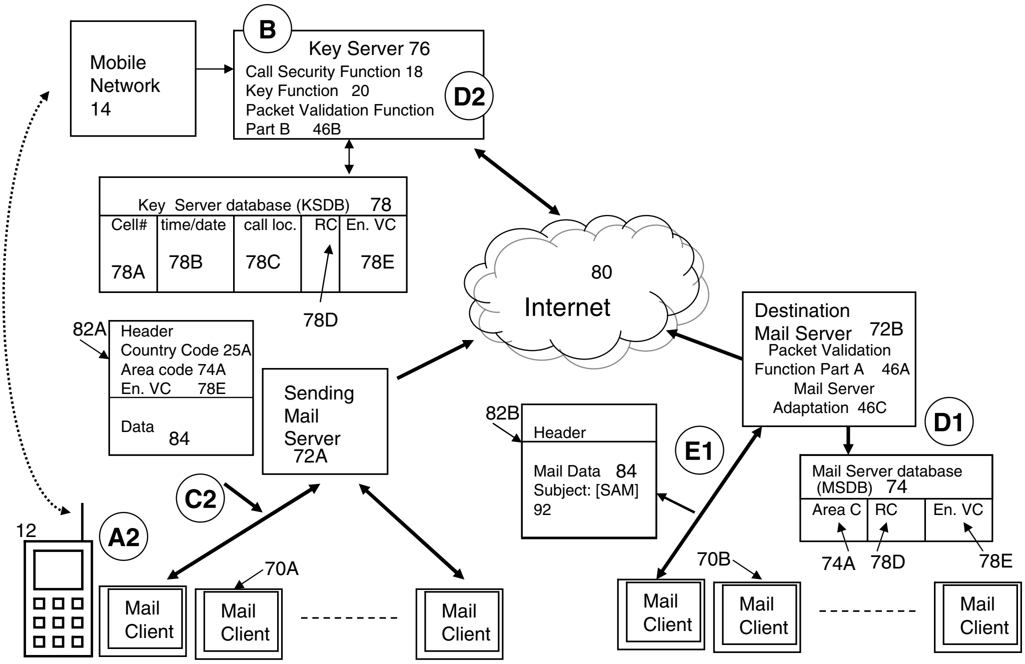

EXHIBIT 59.11 E-mail application of PSVAS.

If a Web-mail application is used, the adapted sending mail server 72A generates the mail security window 86. The adapted mail client program 88 or the adapted mail server 72A from this entered information creates a secure data string that is made up of country code, area code and an encrypted validation code, where the validation code is made up of the telephone number and the RC and is then encrypted using the RC as the encryption key.

At step C2, as in Exhibit 59.11, the adapted mail program 88 of the client 70A or the adapted mail server 72A temporarily stores this secure data string and embeds the string in the header of each outgoing header packet 82A with packet data 84 that is sent to the Internet 80 for mail from this particular client 70A. Each time a mail client or the Web mail server is invoked for sending mail, this process step is repeated.

At step D1, as in Exhibit 59.11, the destination mail server 72B performs a packet validation function 46 for each incoming mail packet.

The packet validation function has two parts: part A and part B. The packet validation function part A, 46A, is resident in the destination mail server 72B, whereas the packet validation function part B 46B is resident in the key server 76. The packet validation by the packet validation function 46A is performed first with the help of a mail server database (MSDB) 74. If the validation is successful, the packet is routed to the destination mail client 70B. If the validation is unsuccessful with the help of the MSDB 74, a validation query is then sent, by the mail server 72B to a key server 76 over the Internet 80, where the key server 76 is the one that is identified by the country code 25A, and the area code 74A, that is present in the packet header 82A as part of the secure data string.

At step D2, as in Exhibit 59.11, the packet validation function 46B in the specific key server 76 receives the query and validates the query with the key record data present in the KSDB 78.

At step E1, as in Exhibit 59.11, the destination mail server 72B removes the secure data string from the packets 82B, annotates the mail as validated by placement of sender-assured mail (SAM) annotation in the subject of the mail 92, and forwards the e-mail to the mail client 70B. If the RC was optionally also used to encrypt the message content, the message content is decrypted using the RC 30D by the destination mail server 72B.

At step E2, as in Exhibit 59.10, the receiving mail client 82B displays the SAM notation 92 in the subject field 90. The receiver of mail may then choose to open only the messages with SAM notation and may choose to discard those messages that are without a SAM notation in the subject field. Having a SAM notation in each e-mail assures the mail receiver that the sender of the mail has been assured and can be identified if necessary by law enforcement, if the mail does contain harmful contents.

Alternatively, and optionally, the destination mail server 72B, for those messages, that do not have a validated SAM notation, may store such messages for later analysis and only forward those messages that have SAM notation to the mail client 70B.

The later analysis by the destination mail server 72B may include, (1) detailed examining of the mail for harm, and/or (2) for sending a return notification to the mail sender client 70A on a procedure on how to use this security feature, and (3) advising the mail-sending client 70A that their mail without such a SAM is not being forwarded to the mail recipient 70B and is being delayed and then deleted by the mail server 72B.

The key servers are standard servers that have been adapted with a telephone network interface 336, an IVR system 338, and a set of call security and packet source validation software functions that are described later. The key servers are capable of high-volume processing, including receiving many calls at the same time, and use a KSDB 30 and 78. Because each server is restricted to receive calls from only certain area codes, the server capacity may be sized to correspond to the number of users in that area code.

In the distributed set of key servers, each key server is adapted with an interface to the telephone network 336 and can only receive calls from the telephone network. Each key server in addition to the standard set of operating system 302 has special functions. These special functions are: a call security function 304, a key function 306 that includes a key generation function, a key distribution function, a key validation function, and may also have a fee function. Each key server in addition to the telephone network interface 336 with an interactive response system 338 also has a global network interface 332 to be able to receive validation queries and respond with validation message responses to major routers 44A and mail servers 72B on the Internet. The key server may also have an internal network interface 334 that may be used to monitor the status and operation of the key server.

The distributed set of key servers are independent of each other and are assigned to countries and area codes within each country. Each server has an identity that is defined by a country code and a set of area codes within that country. This identity, along with the call-security function, is used to receive calls from the specific countries and specific area codes within that country.

The key servers are specific to an area code and may be provided by the telephone companies themselves. The functions of the key server may be split, where the call-security function is provided by the telephone company and the remaining part of the key server functions may be provided by and managed by the Internet authority that manages and oversees the major routers.

59.3.3.2 Trojan Horse Security

Because a prevalent security weakness is that a Trojan horse may take over or hijack someone's computer without their knowledge and use it to send internet traffic in the form of either e-mail or other data packets using the hijacked computer as the sending computer, a security feature is provided herein to thwart such an attack.

This security feature is that the SDS is not saved in the computer on the hard disk in a file. Instead, when the SDS is created, it is stored in some random part of the free RAM and the address of that RAM is then saved in the NAF. The NAF 22B reads the RAM for the data string, when sending out the packets. When the computer is powered down, the secure data string is destroyed. When the computer is powered up again, the process of entering the caller ID and the code is repeated and the secure data string is computed anew and saved anew in a new random part of the memory for use by the NAF. When the packets are sent, the NAF uses this new secure data string at a new location in the RAM for embedding in the header of the packet.

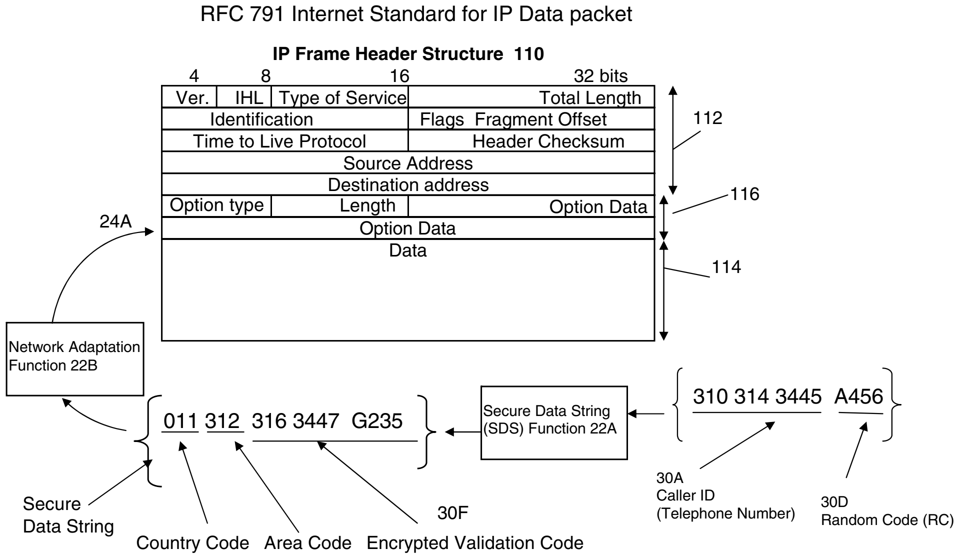

EXHIBIT 59.12 RFC 791 Internet Standard for IP Data packet.

As illustrated in Exhibit 59.12, each time a computer is powered up, the user can use the code received previously or make a new call to the key server to receive a new RC.

59.4 Intelligent Shredding & Aliasing: A New Identity Security Technology

Industries, organizations, associations, and government agencies that need, use, and electronically store sensitive identity data on someone else, such as their customers and employees for their business operation, are the ones that can benefit from this new identity security technology.

The government applications can include the IRS, the Social Security Administration, departments of motor vehicles, and so on. The industries include: retail industry merchants, the financial services industry such as insurance companies and banks, and the medical service industry such as hospitals and medical groups.

The theft and misuse of identity and identity data has emerged as a new modern-day evil. Those who might disagree with this powerful assertion are referred to the astronomical rise in calls to the FBI 800-ID-theft hotline from victims of such crime, and unending media stories about data theft and identity theft crimes.

Therefore, identity data security is a must. The identity data refers to a person's personal data of name, address, e-mail address, telephone number, bank account data, social security number and driver license number. With this data, thieves have discovered that in the modern e-commerce-centric world, anyone can masquerade as anyone else for the purpose of loans, purchases, and so on.

59.4.1 Clear and Present Danger

How does one lose identity data in the first place? Two things have become very clear. First, identity data is being spread in too many places too many times. When you conduct any kind of payment transaction online or offline and fill out any kind of application, you are giving away your identity of name, credit card number, and signature, and sometimes more personal data. These data are collected and stored in paper records, computer records, and databases everywhere.

Second, all these personal data are subject to theft and misuse. When, where, and how these thefts and misuses occur you may not know. There is a new breed of clever criminals who are committing identity theft crimes. Criminal punishment for identity theft crimes would not deter these criminals.

59.4.2 Why a Business Should Care About Identity Security

Your systems hold nations' commercial secrets, if not military ones. If you are an e-commerce retail operation, and your systems keep one million customer names, addresses, and credit and bank data, you hold nations' commercial secrets. If you are a government agency or a financial institution and not only store everyone's name and address but also their social security number, date of birth, and other data, you hold the nations' commercial secrets. If these are not secrets, then why are your systems under attack?

It is common perception that once sensitive personal data is behind a firewall in a computer system, it is safe from theft. It is also a common perception that if it is saved as an encrypted data file, it is safe from theft. That is far from the truth, as anyone in the security industry knows. A firewall is not a panacea and it gives a false sense of security. The threat to your data lies from both sides of the firewall.

Shon Harris, in her book on CISSP certification says, "A majority of security professionals know that there is more risk and higher probability of an attacker causing mayhem from within an organization than outside the organization."

There is no question that a business and the identity owner both need to protect sensitive identity data. To address this need, a new identity security technology was developed. This technology is known as *ISA* and was developed exclusively for the security of identity-sensitive data. ISA is not encryption in the traditional sense of encryption. ISA uses an entirely different approach to identity data security. How, then, is ISA different or better than encryption?

Exhibit 59.13 describes the differences. In encryption, the encrypted and unencrypted data look different. Hence, you can tell when you have broken the encryption code after so many large but finite number of attempts. In the identity security algorithm, the original identity data and the aliased identity

EXHIBIT 59.13 Encryption vs. GOPAN Identity-Security Technology

Attribute	Encryption	GOPAN Security Technology
Primary purpose	For transfer of information over an unsecured and open channel such as internet between source and destination	For storage of identity-sensitive data in an information system of a business or government agency
How it works	A mathematical encryption algorithm encrypts information at the source, and the receiver decrypts using an encryption key. The key is exchanged before hand between the sender and the receiver	The identity sensitive information is anchored by a new form of access key (APIN) that is created by the identity owner. The identity sensitive data then goes through random and heuristic techniques to electronically shred and alias the data before storing it in a database server. The identity data is retrieved in real time by un-aliasing and un-shredding for a specific transaction, and then deleted as soon as the transaction is completed
Main characteristics	The original (unencrypted) and encrypted information is different. What stands between them is a well-known mathematical technique and a key. The probability of breaking is finite and is the inverse of the possible key combinations	The original and the GOPAN processed information looks the same in character and format. The probability of breaking is not calculable as there is no correlation between the two
Industry applications	PKI, digital signatures	For storage of Identity sensitive data such as social security numbers, credit card numbers, and name and addresses as well

data look the same because they are made up from same shreds of identity. Hence, the probability of breaking does not even exist.

The techniques underlying this algorithm are shredding and aliasing. These act like building blocks on which the algorithm is built. The end result is an identity data security, where you do not need to store identity data and you can still seamlessly conduct those transactions that depend upon using the identity data.

59.4.3 Identity Security Algorithm

The collection of underlying techniques is called GOPAN®, a Sanskrit word meaning concealment, protection, and defense.

59.4.4 Keeping Identity Sensitive Data, a Higher Degree of Risk

If your business keeps sensitive identity data, then you have a higher degree of business risk. It is also expensive to abide by the laws and regulations and be constantly secure and on safeguard from attack from inside and outside. The identity security architecture of this technology makes it possible to outsource this business risk. You obtain the identity data when you need it for a transaction, at the time of the transaction in real time, without the risk of keeping it and securing it.

59.4.5 Identity Security Technology Architecture Overview

Refer to Exhibit 59.14. In simple terms, there is an interface to an identity security server, an identity security server, database servers, and a transaction server. All these parts work together to provide and implement identity security. These parts, their use and/or implication for identity security are described one at a time.

59.4.6 The Special Interface: Anonymous Personal Identification Number (APIN™)

This interface enables a special access by the person whose identity is being secured. Traditionally, a server would store a user ID, which is used to identify the user, and a password in hash encrypted

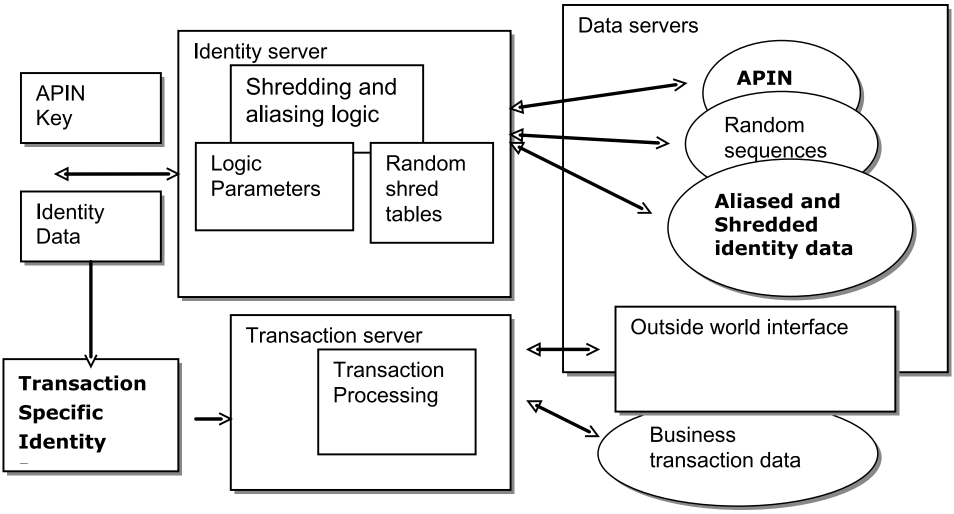

EXHIBIT 59.14 Identity security technology architecture overview.

form to verify the user. In this special interface, neither exists. What exists is an APIN access key. This access key is created entirely by the owner and is used by the owner to directly provide the identity data to the identity server. The APIN access key, a new form of access key, is discussed in the fourth part of the series.

59.4.7 The Identity Security Server

The server has three software code/data components. One is to identity security logic, which I call "shredding and aliasing" logic. The other two are: logic parameters and a set of random shred tables. How this logic operates is described later.

59.4.8 The Database Servers

There are three data servers. One keeps the access key, the second keeps a set of random sequences, and the third keeps aliased and shredded data.

59.4.9 The Transaction Server

The transaction server creates, uses, and maintains business-specific transaction data, and stores it in the transaction-related information database. This server operates on a specific need-to-know basis and receives only those parts of identity data from the identity server that are relevant to a specific transaction and only at the actual time of the transaction. Once the transaction for which purpose the need to know existed is completed, the identity data is deleted. This server also interfaces with the outside world when necessary, such as to process a payment transaction using a bank account with a financial network, or to send information to the customers' computers.

59.4.10 How These Parts Operate Together

A user first creates the APIN™ access key, and then provides the identity data. The logic, from the access key, creates a reference number. Then, using the parameters and random tables, the logic creates a fake or pseudo and aliased identity data and scatters it in the other database server, each data referenced by its reference number.

Transaction data related to a specific transaction is stored in a separate set of database servers referenced by the same reference key. The identity owner only and certain pre-defined system actions, for a specific transaction authorized and initiated by the owner, can retrieve the identity data and enable it to be linked to the transaction data. The pieces of identity data relevant to a transaction are re-created by reversing the shredding and aliasing logic on the moment when a transaction requires this identity data, and are then deleted.

For anyone to reverse engineer the system to get at the identity data, they would require access to and knowledge of all five pieces of the logic, parameters, random tables, random sequences, and shredded and aliased data. The first three pieces are embedded in the identity server code, whereas the last two are stored in database servers. Of these five pieces, if any one is missing, the identity data cannot be retrieved. No one, except the owner, has access to his identity data. The system administrative personnel do not have it. A hacker cannot have it.

59.4.11 Applications to All Identity Data

The identity security technology using shredding and aliasing logic was specially developed for and works equally well for all identity-related data of name, address, e-mail address, social security number, driver license number, and bank and credit card account numbers.

59.4.12 Independent Validation

Professor Kenneth Alexander, Professor of Mathematics at University of Southern California, analyzed the shredding and aliasing technologies. He came to the conclusion that, to the best of his knowledge, there is no correlation between the original and aliased data, and that a probability of correlation could not even be calculated.

59.4.13 Shredding and Aliasing, Building Blocks

Shredding (or breaking apart) and aliasing (creating another equivalent) are very simple concepts used here with an uncanny twist. As a simplified illustration, consider three lists where list one has 10,000 unique first names, list two has 20,000 unique middle names, and list three has 50,000 unique last names. From these building-block lists there are billions of unique name combinations. There are only six billion people in the world.

Consider a person named John Habachi Hawkins residing at 123 Maple Street, Anytown, Colorado, 80445, with email address jhawk@aol.com who wants to protect his privacy and identity in this wired and untrustworthy world.

59.4.14 How Shredding and Aliasing Use Randomness Concept

The GOPAN system electronically shreds the man's name into three different parts: first, middle, and last name shreds (intelligent shredding). Within the GOPAN system, there are three corresponding name shred lists. These lists are randomly ordered.

Each shred is looked up in the corresponding random-name list, and a number identifies its position on that list. If the name is not in the list, it is added. This is done for every shred, resulting in three numbers corresponding to the list positions of these name shreds.

For each customer, the GOPAN system creates three random number series. Each random number series may have one or more bounded random numbers (BRNs). These random number series are used to modify the name list positions to come up with three modified list position numbers. The modification may involve any combination of operators such as add, subtract, or multiply. These modified list position numbers are used to find name shreds from the three random-order name lists corresponding to these modified list positions.

These name shreds are called *aliased name shreds*, and are saved in the GOPAN database along with the three random-number series.

The random-name shred lists, the random-series generator, and the modification logic are all part of a black-box executable program. The GOPAN databases contain the aliased name identities and the BRNs.

59.4.15 Aliased Identity

The shredding and aliasing process just described is repeated for the physical and e-mail addresses. The shreds for the physical address are: street number, street name, city name, state name and ZIP code. The shreds for the e-mail address are e-mail and ISP names. The shredding and aliasing are done with a street name, city name, state name and ISP name using random lists for each of these shreds.

The parts of the physical and e-mail addresses consisting of numeric and/or alphanumeric strings are shredded and aliased in a similar way but differing in detail. The street number "123," ZIP code "80445," and e-mail "jhaw," are numerical or alphanumerical strings. There may be four random lists called numeric, consonant, vowel, and special character. The numeric list has 0–9, the consonant list contains A–Z minus the vowels, the vowel list has the five vowels and the special-character list has characters such as period and hyphen. Each character of the string is aliased. The aliased string and its corresponding BRNs are saved in GOPAN databases.

In summary, an alphanumeric string that is part of the man's identity is aliased into another alphanumeric string equivalent in character and format, whereas a name string is aliased into another name string equivalent in character and format. A true identity and an aliased identity are indistinguishable from each other.

59.4.16 Find Me If You Can: A Challenge

John Habachi Hawkins residing at 123 Maple Street, Anytown, Colorado, 80445, with email address jhaw@aol.com goes into the GOPAN system embodying shredding and aliasing technology, and may be stored as Michael Sebastian Pool, residing at 492 Culver Blvd., Poinsettia, California 90464, with an e-mail address of sawh@home.com as his aliased identity.

In the GOPAN system, a person does not know his aliased identity. The only participant in a transaction who knows his real identity is the person himself. Therefore, in the GOPAN system, a person rests assured with the knowledge that he alone is in control of his personal information and his APIN is required to access it. The APIN is made of user chosen place holder constructs that a user is already familiar with by memory association such as a date, a ZIP code, name initials, gender, and a personal like and dislike phrase.

59.5 Secure Overlay™ Technology Payment Card

According to the FBI and FTC, ID theft is the fastest growing crime. The problems and the pain of ID theft is very well stated by the FTC report. The key point to note is that 65% of the ID theft manifests in abuse of credit cards.

The entirety of the payment transactions industry, more than ever, has become acutely conscious of security and privacy implications in electronic payment transactions. Giving your name, bank account data and signature (highly private indices of personal sensitive information) to strangers to effect a payment transaction in this era of Internet economy, has grave implications. Hence protecting the privacy and private data of a customer in data storage and during transactions while facilitating payment transactions to merchants using existing bankcards and bank accounts of a customer is critical.

The solution the banking industry has developed for the problem of ID theft and misuse of credit cards is back-end filtering and monitoring of their customer's purchasing habits.

The industry has been running commercials using a person surfing the Internet in his living room. He receives a call from his bank that his card has been stolen. Back-end filtering is not a real solution and occurs after the ID data theft has already occurred. This solution also has many other problems as well.

This new emerging technology is for a secure overlay-technology payment card that facilitates the use of existing bankcards of the customer to conduct a particular transaction from any of his/her existing bankcards without giving and or transferring any private data to merchant's paper and computer systems. As a result thereof, the secure overlay-technology payment card system minimizes the number of people, businesses, and institutions that have access to the private data of the customer. This minimizes the opportunity for the private data of the customer to be improperly disseminated and thus subjected to ID theft.

The secure overlay-technology payment card has been named The Ultimate®. The Ultimate is a new breed of a secure payment card, because this card is a secure overlay over other existing cards. In its operation, it is transparent to both the merchants and the card-issuing banks. This international patent-pending technology elegantly and conveniently solves many of the problems related to privacy, security, and fraud that the payment-card industry is facing.

The secure overlay-technology payment card enables the existing cards to be used in a safe and secure manner, without actual use of such cards at the point of sale of a merchant. The secure overlay-technology card is transparent to the card issuing banks and does not change the nature of existing banking relationships and bank statements from card issuing banks. The project entails development of specifications for a prototype, and an analysis of issues related to initial deployment.

This technology enables a secure overlay-technology payment card that facilitates the use of existing bankcards of the customer to conduct a particular transaction from any of his/her existing bankcards without giving and or transferring any private data to merchant's paper and computer systems. As a result, the secure overlay-technology payment card system minimizes the number of people, businesses, and institutions that have access to the private data of the customer. This minimizes the opportunity for the private data of the customer to be improperly disseminated and thus subjected to ID theft.

Sixty-five percent of ID thefts result in abuse and misuse of credit cards. The secure overlay technology kills such abuse in its entirety. The secure overlay-technology payment card protects a payer's identity data that is subject to ID theft.

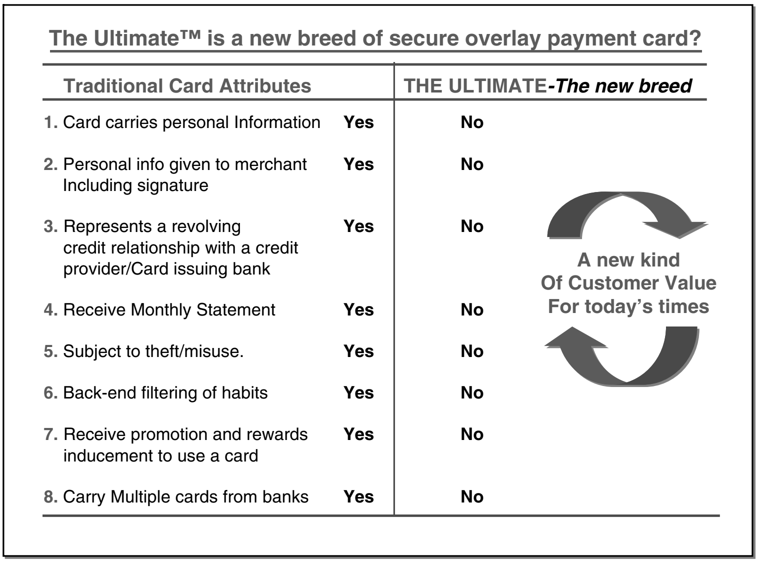
The Ultimate is a secure payment transaction vehicle with multiple (three distinct) value propositions for the end user, the cardholder: privacy, security, and convenience. First, The Ultimate card enables any one of existing bankcards to be used/selected for use at a point of sale by the customer without carrying all the cards with him/her. In addition, first and foremost, The Ultimate is substantial new revenue-making service technology. Second, it provides substantial benefits to all participants, as the security, privacy, and fraud costs related to payment cards are borne by everyone. Third, it reduces the regulatory compliance burden of merchants related to security of private data of its customers.

The Ultimate, by providing a PIN-based secure overlay over all of a customer's bankcards from any bank, hides the customer's bank data from the merchant. But, at the same time, The Ultimate provides a new service technology related to privacy, security, and identity theft that everyone, including the banks' customers, is waiting for.

59.5.1 Secure Overlay-Technology Payment Card Description

Exhibit 59.15 through Exhibit 59.18 describe the operation and features of the secure overlay-technology card. One major feature of the secure overlay technology is that no information is transferred to a merchant and that benefits the merchant by reducing the compliance burden related to security of data.

Exhibit 59.15 shows why The Ultimate is a new breed of payment card based on secure overlay technology that solves all of these ID theft problems. Exhibit 59.16 shows the simplicity of the secure overlay technology. Exhibit 59.17 shows the use of GOPAN technology with ISA for the protection of customer data in the database. Exhibit 59.18 summarizes the features of The Ultimate card based on secure overlay technology.



The Ultimate™ is a new breed of secure overlay payment card?

Traditional Card Attributes		THE ULTIMATE-*The new breed*
1. Card carries personal Information	**Yes**	**No**
2. Personal info given to merchant Including signature	**Yes**	**No**
3. Represents a revolving credit relationship with a credit provider/Card issuing bank	**Yes**	**No**
4. Receive Monthly Statement	**Yes**	**No**
5. Subject to theft/misuse.	**Yes**	**No**
6. Back-end filtering of habits	**Yes**	**No**
7. Receive promotion and rewards inducement to use a card	**Yes**	**No**
8. Carry Multiple cards from banks	**Yes**	**No**

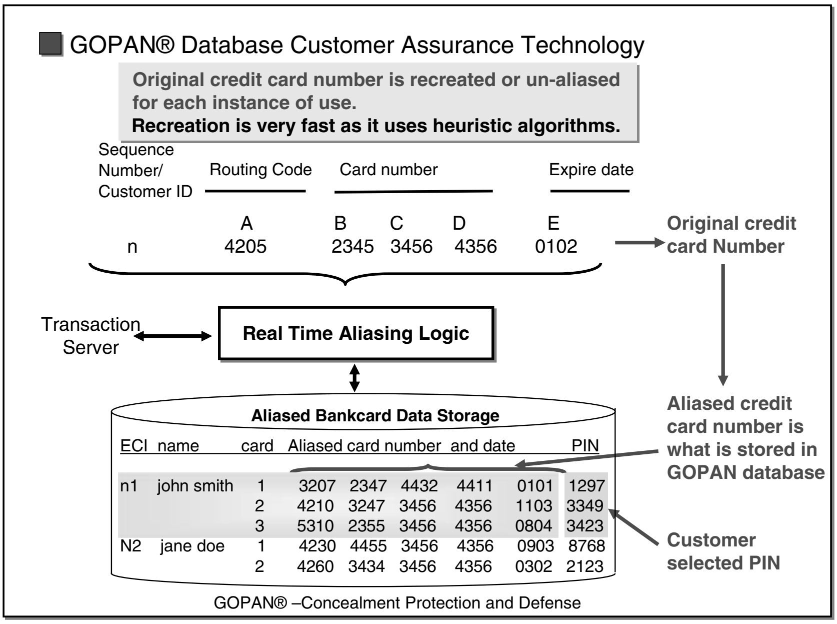
59.6 Ambiguity Envelope™ Wireless Encryption

Use of wireless technology has grown in many applications. These wireless technologies use digital transmission of data packets. A digital data packet has a header and a data body. The data in the body is encrypted during transmission.

One of the popular uses of wireless transmission has been and is between a laptop computer and a wireless access point (WAP) or router to a company network or the Internet. Other uses have been between the sales terminal of a business and their central server.



GOPAN® Database Customer Assurance Technology

Original credit card number is recreated or un-aliased for each instance of use.
Recreation is very fast as it uses heuristic algorithms.

Sequence Number/ Customer ID	Routing Code	Card number			Expire date

EXHIBIT 59.18 The secure overlay technology solution and value in a nutshell.

Such WAPs are commonly used in businesses and in offsite locations such as airports, hotels, and coffee shops as well as in homes. These uses typically operate for a few hundred meters, based on the strength of the transmission. To facilitate the widespread use and manufacture of such devices, various industry standards have been developed, such as 802.11b and 802.11g.

Another use of wireless that is emerging is the use of Bluetooth, where cellular phones equipped with Bluetooth capability communicate to a wireless earpiece. Still another use is in military applications such as ad hoc mobile wireless networks in a theater of operation.

A standard called *wired equivalent privacy* (WEP) has been developed for these wireless transmissions. The WEP is designed to deliver the same encryption as available on a wired transmission.

It has become well known that others may capture and decipher private wireless transmissions to steal private information. In spite of WEP, hackers have been successful in stealing private transmissions. The weaknesses that have been demonstrated are:

1. The capture of transmissions from very great distances using special telescopic antennas. For example, in tests conducted with wireless transmissions between a laptop and WAPS that from a user point of view are limited to a few hundred feet, can be captured from as far away as 11 miles using a special antenna. Wireless transmissions using Bluetooth that from a user perspective are good for 10–20 ft. can be captured from as far away as a city block.
2. Theft of private transmissions via a specially equipped roving van that roves around city blocks to find and capture transmissions.
3. Defeat of the authentication between the user and the WAP and the setting up of rogue WAPs between the user and the real WAPs that redirect traffic to a spoofed access point.
4. The breaking of the encryption key that is used for encryption. A 128-bit key, for instance, is easily broken given access to samples of plain text and encrypted text. Even though the wireless transmissions are encrypted using such techniques, they are still compromised by hackers.

The ease with which the security of wireless transmission have been compromised have been demonstrated to many of the information security personnel of banks by the special agents of the FBI in local chapter security briefings.

A new technology for wireless security has been developed and is named Ambiguity Envelope (AE) security based on use of Jitter™ keys. AE and Jitter keys are both new technologies that provide wireless security by using an AE that uses keys that are jittered or are variants of the standard key and are different for each packet and different for each incoming and outgoing packet.

The jittered keys are neither exchanged nor stored by creating them in advance and are only created at the instance of use for each packet at the time of use and then immediately destroyed. Millions of unrelated keys provide for a new form of encryption that is suitable for wireless security as compared to standard encryption techniques that use a fixed key for a session. Hence, AE and Jitter keys provide wireless security that is impossible to hack as the key is infinitely variable for each packet and such keys are not stored or even exchanged between the points of transmission. AE uses the standard encryption technology except the variation in keys.

AE also provides authentication of WAPs that is better than the current approach in the industry that allows spoofing because the AE is unique to each sender and receiver pair. Furthermore, AE provides a different mechanism of authentication that does not have the problems described above.

If the promise of AE and Jitter keys holds true, it will solve a critical security shortcoming of wireless security. Chips, firmware, and components that facilitate use of AE can be manufactured and will be sold to manufactures of wireless devices such as cellular phones and WAPs.

60

Sensitive or Critical Data Access Controls

Mollie E.Krehnke

David C.Krehnke

60.1 Introduction

Corporations have incredible amounts of data that is created, acquired, modified, stored, and transmitted. This data is the life blood of the corporation and must be protected like any other strategic asset. The controls established to prevent unauthorized individuals from accessing a company's or a customer's data will depend on the data itself and the laws and regulations that have been enacted to protect that data. A company also has proprietary information, including research, customer lists, bids, and proposals—information the company needs to survive and thrive. A company also has personal, medical, and financial information and security-related information such as passwords, physical access control and alarm documentation, firewall rules, security plans, security test and evaluation plans, risk assessments, disaster recovery plans, and audit reports. Suppliers and business partners may have shared their proprietary information to enable business processes and joint ventures. Appropriate access controls should be implemented to restrict access to all of these types of information. The effectiveness of any control will depend on the environment in which it is implemented and how it is implemented.

The need to protect individual, business, financial, and technology data in the United States has become paramount in the last 40 years because of the impact of unauthorized disclosure of such information. Key examples are the Privacy Act, the Health Insurance Portability and Accountability Act (HIPAA), the Sarbanes–Oxley Act (SOX), the Department of State International Traffic in Arms Regulations (ITAR), and the Department of Commerce Export Administration Regulations (EAR). The presence of this legislation regarding the protection of certain types of information has mandated the implementation of security controls in many sectors of the U.S. economy. Companies are required to show due diligence in the protection of such information, which is a worthwhile objective, given the impact on an individual, a company, or the nation if this information is disclosed.

Depending on the legislation, the ramifications associated with noncompliance may be minimal or very significant. The penalty for the unlawful export of items or information controlled under the ITAR is up to ten years' imprisonment or a fine of up to $1,000,000, or both, for criminal charges; civil charges have fines up to $500,000 per violation. The penalty for the unlawful export of items or information controlled under the EAR is a fine of up to $1,000,000 or five times the value of the exports, whichever is greater. For an individual, the fine is imprisonment up to ten years or a fine of $10,000 to $120,000 per violation, or both. These are just the fines; not included are the costs of frequent reporting to the auditors for a designated time period regarding resolution of the data exposure and new corrective actions, damage to the brand of the company, or loss of current or prospective customers who will go elsewhere for their products and services. The cost of controls to protect such information is likely to be considerably less.

60.2 Identify the Organization's Data and Its Characteristics

To identify the controls required to protect data, it is necessary to know what data the organization has. Some information may be more readily identified because human resources and finance departments and privacy offices have been identifying such data for a long time. But, to be complete in an analysis of corporate data, it is necessary to document all business processes and the associated data. What information is being created when the corporation builds a product, sells a product, or provides technical support on a product to a customer?

When the data has been identified, it is then necessary to determine its characteristics. Is it public data? Should access be restricted? Who can see and use the data? What persons cannot? Determining what information has to be protected will depend on the expertise of the data owners, account managers, program managers, business managers, research directors, and privacy and legal staff (and possibly others). In some instances, government legislation and regulations for certain types of data change over time, so a regular review of procedures and controls may be required to determine if the established controls are still appropriate. For the purposes of this chapter, the terms "sensitive" or "restricted" data are used to represent data that must be protected from access by individuals not authorized to have that data. This chapter is not addressing the protection of classified data, although many of the controls being described are used in protecting classified data.

60.2.1 Identify Data Owner and Data Custodians

After the company's data has been determined, an individual who is responsible for that data must be identified, The data owner is a key resource in the definition of the company's data, including the source, the type of data (personal, medical, financial), the business processes that use the data, the data form, the storage location of the data, and the means by which it is transmitted to others. This individual is also (ultimately) responsible for the integrity, confidentiality, and availability of the data under consideration. The data custodian is the person (or organization) entrusted with possession of and responsibility for the security of the specified data and must apply the rules established to protect the data. The cooperation of these individuals is vital to the determination of information sensitivity and criticality and the associated content-based data access controls.

60.2.2 Determine Information Sensitivity and Criticality

The two information designation categories are sensitivity and criticality, and each category may have multiple levels. The number of levels will depend not only on the varying type of information requiring protection but also on the protection measures available to protect a particular level of information. For example, if it is possible to implement only three levels of controls for a particular category because of resource restraints, then having five levels for that category will be more differentiation than can be implemented given those restraints. In instances where several levels have been identified, only the protection measures required for that specific level are applied to data associated with that level. The levels of sensitivity and criticality are usually determined by conducting a business impact assessment (BIA).

Sensitivity reflects the need to protect the confidentiality and integrity of the information. The minimum levels of sensitivity are sensitive and nonsensitive. Criticality reflects the need for continuous availability of the information. Here, the minimum levels are critical and noncritical. Sensitivity and criticality are independent designations. All corporate information should be evaluated to determine both its sensitivity and criticality. Information with any criticality level may have any level of sensitivity and *vice versa*.

60.2.3 Involve Key Resources in the Definition of Access Controls

When the data designations have been established for a given set of data, the controls to protect information with that sensitivity and criticality must then be defined. The information security organization will not be able to establish controls unilaterally and will require the cooperation and input of the human resources, legal, physical security, and information technology organizations—and, of course, senior management—to make this happen. These organizations will have to provide input regarding the mandated controls for protecting the data, identification of individuals or groups of individuals who are permitted to access the data, and what protective measures can be implemented and not adversely impact the conduct of business. Defining the required controls will also require knowledge of how they systems are configured, where the information is located, and who has access to those systems. This will require knowledge of the organization's enterprise information technology architecture and its security architecture in order to implement the appropriate physical and logical access controls. All types of restricted data can all be protected in the same way (system high), or the information can be grouped into different types by content and data-dependent access controls specified.

60.3 Establish Personnel Controls

60.3.1 Identify Job Functions Requiring Access Restricted Data

In many cases, the ability to access data is defined by the individual's job responsibilities; for example, human resources (HR) information is handled by HR specialists, medical information is handled by medical staff, and insurance information is handled by claims specialists. But, other company information will cross many organizational activities, including manufacturing, sales, and technical support for products sold. Identifying who is handling restricted information in an organization is not an easy process and requires an in-depth understanding of the company's business processes and data flows. The data access flows for a particular company depends on the demographics of the employees, characteristics of the data, business functions and associated processes, physical configuration of the business facilities, and information technology infrastructure characteristics and configuration.

60.3.2 Screen Personnel Prior to Granting Access

Personnel accessing restricted information as part of their job responsibilities should have a level of background screening that is based on the sensitivity and criticality of the information. Data that has a higher sensitivity or higher criticality should be accessed only by trustworthy individuals, and this may require a more extensive background screening process. Individuals providing support to applications, systems, or infrastructure—for the organization or for a customer—should also meet the established access requirements. This would include employees and consultants who are providing administrative or technical support to the company databases and servers. With off-shore technical support being provided for many commercial off-the-shelf (COTS) products and company services, there is a greater risk that unauthorized individuals may, inadvertently, have access to restricted information.

60.3.3 Badge Personnel

Each person should have a picture badge. (In the U.S. government, this badge is referred to as a personal identification verification [PIV] card.) The badge may contain a magnetic strip or smart chip that can be used to access areas where restricted data is used or stored. Those pictures can also be used in organizational charts for each business function to help employees understand who is authorized to access a given area. Permission to access areas containing restricted information can also be indicated on the badge by background color, borders, or symbols.

60.4 Establish Physical Security Controls

Legislation and federal regulations may mandate that an individual who does not have authorized access to information cannot be provided with an "opportunity" to access that information; whether or not the individual would try to access the information has no bearing on this requirement—the possibility for exposure must not exist. What does this mean for the organization and its business processes?

60.4.1 Group Employees Working on Restricted Information

If possible, group individuals requiring access to a particular type of restricted information by floors or buildings. This reduces the opportunity for access by unauthorized individuals. If floors in a multiple-story building contain restricted information, badge readers can be installed to permit access to particular floors or corridors. Personnel granted access should not allow unauthorized persons to tailgate on their badges. Badge readers can also be installed in elevators that only permit access to certain floors by individuals with badges for those areas. Of course, persons exiting at a given floor must ensure that only authorized persons leave the elevator on that floor.

60.4.2 Define and Mark Restricted Areas

Persons who need to use restricted data as part of their job responsibilities should be physically separate from other employees and visitors in order to prevent inadvertent access to restricted data. Areas of restricted access should be defined based on employee job functions and marked with signs indicating that the area is a controlled access area, with a point of contact and telephone number for questions or assistance.

60.4.2.1 Implement Badge Readers

Each area containing restricted data should be controlled by a guard and hardcopy access control log or by a badge or biometric reader to grant and document access. The badge reader could be a contact reader or a proximity reader.

60.4.2.2 Provide Secure Storage for Data

Employees using restricted data as part of their work responsibilities need to a have a secure location to store that information when it is not in use. This storage could be locked drawers and cabinets in the employee's work space or specifically created access-controlled filing areas.

60.4.2.3 Install Alarms

Install physical alarms in restricted areas to alert guards regarding unauthorized physical access. Install electronic alarms on devices on the networks to alert security administrators to unauthorized access. Ensure that trained individuals are available to readily respond to such an alarm and reduce, if not resolve, the impact of the unauthorized access.

60.4.2.4 Mark Hardcopy and Label Media

Restricted information, whether in electronic or nonelectronic format, should be legibly and durably labeled as "RESTRICTED INFORMATION". This includes workstation screen displays, electronic media, and hardcopy output. The copy number and handling instructions should be included on hardcopy documents.

60.5 Establish Management Controls

60.5.1 Develop Content-Dependent Access Control Policies and Procedures

Policies provide high-level direction and set management expectations, and procedures provide the step-by-step instructions for controlling access. It is human nature for users to perform tasks differently and inconsistently without proper direction. Inconsistent task performance increases the potential for unauthorized (accidental or intentional) access to take place. An acceptable and appropriate use policy sets management's expectations concerning the protection of sensitive and critical information and the work-related use of e-mail and the Internet, as well as browsing, modifying, or deleting information belonging to others.

60.5.2 Establish Visitor Controls

Visitors may be required to access individuals and information residing in a restricted area. Before the visitor can be granted access to the area, it is important to document the purpose of the visit, determine need-to-know and fulfillment of legislative requirements, and provide a trained escort for the visitor. Information about a visitor, such as the purpose of the visit, employer (or organization the visitor represents), proof of citizenship, need-to-know, length of visit, and point of contact at the company, should be reviewed, approved, documented, and maintained by a security organization. If proof of citizenship is necessary, the visitor should bring a passport, birth certificate, or notarized copy of either for a security officer to review and verify. If a birth certificate is used, the individual should also bring government proof of identity (e.g., driver's license).

A company should not allow individuals access to the company who have arrived at the last minute as part of a larger group from anther organization. This is a common practice used by industrial espionage specialists, and it is quite effective because general courtesy would make it seem rude to exclude that person.

The escort for a visitor should be an individual who has an understanding of the information being requested, discussed, or presented and can make an accurate determination as to whether or not the visitor can receive, hear, or see the information. The escort should be prepared to remain with that individual throughout the visit or identify another appropriate employee who can assume the escort responsibilities as required.

Secure storage for a visitor's unauthorized personal items should be provided. Depending on the sensitivity of the visit and the information being discussed, visitors may not be permitted to bring cellular phones, camera phones, pagers, personal digital assistants (PDAs), laptop computers, or other data collection instruments into the restricted areas.

Secure visitor passage corridors should be established. A walk-through prior to the visit can be used to verify that restricted information is properly secured. Escorts assigned to visitors should ensure that the visitors are not exposed to information for which they are not authorized, such as on whiteboards in meeting rooms or employee cubicles, in conversations overheard in hallways or breakrooms, or in documents in employee cubicles, in conversations overheard in hallways or breakrooms, or in documents in employee cubicles. The escort should control tour groups to prevent one or more individuals from breaking away from the group to pursue unauthorized discussions or observations.

60.5.3 Prevent Information leakage at External Gatherings

Presentations and presentation materials for trade shows, conferences, and symposiums should be approved in advance. Attendees should be instructed about what topics can and cannot be discussed. Employees should be trained on the risks of discussing business functions or products with family, friends, colleagues, and acquaintances.

60.5.4 Authorize Access

Each person's qualification for access should be verified based on job responsibilities (need to know), background screening, and any legislative requirements (e.g., U.S. citizen). This authorization should be documented in the individual's personnel file and electronic files such as Microsoft's Active Directory. Several control models can be used to grant access to corporate information. Organizations implementing mandatory access controls assign security labels to each subject (user) and each data object; man-datory access control consists of the owner authorizing access based on need to know and the system allowing access based on the labeling. Discretionary access control allows data owners (representing organizational units) to specify the type of access (e.g., read, write, delete) others can have to their data; this decentralized approach is usually implemented through access control lists. Rule-based discretionary access control is based on specific rules linking subjects and objects. Administrator-based discretionary access control allows system administrators to control who has access to which objects. Role-based access control grants and revokes access based on a user's membership in a group; this method is used in most large organizations. For organizations with large data warehouses, data views are preapproved for various role-based groups. Content-based access control uses an arbiter program to determine whether a subject with discretionary access to a file can access specific records in the file. This model provides greater granularity than simple file access. Similar granularity is available using views for access to a database. Regardless of the access control model used, the design of access controls should be based on the principle of least privilege, and the continuing need for access should be revisited on an annual basis for each individual.

60.6 Establish Enterprise Security Architecture

60.6.1 Require Approved Hardware and Software

To ensure the integrity of the computing infrastructure and the associated information, hardware and software should be standardized and controlled by an information technology governance committee or organization; that is, the hardware and software should be on the approved list and only acquired from approved sources. Personnel wishing to use hardware and software not on the list should first obtain approval from the information technology governance committee or organization.

60.6.2 Harden Computing Platforms

Hardening control standards should be implemented specific to each platform. These standards should be updated as new vulnerabilities are uncovered and updates are available. Platforms should not be deployed to a production environment prior to hardening. Unnecessary services and applications should be removed or disabled. Unnecessary default accounts and groups should be removed or disabled. Computers should be configured to deny log-in after a small number of failed attempts. Controls should be configured to limit privileged access, update and execute access to software, and write access to directories and files. Guidelines should be established regarding a user's password length and associated format complexity. Security mechanisms, such as tokens or certificates, can be configured to strengthen the system administrator authentication requirements.

60.6.3 Track Hardware and Software Vulnerabilities

Vulnerability advisories involving the software and hardware in use within the corporation should be tracked and corrective actions implemented as deemed appropriate. Vulnerabilities within a Web server might allow attackers to compromise the security of the servers and gain unauthorized access to resources elsewhere in the organization's network.

60.6.4 Implement configuration and Change Management

Changes to hardware and software configurations should be managed to ensure that information resources are not inadvertently exposed to unnecessary risks and vulnerabilities. All changes should be appropriately tested, approved, and documented. Inappropriate configuration or improper operation of a Web server may result in the disclosure of restricted corporate information, information about users or administrations of the Web server including their passwords, or the configuration of the Web server or network that could be exploited in subsequent attacks.

60.6.5 Implement Software Security Features and Controls

Safeguards embedded in computer software should be activated to protect against compromise, subversion, or unauthorized manipulation. All features and files that have no demonstrable purpose should be disabled or removed. Default privileged log-on IDs, default passwords, and guest accounts should be disabled or removed. The use of administrative and root accounts for running production applications should be prohibited. Access to specific applications and files should be limited. Access to systems software utilities should be restricted to a small number of authorized users. Software that unlicensed, borrowed, downloaded from online services, public domain shareware/freeware, or unapproved personal software should not be installed.

60.6.6 Sanitize Memory and Storage To Remove Data Residue

Allocated computer memory of shared devices should be sanitized before being made available for the next job (i.e., object reuse). Likewise, file storage space on shared devices should be sanitized before being reassigned.

60.6.7 Implement Virus Protection

Virus protection software should be installed and enable. Centralization of automatic updates ensures that the latest versions of virus detection software and signature files are installed.

60.6.8 Implement Audit Logs

Audit logs should record significant operation-related activities and security-related events. Audit logs must be reviewed periodically for potential security incidents and security breaches. The use of an audit reduction tool increases the efficiency and accuracy of the log review.

60.6.9 Establish Separate Database Servers for Restricted Data

Corporate data is often stored in large databases or data warehouses that are accessible to all employees and contractors, but not all employees and contractors should have access to the data. The use of knowledge discovery in database (KDD) tools for data exploration (often called data mining) in an iterative process can result in the discovery of "interesting" outcomes. It is possible that those outcomes can support the inference or actual discovery of restricted information, even with individual identification and authentication measures for data access in place. Information systems and databases containing restricted information should be separate from other servers, including Web and application servers, in order to ensure that unauthorized individuals cannot gain access to restricted information. Such database servers must also implement security controls appropriate for the level of sensitivity and criticality of the information they contain.

60.6.10 Control Web Bots

Web bots (also known as agents or spiders) are software applications used to collect, analyze, and index Web content. An organization may not want its Web site appearing in search engines or have information disclosed that it would prefer to remain private or at least unadvertised (e.g., e-mail address, personal Internet accesses).

60.6.11 Implement File Integrity Checkers

A file integrity checker computes and stores a checksum for every guarded file. Where feasible, checksums should be computed, stored, and continually checked for unauthorized changes on restricted data.

60.6.12 Implement Secure Enclaves

Information designated as restricted may be placed in a secure enclave. Secure enclaves are network areas where special protections and access controls, such as firewalls and routers, are utilized to secure the information. Secure enclaves apply security rules consistently and protect multiple systems across application boundaries. Secure enclaves should employ protection for the highest level of information sensitivity in that enclave.

60.6.13 Protect the Perimeter

The perimeter between the corporate network and the Internet should be protected by implementing firewalls and demilitarized zones (DMZs). Firewalls should run on a dedicated computer with all non-essential firewall-related software, such as compilers, editors, and communications software, deleted. The firewall should be configured to deny all services not expressly permitted, audit and monitor all services including those not permitted, detect intrusions or misuse, notify the firewall administrator in near real time of any item that may require immediate attention, and stop passing packets if the logging function becomes disabled. Web servers and electronic commerce systems accessible to the public must reside within a DMZ with approved access control, such as a firewall or controlled interface. Sensitive and critical data should not reside within a DMZ. All inbound traffic to the intranet from the DMZ must be passed through a proxy-capable device.

60.6.14 Control Business Partner Connections

When establishing third-party connections, access controls and administrative procedures should be implemented to protect the confidentiality of corporate information and that of its business partners when such information is maintained in the corporate network.

60.7 Implement Operational Controls

60.7.1 Authenticate Users

Authentication can be bases on something the user knows (password, personal identification number [PIN], or pass phrases), something the user holds (token), or some user characteristic (biometric). The use of PINs should be restricted to applications with low risk. Passwords should be complex and at least eight characters in length. Personal passphrases are the preferred knowledge-based authenticator because they can be 15 or more characters in length; they can be made more complex by the use of upper- and lowercase alphabetic characters, numbers, and special characters; and they are easy to remember (i.e., they do not have to be written down). The number of unsuccessful authentication attempts should be limited, and the user should just be told that the access attempt failed, not why it failed.

60.7.2 Implement Remote Access Controls

Where remote access is required, remote access security should be implemented. Information resources requiring remote access should be capable of strong authentication. Remote access from a non-corporate site should require users or devices to authenticate at the perimeter or connect through a firewall. Personnel outside corporate firewalls should authenticate at the perimeter. In addition, personnel outside corporate firewalls should use an encrypted session, such as a virtual private network (VPN) or Secure Sockets Layer (SSL).

60.7.3 Implement Intrusion Detection and Intrusion Prevention Systems

Intrusion detection and prevention systems should be implemented to detect and shutdown unapproved access to information resources.

60.7.4 Encrypt Restricted Information

Restricted information transmitted over untrusted networks should be encrypted. Restricted information stored on portable devices and media (e.g., backups) that leave a secured area should be encrypted. Depending on the level of sensitivity, it may also be prudent to encrypt information in storage.

60.7.5 Implement Workstation Controls

Workstations should have an approved personal firewall installed. Other security controls may include, but are not limited to, positioning screen to restrict viewing from passersby, lockable keyboard, power lock, and desk-fastening hardware. Computer sessions should time out after a period of inactivity and require reauthentication to continue the session. The reauthentication can be a password, a token such as a fob or smart card, or a biometric. The location of the workstation and signal strength of the device must be considered for proximity fobs and smart cards to ensure that the session is not reactivated when the user and the user's device are in an adjacent hallway, breakroom, restroom, etc. because the signal may not be attenuated by interior wall and cubicles.

60.7.6 Implement Controls for Portable Devices

Portable devices must be protected against damage, unauthorized access, and theft. All personnel who use or have custody of portable devices, such as laptop computers, notebook computers, palm tops, handheld devices, wireless telephones, and removable storage media devices, are responsible for their safekeeping and the protection of any sensitive or critical information stored on them. Laptop and notebook computers should connect to the corporate intranet at least once a week to receive the latest software patches, antivirus pattern recognition files, and personal firewall patterns. In addition, sensitive information on portable devices must be protected (e.g., encrypted) when leaving a secure environment.

60.7.7 Release Information on Factory-Fresh or Degaussed Media

Before releasing information on electronic media outside the corporation, the information should be copied into factory-fresh media (never used) or onto media appropriately degaussed to prevent the inadvertent release of restricted information.

60.7.8 Implement Precautions Prior to Maintenance

To prevent inadvertent disclosure of restricted information, all hardware and electronic media being released for maintenance outside of corporate facilities should, prior to release, undergo data eradication or the corporation should have in place a legally binding contract with the contractor or vendor regarding the secure handling and storage of the hardware and electronic media.

60.7.9 Eradicate Electronic Hardware and Media Prior to Disposal

To prevent inadvertent disclosure of restricted information, all electronic hardware and media must, prior to being disposed of, undergo data eradication. Unacceptable practices of erasure include a high-level file erase or high-level formatting that only removes the address location of the file. Acceptable methods of complete erasure include zero-bit formatting, degaussing, overwriting several times (the number depends on information sensitivity), and physical destruction.

60.7.10 Remove Access on Terminations and Transfers

Routine separation of personnel occurs when an individual receives reassignment or promotion, resigns, retires, or otherwise departs under honorable and friendly conditions. Unless adverse circumstances are known or suspected, such individuals should be permitted to complete their assigned duties and follow official employee departure procedures. When personnel leave under nonadverse circumstances, the individual's manager, supervisor, or contracting officer must ensure that all accountable items, including keys, access cards, laptop computers, and other computer-related equipment are returned; the individual's computer log-on ID and building access authorizations must be terminated coincident with the employee's or contractor's effective date of departure, unless needed in the new assignment; and all restricted information, in any format, in the custody of the terminating individual must be returned, destroyed, or transferred to the custody of another individual.

Removal or dismissal of personnel under involuntary or adverse conditions includes termination for cause, involuntary transfer, and departure with pending grievances. In addition to the routine separation procedures, termination under adverse conditions requires extra precautions to protect corporate information resources and property. The manager, supervisor, or contracting officer of an individual being terminated under adverse circumstances must ensure that the individual is escorted and supervised at all times while in any location that provides access to corporate information resources; immediately suspend and take steps to terminate the individual's computer log-on IDs, physical access to information systems, and building access authorizations; ensure prompt changing of all computer passwords, access codes, badge reader programming, and physical locks used by the individual being dismissed; and ensure the return of accountable items and correct disposition of "restricted information" as described under routine separation.

60.7.11 Train Users To Protect Restricted Data

Employees must be trained in the identification, marking, handling, and storage of restricted data. A company with a large number of employees that handle restricted information should consider creating an automated mechanism for training and tracking of training, so the security personnel are not bogged down. Security personnel should be available to answer questions, however. Materials and periodic opportunities should be created to remind employees of their responsibilities to protect information and provide annual refreshers.

60.7.12 Destroy Information No Longer Needed

Hardcopy containing restricted information no longer needed should be cross shredded on site or stored in a secure container for pickup by a service provider. Electronic removable media containing restricted information should be sanitized before reuse or destroyed.

60.8 Monitoring for Compliance

60.8.1 Inspect Restricted Data Areas

Physical reviews of areas containing restricted data should be conducted to ensure the data is being appropriately handled, marked, and stored. Other areas of the company should be reviewed to ensure that restricted data is not located in those spaces.

60.8.2 Review Electronic Data Access

System and applications logs should be reviewed for intrusion and unauthorized access to restricted information. Access authorizations should also be reviewed periodically to ensure that individual's who no longer require access have been removed.

60.8.3 Ramifications for Noncompliance

What will be the costs to a company for not implementing required information security controls? What fines would be imposed on its operations? Could the company be sued because exposure of an employee's personal information caused significant embarrassment or harm? Will the company's image be tarnished? What would the costs be in terms of loss of customers? It is hoped that the experiences of others can provide an incentive for action, although organizations must be prepared to address the 'it can't happen here" attitude. They will have to depend on the expertise of the data owners, account managers, program managers, business managers, research directors, and privacy and legal staff (and possibly others) not only to determine what information has to be protected and how to protect it but also to help justify why it must be protected. The controls that may have to be put into place to protect the company's data may seem extensive, but the costs associated with not protecting the information can be enormous.

61

An Introduction to Role-Based Access Control

Ian Clark

61.1 Introduction

Today's large organization's information technology (IT) infrastructure is a mix of complex incompatible operating systems, applications, and databases spread over a large geographical area. The organization itself has a dynamic population of employees, contractors, business partners, and customers, all of whom require access to various parts of the infrastructure. Most companies rely on manual or semiautomated administration of users and their access to and privileges for various systems. Often different systems will have their own sets of access requirements with different sets of administrators who will have different but often overlapping skill sets, leading to poor use of resources. This increasing number of disparate systems creates an enormous administrative overhead, with each group of administrators often implementing their own policies and procedure with the result that access control data is inconsistent, fragmented across systems, and impossible to analyze.

As the complexity of the organization's IT infrastructure increases, the demand for access control administration across the enterprise outgrows the capacity of manual administration across the distributed systems; the increased administrative complexity can also result in increased errors that in turn can lead to increased security risks (Allen 2001). Additionally, a raft of new legislation, such as Sarbanes-Oxley (SOX) (Sarbanes-Oxley 2005), means that companies now must be able to prove compliance with well-defined security policies, must be able to provide adequate proof of who has access to which data, and must maintain access and authorization audit trails.

Role-based access control (RBAC) is purported to give a new, fresh approach to access control. It has the ability to represent the organizational structure and enforce access control policies across the enterprise while easing the administrative burden. Additionally, it encompasses the best design principles from earlier modes, such as the principle of least privilege and separation of duties, and can assist in proving compliance with company security policies and legislative requirements.

61.2 Role-Based Access Control

Traditional access control models, such as Bell LaPadula and Clark-Wilson, rely on an access control matrix where subjects are assigned specific sets of rights according to their level of access. This approach to access control is still the most popular form of access control today, albeit slightly less complicated in modern operating systems; however, the thinking surrounding access control and access control management has slowly been shifting away from the more traditional subject–object models, where the focus is on the action of the subject, towards task- or role-based models (Sandhu 1995–1997; Thomas and Sandhu 1993). These models encompass organizational needs and reflect the organizational structure, with a focus on the tasks that must be accomplished. Although the idea of roles has been used in software applications and mainframe computers for over 20 years (NAC 2002), the last decade has seen a rise in interest in the field, as can be seen in the work of Thomas and Sandhu (1993), Ferraiolo and Kuhn (1992) and Baldwin (1990), where the traditional concepts of access control are challenged and task-and role-based approaches are presented.

A survey by the U.S. National Institute of Standards and Technology (NIST) (Ferraiolo et al. 1993), showed that many organizations base their access control decision on the role of the user within the organization, with the main drivers for access control decisions being customer and shareholder confidence, privacy of data, and adherence to standards, none of which can be easily accomplished using traditional models. These findings were further supported and enhanced by a follow-up survey conducted by SETA Corp. (Smith et al. 1996).

Role-based access control (RBAC) has emerged as the new model to embrace the concept of using roles to enforce enterprisewide security policies while providing a platform to streamline and simplify access control management. The basic concept of RBAC, as shown in Exhibit 61.1, is very simple (Sandhu, 1998b): "Permissions are associated with roles, and users are made members of appropriate roles thereby acquiring the roles' permissions." This is, of course, a simplistic view of RBAC; we will see how the basic concept can be further extended to make it quite complex.

Within an RBAC system, roles are created that mirror the organizational structure. Users are assigned to roles according to their job functions and responsibilities within the organization, and permissions are then assigned to the roles. This allows the access control policy to closely match the organizational structure of the company. For example, roles in a hospital may include doctor, nurse, or surgeon; in a bank, they may include accountant, cashier, or loan officer. All of these roles can be defined in the RBAC system and the appropriate permissions assigned to each.

From its early inception, the concept of RBAC has meant different things depending on where it is being applied or who has written the paper defining it. The first published RBAC model, which forms the basis of the standards we have today, came from Ferraiolo and Kuhn (1992) and was further revised in 1995, after a successful reference implementation (Ferraiolo et al. 2001a). Also in 1995, the Association

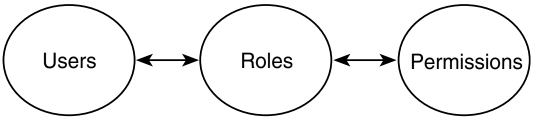

EXHIBIT 61.1 Core RBAC concept.

for Computing Machinery (ACM 1995) held its first RBAC workshop, which brought together both researchers and vendors from across the globe to discuss the salient issues surrounding RBAC.

In 1996, Sandhu et al. (1996) introduced a framework of four reference models to provide a uniform approach to RBAC; this framework clearly defined each of the four reference models and allowed them to be interchanged to create an RBAC system to meet differing implementation needs. In 2000, the model from Ferraiolo et al. and the framework from Sandhu et al. were combined by NIST to create a standard RBAC model (Sandhu et al. 2000). After this proposal was further refined by the RBAC community (Jaeger and Tidswell 2000; Jansen 1998), it was proposed by NIST as an RBAC standard (Ferraiolo et al. 2001b). The model proposed by NIST was adopted in 2004 by the American National Standards Institute/International Committee for Information Technology Standards (ANSI/INCITS) as ANSI INCITS 359-2004 (ANSI 2004). In the following sections, we will take an-depth look at the RBAC model using the approved ANSI standard as our reference.

61.3 The RBAC Reference Model

The ANSI standard consists of two parts: the RBAC reference model and RBAC and administrative functional specification. For the purposes of this article, we will only consider the RBAC reference model. Terms used in the RBAC reference model are defined in Exhibit 61.2. Because not all RBAC features are either appropriate or necessary for all implementations, the reference model has been broken down into three distinct but interchangeable components (we will consider each of these components in turn):

- Core RBAC
- Hierarchical RBAC[1]
- Constrained RBAC
- Static separation of duty (SSD) relations
- Dynamic separation of duty (DSD) relations

EXHIBIT 61.2 Role-Based Access Control Terms

Term	Description
User	A human being. Although the concept of a user can be extended to include machines, networks, or intelligent autonomous agents, the definition is limited to a person in this paper for simplicity
Role	A job function within the context of an organization with some associated semantics regarding the authority and responsibility conferred on the user assigned to the role
Objects	Any passive system resource, subject to access control, such as a file, printer, terminal, database record, etc.
Component	One of the major blocks of RBAC (i.e., core RBAC, hierarchical RBAC, SSD relations, and DSD relations)
Permissions	An approval to perform an operation on one or more RBAC protected objects
Operations	An executable image of a program, which upon invocation executes some function for the user
Sessions	A mapping between a user and an activated subset of roles that are assigned to the user
Constraints	A relationship between or among roles

Source: From ANSI/INCITS. 2004. 359-2004: *Information Technology and Role-Based Access Control*. American National Standards Institute/International Committee for Information Technology Standards, http://www.techstreet.com/cgi-bin/detail?product_id=1151353.

[1] A hierarchy is a partial order defining a seniority relation between roles.

61.3.1 Core RBAC

Core RBAC is the very basis of the model. In order to conform to the ANSI standard, an RBAC system must, as a minimum, implement these core elements. The core model, illustrated in Exhibit 61.3, consists of five basic data elements: users, roles, objects, operations, and permissions. As mentioned earlier, users are assigned to roles and permissions are assigned to roles, in this case to perform operations on objects. Additionally, the core model includes a set of sessions, with each session being a mapping between a user and an activated subset of roles assigned to the user.

The core model also specifies role relations, illustrated in Exhibit 61.4, which are a key concept. Both user assignment and permission assignment are shown in the figure with two-way arrows, indicating that there can be a many-to-many relationship between users and roles (i.e., a user can be assigned to one or more roles and a role can be assigned to one or more users), as well as between roles and permissions. This allowance for many-to many relationships allows the assignment of both roles and permissions to be flexible and granular which enhances the application of the principle of least privilege.[2]

Each session is a mapping of one user to possibly many roles; that is, users establish sessions during which they activate some subsets of roles assigned to them. Each session is associated with a single user and each user is associated with one or more sessions. The function "session_roles" gives us the roles activated by the session, and the functions "user_sessions" gives us the user that is associated with a session. The permissions available to the user are the permission assigned to the roles that are currently active across all of that user's session (ANSI 2004).

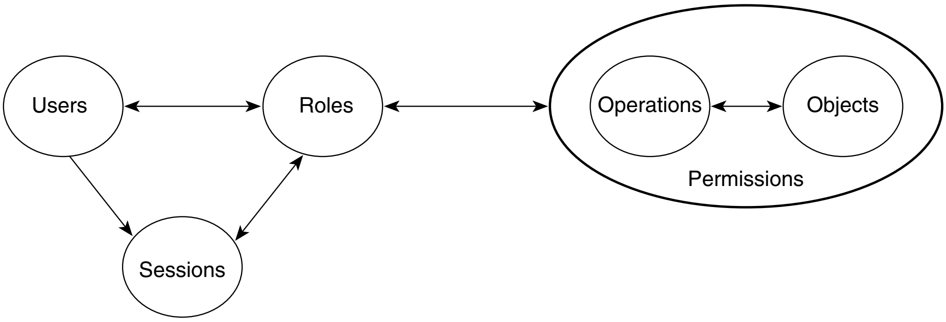

EXHIBIT 61.3 Core RBAC components.

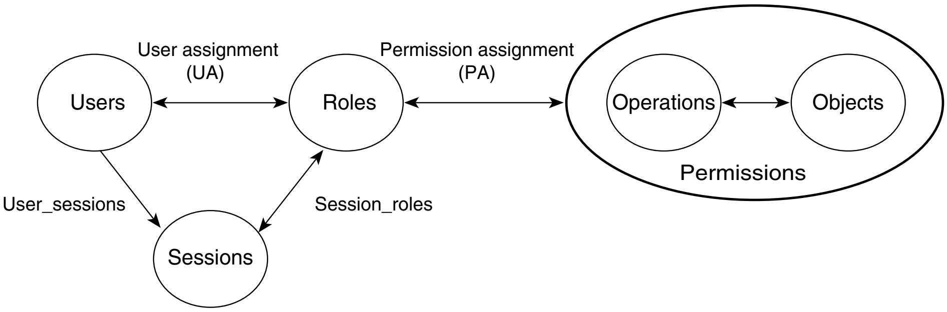

EXHIBIT 61.4 Core RBAC role relations.

[2] Users should have only the minimum set of access rights necessary to perform their tasks.

61.3.2 Hierarchical RBAC

The second component in the RBAC reference model is hierarchical RBAC. In any organization, employees often have overlapping responsibilities and privileges, and generic operations exist that all employees should be able to perform. It would be extremely inefficient and would cause unnecessary administrative overhead to assign these permissions to all roles. To avoid this overhead, role hierarchies are used. A role hierarchy defines roles that have unique attributes and that may contain other roles; that is, "one role may implicitly include the operations, constraints and objects that are associated with another role."

Role hierarchies are consistently discussed whenever considering roles, as they are a natural way to implement roles in such a way as to reflect an organizational structure to show lines of authority and responsibility; conventionally, the more senior role is shown toward the top of the diagram and the less senior role toward the bottom (Sandhu et al. 1996). An example of role hierarchies in a hospital is shown in Exhibit 61.5, where the roles of surgeon and radiologist contain the role of specialist, which in turn contains the role of intern. Because of the transitive nature of role hierarchies, surgeon and radiologist also contain the role of intern.

The RBAC reference model (Exhibit 61.6) describes inheritance in terms of permissions; role r_1 "inherits" role r_2 if all privileges of r_2 are also privileges of r_1. Additionally, role permissions are not

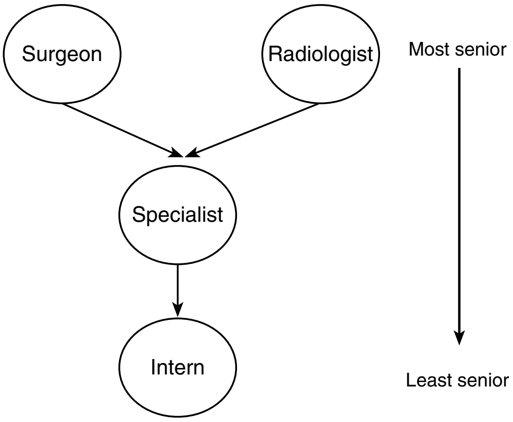

EXHIBIT 61.5 An example of role hierarchies.

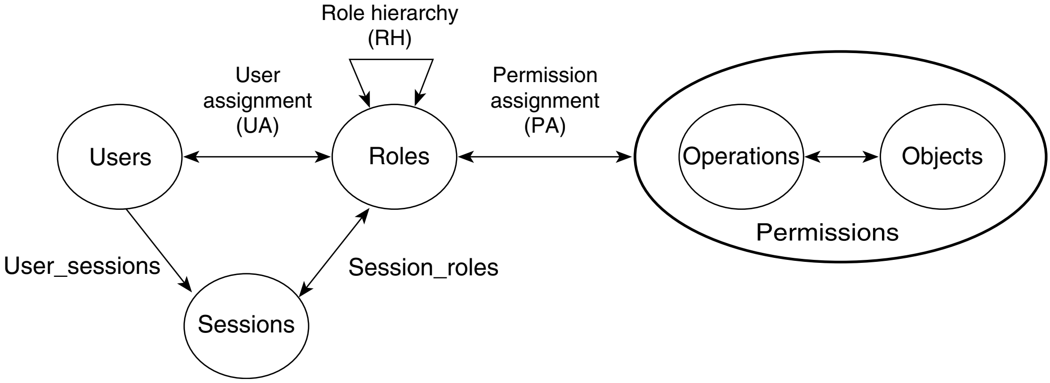

EXHIBIT 61.6 Hierarchical RBAC.

managed centrally for some distributed RBAC implementations; for these systems, role hierarchies are managed in terms of user containment[3] relations: Role r_1 "contains" role r_2 if all users authorized for r_1 are also authorized for r_2 (ANSI 2004). The reference model also recognizes two types of role hierarchies:

- General role hierarchies
- Limited role hierarchies

General role hierarchies support multiple inheritances, which allow roles to inherit permissions from two or more roles; conversely, limited role hierarchies are restricted to inheriting permissions from a single immediate descendent (ANSI 2004).

61.3.3 Constrained RBAC

Constrained RBAC adds separation of duty (SoD) relation to the RBAC model. SoD is a universally practiced principle that helps to prevent fraud and errors by ensuring that "no individual is given sufficient authority within the system to perpetrate fraud on his own" (Sandhu, 1990). SoD ensures that if a person is allowed to create or certify a well-formed transaction he or she is not allowed to execute it, thus ensuring that at least two people are required to make a change to the system. It should be noted that SoD could be bypassed if two employees were to collude to defeat the system. Further reading on SoD can be found in the work by Clark and Wilson (1987), Sandhu (1990), and Gligor et al. (1998).

The RBAC reference model refers to two types of SoD: static separation of duty (SSD) relations and dynamic separation of duty (DSD) relations. As illustrated in Exhibit 61.7, SSD is concerned with ensuring that a user cannot hold a particular role set while in possession of a directly conflicting role set; therefore, within this model it is concerned with constraining user assignments. This makes SSD very efficient at implementing conflict of interest policies. It should be also be noted that SSD relations may exist within hierarchical RBAC; if this is the case, special care must be taken to ensure that inheritance does not undermine SSD policies (ANSI 2004). This could be easily happen; for example, a senior role could inherit two roles of a directly conflicting role set. Various ways to work around this issue have been suggested (Ferraiolo et al. 1999; Sandhu 1998a).

Additionally, within a company, a specific role may only be allowed to be filled with a finite number of users at any given time; for example, the company would only ever have one CEO. Alternatively, a single user may only be allowed to hold a finite number of roles. SSD allows enforcement of these cardinally constraints;[4] however, despite its obvious advantages, SSD can be considered as being too inflexible in the

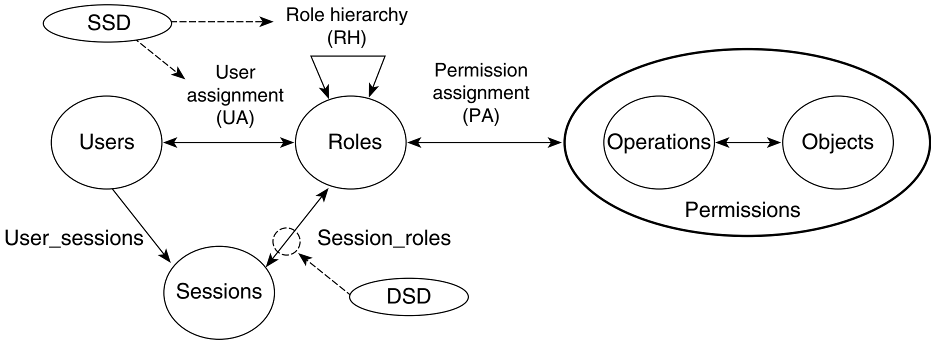

EXHIBIT 61.7 Constrained RBAC.

[3] User containment implies that "a user of r_1, has at least all the privileges of r_2, while the permission inheritance for r_1 and r_2 does not imply anything about user assignment" (ANSI 2004).

[4] Restricting the number of roles a user may hold or the number of users who may hold a given role.

area of granularity of specification of conflict of interests. These criticisms are similar to those leveled against the Chinese Wall model (Brewer and Nash 1989). These issues have been addressed by the introduction of DSD, which allows a user to hold two roles that would conflict if activated together but ensures that the roles are not activated during the same session, thus removing the possibility of any conflict being realized (ANSI 2004).

61.3.4 RBAC *versus* Traditional Access Control Methods

No look at RBAC would be complete without comparing RBAC to some of the more traditional access control methods, such as:

- Discretionary and mandatory access controls
- Access control lists
- Groups

61.3.4.1 Discretionary and Mandatory Access Controls

Mandatory access control (MACs) and discretionary access controls (DACs), are sill the most widely used form of access control in today's commercial and military access control systems (Ferraiolo et al. 2003). A lot of research has been published that discusses the similarities and differences between RBAC and MAC and DAC (Nyanchama and Osborn 1995; Osborn 1997; Osborn et al. 2000; Ferraiolo et al. 2003); however, one question that remains unanswered is does the introduction of RBAC mean that MAC and DAC will be replaced? Positions on this question differ. In a survey by the SETA Corp. (Smith et al. 1996), it was stated that "RBAC is not a replacement for the existing MAC and DAC products, it is an adjunct to them." Conversely, Kuhn (1998) stated that "RBAC is an alternative to traditional MAC and DAC policies." Kuhn's statement would seem to be supported by research that shows that RBAC can successfully implement both MAC and DAC policies (Nyanchama and Osborn 1995; Osborn 1997; Osborn et al. 2000); for completeness, it should be noted that additional research shows that RBAC can be implemented using MAC policies (Ferraiolo et al. 2003).

It, therefore, appears initially that because RBAC can so successfully implement MAC and DAC policies they could not become redundant; however, Osborn (1997) showed that significant constraints exist on the ability to assign roles to subjects without violating MAC rules (Ferraiolo et al. 2003). These constraints, the lack of guide in this area from the current standards, and the proliferation of their use in many of today's systems mean that, regardless of whether or not RBAC is an adjunct to or replacement for MAC and DAC, they will remain widely used forms of access control for the foreseeable future. This will undoubtedly mean that we will see implementations that use RBAC and MAC and DAC as well as implementations where RBAC interfaces with legacy MAC and DAC systems.

61.3.4.2 Groups

The use of groups[5] (Exhibit 61.8) in modern operating systems such as Windows 2000 can be considered very similar to the core RBAC concept illustrated in Exhibit 61.1; however, some fundamental differences

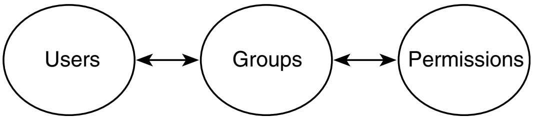

EXHIBIT 61.8 User and group permission assignment.

[5] A group is usually described as a collection of users (Sandhu et al. 1996).

exist. Groups are generally considered to be collections of users, and determining which users are members of a given is extremely easy; however, as permissions can be granted to a group on an *ad hoc* basis across several systems, it can be a nearly impossible task to determine exactly where the group has been granted permission across an enterprise. Because a role is a collection of both users and permissions it is equally as easy to determine which users and permissions are assigned to the role, and roles cannot be bypassed. A more fundamental difference is that a role can be considered a policy component; groups cannot. A role in an enterprise will adhere to a given rule set and exhibit the same properties regardless of the implementation. Groups, on the other hand, are implementation specific, therefore, their properties may change form one implementation to another within the same enterprise—for example, between a Windows 2000 implementation and a UNIX implementation (Sandhu 1994).

61.3.4.3 Access Control Lists

The discussion regarding RBAC and access control lists (ACLs) could be very similar to that of RBAC and groups; in really, it would merely be an extension of that discussion. With ACLs, the access rights to an object are stored with the object itself, and these access rights are either users or groups. The fact that users can be entries in the ACL can complicate management and result in legacy access permissions for a user being left after group access has been revoked (Ferraiolo et al. 1999); this can make security assurance extremely difficult and devalues the overall security infrastructure. Barkley (1997) illustrated how a simple RBAC model can be compared to ACLs if the only entries permitted in the ACL are groups. While this is a very good argument and is certainly true in the context in which it is presented (i.e., a basic RBAC model), it does not hold when we consider the more complex RBAC models we have seen, which are far more flexible and useful than basic ACLs. Additionally, the real power of RBAC is its ability to abstractly represent the access control policy across the enterprise rather than to the individual system, which is where an ACL model such as Barkley's would have to implemented; however, ACLs will continue to be used throughout operating systems for the foreseeable future, with an overlaying RBAC system managing their entries, an example of which can be seen in Karjoth's work (Karjoth 2003).

61.4 Commercial RBAC

Role-based access control has already been successfully implemented to varying degrees in many commercial systems. In a report submitted to NIST in 2002, Gallaher et al. (2002) identified organizations offering RBAC-enabled products at the time (see Exhibit 61.9). These commercially available products range from database management systems (DBMSs) and application management to operating systems; in most cases, they meet basic requirements for RBAC as laid out in the ANSI standard, but few of the products offer enterprisewide solutions as they mainly focus on their own systems or related applications. Of course, this list has grown since the original research in 2002, with improved offerings and an increasing number of companies moving into the "enterprise RBAC" niche; however, the number of companies offering truly enterprisewide RBAC is still minimal. This seems a shame because the strength of RBAC over other access control systems is its ability to represent the organizational structure and enforce access control policies across the enterprise; this is area vendors must address if RBAC is to become a viable and easy option for today's enterprises. That said, this does not mean that RBAC is not ready for the enterprise today; rather, several issues must simply be taken into account when planning an RBAC implementation.

61.5 Implementing RBAC

Before an organization can even consider the actual RBAC implementation, they must consider all of the additional work, as illustrated in Exhibit 61.10, which must be successfully completed before such an implementation can be achieved. Much has already been written about access control policies so they will not be considered here.

61.5.1 Identify the Scope and Motivation

It should be remembered when implementing an RBAC system that technology is only a small part of the overall solution. Before making any technology choices the implementing organization should ensure that the scope and requirements are clearly defined. One of the biggest challenges to implementing an enterprisewide RBAC system is integration with legacy systems.[6] As with all new initiatives within an

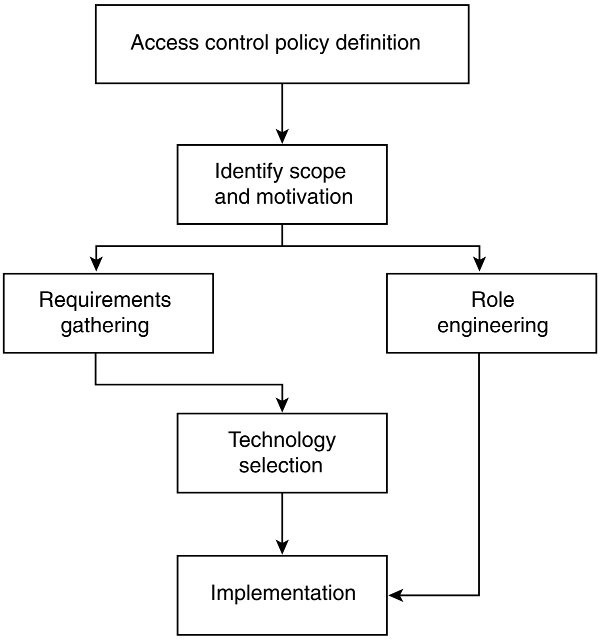

EXHIBIT 61.10 Implementation flow.

[6] Refers to all existing systems regardless of age.

enterprise, an RBAC implementation requires support from senior management to be successful. If implementation required the costly replacement of all legacy systems with more compatible systems, that support would not be forthcoming and the project would fail. It is for this reason that the scope of a potential project must be well defined in the early stages and expectations set at the correct level. If the project is sold as the silver bullet that will end all access control woes, it is likely to be approved, but when the final solution can only cover 45 percent of the organization's systems some tough questions will have to be answered. To fully understand the scope of the implementation and ensure that the scope can be achieved, the motivation for implementing RBAC must also be fully understood. If the motivation is purely for regulatory compliance, then all systems affected by that legislation must fall under the scope; if the motivation is to bring together existing user management and access control systems in one unified solution, then all existing systems must be identified. The motivation may be also have an impact on the project schedule, which in turn may have a direct impact on which vendors can offer a solution to meet the organization's needs.

61.5.2 Requirements Gathering

Today's large and complex enterprise may have many incompatible operating systems, applications, and database spread over a large geographical area; each may have its own requirements when it comes to access control. Once the systems within the scope of the project have been identified, the requirements of each must be understood and documented so they can be conveyed to potential vendors. It is important to understand which requirements are primary and which are secondary, so vendors can get a true understanding of which solutions will meet the organization's core needs. Time spent on this area early on will undoubtedly save time with vendor selection and implementation later.

61.5.3 Role Engineering

The process of defining roles, permissions, role hierarchies, and constraints and assigning permissions to roles is known as role engineering (Qingfeng 2003). Role engineering is an essential first step when implementing RBAC and possibly the most important step to ensuring success. The task of identifying roles and their associated permissions in an enterprise is an extremely large and onerous one. An estimation of the number of roles within a given organization is 3 to 4 percent of the user population. This number is backed up by an RBAC implementation within the Dresdner Bank, Germany, where a user population of 40,000 yielded 1300 roles (approximately 3.2 percent of the user population) (Schaad et al. 2001), this can be attributed to the fact that one person can hold multiple assume number in the thousands. Indeed, role engineering in a large enterprise is seen as such a complex task that appointing a new position of role engineer has been suggested (Schimpf 2000); this position would assume a linking role between the various corporate business units, systems management, and security administration and would require skills such as those of a business analyst, platform specialist, and security administrator.

Role engineering was identified as being an important part of RBAC by Coyne as early as 1995 (Coyne, 1995); however, it was largely neglected in early RBAC research and is not mentioned in the standard or much of the work conducted in the area. More recent research has focused on role engineering, and several approaches have been identified, such as scenario-driven role engineering (Neumann and Strembeck 2002), determining role rights from use cases (Fernandez and Hawkins 1997), adopting a process-oriented approach (Roeckle et al. 2000), and using Unified Modeling Language (UML)[7] for role engineering (Epstein and Sandhu 1999), among others. The actual processes behind these different approaches are outside the scope of this article; however, we can see from the research that many ways to

[7] Unified Modeling Language is an industry-standard language for specifying, visualizing, constructing, and documenting the artifacts of software systems (UML 2005).

approach the problem have been proposed. Some of the approaches address only a small part of the whole process, but others endeavor to create a holistic approach to encompass the entire enterprise.

Each role-engineering approach introduces additional components, such as both organizational and functional roles (Neumann and Strembeck 2002), that are different from the composite roles—organizational and system (Park et al. 2004)—both of which extend the core RBAC model that defines only roles. Moreover, although each approach purports to lead to a simplified RBAC implementation, no mapping between the components used for role engineering and the components identified in the RBAC standard has been provided. Because role engineering is such a large task, it should not be left until the last minute. As soon as systems within the scope of the project have been identified, then role engineering should be initiated.

61.5.4 Technology Selection and Implementation

We have already seen that many vendors offer RBAC solutions, but choosing the correct one can be a difficult task. If the project has been correctly scoped and the requirements understood, however, the task will be simpler. It is essential at this stage to understand what each vendor is actually offering and separate the facts from marketing hype; visiting reference implementations and speaking to existing customers are excellent ways to achieve this. It should also be remembered that a phased approach to implementation can also help with technology selection. If a particular vendor has a solution that meets the organization's requirements but does not support all of the systems within the desired scope, then it may still be the solution to go for if the vendor has plans to widen its system support. This is, of course, dependent on the project schedule and motivations. A phased approach to implementation is also the best way to proceed with this type of project; choosing a smaller system on which to pilot the solution will help to iron out any glitches before tackling larger systems that are more critical.

61.6 Conclusion

The principle motivations behind RBAC are sound: to create an access control model that has ability to represent the organizational structure and enforce access control policy across the enterprise while easing the administrative burden. It also encompasses the best design principles from earlier models, such as the principle of least privilege and separation of duties, and applies them across the enterprise to create an all-in-one access control framework. For these reasons, RBAC is a viable proposition for today's enterprise. Many vendors are getting into this growing market with offering that can go some way toward realizing an all-in-one solution, and now is certainly a good time for organizations to consider moving toward such a solution. In addition to simplifying the administrative nightmare that access control can cause, RBAC can also vastly simplify auditing who has access to where, a key requirement in legislation such as Sarbanes-Oxley; however, it should be remembered that RBAC is still a relatively immature area and many solutions still have quite some way to go before reaching their true potential. It is for these reasons that organizations should be sure they properly understand their own scope, motivations, and requirements before committing large amounts of time and money to such a project.

Smart Cards

James S. Tiller

62.1 Introduction

Smart cards are fascinating creatures of technology. They literally hold the key to enhanced security. One of the many challenges to information security is controlling access to resources such as information, applications, services, or system devices. Today, username and password combinations are the norm for authenticating users, but this approach represents fundamental weakness in security. Poor password usage and a myriad of potential exposures are beginning to become a significant hurdle in applying meaningful security controls in the ever-increasing complexity of information technology. As businesses place greater demands on information access and availability to a growing number of disparate entities, username and password combinations will simply not keep up. Not only do smart cards provide a mechanism to ensure long-term scalability and functionality for controlling access, but they also provide business-enabling services. It is within this context that the virtues of smart cards are discussed in this chapter, which examines some of the key benefits of smart cards and demonstrates how organizations of all types can leverage the technology to significantly improve security in many areas.

62.2 What Is a Smart Card?

The term *smart card* is ambiguous at best and can be used in a multitude of ways. The International Organization for Standardization (ISO) uses the term *integrated circuit card* (ICC) to encompass all those devices where an integrated circuit (IC) is contained within an ISO 1 plastic identification card. The card is 85.6×53.98×0.76 mm and is essentially the same size as a bank or credit card. The embedded IC is, in part, a memory chip that stores data and provides a mechanism to write and retrieve data. Moreover, small applications can be incorporated into the memory to provide various functions.

62.2.1 Memory

Several types of memory can be integrated into a smart card, for example:

- ROM (read-only memory)—ROM, or better yet the data contained within ROM, is predetermined by the manufacturer and is unchangeable. Although ROM was used early in the evolution of smart cards, it is far too restrictive for today's requirements.
- PROM (programmable read-only memory)—This type of memory can be modified, but requires the application of high voltages to enact fusible links in the IC. The requirement for high voltage for programming has made it unusable for ICC, but many have tried.
- EPROM (erasable programmable ROM)—EPROM was widely used in early smart cards, but the architecture of the IC operates in a one-time programmable (OTP) mode, thus restricting the services offered by the ICC. Moreover, it requires ultraviolet light to erase the memory, which makes it difficult for the typical organization to manage the cards.
- EEPROM (electrically erasable PROM)—EEPROM is the IC of choice because it offers user access and the ability to be rewritten, in some cases up to a million times. Clearly these attributes are those that smart cards must have to be usable in today's environment. Typically, the amount of memory will range from 8 to 256 KB.
- RAM (random access memory)—Up to this point, all the examples were nonvolatile, meaning that when power is removed the data remains intact. RAM does not have this feature, and all data is lost when the unit is not powered. For some smart cards that have their own power source, RAM may be used to offer greater storage and speed; however, at some point the data will be lost—this can be an advantage or disadvantage, depending on one's perspective.

62.2.2 Processor

Memory alone does not make a card "smart." In the implementation of an IC a microcontroller (or central processing unit) is integrated into the chip, effectively managing the data in memory. Control logic is embedded into the memory controller and provides various services, the least of which is security; therefore, one of the most interesting aspects of smart cards (and their use in security-related applications) is founded on the fact that controls associated with the data are intrinsic to the construction of the IC. To demonstrate, when power is applied to the smart card, the processor can apply logic in an effort to perform services and control access to the EEPROM. The logic controlling access to the memory is a significant attribute with regard to ensuring that the security of private data, such as a private key, is not exposed; therefore, smart cards can be configured to allow only a certificate containing a private key for digital signing purposes to be written onto the card but never accessed by external processes or applications. For example, the processor has the ability to perform cryptographic functions to data supplied by an outside source using an algorithm embedded in the processor and a key maintained in the memory. Moreover, programs can be embedded in portions of the memory that the processor utilizes to offer advanced services. We will discuss these in more detail later. Nevertheless, simply put, a smart card has a processor and nonvolatile memory, allowing it to be, well, smart as well as secure.

Following are examples of smart-card features that ate typically found on smart cards today:

- 64-KB EEPOM—This is the typical amount of memory found on contemporary cards.
- 8-bit CPU microcontroller—This is a small controller for which several forms of logic can be implemented. For example, it is not uncommon for a processor to perform cryptographic functions for DES, 3DES, RSA 1024-bit, and SHA-1, to name a few.
- Variable power (2.7 to 5.5 V)—Given advances in today's IC substrate, many cards will operate below 3 V, offering longer life and grater efficiencies. Alternatively, they can also operate up to 5.5 V to accommodate old card readers and systems.

- Clock frequency (1 to 7.5 MHz)—In the early developments of smart-card technology, the clock was either 3.57 or 4.92 MHz, primarily because of the inexpensive and prolific crystals that were available. In contrast, today's IC can operate at multiple speeds to accommodate various applications and power levels.
- Endurance—Endurance refers to the number of write/erase cycles. Obviously, this is important when considering smart-card usage. Typically, most smart cards will offer between 250,000 and 500,000 cycles. Because the primary use of a smart card in a security scenario is permitting access to read data on the card, it is highly unlikely that someone would reach the limits of the IC; however, as more complex applications, such as Java, are integrated into the IC the data will require more management, forcing more cycles upon each use.
- Data retention—User data and application data contained within the memory have a shelf life; moreover, that life span is directly related to the temperatures to which the smart card is exposed. Also, the proximity to some materials or radiation will affect the life of the data on a card. Most cards offer a range of 7 to 10 years of data retention.

It is important to understand that a smart card is effectively a computer with many of the same operational challenges. It has an IC that incorporates the processor and memory, logic embedded in the processor that supports various services, and applications built into the processor and housed on the EEPROM for on-demand use. It also requires protocol management (how it is supposed to interface with other systems) and data management. All of these components and more exist in a very small substrate hidden in the card and will only become more complex as technology advances.

62.2.2.1 Card Types

At the most basic level, there are two types of smart cards, which differ in how they interact with other systems: contact cards, which use physical contact to communicate with systems, or contactless cards, which interface using proximity technology.

62.2.2.2 Contact Cards

Contact cards are fairly self explanatory. Based on the ISO-7816-2 standard, a contact ICC provides for eight electrical contacts (only six are used) to interact with other systems or devices. The contacts on a smart card, as shown in Exhibit 62.1, provide access to different elements of the embedded IC. The

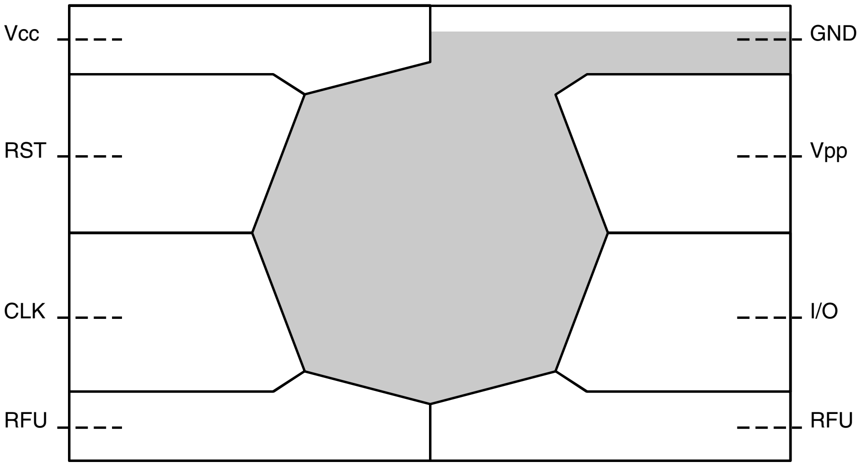

EXHIBIT 62.1 Contact plate on a smart card.

EXHIBIT 62.2 Contact Descriptions

Contact	Designation	Use
C1	Vcc	Power connection through which operating power is supplied to the microprocessor chip in the card
C2	RST	Reset line through which the interface device (IFD) can signal to the microprocessor chip of the smart card to initiate its reset sequence of instructions
C3	CLK	Clock signal line through which a clock signal can be provided to the microprocessor chip; this line controls the operation speed and provides a common framework for data communication between the IFD and the integrated circuit card (ICC)
C4	RFU	Reserved for future use
C5	GND	Ground line providing common electrical ground between the IFD and the ICC
C6	Vpp	Programming power connection used to program electrically erasable programmable read only memory (EEPROM) of first-generation ICCs
C7	I/O	Input/output line that provides a half-duplex communication channel between the reader and the smart card
C8	RFU	Reserved for future use

contact designation (C*n*) starts with C1, Vcc, and continues counter clockwise around the plate. As shown in Exhibit 62.2, each contact has a specific purpose for interacting with the embedded chip.

62.2.2.3 Contactless Cards

Cards that are founded on proximity communications are growing in demand and in use. They are increasing in adoption because of their durability, applications in use, speed, and convenience. Their design eliminates the physicality of interacting with disparate systems, thus eliminating the type of damage incurred by contact cards with plates or magnetic stripes. Finally, a contactless card offers a multitude of uses and opportunity for integration with, for example, cell phones or PDAs. Typically, the power and data interchange is provided by an inductive loop using low-frequency electronic magnetic radiation. The ISO 14443 defines the physical characteristics, radiofrequency (RF) power and signal interface, initialization and anticollision, and transmission protocol for contactless cards. The proximity coupling device (PCD) provides all the power and signaling control for communications with the card, which in this case is referred to as a proximity integrated circuit card (PICC). The PCD produces a RF field that activates the card when it is within the electrometric field loop. The frequency of the RF operating field is 13.56 MHz ± 7 kHz, and it operates constantly within a minimum and maximum power range. When a PICC is incorporated into the loop, the PCD begins the communication setup process. The PCD alternates between two types of modulation (or signal types)—type A and type B—until a PICC is incorporated and interacts on a given interface. The important point is that both types support 106 kbps (kilobits per second) in bidirectional communications. This can be best compared to selecting the equivalent to layer 1 and 2 of the OSI model for computer networking. Many of the PICC and PCD solutions today are provided by or founded on Mifare and HID products and solutions, the *de facto* proximity solutions.

62.3 Smart-Card Uses

Organizations can consider using smart cards in many ways: physical access, security, and even application extensions. Although each is helpful in its own right, the value lies in the singularity of the solution—a card; therefore, if any of the uses described below are seen as meaningful options, then by default all others are plausible and offer the potential for significant returns on related investments.

62.3.1 Physical Access

Many companies employ building access credentials in the form of a common card. It is not unusual for a new employee to be issued an access card to allow entry into the building. Moreover, that same card can be used to determine varying levels of access to internal zones, furthering control of employee movements. The use of cards for access can encompass a wide range of solutions, such as controlling entry into parking lots, garages, main entry ways, data rooms, floors in a building, cabinets, and even trash bins. In most cases, access cards will bear the company name or logo and have a magnetic strip for interfacing with control systems; however, some organizations use proximity cards to accomplish the same functions as the magnetic strip. Usually, the card provides a unique identifier, nothing extraordinarily complex, which allows a central system to identify the card. The association of the card to the holder is assumed. The use of a smart card can provide enhanced services in certain scenarios. For example, verifying the association of a user with a card to provide access to a parking lot is not as important as ensuring that association when the user wants to access the data center; therefore, a smart card may not be queried for user data at the driveway but can be forced at the door of a computer room. The simplicity of traditional access cards does not provide data that can authenticate the holder of the card. Today, as the price of smart cards decreases and more service types are incorporated into them, such as magnetic strips and proximity features, the use of a single smart card is growing in demand.

62.3.2 Employee Identification

In addition to providing a card for physical access, many companies will take the next step and leverage the same substrate as employee or even visitor identification. In these scenarios, the employee information is emblazoned on the card, such as the employee's photograph, name, designation, and department. Organizations that utilize access badges for employee identification clearly have taken advantage of the initial investment in the physicality of the badge. One could conclude that the added advantages offered by smart cards would fit within that philosophy.

62.3.3 Logging On

When people think about a smart card, the first thing that comes to mind is access to systems and data. Interestingly, smart cards have two basic uses for logging on to systems and applications. The first is pseudo-single sign-on (PSSO), where different username and password combinations are stored on the smart card and accessed upon future authentication challenges. A good example is RSA's Sign-On Manager. Software is loaded onto the end user's system that provides tools for using the smart card. One of the features of the Sign-On Manager is its ability to identify when a user is being challenged for credentials. When this occurs, the application provides the option to remember the credentials and store them securely on the card. The next time the user is challenged, the application will identify the authentication and act on behalf of the user entering their information. At this point, one might ask, "What is the difference between this and Microsoft's 'Remember Password' function?" The most significant difference is that the credentials are securely stored on the care, and access to that information is controlled by a personal identification number (PIN) (in reality, it can be a phrase, like a password). Also, it provides the option to remember data associated with a diverse number of applications. The second, and perhaps most important, use of a smart card is to store digital certificates. Certificates can be used in combination with asymmetrical cryptographic functions to allow strong authentication utilizing public-key cryptography, greatly enhancing the identification and authentications of a given user. Again, access to the certificate and related keys is controlled by the smart card and ultimately a pass phrase to gain access to and use those stored credentials by embedded cryptographic functions on the card.

62.4 Features and Benefits

Some uses of smart cards were introduced above, but what about the technical attributes of smart cards? The best way to consider use of consider use of smart cards in an enterprise is to understand that a smart card is a tool that can support a multitude of functions; however, it is common to confuse the smart card with its underlying services, such as public-key infrastructure (PKI) and digital signatures. To clarify, the card is a container of information, and the logic in the card supports the use of that data, but the card itself is not the provider of the broader set of services. To digitally sign a document, such as an e-mail, the card allows utilization of private-key cryptographic functions in a secure and authenticated manner. The application, in most cases, is unaware that the private data is being supplied by a smart card. More accurately, the smart card interacts with the user and system to allow use of the data. When this has occurred, the application will operate utilizing the operating system of the end system or other tools that permit the use of the data for the transaction.

For example, consider a Microsoft XP user who wishes to sign an e-mail. The user authentications to the smart card permitting the use of a S/MIME private key. That key, utilizing various forms of security, is accessed by way of the PKUS #11 standard and Microsoft's CAPI, which links into the local store of the operating system where certificates are typically maintained. The e-mail application then utilizes that store to perform the signing. In reality, however, the certificate in the store is nothing more than a pointer to the smart card that allows the process to be performed on the card in a protected manner. By leveraging PKCS #11 throughout applications and services, smart cards can perform signing services to any data regardless of architecture. For example, a smart-card-enabled user may access a Citrix system to utilize an application client that interfaces with a centralized enterprise resource planning (ERP) system. Given that the MS client supports local store linking and PKCS #11 and Citrix supports PKCS #11 with its client, then all the ERP client application has to do is request signing services from the Citrix server and the physical card will be accessed via the Citrix client on the remote system. As far as the ERP client application knows, a signing certificate in the local store of the system is associated with the remote user via Citrix and it passes data for signing from the ERP database to the CAPI. At that point, Citrix sees the request to the local certificate store and generates a PKCS #11 request via the Citrix client to the remote user. The data is then passed through the local store on the user's system and ultimately to the card for processing.

This process allows application developers to be concerned only with typical MS CAPI calls to the operating system for certificate services. The association of the smart card is irrelevant to the application. When the data is sent to the card, it simply provides the requested functions and passes then back through the secured channels. A multitiered architecture with PKCS #11-enabled systems will effectively present a virtual smart card to the system accessible by way of the local certificate store on the operating system. The example provided here was for Microsoft applications; however, other operating systems employ similar certificate services to applications that can be tied to remote physical devices.

62.4.1 What Is PKCS #11?

PKCS #11 is a standard developed by RSA to allow access and sharing of tokens, such as smart cards. Cryptoki (short for "cryptographic token interface" and pronounced "crypto-key") follows a simple object-based approach that addresses the goals of technology independence (any kind of device) and resource sharing (multiple applications accessing multiple devices), presenting to applications a common, logical view of the device referred to as a *cryptographic token*. Cryptoki is intended to be an interface between applications and all kinds of portable cryptographic devices, such as smart cards. Although some standards existed for interfacing hardware tokens, what remained were particular details for performing cryptography services, Also, the ability to offer resource sharing of the hardware token and allowing for provisional services in a multitiered architecture had yet to be defined. While PKCS #11 (Cryptoki) offers an object-based approach to accessing and process in data on smart cards, its adoption as a standard has resulted in simplified application development and greater options for smart-card integration. Since the introduction of PKCS #11 2.20 in June 2004, many vendors have used it as a mechanism to motivate smart-card solutions. One could conclude that the barrier to broad adoption of smart-cards was the lack of a comprehensive process for token interface, and PKCS #11 has satisfied that requirement; therefore, the industry's interest in smart cards has increased several fold because of the advances in deployment options and use.

62.4.2 Multifactor Authentication

In general, the three types of authentication are:

- *Single-factor*—Something you know, such as a password
- *Two-factor*—Something you know and Something you have, such as a password and a token together
- *Three-factor*—Something you know, have, and are, such as a biometric mechanism coupled with a token and password

Smart cards represent something you have. A user is in possession of a smart card and that, in and of itself, is helpful in offering two-factor authentication; however, an added layer of security and authentication is provided by the fact that the smart-card transaction is based on possession of the card and the existence of a pass phrase in combination with the data on the card. Based on these inherent attributes (e.g., possession, access control, and data) the use of the smart card meets, and arguable exceeds, the essential requirements for two-factor authentication.

Typically, the way smart cards are used for accessing computer and network resources is that a user inserts the smart card into a reader and then enters the PIN associated with that card in order to unlock the services of the card. In such a scenario, the first factor of security is providing something you have—a smart card. The second factor of security in this case is providing something you know—the PIN. The data on the card, validated by the existence of the card in combination with the access authenticated by the PIN, adds another layer to the security of the authentication process.

Is this better than a traditional SecurID token solution? A typical two-factor authentication token provides individuality in the form of a cryptographic key embedded in the token that produces a unique number in a given time frame (e.g., every 60 seconds). The authenticating system, in this example an ACE server, will know, based on the token serial number, what number will appear on the token at the time of the challenge. If the correct number is provided by the user within the window of opportunity, along with other identification information (such as username and password), it is concluded that the user is in possession of the assigned token—the second factor.

A smart card adds another level of integrity. The PIN provides access to the information on the card (not simply displayed as with a token), and the key on the device is used in the authentication process. When used in combination with certificates, one would conclude that a smart card is better, as the certificate participates in a larger infrastructure to maintain the integrity of the authentication process; however, if the smart card is simply providing stored credentials when a PIN is provided, it is effectively the same as a token and arguably less effective.

62.5 Leveraging Certificates

With very little doubt, digital certificates can offer a great deal of security features to an organization. Certificates are founded on a trust model that is supported by the combination of technology, process, and, in many cases, legally binding attributes to ensure that the keys associated with the certificate are valid; however, one of the weakest elements of certificates and public-key cryptography, in general, is maintaining a level of assurance that the private key of an individual is in the sole possession of the user it was assigned to. Certificates primarily speak to the validity of the keys, the owner, and the issuer, but the private-key status is the other half of the equation, and it is feasible for that private key to have multiple instances if not designed and administered correctly—although this is not a recommended practice, as some solutions lack this control. Many technical solutions to dealing with private-key instances have been proposed, such as key escrows that divvy out the key upon authenticated request for temporary transactional use, but, it is important to know that, potentially, a private key can be loaded onto any system with only some controls in place to ensure that no duplicity occurs.

Private-key multiplicity breaks several layers of security and trust. Although a certificate associated with a private key can be password protected, thus limiting its exposure to unauthorized use, this is not a forgone conclusion or a default configuration. Moreover, if the use of the key pair is related to nonrepudiation requirements, the single instance is further refined by the fact that the assigned user must be in possession of the key material. The entire concept of nonrepudiation is founded on a user being the sole owner and having possession of the private key. When it is copied, it can be assumed that the foundational integrity of the solution is completely undermined. In this light, smart cards offer an excellent option to greatly enhance the management of private keys and related certificates. Mind you, it is far from perfect, but the mobility offered by smart cards significantly reduces the exposure or any potential need or capability to copy the private key and allows for secure interaction with the private key; therefore, although the use of smart cards is not directly related to a PKI solution, the use of them significantly enhances the overall PKI solution. If nonrepudiation is a prerequisite, it is safe to say that smart cards are a requirement.

62.5.1 Custom Economy

Every new, interesting comes with a “cool factor,” and smart cards are no different. As mentioned earlier, smart cards have integrated circuits that are comprised of memory, a processor, and built-in logic controls. The memory of the smart card can contain applications that, although small, can offer advanced services. Today, the application platform of choice is a Java Virtual Machine (JVM). Organizations can leverage a series of application building blocks to contrast custom applications that can interact with systems in a secure manner. For example, it is a simple matter for a company to develop an internal prepaid or credit mechanism for employees purchasing items within the domain of that company. To demonstrate, an employee armed with a smart card, normally used as an employee identification badge, access card, and for signing e-mails, can insert the smart card into a reader in the company cafeteria to purchase lunch. In its most basic form, the card can maintain a copy of transactions that can be reconciled with direct payment from payroll. In a more complicated solution, the employee can load the card with credit at their workstation and then use the credit for lunch or buying a new mug in the company store.

In Europe, smart-card readers are located at almost every cash point and are spreading to point-of-sale (POS) systems. For example, to buy a train ticket from Zurich to Geneva, a passenger inserts a credit card into the reader. If the card is not smart, the reader will simply access the magnetic strip; however, if an IC is present, it will interact with the embedded application for authentication and verification of the transaction. Another example is American Express’s Blue Card and others that have an embedded IC; people can use these cards at home for online transactions via a common card reader. The application on the card provides the services for interacting with an E-commerce Web site.

62.6 Challenges

Nothing is perfect, and any technical that is positioned as the ultimate integrator is destined to disappoint at some point during its adoption, especially if its application security related. Of course, smart cards are not immune to this and have challenges in their own right.

62.6.1 Operational Considerations

Obviously, the physically of a card represents opportunities to lose, misplace, or forget it. Additionally, cards can be stolen, either by a motivated thief or indirectly in a stolen purse or car. Very little can be done from a business perspective. When a card is gone, it should be assumed that it will not be found or returned. It is hoped that the card does not have the PIN written on it or the thief does not know the PIN. Outside of these assumptions, the organization is relegated to reissuing the card and any credentials that are under the control of the company, such as certificates, and changing domain and application level passwords. If the card is associated with physical access, the association of the card to those controls must be permanently eliminated. It is apparent that companies depending on use of the card and information contained within the card must have a decommissioning process that includes emergency scenarios, much like an incident process. It must also include the ability to determine if a lost or stolen card is being used.

Another set of issues that may arise given the physicality of the card and the nature of human beings is simply leaving the card in a system. In many cases, the PIN has a memory lifespan. Users insert their cards, enter their PINs, and begin their daily work. To avoid the constant challenge of entering a PIN, users have the option of setting a reauthentication window. If that window is too short, users will become frustrated by having to continually enter their PINs; however, setting it too long increase the risk of inappropriate use if and when a user steps away from the workstation, leaving the card in the system. Organizations that have very dynamic environments have opted for proximity cards for workstation access. Users maintain their cards somewhere on their person, and when the workstations are in use their cards are accessed. This procedure generally reduces the need for concern but does not eliminate it completely. All in all, it is a cultural challenge, and as with most things related to security it requires regular training and awareness campaigns to reduce people-related exposures.

The cost of the card may seem palatable given the services it can provide and the overall enhancement of security, but a smart card is only one element of the entire solution. A card may cost, for example, US$10, but the provisioning, management, maintenance, and, most importantly, processes that must be performed to reissue a card can become very costly. Add to this the typical user's limited understanding of how to employ the card and it becomes necessary to add the costs of help-desk-related activated. Of course, investments in training, process development, and proper planning of the solution will begin to take shape over time, reducing overhead related to card usage. Efficiencies will surface, and greater visibility with regard to management of the solution will help recoup initial investments to a point where returns can be realized.

62.6.2 Technical Considerations

Although smart cards have several different applications, the attribute that stands out most is the use of Java applications embedded in the card. It is important to realize that many applications can be incorporated onto a single card, so it is necessary to test and trust these applications prior to integration with the card and extended applications, as well as have an understanding of the potential interactions of these applications within the card upon use and the effects on external applications and data. For example, when an applet is accessed to perform a function, another application may have the ability to interact with the transaction or even data on the card that is assigned to the originating application.

Because a Java-enabled card allows multiple and possibly competitive applets to be maintained on the same card, the potential for security problems may arise. Many cards will have an application firewall embedded in the system to isolate functions performed by a given applet and to control access to data that may be stored or in use by that application. The firewall will prevent access to objects owned by other applets; however, in some situations multiple objects stored in memory may be required by different applets for various services. In these cases, the firewalling capability is challenged to maintain isolation in the event that common objects are required. A normal computer typically has ample memory to avoid object sharing; however, smart cards have only limited memory, potentially forcing the use of an object by different applications. The firewall must be able to assert privileges for object usage, but this is not always possible or within the capabilities of the smart-card vendor's firewall code.

As mentioned earlier, ISO 7816-2 defines the physical contacts of a smart card, and ISO 7816-4 seeks to define command sets for card operating systems. As with many standards, however, there is room for interpretation, and vendors will stretch the envelope of what can be performed by the card in an effort to offer new and exciting services. This is not new to technology, by any means, and it drives the entrepreneurial spirit to ensure liveliness in product development; however, the byproduct of early adoption of what could be construed as proprietary solutions sets the foundation for interoperability issues. Until grater convergence in the expectations of services and card production exists, complexities will always be encountered in a heterogeneous smart-card-driven environment. Unfortunately, no hard and fast answers exist to accommodate disparate cards in an organization. Although support for one card may be applicable in some situations, with another vendor's application it can be expected that many of the unique services of the card will evaporate.

62.7 Conclusion

Smart cards can be very effective in enhancing the security posture while simultaneously offering efficiencies within the enterprise. Moreover, they allow an organization to push the limits by digitizing common transactions and expanding the horizon of existing infrastructures. But these features and benefits come with a cost. Challenges in implementation, interoperability, and functionality will most certainly surface during adoption. Culturally, many users are typically unaware of what is going on within a seemingly innocuous piece of plastic and may have difficulty accepting its use or understanding the responsibility that comes with the card. Nevertheless, it is clear that smart cards are here to stay, and no doubt organizations have implemented smart cards, or are in the process of doing so, because the advantages can significantly outweigh the disadvantages of such a technology.

63

A Guide to Evaluating Tokens

Joseph T. Hootman

63.1 Introduction

Fixed passwords are no longer appropriate for controlling computer access. Effective access control calls for the use of dynamic passwords, which are generated by tokens, a calculator-type device. Many such devices have now been introduced into the marketplace, but no one is necessarily appropriate for all situations. This chapter discusses the use of dynamic passwords and describes the characteristics of currently available password generators and their advantages and disadvantages in particular situations. A table comparing the features of a selected group of tokens is included.

63.2 Dynamic Passwords

The dynamic, or one-time, password is becoming a popular alternative to the fixed password. The basic concept of dynamic passwords is to prove a person's identity by testing to ensure that that person possesses a unique key or password generator. The user is provided with a special-purpose calculator that generates an unpredictable number. This number is then used as a one-time password to enter into the computer. In some cases, the number is produced unilaterally by the token; in others, it is calculated in response to a challenge from the computer. In all cases, for each requested entry, the security software or hardware installed at the access control point calculates an expected response to the one-time password calculated by the token. If the two numbers match, the security system grants computer access to the individual carrying the token.

Because a new password is produced or calculated each time access is requested, no password need ever be written down or memorized. Even if a password is copied, it is useless because a new password is generated each time. In some systems, reuse of the same password by the same user is extremely unlikely but statistically possible. Other systems offer protection against all reuse. In newer product offerings, the token may also be used as an employee ID card, a physical access control device, a calculator, or a credit card.

Token-based access control has two essential parts: the unique tokens issued to the authorized users and the access control security system (software of hardware) installed at the access control point. (See the following section for a further discussion of authentication architectures for use at access control points). A user gains computer access by entering a unique user ID into the access control system through the terminal or workstation. The access control system evaluates the user ID and determines whether it is authorized and, if so, how user authentication should occur—through a fixed password, a dynamic password, or, in some cases, a biometric device.

For dynamic password authentication, the access control system database contains the type of token and the unique seed, or cryptographic key, stored in the token for each user ID. Other information about that user is also stored in the access control system, including authority group, location, fixed passwords, and authorization controls. Most access control systems have addressed the problem of lost tokens or unauthorized use of legitimate tokens. If an authorized user's token is lost, the user cannot access the system and would therefore report the token as missing. The computer security administrator simply deletes the information on the prior token and replaces it with new data on the replacement token. To prevent unauthorized use, most systems use a personal identification number (PIN) to active tokens. Without the proper PIN, the token still provides a password, but an incorrect one. Some tokens also provide duress codes, so the security software can recognize when users are being forced to use the token and issue appropriate warnings.

63.3 Authentication Architectures

Five security architecture are currently available for access control and user authentication.

63.3.1 Workstation Authentication

This approach, sometimes referred to as peripheral defense, places the authentication and access control system in the workstation. Normally, boot protection is also provided. Essentially, a user cannot gain access to the workstation nor to its ability to gain access to other resources without first proving that the specific requesting user is entitled to have such access. Generally, all workstations that have the capability to access protected target resources must have authentication capability.

63.3.2 Dedicated Authentication Systems

Dedicated authentication systems are generally freestanding hardware devices installed in front of the computer resources to be protected. They are designed to protect access to the protected resources and also generally offer such nonsecurity capabilities as menuing and session logging.

63.3.3 Access Server Authentication

Access server authentication systems are general-purpose communication devices, with various control, user menuing, and routing/switching features, to which security and authentication functions have been added.

63.3.4 Host-Based Authentication

Host-based authentication software systems are designed to be installed on the protected resource itself to control access at the first entry port level or host communication point-of-entry. On large mainframes, the access control and authentication functions are usually coupled to the functions of a resource control program (e.g., Resources Access Control Facility, or ACF2).

63.3.5 Authentication Nodes

An authentication node system offers an authentication server for the entire network. Either operating under Kerberos or a single sign-on approach, the user authenticates only once and either is given a ticket allowing access to other network resources or is granted access to a macro auto-log-on script files that can then be used to obtain access to other resources on the network.

63.4 Modes of Token Operation

The two most common modes of operation are asynchronous and synchronous. In the asynchronous mode, the access control software issues a cleartext challenge to the user that is displayed on the terminal or workstation screen. The user turns on the password generator, enters a PIN, enters the cleartext challenge into the token, and presses a key to cause the token to calculate the response. The response is then displayed on the token and the user keys that value into the terminal or workstation. Because the access control software in the protected computer knows the unique seed (i.e., encryption algorithm) assigned to that user's token, it can calculate the expected response. If the two responses match, the user is granted access.

In the synchronous mode, the access control software requests the password without calculating and presenting a challenge to the user. The user turns on the password generator, enters a PIN, reads the response from the display, and keys that value into the keyboard of the terminal or workstation. The computer knows the expected response through a combination of three factors: It knows the algorithm the token uses to calculate the response, it knows the unique key assigned to that token that will be used in calculating the response, and it knows the method used by the token to maintain dynamic password synchronization with the access control system. Maintaining password synchronization is a key factor in synchronous token. Asynchronous tokens essentially are resynchronized each time they are used, because the access control system issues a new challenge on each use. Synchronous tokens essentially issue their own challenge, and the access control system must be able to determine what that challenge is. The three common methods to do this are time synchronous, involving the use of time and other factors (using the clocks in the token and in the access control systems and allowing for clock drift); event synchronous, involving use of a value developed from one-time modification of the last entry; and algorithmic synchronous, involving reverse engineering of the response to determine if the specific token could have generated that response. As in the asynchronous mode, if the two responses match then the user is granted access.

63.5 Passing Authentication between Computers

In addition to the conventional use of tokens, it is important to consider five variations in authentication:

- Workstation-to-host authentication
- Workstation single sign-on
- Network authentication nodes
- Host-to-host authentication
- Host-to-user authentication

In certain applications, it may be desirable to authenticate the workstation rather than the individual user. This is generally the case when the workstation is in a secured area and may be used by multiple people. Sometimes the use of tokens is not acceptable or cost justified. In these cases, a noncopyable software token may be installed in the workstation. (This approach obviously will not work with dumb terminals.) The user or system administrator will be required to authenticate at boot-up, generally with a fixed password; subsequently, any access request that is challenged will be answered automatically by the software token, transparently to the user. In cases where dynamic password security is used, no password aging is required; otherwise the user or the software token must be able to respond to requests for password aging from the host system.

An important variation of the software token is the use of a single sign-on software module in the workstation. For the user who needs to access multiple resources that require authentication (even if only ID and fixed password), single sign-on should be considered. This module works exactly like the software token but has the capability to store multiple software tokens and log-on macro script files. As with the software token, the module is noncopyable and requires workstation authentication to be activated. (Token authentication at the workstation level is highly recommended.) When activated, the module will automatically respond to authentication requests from any protected resources for which the module has an entry.

An important development is the evolution of two types of network authentication nodes:

- *Kerberos authentication nodes*—This type of node is being actively developed by a number of companies working to support this public domain software and by numerous user organizations. In this approach, the user logs into the Kerberos node (with either a fixed or dynamic password) and after authentication is given an encrypted, time-stamped “ticket.” The user can then take the ticket to any resource controlled by a Kerberos access module, present the ticket, and, if the ticket is correct, gain access. There is only one database, no synchronization is required, and access is available from any workstation; however, this approach lacks session control and logging of complete sessions.
- *Session control nodes*—With this type of node, the user logs into the authentication node and after authentication is given a menu that contains that specific user’s choices for system or resource access. When the user makes a selection, the authentication node automatically logs the user into the requested resource and remains present during the entire session. This approach allows for the authentication node to provide the communication pathway to each resource and stay with the user during the entire session, providing complete session control and logging. When users complete their sessions or are logged out of the system, they are once again presented with their menus by the authentication node. It is possible to have only one database or multiple databases. It is therefore also possible to have several authentication nodes to balance the communication load. The functioning of the authentication node is an integral part of the regular network operating system and protocols; therefore, access to the authentication node is available from any workstation.

To date, a limited amount of work has been done with host-to-host (also called peer-to-peer) authentication (except in the area of electronic data interchange); however, interest in this capability is growing rapidly, and it is not difficult to implement. The access control system can be installed as a gateway access system or as a system utility in the host (generally as part of the normal log-on procedure), or it can be software imbedded in an application program that is used in the peer-to-peer process. The responding system (essentially a software token or a secure autolog script file) can be installed as part of the telecommunications access software or can be imbedded in the application program that requests the peer-to-peer process. Note that it is not the user who is being authenticated here but rather the host or host application. It is probably wise to have users who initiate the process authenticate themselves to the system or application to enable use of the peer-to-peer authentication process. Host-to-user authentication has a limited purpose—to assure the user that the correct host has been accessed. This prevents simulating the intended host and trapping the user access to obtain IDs and passwords.

63.6 Types and Characteristics of Tokens

A wide range of token devices is on the market. Most are area synchronous, using full challenge and response. All have some form of encryption, ranging from the full Data Encryption Standard (DES) to a variety of proprietary algorithms. Some tokens are calculators, most are not; some have replaceable batteries, and some are disposable after the batteries wear down (usually within three to five years). Smart cards are now being developed for use as tokens with both hard-wired and portable readers. Some smart cards and tokens can store multiple seeds and synchronization information that enable the user to access more than one computer without having to enter a long, random challenge. Some have the ability to operate with multiple encryption algorithm in multiple modes. All are easy to use to and carry. The following sections describe some of these characteristics and their advantages and disadvantages.

63.6.1 Initialization

Some tokens are initially programmed at the factory, with the unique key being inserted or developed before shipment. Many tokens, however, are shipped blank, and data security administrator must do the programming. (Generally, factory-programmed tokens can be ordered at an extra charge.) Although blank tokens may require more work for the data security administrator, they are often considered more secure than preinitialized tokens, which could be compromised between shipment from the factory and receipt. On the other hand, if the keys are developed under factory control, the data security administrator cannot compromise the tokens.

To eliminate both these concerns, some tokens are designed to be field initialized by the end user. This type of token can be securely initialized even if the initialization is carried out across an unsecured network. Such cards were originally designed for online information services providers to be sent out through the mail to remote users, who would then log onto the system and initialize their cards by themselves. Only after this secure initialization process is completed can the privileged security supervisor gain access through the security software to the unique key. The user may reprogram the card at any time. This type of token was designed to provide direct accountability for system use. When users log onto the online system, they must prove their identity to gain access and, unless a token is reported lost or stolen, they are then held accountable for the resulting bill for services.

When tokens are not initialized at the factory, the method for programming the tokens must be decided. Manually programming a few tokens is fine and may be necessary for some remote sites. Programming hundreds of tokens, however, is tedious and time consuming. An automatic programming device is recommended when tokens are not programmed at the factory.

63.6.2 Physical Characteristics

Tokens are available in five basic physical types:

- Hand-held calculator type with replaceable batteries
- Flat calculator-type card without replaceable batteries (sometimes referred to as a supersmart card)
- Conventional smart card with a chip embedded in the card, usually accompanied by a handheld device into which the card is slipped to provide the keyboard and display
- Software token (described earlier)
- Hardware device without a keyboard or display, manually installed by the user on a dial-up line, programmed to automatically respond to access control security system challenges

Two main issues related to the physical characteristics of token are user friendliness and alternative application of the token. User friendliness is of particular concern to organizations issuing tokens for the first time, especially to outside customers or to senior managers. They want to have a token that is unobtrusive and very easy to carry and use. Some of the newer tokens can be used as employee ID cards, physical access control devices, calculators, or credit cards. Opinions differ on whether tokens should be single-use devices (emphasizing the importance of security) or multiple-use devices (increasing user friendliness).

63.6.3 Keyboard and Display

All of the devices come with a from of liquid crystal display (LCD), and most have a numeric keyboard. Some have keys for clearing the display and backspacing, making it easier for the user to correct mistakes when entering the challenge or programming the card. In both Europe and the United States, the introduction of the credit-card type smart card has brought about the need for a handheld device into which the card can be inserted to provide for standard token operation. (Normal use of these type of tokens is with a cable-connected card reader.) These hand-held devices have battery power, a keyboard, and a display but rely on the smart card itself for memory and processor capability.

Three modes of display are commonly offered in the most popular tokens: straight decimal, hexadecimal, and a modified, nonambiguous hexadecimal. Some of the characters used in the hexadecimal display have the potential of being confusing (e.g., the number 6 and the lowercase letter b). Users who have problems with this display mode should be given tokens that use a straight decimal or nonambiguous hexadecimal mode, which substitutes ambiguous characters with less confusing characters. Hexadecimal displays provide greater security because of the greater number of combinations that can be represented.

A final point about the display regards automatic shutoff, which is offered with most cards. This feature conserves battery power and reduces the exposure of information on the card display.

63.6.4 Maximum Password Length

The longer the response to a challenge, the greater security. This is simply a function of the complexity and time required to crack an encrypted response. At some point, however, additional security is not feasible or economical in light of the marginal gain that it provides. The maximum password length for two of the cards compared in Exhibit 63.1 is 16 digits. (It could have been higher in those tokens but was limited to 16.) In the other tokens, the limit is 7 or 8. These limits are built into the tokens themselves, rather than in the supporting software. The chances of guessing a dynamic 8-digit password are 1 in 108, a large enough number to discourage most intruders.

63.6.5 Minimum Challenge Length

The challenge is used only in asynchronous tokens. The supporting software controls the challenge length. Many security supervisors reduce the size of the challenge to improve ease of use. In some of the tokens a soft PIN (discussed in a later section) is used, which can also be used to reduce the number of characters in the challenge or eliminate it.

63.6.6 Synchronous Host Support

If a user is working on more than one computer, secure access can be ensured in the following ways:

- Use multiple tokens, one for each resource.
- Place the same unique key in the database of each of the supporting software systems. This solution, however, could compromise the secrecy of the key because it is the same on each machine; therefore the security of each system depends on all the others.
- Use a different PIN or password for each machine, where the PIN or password is combined with the one-time response.

EXHIBIT 63.1 Token Comparison Chart

	Vendor							
Comparison Criteria	Safeworld MultiSync	Safeworld Access Card	Racial Watch Word	Secure Net-Key	Safeworld DES Gold	Safeworld DES Silver	Sec Dynamics SecurID Card

Automated programming?	$Option	No	$Option	$Option	$Option	$Option	No	No

- Use a token that has the ability to support multiple keys.
- Use a software token or single sign-on module that employs asynchronous token technology (full challenge-response) that is transparent or the user when in use.

If a synchronous mode of operation is used and each computer has a different synchronization factor, the token must have multiple synchronous host support; that is the token must be able to keep track of the synchronization factor for each machine. This is relatively easy for time-dependent tokens because of the clock in each machine and in the token control synchronization. The software must allow for clock drift between the two clocks to be in synchronization (current systems do so). The primary risk of drift allowance is exposure of the password; during the time when the validity of the password is being confirmed, it must be protected so that it cannot be used on other resources under the same software system. With event-synchronous tokens, on the other hand, the token must be able to keep track individually of the last event for each computer used. Without that capability, accessing a different computer causes the synchronization to change, destroying the synchronization for the previous computer and requiring a full challenge and response sequence to be performed to reestablish synchronization. Algorithmic-synchronous token have neither of these problems.

63.6.7 Hard *versus* Soft PINs

Two types of PINs are used in tokens: hard PINs and soft PINs. A hard PIN is entered into the token by the user and is evaluated in the hardware of the token logic. Because it is not known or evaluated by the software in the host computer, the hard PIN need never traverse a network nor be entered into the host computer software. A hard PIN can be changed in the token without coordinating that change in the host computer. Data security administrators have minimal control over hard PINs. A soft PIN is entered into the token by the user and directly influences the way in which the dynamic password is calculated. Unlike conventional fixed passwords, the soft PIN never traverses the network and is never directly entered into the host system by the user. The host computer software evaluates the dynamic password to determine whether the user entered the correct soft PIN; therefore, a change in the soft PIN in the token must be coordinated with the host computer software, usually by the data security administrator.

The use of either type of PIN is highly recommended by token vendors because unauthorized users cannot use a token to gain access without knowing the PIN. Hard PINs are usually programmed into the token at the factory; some can be changed in the field. Soft PINs are generally set up by the factory or the data security administrator but are then changed at once by the user with a utility that interacts with the user and the host software. The utility software reverse engineers the soft PIN to determine the new PIN using constants known to both the token and the utility software.

Opinions differ as to which type of PIN is best. Hard PINs are much simpler to administer, but soft PINs are much more flexible and can provide an additional level of security. Some tokens support both hard and soft PINs. When deciding whether to use a hard PIN or a soft PIN, the data security administrator should consider the following factors:

- Does the token accept a hard PIN, or is a hard PIN optional?
- What is the PIN size? A larger PIN is more difficult to break, but a four-digit PIN is considered standard and in most cases offers adequate security.
- Can the hard PIN be changed in the field?
- Does the token have an attack deactivation? This feature disables the card after a certain number of wrong entries and can be a desirable feature for foiling unauthorized users.

The key factors in evaluating soft PINs primarily deal with whether support exists in the host security software and the size of the PIN supported. It is assumed that soft PINs are always user changeable.

63.6.8 Encryption Algorithms

Three types of encryption are used in tokens to calculate unique dynamic passwords:

- The Data Encryption Standard (DES)—The application of DES to tokens does not carry the strict export restrictions imposed by the U.S. government, DES is used here to encrypt only the passwords, not user data.
- ANSI X9.9—This one-way encryption variant of DES is primarily used in message authentication.
- Proprietary algorithms.

A discussion of the advantages and disadvantages of various algorithms is beyond the scope of this chapter; company policy often dictates which algorithms may be used and therefore which tokens may be selected. It should be pointed out that encryption used in token authentication is not subject to export controls as are encryption systems for use in encoding user data. Because the only thing that is being encrypted and decrypted is the one-time password, the federal government does not restrict export of token technology. Smart cards that have encryption algorithms and cipher storage capability are subject to export controls.

63.6.9 Operation Mode

As discussed previously, the two main modes of token operation are asynchronous and synchronous. The asynchronous mode always uses a challenge and response, but the synchronous mode does not use the challenge. Some tokens offer both modes; some only one. The buyer must carefully consider the environment that is to be secured and the characteristics of the user community before choosing an operation mode. The following six factors may influence token selection:

- Asynchronous tokens require more keystrokes than do synchronous tokens and are therefore considered less user friendly.
- No synchronous tokens have replaceable batteries (some buyers prefer not to use throwaways).
- If only software tokens are used, synchronous tokens offer no advantages.
- Synchronous tokens may require additional administration by the security administrator for token/system synchronization.
- Users may already have tokens from another environment or application that can be used in the new environment.
- In multiple host environments, some administrative or security issues may be avoided with the use of asynchronous tokens.

63.6.10 Battery

All handheld tokens run on batteries. Batteries are evaluated according to their lifetime, whether or not they are replaceable, and whether or not the token must be reprogrammed when the battery is replaced. Batteries that are not replaceable should be guaranteed for long life. If the batteries are replaceable, it is preferable not to have to reprogram the token when the batteries are replaced. The major disadvantage of replaceable batteries is that access into the token case must be provided; because of this need to provide access, as well as the bulk of the battery, the cases must be larger than they are for tokens that have nonreplaceable batteries. Many users prefer smaller cases. Size preferences must be weighed against the cost of replacing the entire token when the battery dies.

63.6.11 Warranty

The standard warranty for tokens is now generally one year, and the tokens have proved to be quite reliable.

63.6.12 Keystroke Security Ratio

The keystroke security ratio is the number of keystrokes required to generate a password with a token, using a four-digit PIN, that reduces the possibility of guessing the correct password to less than 1 in 1 million. Exhibit 63.1 includes the keystroke security ratio for various tokens. Tokens that operate in the synchronous mode have an advantage in that no keystrokes are required to enter the challenge. Token keyboard controls also play a role in that on buttons and enter keys can add to keystrokes. The point of applying this ratio is to gain the best balance between user friendliness and adequate security.

63.7 Product Offerings

Several implementations of token technology have used the smart card format. AT offers a smart-card system with both a portable reader and an adjunct reader coupled to the user workstation. The portable reader is equipped with a full keyboard. When the user inserts the smart card into the reader and turns it on, the unit functions just like a conventional challenge-response token. With the adjunct reader, the user inserts the smart card and performs the initial host log-in, and the challenge-response is done automatically by the unit, transparently to the user, thereby eliminating the keystrokes. The AT smart card uses DES and has its own storage and directories, PIN security, and message authentication capability. Up to four secret keys can be programmed for each of eight different host systems. A similar system is offered by ThumScan.

A portable, pocket-sized device for remote authentication is offered by LeeMah DataCom Security Corporation. The InfoKey works in conjunction with the LeeMah TraqNet security system. It is about the size of a cigarette package and is easily jackplugged into the line by users, who then use their workstations or laptops to log into the assigned TraqNet system. When Traqnet has verified the selected host, it issues a challenge to the user that will be automatically answered by the InfoKey for the user. The user does not have to do any key entry of either a challenge or a response.

Vendors that offer software tokens include Digital Pathways, LeeMah, and Enigma Logic. These tokens are software modules installed on the user workstation, rather than handheld hardware devices carried by the user. They function exactly like a challenge–response hardware token but eliminate the need for the user to carry a token or to key in challenge or response data. Because the software token is a valuable item, it must be properly secured to prevent people other than the authorized user from copying or removing the module. Also, because it must be installed on the workstation being used by the user to access the secured resource, it is normally installed only on that one workstation and is not moved from one workstation to another.

63.8 Recommended Course of Action

With the increasing use of networks and of outside access to computer resources, the need for security has never been greater. Authentication is the keystone in a sound security program. Based on knowledge of who the user is (with a high degree of certainty), we can control access, authorize the user privileges to perform functions and manipulate data, allow the use of encryption/decryption engines, and log and effectively hold users accountable for their actions. Without effective authentication, these functions cannot be performed with certainty. Dynamic password technology, whether implemented via hardware tokens or software, is a sound, secure, and reliable way to obtain effective authentication. Security administrators responsible for selecting tokens should evaluate vendor offerings on the basis of cost, ease of use, level of security, and industry or corporate standards, with each factor being weighted according to its importance to the organization. The host-system security software should also be selected with as much care as the token to achieve optimal security.

Controlling FTP: Providing Secured Data Transfers

Chris Hare

Several scenarios exist that must be considered when looking for a solution:

- The user with a log-in account who requires FTP access to upload or download reports generated by an application. The user does not have access to a shell; rather, his default connection to the box will connect him directly to an application. He requires access to only his home directory to retrieve and delete files.
- The user who uses an application as his shell but does not require FTP access to the system.
- An application that automatically transfers data to a remote system for processing by a second application.

It is necessary to find an elegant solution to each of these problems before that solution can be considered viable by an organization.

Scenario A

A user named Bob accesses a UNIX system through an application that is a replacement for his normal UNIX log-in shell. Bob has no need for, and does not have, direct UNIX command-line access. While using the application, Bob creates reports or other output that he must upload or download for analysis or processing. The application saves this data in either Bob's home directory or a common directory for all application users.

Bob may or may not require the ability to put files onto the application server. The requirements break down as follows:

- Bob requires FTP access to the target server.

- Bob requires access to a restricted number of directories, possibly one or two.
- Bob may or may not require the ability to upload files to the server.

Scenario B

Other application users in the environment illustrated in Scenario A require no FTP access whatsoever. Therefore, it is necessary to prevent them from connecting to the application server using FTP.

Scenario C

The same application used by the users in Scenarios A and B regularly dumps data to move to another system. The use of hard-coded passwords in scripts is not advisable because the scripts must be readable for them to be executed properly. This may expose the passwords to unauthorized users and allow them to access the target system. Additionally, the use of hard-coded passwords makes it difficult to change the password on a regular basis because all scripts using this password must be changed.

A further requirement is to protect the data once stored on the remote system to limit the possibility of unauthorized access, retrieval, and modification of the data.

While there are a large number of options and directives for the `/etc/ftpaccess` file, the focus here is on those that provide secured access to meet the requirements in the scenarios described.

64.1 Controlling FTP Access

Advanced FTP servers such as wu-ftpd provide extensive controls for controlling FTP access to the target system. This access does not extend to the IP layer, as the typical FTP client does not offer encryption of the data stream. Rather, FTP relies on the properties inherent in the IP (Internet Protocol) to recover from malformed or lost packets in the data stream. This means one still has no control over the network component of the data transfer. This may allow for the exposure of the data if the network is compromised. However, that is outside the scope of the immediate discussion.

wu-ftpd uses two control files: `/etc/ftpusers and /etc/ftpaccess`. The `/etc/ftpusers,` file is used to list the users who do **not** have FTP access rights on the remote system. For example, if the `/etc/ftpusers` file is empty, then all users, including root, have FTP rights on the system. This is not the desired operation typically, because access to system accounts such as root are to be controlled. Typically, the `/etc/ftpusers` file contains the following entries:

- `root`
- `bin`
- `daemon`
- `adm`
- `lp`
- `sync`
- `shutdown`
- `halt`
- `mail`
- `news`
- `uucp`
- `operator`
- `games`
- `nobody`

EXHIBIT 64.1 Denying FTP Access

```
C:\WINDOWS>ftp 192.168.0.2
Connected to 192.168.0.2.
220 poweredge.home.com FTP server (Version wu- 2.6.1(1) Wed Aug 9 05:54:50 EDT 2000)
  ready.
User (192.168.0.2:(none)): root
331 Password required for root.
Password:
530 Login incorrect.
Login failed.
ftp>
```

When users in this list, root for example, attempt to access the remote system using FTP, they are denied access because their account is listed in the `/etc/ftpusers` file. This is illustrated in Exhibit 64.1.

By adding additional users to this list, one can control who has FTP access to this server. This does, however, create an additional step in the creation of a user account, but it is a related process and could be added as a step in the script used to create a user. Should a user with FTP privileges no longer require this access, the user's name can be added to the `/etc/ftpusers` list at any time. Similarly, if a denied user requires this access in the future, that user can be removed from the list and FTP access restored.

Recall the requirements of Scenario B: the user has a log-in on the system to access his application but does not have FTP privileges. This scenario has been addressed through the use of `/etc/ftpusers`. The user can still have UNIX shell access or access to a UNIX-based application through the normal UNIX log-in process. However, using `/etc/ftpusers` prevents access to the FTP server and eliminates the problem of unauthorized data movement to or from the FTP server. Most current FTP server implementations offer the `/etc/ftpusers` feature.

64.2 Extending Control

Scenarios A and C require additional configuration because reliance on the extended features of the wu-ftpd server is required. These control extensions are provided in the file `/etc/ftpaccess`. A sample `/etc/ftpaccess` file is shown in Exhibit 64.2. This is the default `/etc/ftpaccess` file distributed with wu-ftpd. Before one can proceed to the problem at hand, one must examine

EXHIBIT 64.2 Sample `/etc/ftpaccess` File

```
class all real,guest,anonymous *

```

the statements in the /etc/ftpaccess file. Additional explanation for other statements not found in this example, but required for the completion of our scenarios, are also presented later in the article.

The class statement in /etc/ftpaccess defines a class of users, in the sample file a user class named all, with members of the class being real, guest, and anonymous. The syntax for the class definition is:

```
class <class> <typelist> <addrglob> [<addrglob>...]
```

Typelist is one of real, guest, or anonymous. The real keyword matches users to their real user accounts. Anonymous matches users who are using anonymous FTP access, while guest matches guest account access. Each of these classes can be further defined using other options in this file. Finally, the class statement can also identify the list of allowable addresses, hosts, or domains that connections will be accepted from. There can be multiple class statements in the file; the first one matching the connection will be used.

Defining the hosts requires additional explanation. The host definition is a domain name, a numeric address, or the name of a file, beginning with a slash ('/') that specifies additional address definitions. Additionally, the address specification may also contain IP address:netmask or IP address/CIDR definition. (CIDR, or Classless Internet Domain Routing, uses a value after the IP address to indicate the number of bits used for the network. A Class C address would be written as 192.168.0/24, indicating 24 bits are used for the network.)

It is also possible to exclude users from a particular class using a '!' to negate the test. Care should be taken in using this feature. The results of each of the class statements are OR'd together with the others, so it is possible to exclude an allowed user in this manner. However, there are other mechanisms available to deny connections from specific hosts or domains. The primary purpose of the class statement is to assign connections from specific domains or types of users to a class. With this in mind, one can interpret the class statement in Exhibit 64.2, shown here as:

```
class all real,guest,anonymous *
```

This statement defines a class named all, which includes user types real, anonymous, and guest. Connections from any host are applicable to this class.

The email clause specifies the e-mail address of the FTP archive maintainer. It is printed at various times by the FTP server.

The message clause defines a file to be displayed when the user logs in or when they change to a directory. The statement

```
message /var/ftp/welcome.msg login
```

causes wu-ftpd to display the contents of the file /var/ftp/welcome.msg when a user logs in to the FTP server. It is important for this file be somewhere accessible to the FTP server so that anonymous users will also be greeted by the message.

NOTE: Some FTP clients have problems with multiline responses, which is how the file is displayed. When accessing the test FTP server constructed for this article, the message file contains:

```
***** WARNING *****
This is a private FTP server. If you do not have an account,
you are not welcome here.
*******************
It is currently %T local time in Ottawa, Canada.
You are %U@%R accessing %L.
for help, contact %E.
```

The `%<char>` strings are converted to the actual text when the message is displayed by the server. The result is:

```
331 Password required for chare.
Password:
230-***** WARNING *****
230-This is a private FTP server. If you do not have an account,
230-you are not welcome here.
230-*******************
230-It is currently Sun Jan 28 18:28:01 2001 local time in Ottawa, Canada.
230-You are chare@chris accessing poweredge.home.com.
230-for help, contact root@localhost.
230-
230-
230 User chare logged in.
ftp>
```

The `%<char>` tags available for inclusion in the message file are listed in Exhibit 64.3.

It is allowable to define a class and attach a specific message to that class of users. For example:

```
classrealreal*
classanonanonymous*
message/var/ftp/welcome.msg login real
```

EXHIBIT 64.3 `%char` Definitions

Tag	Description
%T	Local time (form Thu Nov 15 17:12:42 1990)
%F	Free space in partition of CWD (kbytes)
%C	Current working directory
%E	The maintainer's e-mail address as defined in ftpaccess
%R	Remote host name
%L	Local host name
%u	Username as determined via RFC931 authentication
%U	Username given at log-in time
%M	Maximum allowed number of users in this class
%N	Current number of users in this class
%B	Absolute limit on disk blocks allocated
%b	Preferred limit on disk blocks
%Q	Current block count
%I	Maximum number of allocated inodes (+1)
%i	Preferred inode limit
%q	Current number of allocated inodes
%H	Time limit for excessive disk use
%h	Time limit for excessive files
%xu	Uploaded bytes
%xd	Downloaded bytes
%xR	Upload/download ratio (1:n)
%xc	Credit bytes
%xT	Time limit (minutes)
%xE	Elapsed time since log-in (minutes)
%xL	Time left
%xU	Upload limit
%xD	Download limit

Now, the message is only displayed when a real user logs in. It is not displayed for either anonymous or guest users. Through this definition, one can provide additional information using other tags listed in Exhibit 64.3. The ability to display `class`-specific message files can be extended on a user-by-user basis by creating a class for each user. This is important because individual limits can be defined for each user.

The message command can also be used to display information when a user enters a directory. For example, using the statement

```
message/var/ftp/etc/.message CWD=*
```

causes the FTP server to display the specified file when the user enters the directory. This is illustrated in Exhibit 64.4 for the anonymous user. The message itself is displayed only once to prevent annoying the user.

The `noretrieve` directive establishes specific files no user is permitted to retrieve through the FTP server. If the path specification for the file begins with a '/', then only those files are marked as nonretrievable. If the file specification does not include the leading '/', then any file with that name cannot be retrieved.

For example, there is a great deal of sensitivity with the password file on most UNIX systems, particularly if that system does not make use of a shadow file. Aside from the password file, there is a long list of other files that should not be retrievable from the system, even if their use is discouraged. The files that should be marked for nonretrieval are files containing the names:

- `passwd`
- `shadow`
- `.profile`
- `.netrc`
- `.rhosts`
- `.cshrc`
- `profile`
- `core`
- `.htaccess`
- `/etc`
- `/bin`
- `/sbin`

This is not a complete list, as the applications running on the system will likely contain other files that should be specifically identified.

EXHIBIT 64.4 Directory-Specific Messages

```
User (192.168.0.2:(none)): anonymous
331 Guest login ok, send your complete e-mail address
  as password.
Password:
230 Guest login ok, access restrictions apply.
ftp> cd etc
250-***** WARNING *****
250-There is no data of any interest in the /etc directory.
250-
250 CWD command successful.
ftp>
```

Using the `noretrieve` directive follows the syntax:

```
noretrieve [absolute|relative] [class=<classname>] …
[-] <file- name> <filename> …
```

For example,

```
noretrieve passwd
```

prevents any user from downloading any file on the system named passwd.

When specifying files, it is also possible to name a directory. In this situation, all files in that directory are marked as nonretrievable. The option `absolute` or `relative` keywords identify if the file or directory is an absolute or relative path from the current environment. The default operation is to consider any file starting with a '/' as an absolute path. Using the optional `class` keyword on the `noretrieve` directive allows this restriction to apply to only certain users. If the `class` keyword is not used, the restriction is placed against all users on the FTP server.

64.2.1 Denying Connections

Connections can be denied based on the IP address or domain of the remote system. Connections can also be denied based on how the user enters his password at log-in.

NOTE: This password check applies only to anonymous FTP users. It has no effect on real users because they authenticate with their standard UNIX password.

The password-check directive informs the FTP server to conduct checks against the password entered. The syntax for the password-check directive is

```
passwd-check <none|trivial|rfc822> (<enforce|warn>)
```

It is not recommended to use `password-check` with the none argument because this disables analysis of the entered password and allows meaningless information to be entered. The `trivial` argument performs only checking to see if there is an '@' in the password. Using the argument is the recommended action and ensures the password is compliant with the RFC822 e-mail address standard.

If the password is not compliant with the `trivial` or `rfc822` options, the FTP server can take two actions. The `warn` argument instructs the server to warn the user that his password is not compliant but still allows access. If the `enforce` argument is used, the user is warned and the connection terminated if a noncomplaint password is entered.

Use of the `deny` clause is an effective method of preventing access from specific systems or domains. When a user attempts to connect from the specified system or domain, the message contained in the specified file is displayed. The syntax for the `deny` clause is:

```
deny <addrglob> <message_file>
```

The file location must begin with a slash ('/'). The same rules described in the class section apply to the `addrglob` definition for the `deny` command. In addition, the use of the keyword `!nameservd` is allowed to deny connections from sites without a working nameserver.

Consider adding a deny clause to this file; for example, adding `deny!nameservd /var/ftp/.deny to /etc/ftpaccess`. When testing the `deny` clause, the denied connection receives the message contained in the file. Using the `!nameservd` definition means that any host not found in a reverse DNS query to get a host name from an IP address is denied access.

```
Connected to 192.168.0.2.
220 poweredge.home.com FTP server (Version wu-2.6.1(1)
Wed Aug 9 05:54:50 EDT 2000) ready.
User (192.168.0.2:(none)): anonymous
331 Guest login ok, send your complete e-mail address as password.
Password:
```

```
530-**** ACCESS DENIED ****
530-
530-Access to this FTP server from your domain has been denied by the
   administrator.
530-
530 Login incorrect.
Login failed.
ftp>
```

The denial of the connection is based on where the connection is coming from, not the user who authenticated to the server.

64.2.2 Connection Management

With specific connections denied, this discussion must focus on how to control the connection when it is permitted. A number of options for the server allow this and establish restrictions from throughput to access to specific files or directories.

Preventing anonymous access to the FTP server is best accomplished by removing the ftp user from the /etc/passwd file. This instructs the FTP server to deny all anonymous connection requests.

The guestgroup and guestuser commands work in a similar fashion. In both cases, the session is set up exactly as with anonymous FTP. In other words, a chroot( ) is done and the user is no longer permitted to issue the USER and PASS commands. If using guestgroup, the groupname must be defined in the /etc/group file; or in the case of guestuser, a valid entry in /etc/passwd.

```
guestgroup <groupname> [<groupname> ...]
guestuser <username> [<username> ...]
realgroup <groupname> [<groupname> ...]
realuser <username> [<username> ...]
```

In both cases, the user's home directory must be correctly set up. This is accomplished by splitting the home directory entry into two components separated by the characters '/./'. The first component is the base directory for the FTP server and the second component is the directory the user is to be placed in. The user can enter the base FTP directory but cannot see any files above this in the file system because the FTP server establishes a restricted environment.

Consider the /etc/passwd entry:

```
systemx:<passwd>:503:503:FTP Only Access from
systemx:/var/ftp/./systemx:/etc/ftponly
```

When systemx successfully logs in, the FTP server will chroot("/var/ftp") and then chdir("/systemx"). The guest user will only be able to access the directory structure under /var/ftp (which will look and act as / to systemx), just as an anonymous FTP user would.

Either an actual name or numeric ID specifies the group name. To use a numeric group ID, place a '%' before the number. Ranges may be given and the use of an asterisk means all groups. guestuser works like guestgroup except uses the username (or numeric ID).

realuser and realgroup have the same syntax but reverse the effect of guestuser and guestgroup. They allow real user access when the remote user would otherwise be determined a guest. For example:

```
guestuser *
realuser chare
```

EXHIBIT 64.5 Timeout Directives

Timeout Value	Default	Recommended
Timeout accept <seconds>	120	120
Timeout connect <seconds>	120	120
Timeout data <seconds>	1200	1200
Timeout idle <seconds>	900	900
Timeout maxidle <seconds>	7200	1200
Timeout RFC931 <seconds>	10	10

causes all nonanonymous users to be treated as `guest`, with the sole exception of user chare, who is permitted real user access. Bear in mind, however, that the use of `/etc/ftpusers` overrides this directive. If the user is listed in `/etc/ftpusers`, he is denied access to the FTP server.

It is also advisable to set timeouts for the FTP server to control the connection and terminate it appropriately. The timeout directives are listed in Exhibit 64.5. The `accept` timeout establishes how long the FTP server will wait for an incoming connection. The default is 120 seconds. The `connect` value establishes how long the FTP server will wait to establish an outgoing connection. The FTP server generally makes several attempts and will give up after the defined period if a successful connection cannot be established.

The data timeout determines how long the FTP server will wait for some activity on the data connection. This should be kept relatively long because the remote client may have a low-speed link and there may be a lot of data queued for transmission. The idle timer establishes how long the server will wait for the next command from the client. This can be overridden with the `-a` option to the server. Using the `access` clause overrides both the command-line parameter if used and the default.

The user can also use the `SITE IDLE` command to establish a higher value for the idle timeout. The `maxidle` value establishes the maximum value that can be established by the FTP client. The default is 7200 seconds. Like the idle timeout, the default can be overridden using the `-A` command-line option to the FTP server. Defining this parameter overrides the default and the command line. The last timeout value allows the maximum time for the RFC931 `ident/AUTH` conversation to occur. The information recorded from the RFC931 conversation is recorded in the system logs and used for any authentication requests.

64.2.3 Controlling File Permissions

File permissions in the UNIX environment are generally the only method available to control who has access to a specific file and what they are permitted to do with that file. It may be a requirement of a specific implementation to restrict the file permissions on the system to match the requirements for a specific class of users.

The `defumask` directive allows the administrator to define the umask, or default permissions, on a per-class or systemwide basis. Using the `defumask` command as

```
defumask 077
```

causes the server to remove all permissions except for the owner of the file. If running a general access FTP server, the use of a 077 umask may be extreme. However, umask should be at least 022 to prevent modification of the files by other than the owner.

By specifying a class of user following the umask, as in

```
defumask 077 real
```

all permissions are removed. Using these parameters prevents world writable files from being transferred to your FTP server. If required, it is possible to set additional controls to allow or disallow the use of other commands on the FTP server to change file permissions or affect the files. By default, users are allowed to change file permissions and delete, rename, and overwrite files. They are also allowed to change the umask applied to files they upload. These commands allow or restrict users from performing these activities.

```
chmod <yes|no> <typelist>
delete <yes|no> <typelist>
overwrite <yes|no> <typelist>
rename <yes|no> <typelist>
umask <yes|no> <typelist>
```

To restrict all users from using these commands, apply the directives as:

```
chmod no all
delete no all
overwrite no all
rename no all
umask no all
```

Setting these directives means no one can execute commands on the FTP server that require these privileges. This means the FTP server and the files therein are under the full control of the administrator.

64.3 Additional Security Features

There are a wealth of additional security features that should be considered when configuring the server. These control how much information users are shown when they log in about the server, and print banner messages among other capabilities.

The `greeting` directive informs the FTP server to change the level of information printed when the user logs in. The default is `full`, which prints all information about the server. A `full` message is:

```
220 poweredge.home.com FTP server (Version wu-2.6.1(1)
Wed Aug 9 05:54:50 EDT 2000) ready.
```

A `brief` message on connection prints the server name as:

```
220 poweredge.home.com FTP server ready.
```

Finally, the `terse` message, which is the preferred choice, prints only:

```
220 FTP server ready.
```

The full greeting is the default unless the greeting directive is defined. This provides the most information about the FTP server. The terse greeting is the preferred choice because it provides no information about the server to allow an attacker to use that information for identifying potential attacks against the server.

The greeting is controlled with the directive:

```
greeting <full|brief|terse>
```

An additional safeguard is the banner directive using the format:

```
banner <path>
```

This causes the text contained in the named file to be presented when the users connect to the server prior to entering their username and password. The path of the file is relative from the real root directory, not from the anonymous FTP directory. If one has a corporate log-in banner that is displayed when connecting to a system using Telnet, it would also be available to use here to indicate that the FTP server is for authorized users only.

NOTE: Use of this command can completely prevent noncompliant FTP clients from establishing a connection. This is because not all clients can correctly handle multiline responses, which is how the banner is displayed.

```
Connected to 192.168.0.2.
220-
220-*  *
220-*      * W A R N I N G **
220-*  *
220-*ACCESS TO THIS FTP SERVER IS FOR AUTHORIZED USERS ONLY.*
220-*ALL ACCESS IS LOGGED AND MONITORED. IF YOU ARE NOT AN*

220-*  *
220-
220-
220 FTP server ready.
User (192.168.0.2:(none)):
```

At this point, one has controlled how the remote user gains access to the FTP server, and restricted the commands they can execute and the permissions assigned to their files. Additionally, certain steps have been taken to ensure they are aware that access to this FTP server is for authorized use only. However, one must also take steps to record the connections and transfers made by users to fully establish what is being done on the FTP server.

64.4 Logging Capabilities

Recording information in the system logs is a requirement for proper monitoring of transfers and activities conducted on the FTP server. There are a number of commands that affect logging, and each is presented in this section. Normally, only connections to the FTP server are logged. However, using the `log commands` directive, each command executed by the user can be captured. This may create a high level of output on a busy FTP server and may not be required. However, it may be advisable to capture traffic for anonymous and guest users specifically. The directive syntax is:

```
log commands <typelist>
```

As with other directives, it is known that `typelist` is a combination of `real`, `anonymous`, and `guest`. If the `real` keyword is used, logging is done for users accessing FTP using their real accounts. `Anonymous` logs all commands performed by anonymous users, while `guest` matches users identified using the `guestgroup` or `guestuser` directives.

Consider the line

```
log commands guest, anonymous
```

which results in all commands performed by anonymous and guest users being logged. This can be useful for later analysis to see if automated jobs are being properly performed and what files are uploaded or downloaded.

Like the `log commands` directive, `log transfers` performs a similar function, except that it records all file transfers for a given class of users. The directive is stated as:

```
log transfers <typelist> <directions>
```

The `directions` argument is `inbound` or `outbound`. Both arguments can be used to specify logging of transfers in both directions. For clarity, `inbound` are files transferred to the server, or uploads, and `outbound` are transfers from the server, or downloads. The `typelist` argument again consists of `real`, `anonymous`, and `guest`.

It is not only essential to log all of the authorized functions, but also to record the various command and requests made by the user that are denied due to security requirements. For example, if there are restrictions placed on retrieving the password file, it is desirable to record the security events. This is accomplished for real, anonymous, and guest users using the log security directive, as in:

```
log security <typelist>
```

If rename is a restricted command on the FTP server, the log security directive results in the following entries

```
Feb 11 20:44:02 poweredge ftpd[23516]: RNFR dayo.wav
Feb 11 20:44:02 poweredge ftpd[23516]: RNTO day-o.wav
Feb 11 20:44:02 poweredge ftpd[23516]: systemx of localhost.home.com
    [127.0.0.1]
tried to rename /var/ftp/systemx/dayo.wav to /var/ftp/systemx/
    day-o.wav
```

This identifies the user who tried to rename the file, the host that the user connected from, and the original and desired filenames. With this information, the system administrator or systems security personnel can investigate the situation.

Downloading information from the FTP server is controlled with the noretrieve clause in the /etc/ftpaccess file. It is also possible to limit uploads to specific directories. This may not be required, depending on the system configuration. A separate entry for each directory one wishes to allow uploads to is highly recommended. The syntax is:

```
upload [absolute|relative] [class=<classname>]... [-] <root-dir>
<dirglob> <yes|no> <owner> <group> <mode> ["dirs"|"nodirs"]
    [<d_mode>]
```

This looks overly complicated, but it is in fact relatively simple. Define a directory called <dirglob> that permits or denies uploads. Consider the following entry:

```
upload /var/ftp /incoming yes ftpadmin ftpadmin 0440 nodirs
```

This means that for a user with the home directory of /var/ftp, allow uploads to the incoming directory. Change the owner and group to be ftpadmin and change the permissions to readonly. Finally, do not allow the creation of directories. In this manner, users can be restricted to the directories to which they can upload files. Directory creation is allowed by default, so one must disable it if required.

For example, if one has a user on the system with the following password file entry:

```
chare:x:500:500:Chris Hare:/home/chare:/bin/bash
```

and one wants to prevent the person with this userid from being able to upload files to his home directory, simply add the line:

```
upload /home/chare no
```

to the /etc/ftpaccess file. This prevents the user chare from being able to upload files to his home directory. However, bear in mind that this has little effect if this is a real user, because real users will be able to upload files to any directory they have write permission to. The upload clause is best used with anonymous and guest users.

NOTE: The wu-ftpd server denies anonymous uploads by default.

To see the full effect of the upload clause, one must combine its use with a guest account, as illustrated with the systemx account shown here:

```
systemx:x:503:503:FTP access from System X:/home/
systemx/./:/bin/false
```

Note in this password file entry the home directory path. This entry cannot be made when the user account is created. The '/./' is used by wu-ftpd to establish the chroot environment. In this case, the user is placed into his home directory, /home/systemx, which is then used as the base for his chroot file system. At this point, the guest user can see nothing on the system other than what is in his home directory.

Using the upload clause of

```
upload /home/chare yes
```

means the user can upload files to this home directory. When coupled with the noretrieve clause discussed earlier, it is possible to put a high degree of control around the user.

64.5 The Complete /etc/ftpaccess File

The discussion thus far has focused on a number of control directives available in the wu-ftpd FTP server. It is not necessary that these directives appear in any particular order. However, to further demonstrate the directives and relationships between those directives, the /etc/ftpaccess file is illustrated in Exhibit 64.6.

EXHIBIT 64.6 The /etc/ftpaccess File

64.6 Revisiting the Scenarios

Recall the scenarios from the beginning of this article. This section reviews each scenario and defines an example configuration to achieve it.

Scenario A

A user named Bob accesses a UNIX system through an application that is a replacement for his normal UNIX log-in shell. Bob has no need for, and does not have, direct UNIX command-line access. While using the application, Bob creates reports or other output that he must retrieve for analysis. The application saves this data in either Bob's home directory or a common directory for all application users.

Bob may or may not require the ability to put files onto the application server. The requirements break down as follows:

- Bob requires FTP access to the target server.
- Bob requires access to a restricted number of directories, possibly one or two.
- Bob may or may not require the ability to upload files to the server.

Bob requires the ability to log into the FTP and access several directories to retrieve files. The easiest way to do this is to deny retrieval for the entire system by adding a line to `/etc/ftpaccess` as

```
noretrieve /
```

This marks every file and directory as nonretrievable. To allow Bob to get the files he needs, one must set those files or directories as such. This is done using the `allow-retrieve` directive. It has exactly the same syntax as the `noretrieve` directive, except that the file or directory is now retrievable. Assume that Bob needs to retrieve files from the `/tmp` directory. Allow this using the directive

```
allow-retrieve /tmp
```

When Bob connects to the FTP server and authenticates himself, he cannot get files from his home directory.

```
ftp>pwd
257 "/home/bob" is current directory.
ftp>get.xauth xauth
200 PORT command successful.
/home/chare/.xauth is marked unretrievable
```

However, Bob can retrieve files from the `/tmp` directory.

```
ftp> cd /tmp
250 CWD command successful.
ftp> pwd
257 "/tmp" is current directory.
ftp> get.X0-lock X0lock
200 PORT command successful.
150 Opening ASCII mode data connection for.X0-lock (11 bytes).
226 Transfer complete.
ftp: 12 bytes received in 0.00Seconds 12000.00Kbytes/sec.
ftp>
```

If Bob must be able to retrieve files from his home directory, an additional `allow-retrieve` directive is required:

```
class real real *
allow-retrieve /home/bob class=real
```

When Bob tries to retrieve a file from anywhere other than `/tmp` or his home directory, access is denied.

Additionally, it may be necessary to limit Bob's ability to upload files. If a user requires the ability to upload files, no additional configuration is required, as the default action for the FTP server is to allow uploads for real users. If one wants to prohibit uploads to Bob's home directory, use the upload directive:

```
upload /home/bob / no
```

This command allows uploads to the FTP server.

The objective of Scenario A has been achieved.

Scenario B

Other application users in the environment illustrated in Scenario A require no FTP access whatsoever. Therefore, it is necessary to prevent them from connecting to the application server using FTP.

This is done by adding those users to the `/etc/ftpaccess` file. Recall that this file lists a single user per line, which is checked. Additionally, it may be advisable to deny anonymous FTP access.

Scenario C

The same application used by the users in Scenarios A and B regularly dumps data to move to another system. The use of hard-coded passwords in scripts is not advisable because the scripts must be readable for them to be executed properly. This may expose the passwords to unauthorized users and allow them to access the target system. Additionally, the use of hard-coded passwords makes it difficult to change the password on a regular basis because all scripts using this password must be changed.

A further requirement is to protect the data once stored on the remote system to limit the possibility of unauthorized access, retrieval, and modification of the data.

Accomplishing this requires the creation of a guest user account on the system. This account will not support a log-in and will be restricted in its FTP abilities. For example, create a UNIX account on the FTP server using the source hostname, such as systemx. The password is established as a complex string but with the other compensating controls, the protection on the password itself does not need to be as stringent. Recall from an earlier discussion that the account resembles

```
systemx:x:503:503:FTP access from System X:/home/
systemx/./:/bin/false
```

Also recall that the home directory establishes the real user home directory, and the ftp chroot directory. Using the upload command

```
upload /home/systemx / no
```

means that the systemx user cannot upload files to the home directory. However, this is not the desired function in this case. In this scenario, one wants to allow the remote system to transfer files to the FTP server. However, one does not want to allow for downloads from the FTP server. To do this, the command

```
noretrieve /
upload /home/systemx / yes
```

prevents downloads and allows uploads to the FTP server.

One can further restrict access by controlling the ability to rename, overwite, change permissions, and delete a file using the appropriate directives in the `/etc/ftpaccess` file:

```
chmodnoguest, anonymous
deletenoguest, anonymous
overwritenoguest, anonymous
renamenoguest, anonymous
```

Because the user account has no interactive privileges on the system and has restricted privileges on the FTP server, there is little risk involved with using a hard-coded password. While using a hard-coded password is not considered advisable, there are sufficient controls in place to compensate for this. Consider the following controls protecting the access:

The user cannot retrieve files from the system.
The user can upload files.
The user cannot see what files are on the system and thus cannot determine the names of the files to block the system from putting the correct data on the server.
The user cannot change file permissions.
The user cannot delete files.
The user cannot overwrite existing files.
The user cannot rename files.
The user cannot establish an interactive session.
FTP access is logged.

With these compensating controls to address the final possibility of access to the system and the data using a password attack or by guessing the password, it will be sufficiently difficult to compromise the integrity of the data.

The requirements defined in the scenario have been fulfilled.

64.7 Summary

This discussion has shown how one can control access to an FTP server and allow controlled access for downloads or uploads to permit the safe exchange of information for interactive and automated FTP sessions. The extended functionality offered by the wu-ftpd FTP server provides extensive access, and preventative and detective controls to limit who can access the FTP server, what they can do when they can connect, and the recording of their actions.

65

End Node Security and Network Access Management: Deciding Among Different Strategies

Franjo Majstor

65.1 Introduction

65.1.1 Acronym Jungle

As in almost any industry, the networking industry contains far too many technical acronyms. Security terminology is unfortunately not immune. Combining of security terms with networking terms has resulted in a baffling array of acronyms that will most probably not decrease in the near future. Therefore, an apology is given in advance to beginner readers with a recommendation to, when confronted with an unfamiliar acronym, refer to the end of the article where all acronyms are defined.

65.1.2 Problem Definition

Acronyms are not the only problem. Currently, modern networks are responsible for employee productivity, product manufacturing, and receiving orders from customers and, as such, are business-critical systems. If these systems are not available or are under attack, the result is a denial of service, theft of sensitive information, or exposure to regulatory penalties. Traditional perimeter-focused security architectures are today powerless against the infected endpoints that connect to enterprise networks from various locations. Information security practitioners are dealing almost on a daily basis with situations such as the following: Sales persons, when traveling, frequently connect to an insecure hotel network or other public Internet service where their laptops could be exposed to a malware infection. Enterprise information technology departments have defined policies and equipped the salesperson's laptop with protections such as the latest anti-virus software, personal firewalls, host intrusion prevention, operating system configurations, and patches to protect the system against compromise. Unfortunately, those protections can be turned off, uninstalled, or may simply have never been updated, leaving the salesperson's computer unprotected. Company guests and visitors would often use offered hospitality to connect via an internal enterprise wired or wireless network to the Internet. Their portable equipment could, if they are not up-to-date with the latest viral protection, already be compromised and, as such, could cause a compromise to the rest of the network resources they are connecting through.

These are just two examples out of many. The latest vulnerability statistics of the most popular computing equipment software platforms show us that, most of the time, an unintentional user or guest visitor caused an avalanche of problems to the rest of the network resources that are crucial for running the business.

Several initiatives from industry vendors have already addressed some problems of the individual endpoint security with applications like anti-virus agents and personal firewalls. Connectivity of the end node to the network infrastructure has already received the end node authentication via 802.1x protocol. However, all of those mechanisms individually have thus far proven to not be sufficient to stop problems of network resources under a threat. Hence, efforts from the leading market vendors as well as standardization organizations have resulted in several individual solutions to address the burning issue of both integrity and policy compliancy of the end node towards accepted rules of behavior from the network infrastructure. Information security practitioners exposed to an end node to an infrastructure interaction problem should be able to understand the essence of the issue and be capable of finding a proper end-node-to-infrastructure-interactivity security mechanism that would fit their business environment.

65.2 End Node Security Solutions

65.2.1 Evolution

Initiatives to the problem of the end node causing availability, integrity, and confidentiality problems to the rest of the network were started by several combined vendor solutions. Networking vendor Cisco Systems, as well as operating system vendor Microsoft, developed unique proposals. Several other end node anti-viral software vendors joined the initiatives of both, while some others created their own solutions. Overall, it has created the panache of closed efforts locking the choice around a particular vendor's solution. To move out of the closed-group proposals, the Trusted Computing Group (TCG) organization of vendors released the Trusted Network Connect (TNC) specification that describes the problem and provides the framework for a vendor-interoperable solution. Even though it was later developed as an umbrella solution, it explains the detailed individual components of the system with their roles and functions. It is therefore the best starting point in explaining the concept of the future end-node security solutions.

65.2.2 Trusted Network Connect Specification

The TNC architecture and specifications were developed with the purpose of ensuring interoperability among the individual components for solutions provided by different vendors. The aim of the TNC architecture is to provide a framework within which consistent and useful specifications can be developed to achieve a multivendor network standard that provides the following four features:

1. Platform authentication: the verification of a network access requestor's proof of identity of their platform and the integrity-status of that platform.
2. Endpoint policy compliance (authorization): establishing a level of "trust" in the state of an endpoint, such as ensuring the presence, status, and upgrade level of mandated applications, revisions of signature libraries for anti-virus and intrusion detection and prevention system applications, and the patch level of the endpoint's operating system and applications. Note that policy compliance can also be viewed as authorization, in which an endpoint compliance to a given policy set results in the endpoint being authorized to gain access to the network.
3. Access policy: ensuring that the endpoint machine and/or its user authenticates and establishes their level of trust before connecting to the network by leveraging a number of existing and emerging standards, products, or techniques.
4. Assessment, isolation, and remediation: ensuring that endpoint machines not meeting the security policy requirements for "trust" can be isolated or quarantined from the rest of the network and, if possible, an appropriate remedy applied, such as upgrading software or virus signature databases to enable the endpoint to comply with security policy and become eligible for connection to the rest of the network.

The basic TNC architecture is illustrated in Exhibit 65.1.

The entities within the architecture are: access requestor (AR), policy enforcement point (PEP), and policy decision point (PDP):

1. Access requestor (AR): the AR is the entity seeking access to a protected network.
2. Policy decision point (PDP): the PDP is the entity performing the decision making regarding the AR's request, in light of the access policies.
3. Policy enforcement point (PEP): the PEP is the entity that enforces the decisions of the PDP regarding network access.

All entities and components in the architecture are logical ones, not physical ones. An entity or component may be a single software program, a hardware machine, or a redundant and replicated set of machines spread across a network, as appropriate for its function and for the deployment's needs. Entities of the TNC architecture are structured in layers. Layered TNC architecture levels (illustrated in Exhibit 65.2) consist of the following:

1. The network access layer: components whose main function pertains to traditional network connectivity and security. Even though the name might imply so, this layer does not refer to the OSI network layer only, but may support a variety of modern networking access technologies such as switch ports or wireless, as well as VPN access or firewall access.
2. The integrity evaluation layer: the components in this layer are responsible for evaluating the overall integrity of the AR with respect to certain access policies.
3. The integrity measurement layer: this layer contains plug-in components that collect and verify integrity-related information for a variety of security applications on the AR.

EXHIBIT 65.2 Layered trusted network connect architecture.

The AR consists of the following components:

1. Integrity measurement collector (IMC): the IMC is a component of an AR that measures security aspects of the AR's integrity. Examples include the anti-virus parameters on the access requestor, personal firewall status, software versions, and others. The TNC Architecture accommodates implementation situations where multiple IMCs reside on a single AR, catering for corresponding different applications.
2. TNC client (TNCC): the TNCC is a component of an AR that aggregates integrity measurements from multiple IMCs and assists with the management of the integrity check handshake for the purpose of measurement and reporting of the AR integrity.
3. Network access requestor (NAR): the NAR is the component responsible for establishing network access. The NAR can be implemented as a software component that runs on an AR, negotiating its connection to a network. There may be several NARs on a single AR to handle connections to different types of networks. One example of a NAR is the supplicant in 802.1x, which is often implemented as software on a client system, or could also be VPN client software.

The policy decision point (PDP) consists of the following components:

1. Integrity measurement verifier (IMV): the IMV is a component that verifies a particular aspect of the AR's integrity, based on measurements received from IMCs and/or other data.
2. TNC server (TNCS): the TNCS is a component that manages the flow of messages between.
3. IMVs and IMCs: gathers IMV action recommendations from IMVs, and combines those recommendations (based on policy) into an overall TNCS action recommendation to the NAA.
4. Network access authority (NAA): the NAA is a component that decides whether an AR should be granted access. The NAA may consult a TNC server to determine whether the AR's integrity measurements comply with the NAA's security policy. In many cases, an NAA will be an AAA server such as a RADIUS server, but this is not required.

A third entity of the TNC architecture that sits in the middle of the AR and a PDP is the policy enforcement point (PEP) that consists of the following components:

- Policy enforcement point (PEP): The PEP is a typically the hardware component that controls access to a protected network. The PEP consults a PDP to determine whether this access should be granted. An example of the PEP is the authenticator in 802.1x, which is often implemented within the 802.11 wireless access point. It could also be an 802.1x-enabled switch port or a firewall as well as the VPN gateway.

Although not visibly evident within the TNC architecture, one important feature of the architecture is its extensibility and support for the isolation and remediation of ARs, which do not succeed in obtaining network access permission due to failures in integrity verification. The TNC architecture with provisioning and remediation layer is illustrated in Exhibit 65.3 and shows an additional layer addressing remediation and provisioning.

To understand the actions needed to remedy ARs that fail integrity verification, it is useful to view network connection requests in three basic phases from the perspective of integrity verification:

1. Assessment: in this phase, the IMVs perform the verification of the AR following the policies set by the network administrator and optionally deliver remediation instructions to the IMCs.
2. Isolation: if the AR has been authenticated and is recognized to be one that has some privileges on the network but has not passed the integrity verification by the IMV, the PDP may return instructions to the PEP to redirect the AR to an isolation environment where the AR can obtain integrity-related updates. Isolation environment mechanisms could be:
   a. VLAN containment: VLAN containment permits the AR to access the network in a limited fashion, typically for the purpose of the limited access and to allow the AR to access online sources of remediation data (e.g., virus definition file updates, worm removal software, software patches, etc.)
   b. IP filters: In the case of IP filters, the PEP is configured with a set of filters which define network locations reachable by the isolated AR. Packets from the AR destined to other network locations are simply discarded by the PEP.

EXHIBIT 65.3 TNC architecture with provisioning and remediation layer.

3. Remediation: Remediation is the process of the AR obtaining corrections to its current platform configuration and other policy-specific parameters to bring it inline with the PDP's requirements for network-access.

The remediation process requires remediation provisioning application and resources that can be implemented in several forms. An example would be the anti-virus application software that communicates with sources of anti-virus parameters (e.g., latest AV signature files) or could be an agent that updates the latest patches from the ftp server that contains the latest patches. Note that remediation is beyond the scope of the current TNC architecture document; it is treated briefly only for completeness.

Although integrity measurement and reporting is core to the value proposition of the TNC philosophy and approach, the TNC architecture acknowledges other networking technologies as providing the infrastructure support surrounding the core elements of the TNC architecture. Note that the TNC specification is not standardizing specific protocol bindings for these technologies; it is rather defining only layer interfaces (as seen on the TNC architecture figure with an appendix IF-…) and is relying on already existing protocols, such as 802.1x, IPsec/IKE, PEAP, TLS for network access or RADIUS and DIAMETER for communication with and within PDP.

Although at this writing there is no commercially available nor widely deployed solution implementation based on TNC specification, TNC detailed architecture components description represent an open framework for vendor-neutral solutions where multiple vendors could provide individual modules of the complete end-node security solution. Several individual vendor or vendor alliances that have inspired the TNC specification work are described later.

65.3 Network Admission Control

65.3.1 Network Admission Control Overview

Network admission control (NAC) architecture is an industry effort, led by Cisco Systems that initially started as an interoperable framework between a networking vendor and several anti-virus vendors with a goal to isolate the most urgent problem at the time: virus and worm infections from infected hosts at network connection points. NAC architecture achieves that by checking the end-node security compliancy before admitting it to connect to the network.

Security-policy compliance checks that NAC can perform include:

- Determining whether the device is running an authorized version of an operating system
- Checking to see if the OS has been properly patched, or has received the latest hotfix
- Determining if the device has anti-virus software installed, and whether it has the latest set of signature files
- Ensuring that anti-virus technology is enabled and has been recently run
- Determining if personal firewall, intrusion prevention, or other desktop security software is installed and properly configured
- Checking whether a corporate image of a device has been modified or tampered with

The NAC architecture components (illustrated in Exhibit 65.4) are:

- Endpoint security software: NAC solution requires either a Cisco Trust Agent or a third party software agent that is capable of executing the integrity checks on the end node and communicating that during the network access request phase.
- Network access device: A network access device like a router, switch, VPN gateway, or firewall that can demand endpoint security "credentials" from the endpoint. This is in TNC terminology an analogy of a policy enforcement point.

Security policy creation
Endpoint policy evaluation

EXHIBIT 65.4 Network admission control architecture components.

- Policy/AAA server: This is a RADIUS server that evaluates endpoint security credentials relayed from the network access device and determines the appropriate access policy (permit, deny, quarantine, restrict) to be applied back to the network access device for the particular end node accessing the network.
- Anti-virus policy server: This is a third-party server that evaluates particular policy like anti-virus policy. As the NAC solution includes multiple vendors, third-party policy servers could be used to check the integrity of any application running on the end node system as well as hardware components compliancy. However, they need to interface with the policy/AAA server that is under control of Cisco Systems. Even though there is a plan to open and standardize it, this has not yet happened.

65.3.2 NAC Analysis

Even though the Endpoint Security Software of a NAC architecture uses standard communication protocols between the agent components and even though the interface software is provided free of charge by Cisco Systems, the exchange of “security credentials,” as Cisco Systems refers to an end-node integrity state check, is still not standardized. Standards-based technologies that are used are EAP, 802.1x, and RADIUS. In some cases, these technologies may need to accommodate specific enhancements to support the NAC solution. Cisco Systems expects to drive adoption of these enhancements through appropriate standards bodies.

The Cisco trust agent (Endpoint Security Software) available from Cisco Systems collects security state information from the operating system and multiple security software clients, such as anti-virus and Cisco security agent software clients, and communicates this information to the connected network, where access control decisions are enforced. The Cisco trust agent that has the closest equivalent role of the TNCC in the TNC architecture has in the NAC architecture the following three main responsibilities:

- Network communications: respond to network requests for application and operating system information such as anti-virus and operating system patch details
- Security model: authenticates the application or device requesting the host credentials and encrypts that information when it is communicated
- Application broker: through an API, the application broker enables numerous applications to respond to state and credential requests

The end-node protocol stack that is illustrated in Exhibit 65.5 shows several layers of end-node agent security software. Cisco Systems decided to implement EAP over the UDP protocol exchange first. EAP over UDP made the NAC solution immediately available to work on the layer 3. That helped nodes with

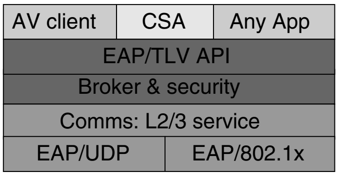

EXHIBIT 65.5 NAC end-node protocol stack.

an IP address that attempt to connect to the rest of the layer-3 network infrastructure to exchange EAP messages with the infrastructure and, based on the overall exchange, obtain access to the network resources. In essence, a router from Cisco Systems, as the very first implementation phase of NAC architecture solution, understands EAP over UDP control messages and performs EAP message exchanges with an Endpoint Security Software and policy server. Follow-up phases brought the EAP over layer 2 that allowed NAC communication to network devices, such as switches or wireless access points, where authentication and policy compliancy message exchanges could happen even before the IP address is obtained. NAC communication flow is illustrated in Exhibit 65.6.

Policy enforcement actions are directly dependent on the communication method between the end-node software agent and the network node and were initially only permit, deny, or quarantine access via a simple layer-3 router access control list filter, while follow-up phases also introduced VLAN isolation.

Both layer-2 and layer-3 end nodes that demand network access, as well as network access devices themselves in the NAC solution, would need to be up to date with a compatible software release to be a valid member of the NAC solution. In the mean time, Cisco Systems also introduced the NAC appliances family of products, but its significance stays as one of the first integrity network access control implementers on the market. The NAC architecture brought an innovative breakthrough in the capability with which network access devices could police the state of the end node and make an intelligent decision before connecting it to the rest of the network. Consequently, Cisco Systems leveraged it as a crucial part of its self-defending network strategy.

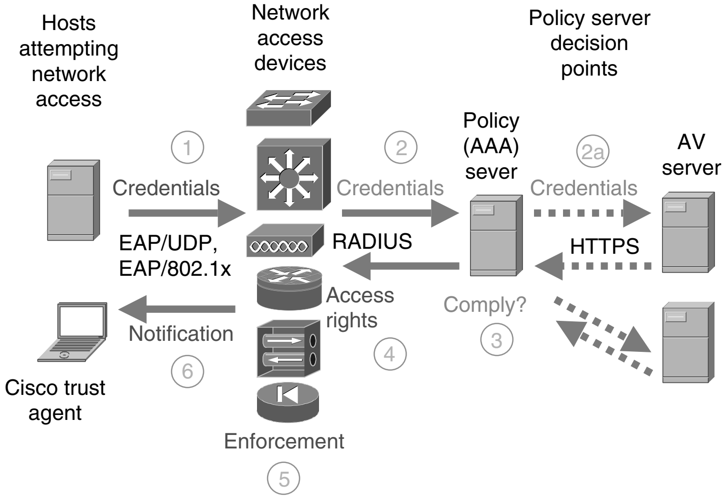

EXHIBIT 65.6 NAC access control flow.

65.4 Network Access Protection

65.4.1 Network Access Protection Overview

The network-access protection (NAP) solution in Microsoft's next-generation Windows server with code name "Longhorn" provides policy enforcement components that help ensure that computers connecting to a network or communicating on a network meet administrator-defined requirements for system health. NAP uses a combination of policy validation and network isolation components to control network access or communication. It can also temporarily isolate computers that do not meet requirements to a restricted network. Depending on the configuration chosen, the restricted network might contain resources required to update the computers so that they then meet the health requirements for full network access or normal communication. When it will be available for deployment, NAP will be able to create solutions for health policy validation, isolation, and ongoing health policy compliance.

NAP is currently defined with a core component of future Windows server and clients, a quarantine server that will be Microsoft Internet Authentication Services (IAS), and one or more policy servers. NAP will work by controlling network access via multiple connectivity mechanisms, as illustrated in Exhibit 65.7.

In the initial release, NAP will require servers to run Windows Server "Longhorn" and clients to run Windows Vista, Windows Server "Longhorn," or Windows XP with Service Pack 2. Network isolation components in the NAP architecture will be provided for the following network technologies and connectivity methods:

- Dynamic host configuration protocol (DHCP)
- Virtual private networks (VPNs)
- 802.1x authenticated network connections
- Internet protocol security (IPsec) with x.509 certificates

DHCP quarantine consists of a DHCP quarantine enforcement server (QES) component and a DHCP quarantine enforcement client (QEC) component. Using DHCP quarantine, DHCP servers can enforce

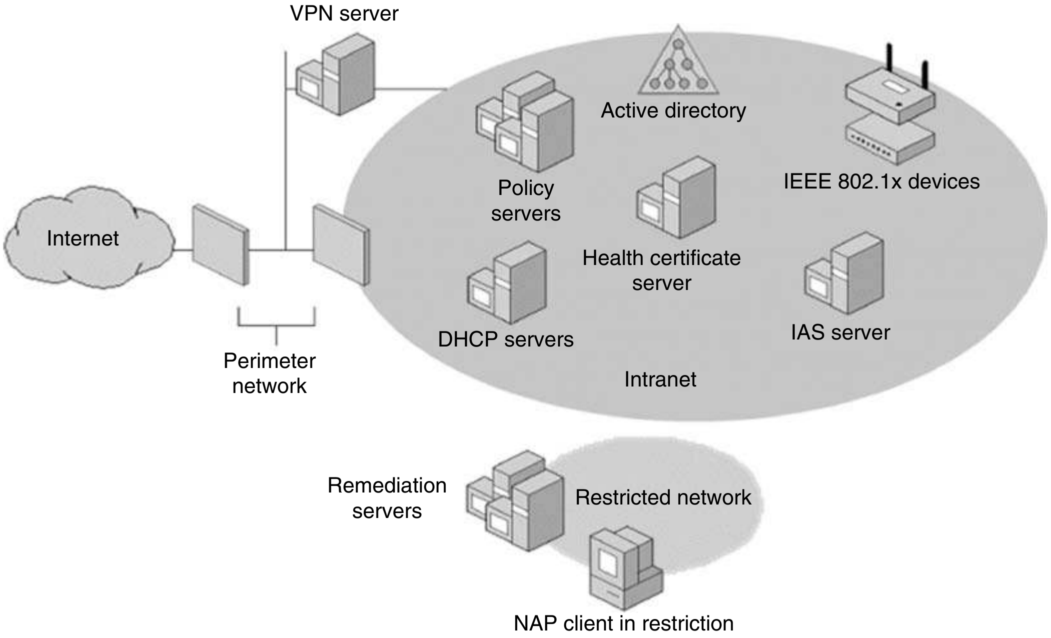

EXHIBIT 65.7 Network access protection architecture.

health policy requirements any time a computer attempts to lease or renew an IP version 4 (IPv4) address configuration on the network. DHCP quarantine is the easiest enforcement to deploy because all DHCP client computers must lease IP addresses. However, DHCP quarantine provides only weak network isolation.

VPN quarantine consists of a VPN QES component and a VPN QEC component. Using VPN quarantine, VPN servers with the VPN QEC component could enforce health policy requirements any time a computer attempts to make a layer-2 tunneling protocol (L2TP) VPN connection to the network. VPN quarantine provides strong network isolation for all computers accessing the network through an L2TP VPN connection.

802.1x quarantine consists of an IAS server and an EAP host QEC component. Using 802.1x quarantine, an IAS server instructs an 802.1x access point (an ethernet switch or a wireless access point) to place a restricted access profile on the 802.1x client until it performs a set of remediation functions. A restricted access profile can consist of a set of IP packet filters or a virtual LAN identifier to confine the traffic of an 802.1x client. 802.1x quarantine provides strong network isolation for all computers accessing the network through an 802.1x connection.

IPsec quarantine comprises a health certificate server (HCS) and an IPsec QEC. The HCS issues x.509 certificates to quarantine clients when they are determined to be healthy. These certificates are then used to authenticate NAP clients when they initiate IPsec—secured communications with other NAP clients on an intranet. IPsec quarantine confines the communication on the network to those nodes that are considered healthy and because it is leveraging IPsec, it can define requirements for secure communications with healthy clients on a per-IP address or per-TCP/UDP port number basis. Unlike DHCP quarantine, VPN quarantine, and 802.1x quarantine, IPsec quarantine confines communication to healthy clients after the clients have successfully connected and obtained a valid IP address configuration. IPsec quarantine is the strongest form of isolation in NAP architecture.

NAP quarantine methods could be used separately or together to isolate unhealthy computers and Microsoft IAS will act as a health policy server for all of these technologies as illustrated in Exhibit 65.8.

There might be several system health agent (SHA) components that define a set of system health requirements such as SHA for anti-virus signatures, SHA for operating system updates, etc. A specific SHA might be matched to a remediation server. For example, an SHA for checking anti-virus signatures could be matched to the server that contains the latest anti-virus signature file. SHAs do not have to have a corresponding remediation server. For example, an SHA can just check local system settings to ensure that a host-based firewall is running or configured properly. To indicate the status of a specific element of system health, such as the state of the anti-virus software running on the computer or the last operating system update that was applied, SHAs create a statement of health (SoH) and pass their SoH to the quarantine agent (QA). Whenever an SHA updates its status, it creates a new SoH and passes it to the QA.

To draw a parallel with the TNC specification, QA can be seen as an equivalent role to TNC Client, whereas multiple SHAs are similar to IMVs and QECs playing the role of NARs, as will be described in more details.

65.4.1.1 Quarantine-Enforcement Clients

A quarantine-enforcement client (QEC) within a NAP client architecture is the one that requests, in some way, access to a network. During that phase, it will pass the end node's health status to a NAP server that is providing the network access, and indicate its status according to the information obtained from multiple SHAs, as illustrated in the NAP client architecture in Exhibit 65.9.

The QECs for the NAP platform supplied in Windows Vista and Windows Server "Longhorn" will be the following:

- A DHCP QEC for DHCP-based IPv4 address configuration
- A VPN QEC for L2TP VPN based connections
- An EAP host QEC for 802.1x authenticated connections
- An IPsec QEC for x.509 certificate-based IPsec-based communications

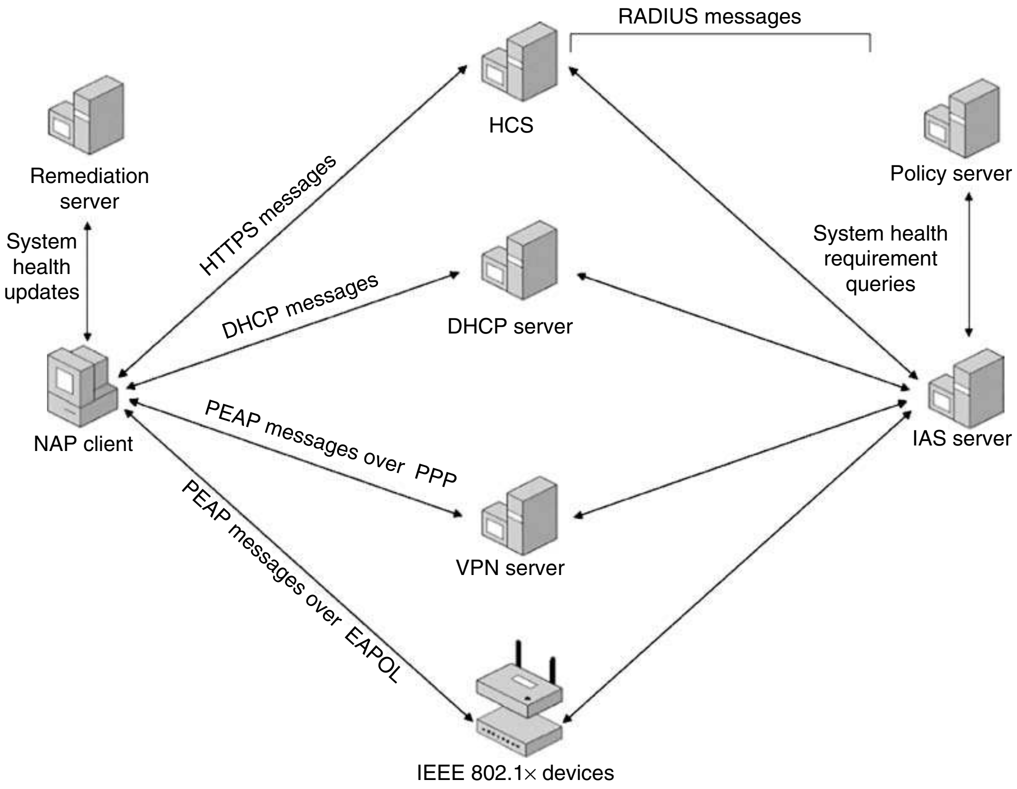

EXHIBIT 65.8 Interaction between network access protection components.

DHCP QEC is a functionality in the DHCP client service that uses industry-standard DHCP messages to exchange system health messages and restricted network access information. The DHCP QEC obtains the list of SoHs from the QA. The DHCP client service fragments the list of SoHs, if required, and puts each fragment into a Microsoft vendor-specific DHCP option that is sent in DHCPDiscover, DHCPRequest or DHCPInform messages. DHCPDecline and DHCPRelease messages do not contain the list of SoHs.

VPN QEC is a functionality in the Microsoft Remote Access Connection Manager service that obtains the list of SoHs from the QA and sends the list of SoHs as a PEAP-type-length-value (TLV) message. Alternately, the VPN QEC can send a health certificate as a PEAP-TLV message.

EAP host QEC is a component that obtains the list of SoHs from the QA and sends the list of SoHs as a PEAP–TLV message for 802.1x connections. Alternately, the EAP host QEC can send a health certificate in a PEAP–TLV message.

IPsec QEC is a component that obtains a health certificate from the HCS and interacts with the following:

- The certificate store to store the current health certificate
- The IPsec components of the TCP/IP protocol stack to ensure that IPsec-based communications use the current health certificate for IPsec authentication
- The host-based firewall (such as, Windows personal firewall) so that the IPsec—secured traffic is allowed by the firewall

65.4.1.2 Analysis of a NAP

Microsoft, with its proven track record of showing how complex things could be simplified to a level where they could be easily and widely deployed, certainly has a significant role in end-node integrity and

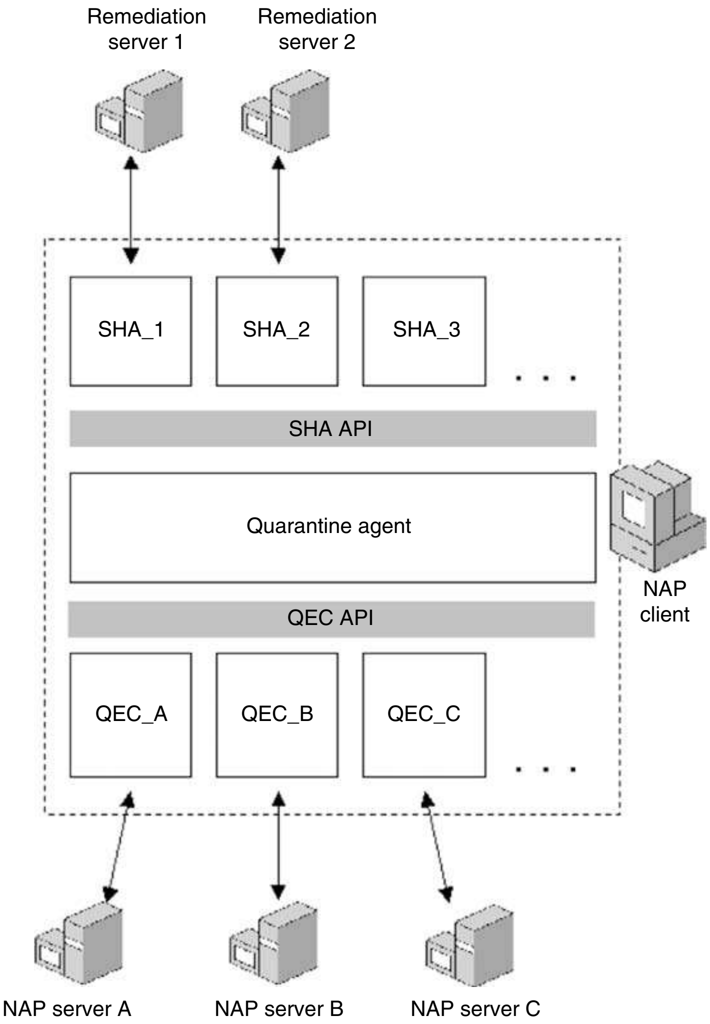

EXHIBIT 65.9 NAP client architecture.

policy-compliancy solution evolution. When it becomes available, NAP seems to be the lowest-cost solution that, for the client side, will require only Windows XP Service Pack 2. Considering the current Microsoft release policies, the server side of the NAP solution will most probably be offered as a free server component with next-generation server software. This means that the NAP solution could come after a regular Windows server update at no additional cost. It is also noteworthy that the NAP solution will not require any proprietary or new hardware because its strengths are all in software development and, in particular, in vendor-specific protocol extensions, such as with DHCP.

65.4.2 Sygate Network Access Control

65.4.2.1 Sygate Network Access Control Overview

Sygate is a vendor that developed its own end-node-to-network-infrastructure interactivity solution with the name *Sygate Network Access Control* (SNAC). In the mean time, Sygate has been acquired by Symantec, who initially kept the current Sygate solutions under the Sygate brand while expecting to re-brand the next version of the products and include additional functionality. However, this solution description will be narrowed only to an initial SNAC concept that allowed enforcement of end-node security in four ways:

1. Create SNAC policies: Using the Sygate Policy Manager for central managed and deployed network access control policies that include: templates for well-known anti-virus software, personal firewalls, anti-spyware, operating system configurations, and security patches.
2. Discover end-node integrity status: Sygate enforcers and agents discover new devices as they connect to the network and then perform baseline end-node integrity checks when they start up, at a configurable interval, and when they change network locations.
3. Enforce network access controls: At the time of network connection and for the duration of the network session, Sygate enforcers apply network access controls to endpoints attempting to connect to the enterprise network. If end nodes are in compliance with the policy, they are permitted on the network. If the end node is noncompliant, then it is either quarantined to a remediation network or blocked from network access.
4. Remediate noncompliant devices: When an end node fails one or more integrity checks, the agent will automatically perform a preconfigured operation to bring the end node into compliance without user intervention. Administrators can customize the user interaction that occurs during the remediation process and even give the user the option to delay noncritical remediation actions for a range of time. Once remediated, the agent will automatically start the SNAC process again and, because the end node is now in compliance, will obtain access to the corporate network.

The SNAC solution performs periodic host integrity checks when an end node starts up, at a configurable interval, and when it changes network locations, to discover its security state through the Sygate Enforcement Agent (SEA). That could be seen as the analogy of the AR in the TNC specification. Components of the SNAC solution are illustrated in Exhibit 65.10.

Sygate also enhanced SNAC to a universal NAC system that combines SNAC with a solution for securing unmanaged devices, with several different enforcement mechanisms to extend SNAC protection

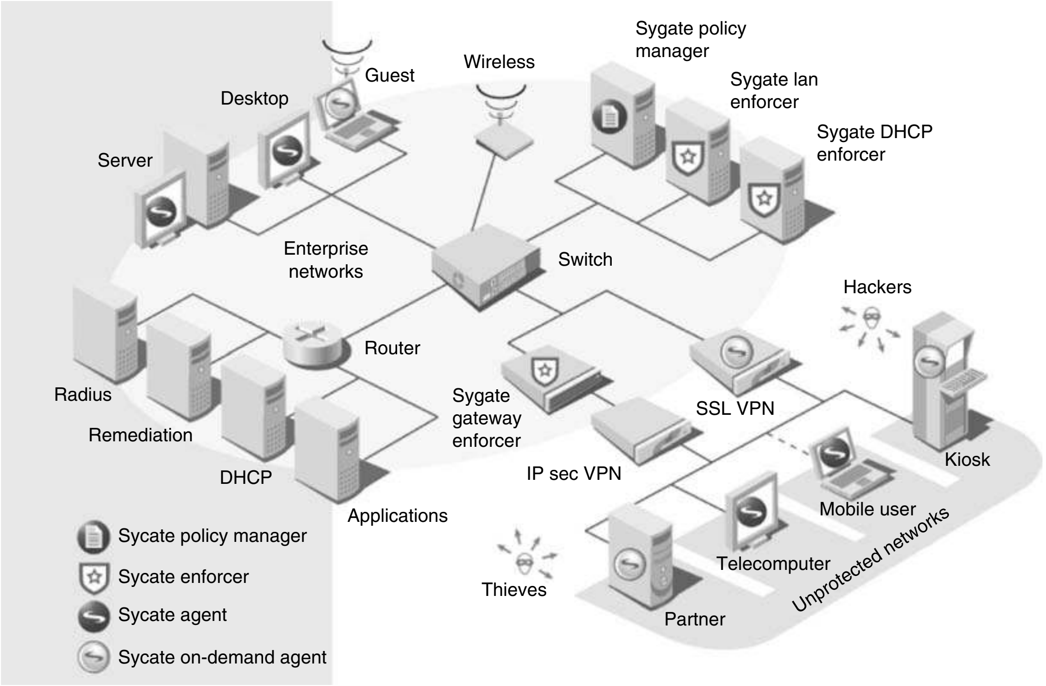

EXHIBIT 65.10 SNAC solution overview.

to every type of network access (VPN, wireless, routers, DHCP, etc.), and on all endpoints, including laptops, desktops, servers, guest systems, and embedded devices.

The Sygate Universal NAC System's enforcement methods include:

1. Self-enforcement when computers leave the network
2. API-based integration with dialers and VPNs
3. Gateway enforcement for in-line enforcement on any network
4. On-demand agents for guests accessing the network
5. DHCP-based approach for LAN and wireless over any infrastructure
6. 802.1x standards-based approach for LAN and wireless networks
7. Cisco NAC technology for Cisco routers

65.4.2.2 SNAC Analysis

The SNAC solution places great emphasis on the client agent software as the vital component of the solution. Even though Sygate is a member of Cisco Systems NAC initiative, it also has its own SNAC appliance, as well as backend policy servers that, as already mentioned, will most probably become part of the enhanced Symantec product portfolio. For an 802.1x access method, SNAC relies, like many other solutions, on third-party 802.1x clients, such as Funk Software (which has recently been acquired by Juniper Networks), Odyssey client, or Meetinghouse Aegis client. This, on top of the additional inline gateway device, represents extra costs in the overall SNAC solution deployment.

65.4.3 Automated Quarantine Engine

65.4.3.1 Automated Quarantine Engine Overview

Alcatel was one of the first vendors to develop a solution that is complementary to those previously described. The main difference is that it does not require any agent-based software on the end-node device to be able to detect, block, or isolate the infected end node. Alcatel has devised a way to implement the concepts of automated end-node isolation by allowing an intrusion detector to pass information to their OmniVista central network management system. OmniVista then works with an integrated automated quarantine engine (AQE) module to apply policies and place the infected system into a penalty VLAN where it can no longer infect the rest of the network. The AQE solution is illustrated in Exhibit 65.11.

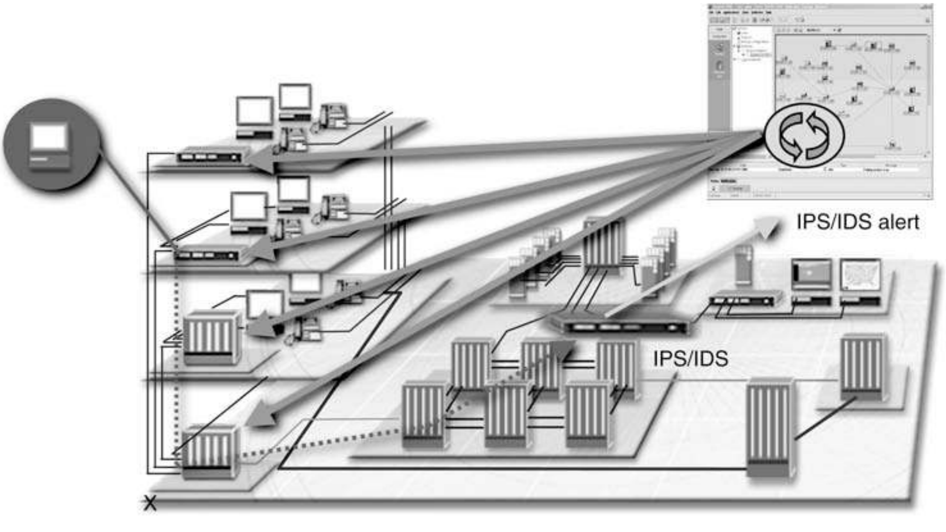

EXHIBIT 65.11 Automated quarantine engine from Alcatel.

Based on the input from a detection sensor such as an intrusion detection/protection system (IDS/IPS) sensor and the Alcatel's home-grown layer-2 media access control (MAC) address trace-back mechanism, the AQE solution is capable of dynamically reconfiguring the access switch to allow or limit access of the particular end node to the rest of the network. This is accomplished via SNMPv3 commands communicated to a switch infrastructure to shut down the port or apply additional filtering mechanisms: either VLAN configuration or a simple access-list filter for the particular node accessing the network.

The important part of the AQE is that it transparently and dynamically applies policies to an individual switched port based on the device behavior accessing the port. The automatic reconfiguration reduces the response time to security threats and removes the need to have a network engineer create and apply an isolation policy (VLAN, ACL) to manage network access. This minimizes the need for manual configuration and application of network user policies. After the infected system is isolated, the network administrator is notified and given choices on how to handle the infected system.

65.4.3.2 AQE Analysis

The AQE solution is unique in the way that it works with IDS/IPS as an alerting mechanism to trigger the blocking, isolation, or protection configuration changes on the access switches' port level. Being an agentless solution makes it a quite powerful and complementary option to all other agent-based proposals on the market. As such, it is a very interesting alternative where end-node software is not possible or difficult to install due to legacy or not-supported end-node software. Alcatel also claims that from a switch network infrastructure viewpoint, their solution is fully interoperable with other vendor switches, which makes it an attractive and open solution for modern end-node access management. A missing part in the AQE solution is that is has only automated isolation, blocking, and quarantine parts, whereas end-node notification or remedy with a return of a cured node must be performed manually by the system operator.

65.4.4 TippingPoint Quarantine Protection

65.4.4.1 TippingPoint Quarantine Protection Overview

Similar to the AQE solution, TippingPoint, now a division of 3Com, came out with an agentless solution based on their home-grown Intrusion Protection Systems (IPS). TippingPoint Quarantine Protection (TPQ) uses a network-based IPS mechanism to detect and stop the viral infection coming from the network attached infected end node. As an inline device to a traffic flow, IPS could stop the viral infection detected on the traffic flow coming from an infected end node and, if combined with a network infrastructure, could apply a blocking function based on the switch port, MAC address, or IP address on the edge switch or router. The quarantine function could be implemented via VLAN isolation and, being an inline-based solution, TPQ provides a possible remedy by performing an HTTP URL redirection. The TPQ solution is illustrated in Exhibit 65.12.

The flow of action goes through an end node connecting to a network and authenticating via the TippingPoint Security Management System (SMS) and RADIUS server, while the IPS engine detects the intrusion activity. Based on the configured policy action, SMS resolves the IP address to a MAC address and could instruct the blacklisting or policing of the access on the ingress access device.

65.4.4.2 TQP Analysis

Technologically speaking, the IPS-based quarantine system is an in-line solution and, as such, avoids an end-node software installation issue. That makes TQP easier to scale for a large number of end nodes. Additionally, TPQ, like Alcatel AQE, is an end-node-operating-system-independent solution that gives an additional benefit of protecting non-user-based end nodes, such as printers, faxes, or IP phones. The biggest concern with both mentioned IPS-based solutions—TQP as well as AQE—is that the end node that is infecting the infrastructure could also infect the other nearby end nodes residing on the same segment before it could be blocked or isolated from the network. A solution to that issue is, however, also possible and is actually existing in the infrastructure functionality itself in the form of so-called private virtual local area networks (PVLANs). Operation of the PVLAN is illustrated in Exhibit 65.13.

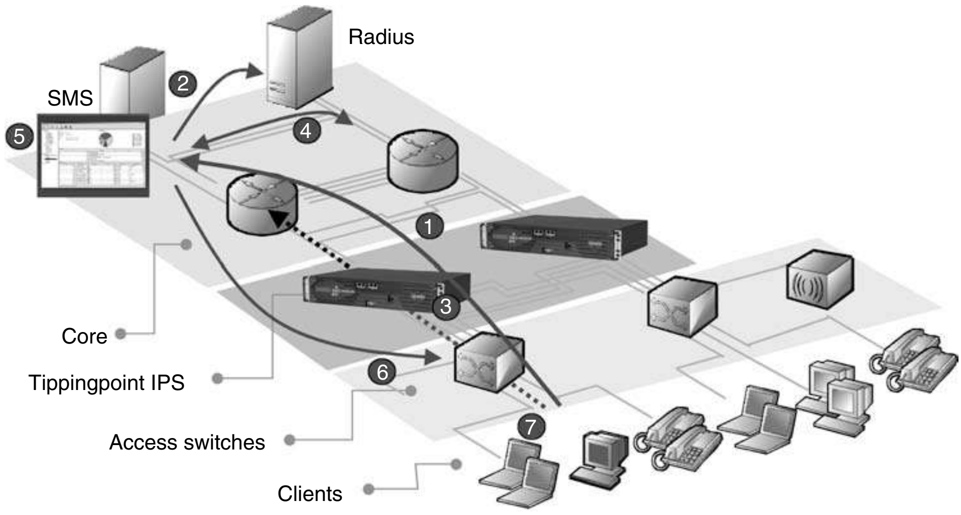

EXHIBIT 65.12 TippingPoint quarantine protection action steps.

Even though not standardized, PVLAN functionality that exists in almost any switch vendor product is, if the application traffic flow permits, a very efficient mechanism to force the traffic from the network edge or access layer devices through the IPS systems. IPSs, which are typically hierarchically aggregated at a network distribution layer, then prevent the end nodes from infecting each other by isolating them before they access the rest of the network resources.

65.4.5 Hybrid Solutions

The previously mentioned solutions are not the only ones on the market. For instance, Enterasys has created both agent- and network-based Trusted End System (TES) solutions where they combine their switches with a policy server and end node agents from Check Point/Zone Labs or Sygate. Enterasys also provides the option to use vulnerability-patch assessment tools from Nessus to perform the end-node

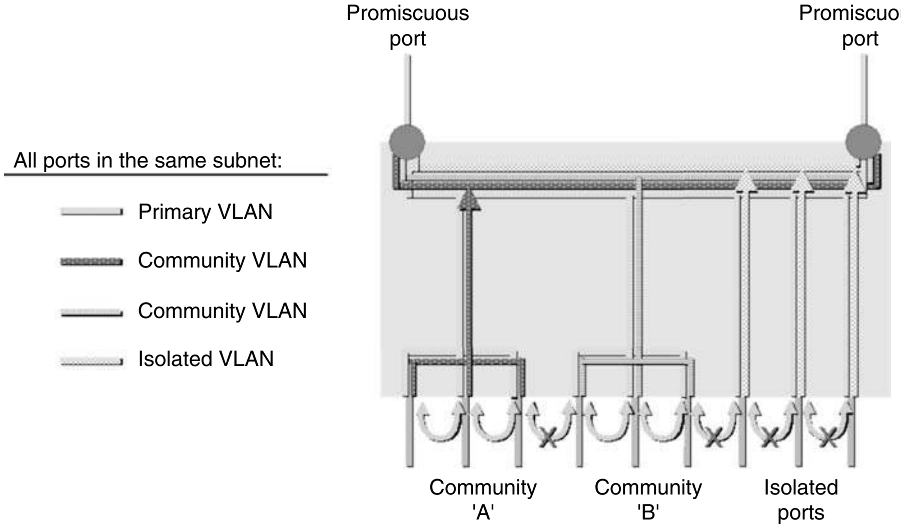

EXHIBIT 65.13 Private VLAN (PVLAN) operation.

scan checks upon the network connections and then provide similar functions as NAC, NAP, or TNC. Foundry and Extreme also offer network-admission solutions with Sygate's client, whereas Vernier Networks, a startup originally focused on wireless security, recently announced its EdgeWall security appliances that also performs NAC. Intel, HP, and Nortel also announced their solutions for the end-node and network access management protection that are very similar or aligned with previously mentioned ones. This shows that the industry players are seriously considering solving the problem of the end-node-to-network-infrastructure interaction. At the same time, unfortunately, it also shows the panacea of solutions that are still mostly isolated from each other. This makes any strategic decision for information security practitioners that are dealing with virus infections a difficult one.

65.5 End-Node Security Solutions Comparison

Information security practitioners are already facing or will face in the near future a decision of which solution to use or deploy. Hence, comparison tables of currently available offers might help in comparing them to each other as well as provide a clear picture of the offered features and functionalities. Such comparisons are provided in Exhibit 65.14 and Exhibit 65.15.

EXHIBIT 65.14 End-Node Security Solutions Comparison

	Features			
Solution	Requires Dedicated HW	Isolation	Access Media Supported	Remedy
TNC	No	VLAN/ACL	Open	Out of Scope
NAC	Yes/No[a]	VLAN/ACL	802.1x, 802.1x/UDP, IPsec VPN	3rd party
NAP	No	Subnet, VLAN, ACL	802.1x, L2TP VPN, IPsec VPN, DHCP	3rd party
SNAC	Yes	VLAN, ACL	802.1x, 802.1x/UDP, L2TP VPN, IPsec VPN, DHCP	Yes
AQE	No[b]	Port block, MAC filter, VLAN, ACL	IP	3rd party
TQP	No[b]	Port block, MAC filter, VLAN, ACL	IP	URL redirection to 3rd party
TES	Yes	Port block, MAC filter, VLAN, ACL	802.1x, IP	Yes

[a] NAC requires Cisco router or switch infrastructure; Cisco also released dedicated NAC appliance.

[b] No dedicated infrastructure HW needed, while both TQP and AQE require dedicated IDS/IPS fro malware activity detection.

EXHIBIT 65.15 End-Node Security Solutions Comparison

	Features			
Solution	Requires End Node Software	End Node OS Supported	Requires SW/HW Upgrade	PVLAN Recommended
TNC	Yes	Open specification	Once implemented—Yes	No
NAC	Yes	Microsoft, Redhat	Yes	No
NAP	No[a]	Microsoft only	Yes	No
SNAC	Yes	Microsoft only	Yes	No
AQE	No	Any	No	Yes[b]
TQP	No	Any	No	Yes[b]
TES	Yes/No[c]	Microsoft/Any[c]	Yes/No[c]	No

[a] Bundled with Microsoft OS.

[b] PVLAN usage is not required, however is strongly recommended.

[c] Entersays TES has agent-based and network-based options.

65.6 Future Directions

Although current proposals offer promising outcomes, looking a bit forward shows that there are still several open issues. Some of these issues are discussed here in no particular order of importance.

- Policy-server protocols are not standardized; they are closed into vendor-to-vendor API and the same goes for the remedy solutions that are out of the scope of the TNC specification.
- 802.1x protocol usage deployment is still very low.
- DHCP extensions are vendor-specific. This makes having a DHCP client and server from the same vendor a requirement. This leads to a locking solution with a single vendor instead of an interoperable scalable solution where different components of the solution could be provided by different vendors.
- EAP methods used are still under development. PEAP, even though in the stable IETF draft at the point in time of writing this chapter, is still not standardized. Hence, its implementations are not always interoperable, whereas new methods such as EAP–FAST are already on the horizon.
- All layer-3 solutions are only IPv4-based and have no solution for the problem of forthcoming new protocols such as IPv6. Clients other than those that are Microsoft OS-based, such as mobile phones, pda's, or legacy OS systems are not covered in most agent-based solutions.
- Most solutions thus far are not focusing on the malicious user, but rather on the accidental problem. Although this might be sufficient for a beginning, follow-up developments for stopping malicious attacks either need to be specified or will again be driven into different proprietary extensions.

All of above are important points to be solved while the main issue going forward will be convincing the major players to commit to the development of interoperable, modular solutions, such as defined in the TNC specification. This is obviously not expected to happen overnight for obvious reasons: the once-lucrative network infrastructure business is now in danger of becoming a commodity, which encourages closed solutions and differentiations among vendors.

65.7 Summary

Will an automated end-node protection mechanism be an ultimate solution for all sizes? Most probably not, but it will certainly add an additional level in the layered security architecture approach that information security practitioners could effectively use to mitigate security problems. However, every network admission solution today is proprietary, and puts information security practitioners into a trap of a single-vendor solution. The TNC specification gives hope to interoperability, but de facto standards will likely be driven by the major players in the networking infrastructure and desktop software market. In essence, it is important to understand that end-node control methods that were discussed in this chapter are, by design, performing end-node integrity and policy-compliance checking and, with that, increasing the security level of the rest of the network. Information security practitioners should also be aware of what different options can and cannot be achieved. They should also be able to distinguish their potential benefits as well as be aware of their disadvantages and limitations.

A key dilemma remains: end node with agent, or agentless deployment. Although agent-based solutions promise resolution to all issues, they also get stacked with scalability and deployment. On the other hand, agentless solutions make an intermediate and fast cure for urgent problems; however, they do not necessarily automate and solve all necessary components. It is also important to look into future development and acceptance of 802.1x-based solutions vs. DHCP-extended solutions. In the 802.1x case, solutions are on solid ground with a standard-based access-control protocol. Even though well-defined for the authentication part, 802.1x still struggles with a variety of different EAP methods and hence is, with the possible exception of the wireless world, facing an issue of wider acceptance together with a scalability of deployment. DHCP, as a protocol, has no built-in authentication; however, DHCP vendor extensions might fulfill the promise of easy and scalable deployment due to its simplicity and possibly faster and wider acceptance. Currently, there is no final conclusion of where to go, so the problem remains on the shoulders of information security practitioners to closely watch and follow the developments and outcomes, while where needed, armed with knowledge from this chapter, deploy the solutions that fit their immediate business demands.

List of Acronyms

AAA	Authentication authorization accounting
ACL	Access control list
AR	Access requestor
AQE	Automated quarantine engine
DIAMETER	(not an acronym)
DHCP	Dynamic host configuration protocol
EAP	Extensible authentication protocol
HCS	Health certificate server
IAS	Internet authentication service
IETF	Internet engineering task force
IDS	Intrusion detection system
IMC	Integrity measurement collector
IMV	Integrity measurement verifier
IPS	Intrusion protection system
L2TP	Layer-2 tunneling protocol
MAC	Media access control
NAA	Network access authority
NAC	Network admission control
NAR	Network access requestor
NAP	Network access protection
PDP	Policy decision point
PEAP	Protected enhanced authentication protocol
PEP	Policy enforcement point
PVLAN	Private virtual local area network
RADIUS	Remote authentication dial-in user service
SNMP	Simple network management protocol
QA	Quarantine agent
QEC	Quarantine enforcement client
QES	Quarantine enforcement server
SHA	System health agent
SoH	Statement of health
SHC	State health certificate
SNAC	SYGATE network access control
TCG	TRUSTED computing group
TLV	Type-length value
TNC	Trusted network connect
TQP	Tippingpoint quarantine protection
TES	Trusted end system
VPN	Virtual private network
VLAN	Virtual local area network
UDP	User datagram protocol

Identity Management: Benefits and Challenges

Lynda L. McGhie

66.1 Introduction

Organizations finding themselves pushed further and further onto the Internet for electronic business are exposed to heightened risk to information security and have greater concerns for data protection and compliance with the ever-emerging and ever-evolving legislation and regulations regarding privacy, data protection, and security. Additionally, customer-facing portals and complex Web services architectures are adding a new complexity to information technology and making it more difficult to protect information. Managing access to information also becomes increasingly more difficult as security administrators struggle to keep up with new technology and integrate it into existing administrative functions. As organizations continue to pursue new business opportunities, move operations off-shore, and out-source day-to-day operations and development support, the “key to the kingdom” and their information assets are increasingly at risk. No question, the business imperative supports accepting and mitigating this risk, thereby further enabling organizations to partner and team externally and electronically with business partners, customers, suppliers, vendors, etc.; however, if organizations wade into this environment blindly, without upgrading the existing information security infrastructure, technologies, tools, and processes, they may inadvertently put their organization at risk. Organizations that embark on identity management implementations, not just for compliance projects but as their core underlying security infrastructure, will ensure consistent, standard, and compliant security solutions for the enterprise.

66.2 Why Is Identity Management a Solution?

The growing complexity of managing identities, authentication, and access rights to balance risks and access, as well as meet the organization's business goals and security requirements, is often forgotten in the haste to implement new and enhanced systems to maintain the competitive edge. An additional outgrowth of this trend has been a dramatic increase in access to information and new and expanded E-business infrastructures. As more and more new systems and applications are being added to existing information technology (IT) and business infrastructures, while legacy systems continue to be retrofitted, increasingly complex access roles (groups) are emerging to accommodate and manage access to information. Additionally, as more and more user IDs and passwords are added to support this new environment, they must be managed in an administrative environment that continues to grow more and more disjointed. Existing security administration and management systems and supporting processes cannot scale without new investment and the addition of new technology and automated processes.

Many organizations are looking toward advancements in identity management (IM) and identity and access management (IAM) products to solve the problems created by the increasing complexity of today's IT environments. Additionally, IM/IAM solutions enhance an organization's effectiveness in managing risks associated with the new technologies. These products have been around for some time, traditionally trying to solve the single sign-on (SSO) problem, but they have adapted and evolved to include other feature sets, such as account provisioning, password management, password self-service, advanced authentication and access management, and workflow. By implementing a well-planned and well-thought-out IM or IAM strategy that provides cost-effective account management and enforceable security policies, organizations can actually recover investments in information security solutions and demonstrate a return on investment (ROI).

66.3 Getting Your IM/IAM Project Started

New and evolving legislation and regulations have been a double-edged sword for information security. In response to these laws and regulations, companies continue to launch separate and distinct compliance projects. Typically, these compliance projects are driven by organizations outside the corporate information security function, such as human resources, finance, legal, audit, compliance, privacy, or information technology. Often, these organizations are totally focused on compliance without knowing or understanding that the necessary technology and processes are already in place, or planned by the security team, to accommodate and manage the overall enterprise information security and risk posture.

The controls mandated by these laws and regulations are not new or unfamiliar to well-seasoned security professionals and are, in fact, part of the "security bibles" that we have been referencing, following, and complying with for decades (e.g., NIST, ISO 17799, COBIT, COSO). These guidelines and standards will be further discussed later in this chapter as they relate to the components of an IM/IAM infrastructure, as well as ways in which they assist with the compliance task, secure the infrastructure, ensure identities and authentication, protect and grant access to information, and manage the administrative security process. The important point here is that the hype and fear surrounding the issue of compliance should not be the tail that wags the dog of a company's overall enterprise security program.

Initially, the information security team will be optimistic and look forward to security investments and enhancements to complement the existing information security program. Most frequently, however, this additional budget outlay will be met with grief by executive management and stakeholders, who will advocate taking the least expensive path to compliance. Security teams will be pressured to utilize existing tools and processes, even though they may be out of date or not up to the challenge of legal and regulatory compliance.

It is difficult to ensure that new compliance investments will complement and enhance existing solutions. Even though laws and regulations are driving the outlay of new funding for information security, the budgets of other projects of the security team may suffer. Another threat to the overall enterprise security posture is the loss of resources or attention to security and privacy as compliance dates come and go, with the result being and increased likelihood of failure, partially implemented technology or processes, the loss of management attention and business and technical resources, and the risk of noncompliance over time.

The information security program must continue to educate the organization and help them understand that information security is not a project but is an ongoing process. Additionally, security is embedded in all aspects of the business and IT infrastructure, with tentacles spreading to all projects and functional areas; therefore, it is essential to involve IT security in new and enhanced processes as well as to continue investing in new technology and process enhancements. Security alone is good business, and security embedded in new and enhanced technology and business processes is simply better business.

66.4 Getting Buy-In and Support

It is important to gain enterprisewide concurrence with the organization's definition of identity management and what it means to the enterprise. Additionally, it is important to agree on what components of IM will be implemented and in what order and what the phased implementation plan and schedule will look like. Understanding the scope of a company's IM solution is important to defining the overall project objectives, meeting goals and timelines, and ensuring overall project success. The IM realm continues to evolve, and more companies offer products and technical solutions. Standards ensuring interoperability are also coalescing, and suites of products work together seamlessly to provide cost-effective IM solutions that can be sized and scoped to the needs of a particular organization. Being armed with a thorough understanding of IM is an asset to gathering support from stakeholders, team members, executive sponsors, and the business.

66.5 Initial Thoughts and Planning

The primary motivation for embarking on an IM project may be to respond to new laws and regulations and the urgency of compliance. If this is the case, a company should assess its current risk and state of compliance and then determine what IM feature set or components with help achieve compliance. For IM projects designed to enhance the effectiveness of existing security administrative systems in order to streamline their effectiveness or improve time to market, the requirements and resultant approaches may differ. For a large, broad project that enhances a current enterprise IT security posture while complying with various new laws and regulations and incorporating IM into other IT infrastructure projects (Active Directory), the project will be a large and complicated one. The issue of who owns the project becomes uncertain. Additionally, the funding source could then span functional organizations and even separate business units within a single entity. Such issues add levels of complexity and potential points of failure throughout the project.

Having acknowledged that an IM project could have many drivers, such a project could also have any number of project sponsors, project owners, and funding sources. Some IM projects may be financially driven, such as Sarbanes–Oxley (SOX), and managed by the chief financial officer (CFO) or the controller's organization. Some IM projects may be driven by other IT enhancements, such as implementation of Microsoft's Active Directory system. Still others could be led by any combination of legal or human resources staffs, the compliance officer, or the chief privacy officer. Ideally, the IT security team is the owner of the IM project, and the executive sponsor is the chief information officer (CIO), coupled with executives from one of the functional areas listed above. Typically, the sponsoring executive would be the one in charge of and managing the project funding. A high-level enterprise executive steering committee can help to guide and govern an IM project while ensuring that its many bosses are served.

66.6 Demonstrating IM Return on Investment

Because information security is typically a cost center rather than a profit center, its function and resultant budget allocation are always in competition with other cost centers. This is particularly painful when competing for budget and resource allocations. Some functional organizations that typically have project overlap, synergies, and shared responsibilities include human resources (HR), finance, legal, compliance, risk management, insurance, and audit. Over the years, these organizations have been viewed as non-contributors to the company's revenue stream and have not fared well when cost-cutting and other reductions are being considered. Additionally, because information security most typically resides in the IT organization, its projects must also compete for resources and funding with other IT projects that are more frequently driven by operations where a return on investment can be easily identified, quantified, and supported.

Several years ago, Gartner, Inc. (Stamford, CT) predicted that by 2005 help-desk costs associated with end-user password resets would be reduced by 70 percent through the implementation of self-service password management. The password management, self-service aspects of IM are frequently one of the first functional or module implementations and help build a ROI for the initial IM investment. Further, Gartner estimated that, by 2007, enterprisewide identity management solutions would demonstrate a net savings in total security administration costs (operations plus administration) of 21 percent. This savings can be realized through centralized provisioning and account management as well as workflow to automate and standardize security administration.

Gartner outlined the costs and projected savings for an average IM implementation including, password self-service, provisioning, and workflow. User provisioning software license costs for a 15,000-user enterprise can run as high as $700,000. Also, password reset and user ID problem represent 15 to 35 percent of help-desk call volume (at a typical cost per call of $10 to $31). It is no wonder that enterprises need, and want, to justify the cost of an identity management project. To do so, they typically consider three factors:

- Head-count reduction of the help desk or security administration organization performing day-to-day activities such as password resets and user account management
- Productivity savings for end users (they can reset their password faster than calling the help desk) and business management (for faster access-request approval processing)
- Risk management, including electronic data processing audit management, best practices, and regulatory compliance

Other sources estimate that as many as 70 percent of the calls to the help desk are for password resets and password problems. As with any project, to best justify project approval and resources, it is necessary to understand the current environment and problems to be solved. Many organizations do not do this or really do not have an understanding of their current environment or the problems they are trying to solve. This is particularly true for security projects traditionally spanned by the FUD (fear, uncertainty, and doubt) principle. On the other hand, help-desk metrics are generally maintained and can be beneficial to building the case for an IM system. If the security administration group keeps metrics, supports a service level agreement (SLA), or even has an overall understanding of the turnaround time for processing user requests for account initiation and management, these will at least further justify such projects, in addition to password resets. Also, with regard to the account/user ID administration function, it is possible that supporting paperwork or authorizations are not being kept or cannot be produced for audits. IM can help with this problem through its workflow and reporting process. This is why IM is finding a new purpose in life with compliance projects. A clean IM implementation can also assist in providing integrity to the identification process through good passwords, good authentication, and password self-service. Other metrics to consider include other IT and functional organizations such as the help desk, security administration, HR, IT services, and contract management (for identifying the number of temporary workers, contractors, and consultants).

For identified cost savings and ROI, Gartner recommends the following four categories for metrics measurement and reporting:

- Transaction volume
- Access request process fulfillment
- It risk management
- Security administration infrastructure

Another area to investigate is replacement of multiple online identities that users are required to know and administrators are required to maintain. In medium to large enterprises, these multiple identities result in a somewhat disjointed administrative environment, where one hand does not know what the other is doing with regard to granting and managing access. A valid IM goal, then, is to consolidate and reduce the numbers of online identities and credentials to be managed for each individual user. In larger organizations, these numbers get interesting very quickly.

According to RSA Security (Bedford, MA), organizations can look for cost reductions and efficiencies through centralized, automated solutions that enable the elimination or reduction of costs stemming from deploying and managing disparate user management systems. Additionally, organizations can derive enhanced security, while differentiating themselves from the competition, by providing a more secure online E-business infrastructure. One example is enforcing privileges and implementing strong authentication, thereby reducing the likelihood that sensitive data may be accidentally exposed to the wrong users.

With an effective identity management solution in place, organizations can manage their business with a degree of flexibility, responsiveness, security, and economy that is simply unattainable with today's fragmented approaches to user management. By considering all of the factors mentioned here, organizations can set realistic ROI goals for identity management solutions and then deliver on plan and on schedule.

66.7 Project Management Challenges

As mentioned previously, different companies have different IM requirements and drivers. While IM projects will have aspects of commonality, they will also be unique and specific to a single entity. Because IM is evolving technically and functionally and standards are finally coalescing, solutions should have an eye toward being adaptive and agile. Additionally, because IM projects could include a variety of component parts, they should have a phased design and implementation structure.

As IM evolves within the organization and within the industry, companies will want to consider incorporating greater IM capabilities, including advanced features of identification, authentication, and authorization. A company can begin with a prototype environment utilizing representative systems from the overall project footprint. After proof of concept, more components can be added to the IM system, as this is where the company will realize greater cost savings and ROI. Also, the company should plan on continuing to enhance baseline system functionality and plan for such future enhancements as single sign-on (SSO), federated identity management, digital certificates, electronic signatures, centralized and decentralized management, provisioning, workflow, and integration with meta-directories and HR systems. These features are all discussed later in this chapter.

The brief discussion here has indicated that an IM project has the potential of growing very quickly, evolving, and quickly becoming unwieldy and unmanageable. To be successful, adherence to a strict project management methodology and governance process is absolutely necessary. Remember, one size does not necessarily fit all, so it is important to seek the counsel of experts in the field, such as consulting firms; vendors; standards bodies; security organizations, such as SANS or Computer Emergency Response Team (CERT); and other professional security groups, such as Information Systems Security Association (ISSA), Computer Security Institute (CSI), or Information Systems Audit and Control Association (ISACA).

One final project goal and objective embedded in all laws and regulations, specified in all security standards and guidelines, and most likely already embedded in an organization's internal information security policies and procedures is the concept of confidentiality, integrity, and availability (CIA). CIA should be highest of the core and fundamental goals of all security projects and resultant and supporting technical infrastructures. The definitions below are universally accepted and have stood over time:

- *Confidentiality*—Data or information is not made available or disclosed to unauthorized persons or processes.
- *Integrity*—Data or information have not been altered or destroyed in an unauthorized manner.
- *Availability*—Data or information is accessible and useable upon demand by an authorized person.

66.8 More on Planning

Companies that are already utilizing the Internet for business and those who already have electronic commerce and Web-based applications have most likely already considered compliance issues and security and are well vested relative to good security practices and compliance. The reality is that all companies will have to make some adjustment to comply with the barrage of legislation and regulations regarding privacy and the protection of information. Because security guidance has been available for some time within the government, across the industry, within universities and national laboratories, and from other research organizations and standards, bodies, many organizations are considering implementing IM solutions or may have already consolidated administrative functions, implemented a workflow system for account/user ID management, or implemented other automated administrative processes.

All security and compliance projects should begin with identification and documentation of the "as is" state as a baseline. This typically requires a new and enterprisewide risk assessment. All existing risk assessments should also be used to provide input to defining the overall as-is state. As mentioned earlier, defining a solid set of project goals and objectives and the creation of a project plan and schedule are the most critical steps in the process. Getting upfront buy-in and approval is also critical, as is obtaining an experienced project manager who has managed enterprisewide IT and business projects.

The results of the risk assessment should be mapped to the controls prescribed in the organization's security policies and procedures and the laws and regulations being addressed. Also, other security feedback can serve as input to the planning process, such as results from vulnerability scans and disaster recovery testing or recent audit reports. The next step is a gap assessment, which will determine the controls to be implemented and project components.

The initial risk assessment must evaluate the entire IT environment, including data, networks, applications, and systems. Organizations will then have to determine what security policies and procedures must be written or augmented. It may be necessary to purchase or acquire new products or technology, in addition to enhancing or augmenting current products and technology. Additionally, it is possible that a simple restructuring of the security organization and a consolidation and centralization project could meet project needs and requirements. Outsourcing is another possibility. This could take many shapes and flavors, such as outsourcing part of security management or the entire security operation. The entire scope of people, processes, and technology should be considered for improvement, automation, and centralization. Remember that IM projects can get big very fast, and the best guidance is to keep it small initially by planning a proof-of-concept pilot and implementing a phased approach.

If it is necessary to acquire new technology or enhance existing technology, a thorough product evaluation should be performed. It should involve IT and business organizations according to the company's established processes of communication and partnership. Trusted vendors and business partners can be involved in the process. Working with vendors who have established themselves as experts in IM and IAM is recommended; do not be lured by new and unproven technology solutions. Products must be able to support heterogeneous and complex environments when necessary. It is important to look beyond systems and networks to large enterprise application support for products such as Oracle and SAP, for example.

Because IT and business training is also critical to the success of a project, vendors not only should be product experts but should also have a track record of supporting their products with ongoing service that includes training. Companies will want to partner with their vendors throughout their IM projects to exploit their experience with other companies and other implementations. Vendors who have well-established products and a significant marketshare will be able to offer a wealth of helpful advice and experience.

66.9 Identity Management Infrastructure

Underlying the need for organizations to establish and maintain a single integrated and authenticated identity management system is the establishment and implementation of a single, universally accessible, common IM infrastructure. Organizations should strive to achieve a centralized and decentralized IM implementation that eliminates the inefficiencies and vulnerabilities of independent decentralized approaches. A unified infrastructure will provide centralized, highly automated capabilities for creating and managing trusted user identities. It will allow administrators to define user access rights with a high degree of flexibility and granularity, in keeping with business goals and security policies. It will also validate identities and enforce rights and policies consistently across the enterprise, thereby further enhancing security and supporting compliance requirements. RSA defines identity and access management (IAM) as "an integrated system of business processes, policies, and technologies that enable organizations to facilitate and control users access to critical online applications and resources — while protecting confidential personal and business information from unauthorized users."

66.10 Administration, Provisioning, and Workflow

One of the biggest challenges to organizations is handling access to data, systems, applications, and networks when employees are hired, moved within the organization, or terminated. This challenge is compounded for external users, such as contractors, vendors, partners, and customers. The larger and more complex the organization is, the greater the challenge. By successfully managing this process from end to end, users will more quickly obtain system and application access, thereby becoming more effective and productive as quickly as possible. Good management represents a cost savings to the organization and can provide a demonstrated ROI. The challenge is even greater for organizations that are highly distributed with independent functions doing the granting and the management of account/user ID management. It is even more complex when parts of the administration function are centrally managed and other parts are decentrally managed. Another complexity is added when employees move from site to site or have access to multiple individual business units within one larger entity, such as company members of a larger corporation.

Provisioning provides automated capabilities for activating user accounts and establishing access privileges for those accounts across the entire enterprise. Many opinions and metrics exist regarding the time it takes to set up a user account initially, manage it over time, incorporate changes, and ultimately delete it. A variety of sources have estimated that it takes an average of 28 hours to set up an initial user account. In theory, then, every subsequent change to a user profile must also touch the same access databases, thereby potentially requiring another 28 hours per change. Some examples of changes include users changing positions or roles, thus requiring a change to access requirements or physically moving access to a different location.

One of the most important changes to an account or a user profile occurs upon termination. It is imperative that terminated employees be immediately removed from the system or, minimally, that their access be immediately terminated. In cases of suspension, after completion of file cleanup and fulfillment of delegated responsibilities and other administrative processes, actual deletion of the account/user ID should quickly follow. In highly decentralized and distributed organizations, supporting many applications and systems, it is important to coordinate the termination and account revocation process centrally and to automate this process to the extent feasible. It is also imperative to have an HR system interface to the IM system to compare the IM database to the HR database to highlight and react to changes. This functionality may be provided by another meta-directory such as Microsoft's Active Directory (AD) as long as it is the designated and established authoritative source.

If one considers this situation logically, there is no effective or manageable way to perform such tasks without automation and centralized management, tools, and processes, but organizations are continuing to fall behind in this process. As a result many systems have outdated user profiles or even "ghost accounts" (outdated accounts for users who are no longer working within the organization or have changed roles and obtained new accounts/user IDs).

An outdated but typical answer to this growing problem has been to add staff and manual processes in an effort to get a handle on the process of granting access, managing user IDs (accounts) and passwords, and granting access to objects within systems, such as data, databases, applications, systems, and networks. As more users are added, more profiles must be managed via a process that becomes increasingly burdensome and costly. Longer term support to sustain the IM system over time is threatened because of changes to the environment such as changes in sponsorship, budget allocations, IT and business priorities, or knowledgeable personnel. The IM team may over time find themselves left with an outdated system and support. Meanwhile, the function continues to expand and problems escalate, causing more risk to the organization.

When organizations struggle with such problems, they often look toward automation. Initially, an organization may think this automation can be achieved by writing programs and scripts. They may turn on other functionalities within operating systems, databases, or applications to make use of a number of utilities. Finally, they will look toward commercial off-the-shelf (COTS) products that integrate access control administration across heterogeneous platforms. Some organizations may be unable to make or support the case for purchasing additional products or technology due to poorly defined and supported cost-benefit analyses. These organizations must rely on efficiencies gained through streamlined manual processes and maximized implementation of each individual product and access control system.

It is this problem that IM products and technology are also trying to solve, in addition to addressing the legal and compliance issues surrounding ensuring that entities are who they claim to be. The administration aspects of granting and managing access greatly contribute to cost-benefit analyses and building case for product and process improvements or investments in this area. The ROI is quantifiable and defendable, but it takes time to understand the current environment, envision an end state, conduct a gap analysis, and lay out an implementation plan for improvement. It should be noted that improvement involves not only faster access to systems, fewer errors in granting access, and compliance with company policies and procedures but also streamlined overall management and compliance.

Many IM or IAM products provide workflow frond ends to automate and streamline the process of gaining access to systems, data, transactions, etc. As noted, this could be a complicated process, particularly for new employees and nonemployees or for systems where the process is not centrally documented and managed. A typical employee requires access to as many as twenty separate applications and systems. The initial setup process can be frustrating and time consuming because often new employees must peel back the onion to figure out what access they may need just as a baseline to being successful.

Through process improvement, automation, workflow management tools, and new supporting infrastructures these processes can be consolidated and centralized. The ongoing goal continues to be finding the optimal blend of centralization and decentralization that will optimize the organization's efficiency. This contributes to the organization's business imperative and bottom line. This case must be made and defended and finally demonstrated throughout each phase of an IM/IAM implementation. Due to its universal reach and complexity, this is a project that can take some time.

During the initial stages of an IM project, organizations determine which systems will take part in the pilot and which systems will be included in the overall project scope, in addition to how systems will be added over time, what the project phases will look like, and how they will be managed. The initial project may envision an end state utilizing all the component parts of a robust IM system, or it may envision a system that provides only provisioning and password management. Done right the first time, the successful initial implementation of a centralized IM infrastructure could have the results promised in the old adage: "Build it and they will come." Minimally this should be the goal.

When users are added to the overall IM system, they reside in the core database and are managed from there out to the distributed environment. The IM system governs the relationship between decentralized systems and supporting administrative systems and underlying process. No matter how it is decided to share and populate the core system (master or system of record) and distributed systems (slaves), it is important to have these systems synchronized in real time. Synchronization is important not only for failover and recovery but also to ensuring that user profiles granting access are up to date and correct. Because this is configurable and can be tailored to each organization's particular needs, workflow and integrated centralized account management do not ever have to happen, or certainly not upfront in the process and within the initial phases of the project.

Workflow provides an automated front-end system that is Web enabled and forms based. It provides a mechanism for end users to communicate with the centralized and decentralized administration management system or IM/IAM system. Users access this system, complete forms, and are granted access. The forms automatically route for approvals and ultimately to the appropriate system administrator. In the best case scenario, users are added to the central database system with approved system access rights and roles during a single single session. New profiles or modified profiles are instantly shared with the decentralized systems for which they have access or authenticated rights. This provides a single record of the process for granting and revoking access to systems and information. The system provides a centralized repository for documentation, as well as audit trail information and a central archive. Archive and retrieval are pivotal components of an IM implementation for compliance purposes and also for information security incident management and forensics. Access management reduces risk by ensuring that access privileges are accurately controlled, consistently enforced, and immediately revoked upon termination.

66.11 Self-Service Password Management

The password management features of IM are among the most attractive to organizations, and many enterprises are implementing third-party self-service password reset tools that enable users to change their own passwords upon expiration or to reset passwords when they have forgotten them and have locked themselves out of the system. With self-service password management, when users have forgotten their passwords they are required to authenticate themselves via an alternative method before being given access to the password reset function. In the case of a forgotten password, the tool requires the user to enter the answers to a predetermined set of questions (the answers have previously been provided during initial registration to the password reset facility).

The prompting question should not conflict with laws and regulations regarding the protection of customer information or privacy information; in other words, prompting for a customer account number or Social Security number is not allowed. Additionally, prompting for commonly known information such as name or mother's maiden name should be avoided. Exploiting such information is a fairly trivial matter for attackers familiar with social engineering or even database look ups. Controls should specify the number of times a user can enter an incorrect answer before alerting the system administrator for manual intervention. The answers must be kept secure and treated like sensitive information, with limited access and audit and monitoring enabled.

Third-party self-service password reset tools are attractive to enterprises in which a large percentage (e.g., 40 percent) of help-desk calls are for password resets. The tools not only reduce the cost of end-user support but also provide a more secure method for resetting a password, because user or requestor identity is authenticated through the prompting for private information, provided earlier by the user. Manual password changes to the help desk are frequently not authenticated without an automated password management process. This practice is not compliant and is heavily subjected to security compromise and error. This is of particular concern for contractors and other nonemployees with access to a company's system. These users are usually not in the identity of HR official record databases.

66.12 Authentication

Authentication establishes an identity owner, and the resultant single credential closely reflects the way identities are established and preserved in the offline world. The identity and supporting authentication system should be robust in detail, integrating data from a multitude of authoritative sources and pushing up-to-the-minute data back to those same sources. The technology and its supporting processes should reach out centrally to the decentralized technical and functional organizations, resulting in provisioning a trusted user with secure access to all applications and resources that an individual needs to be productive in his or her relationship within the organization.

For years, user IDs and passwords have been adequately filling the bill for ensuring that persons or entities requesting access or service are who they say they are. This process is known as *authentication*. As information technology has evolved over the years, the password management process has improved. Many companies continue to rely on standard user IDs and passwords within their secure perimeter or within their company's protected and secured intranet. Many of these same companies do, however, have enhanced IM and authentication to accommodate increased threats and vulnerabilities or changes to trust models. Examples of enhanced risk and trust are remote access, wireless networking, traversing internal trust domains having differing trust levels, and accessing sensitive and high-risk systems and customer confidential data.

The previous discussion has addressed a perfectly acceptable and compliant IM that may be enhanced state-of-the-art user IDs and passwords with a compliant and well-managed administrative and technical support process (identity management or password management). As technology and business drivers have evolved to require employees to be more mobile to increase productivity and ROI, mobile technology has evolved to be cost effective and secure. Most companies today support a mobile work force and mobile computing or access from home for their employees. After assessing the risks associated with such access and the necessary control and process support requirements, a plan can be developed to enhance password management and authentication to include a higher level of authentication, typically migrating from single-factor authentication, passwords, and pins to higher level, more secure two-factor authentication. Single-factor authentication requires something the user knows. Two-factor authentication adds one more dimension, typically something that the user has. In this case, it is a token that generates a time-synchronized number when used in combination with a known password or PIN.

The evaluation and selection of a higher level authentication system and its ongoing management and operation can consume ever-increasing resources, which should be factored into the complexity of technical solutions. Companies should be leery of new, untested, and unproven technologies. An approved, compliant, and sound security strategy may revolve around simply building on the integrity and management of an existing user ID and password management system. Other forms of enhanced authentication are support through the use of USB port authenticators, public/private key encryption, Kerberos, digital certificates, smart cards, etc.

Two-factor authentication provides more integrity to the process, thereby ensuring that the person or entity is indeed who he or she is claiming to be. The authentication is innately stronger than standard user IDs and passwords (something that you know) and actually builds upon sound password management practices by adding an additional layer of authentication and security. Two-factor authentication improves the integrity of the authentication process by adding a second identifier (who the user is or what the user has). Over the years, for remote access the traditional two-factor authentication has been the user ID, standard password, PIN number, or a randomly generated authentication code generated by something the user has, which is typically a SecurID card. Biometric devices, such as those that read a fingerprint or iris pattern, are considered a stronger form of user authentication. When used alone, they are considered one-factor authentication; when combined with a PIN, password, or token, the solution is considered two-factor authentication; and when all three are used, the solution is considered three-factor authentication. Organizations can enhance security by requiring users to present multiple credentials or "factors." The more factors required, the greater the level of protection. Strong authentication validates an audit trail of user activity by requiring conclusive proof of identity before granting access to sensitive resources.

66.13 Password Management

One of the factors driving the growth of identity management solutions is widespread dissatisfaction with password protection. First invented in 1963, password-based authentication systems gained wide acceptance because they were easy to use, came free with various applications, and provided adequate security for most purposes. Equally important—with many organizations supporting dozens of distributed password systems—is the fact that passwords are costly to administer and a major security threat, due to their inherent vulnerability and the lax password practices of some users (such as attaching sticky notes with passwords and usernames to computers or using obvious passwords such as names and dates).

Although they are used widely, single-factor static passwords are the weakest form of authentication and are becoming weaker over time as new technology and hacker skills are finding ways to crack even the most secure password configurations. While six-character passwords combining alphanumerics with special characters have been recommended standards for decades, many companies are tightening up standard password management to enforce eight-character passwords that are a combination of upper- and lowercase letters, numerics, and special characters. In the past this has been recommended but not necessarily enforced at the system configuration level. Most systems previously allowed those characters to be specified in the password string, but today it is becoming mandatory to include each of these elements in a password. If a company is certain that its password configuration or password management approach is sound, it can either eliminate or reduce its password cracking processes to check for good passwords. Most systems today feature secure password configuration and management as the first lines of defense.

Secure password configuration must be followed up with secure password management. If the help desk, security administrators, system administrators, and others with system administrative or security privileges can and do change passwords, it is important to ensure that the password change and management process is secure, up to date, and, most importantly, followed. This process should be monitored closely via ongoing and regular internal and external audits. Passwords should not be reset with telephone calls that do not ensure the identity of the caller or match to the account. Nonemployees or contractors also should not be allowed to reset their passwords over the telephone without a process in place to ensure identity. Also, when nonemployee accounts are suspended by the security group, they should not be allowed to be unsuspended by the help desk, only by the security organization or administrator with authorization from the sponsoring company manager.

Successfully authenticating a user establishes his or her identity, and all activity under that identity is tracked, thereby making the user accountable for the activity, thus the need for good management practices regarding authentication information. PINs or passwords are currently the standard user authentication solutions, both on the Internet and for internal applications. PINs typically control access to personal information (e.g., bank account information), and passwords are used to control access to personal information as well as shared information, such as sensitive or trade secret information contained in data files.

Following is a list of good password management practices; refer to ISO 17799, NIST and other guidance for additional password management standards and practices:

- The best line of defense for secure password management is up-to-date information security that addresses secure password management. By involving users in the process through a strong user awareness program, everyone understands the expectations of their role and the best practices imposed by the organization.
- Most organizations advocate not writing down passwords. Others acknowledge that passwords might need to be written down if users must memorize multiple passwords. Additionally, as organizations move to stronger password configurations or randomly generated passwords, it becomes increasingly more difficult to remember these passwords. Organizations acknowledging the need to write down passwords advocate storing them in a secure place.
- Security awareness programs and communications should warn users about the dangers of social engineering; for example, people posing as systems administrators or managers could request a user's password under the guise of eradicating a system problem.
- Today's acceptable password length is a minimum of eight characters with an enforced password configuration of a combination of upper- and lowercase alphabetic characters, numeric characters, and special characters.
- A default password should be assigned when the account is created and the users should be prompted to change the password upon initial log-on or account access.
- All administrative communications regarding user IDs and password initialization or account creation should be by separate communications—one communicating the user ID and a second separate communication regarding the initial one-time-only password.
- All passwords must be stored in a one-way encrypted format.
- All access to the authentication server must be strictly controlled.
- Passwords must never be displayed on the screen but should always be masked using dummy characters, such as an asterisk.
- Password history should be configured to ensure that users do not reuse the same password over a period of time.
- Passwords should be set to expire with a systemwide parameter within 60 days, minimum.
- Passwords for privileged accounts should be set to expire within 30 days.
- Screen savers or other software capabilities must be utilized to enforce automatic logoff for periods of inactivity greater than 15 minutes.
- Accounts should be locked out following three to five password attempts of guesses. Accounts should automatically be locked out and reenabled by the system administrator.

By tightening password management policies and supporting management systems, an organization can significantly reduce the vulnerabilities related to poor password practices.

66.14 Single Sign-On

Single sign-on (SSO) enhances the integrity of the single credential or password. It is a productivity enhancer for both users and administrators. Users only have to remember one (or, more realistically, a smaller number of passwords). When their passwords expire, they only have to make the change to the central IM system, and the changes are automatically sent out to all decentralized systems registered to the core IM. SSO enhances the productivity of systems administrators because they do not have as many profiles and accounts to manage. They can install an account once, and it is populated out to all the systems the user is approved to access. This process becomes less expensive and faster as a single user accesses many systems and incurs some profile changes over time. Similarly, as illustrated previously, one of the greatest vulnerabilities to the system administration and account management processes is processing terminated users quickly and ensuring that the revocation process immediately follows termination or any change to a user's role within the organization. A user terminated from the master database is instantly denied all access to the decentralized systems simultaneously. By reducing the number of passwords a user must keep track of, SSO also reduces password-related help-desk costs.

For years, companies have sought to implement an SSO or other reduced sign-on solution to achieve economies of scale for end users as well as system and security administrators. Early solutions involved scripting and other hokey back-end or in some cases back-door interfaces to present front-end SSO type systems to the end user. The back-end processes then communicated with each system, sending cleartext passwords around the network from system to system. Highly vulnerable to man-in-the-middle attacks and password sniffing or even unintentional password compromise, these early systems introduced more risk than they tried to mitigate. The initial premise was that, as users were required to remember and manage a greater number of user IDs and passwords, the integrity of these user IDs and passwords would be lost over time, threatening the overall security and integrity of the system. In the early phases of SSO, passwords were the only real solid authentication technology that was technically stable and cost effective to implement, but compromises to a single password or even the entire password file in vulnerable pieced-together SSO systems introduced a vulnerability into an organization and its supporting IT infrastructure that most organizations were not willing to accept.

In an SSO environment, users only need to authenticate themselves once, after which they can directly access any application on the network for which they have permission. This eliminates the annoying stop-and-go user experience that results from multiple log-ins. Best of all, users no longer need to keep track of multiple passwords. Even in environments that continue to rely on a single password for authentication, SSO makes it much easier for users to follow secure practices. For example, with only one password to remember, it is more reasonable for a company to require users to employ strong passwords (ones that contain multiple nonalphabetical characters) and expect that they will not write them down.

66.15 Federated Identity Management

To do business in an online world electronically or further to exploit the productivity and financial gains associated with doing business on the Web with customer-facing portals and online transaction systems, an organization must be able to quickly grant access and the process must be as transparent and as easy as possible. Access should further be self-service, and user IDs, passwords, and other access rights must be easily managed internally and externally. External access typically comes from nonemployees, such as customers, vendors, contractors, business partners, or suppliers. Organizations are challenged to maintain the security and integrity of their internal systems, while enabling external applications access into their internal trusted network. The challenge then becomes one of how an organization can authenticate users outside their own domain and across business boundaries to another organization. In order to capitalize on the business potential afforded by doing business across boundaries, organizations must be able to trust the electronic identities that access their Web-based applications across the Internet.

In business partnerships, applications may be shared across organizations that are in no other way connected, such as in the case of supplier networks for government contractors. Users must be able to navigate and move easily from application to application across domains. One way to do this is through federated identity management, which allows sharing trusted identities across the boundaries of the corporate network—with business partners, autonomous business units, and remote offices. Another example of a federated identity solution is a sales application that enables external users to log-in from an external-facing portal and easily navigate and click on links that lead to new product information at another hosted site or partner site without having to reauthenticate. In this scenario, business partners must be able to trust the identity of an externally hosted federated identity management provider.

An accepted definition of federated identity is "the agreements, standards, and technologies that make identity and entitlements portable across autonomous domains." Federated identity is analogous to a driver's license, where one state provides individuals with a credential that is trusted and accepted as proof of identity by other states. In the online world, this trust is established through a combination of two technologies that prove identity—strong authentication and access management—and the business and legal agreements that enterprises enter into to establish mutual responsibility and commitment concerning the sharing of trusted identities. The end result is that users can benefit from secure SSO access to multiple Web and non-Web applications and network resources, both internal and external to their own organization.

Federated environments facilitate secure collaborations across external networks among business partners, thus enhancing productivity and facilitating partnerships and agreements that otherwise could not happen in a closed networking environment or outside of established trust mechanisms. The federated identity provides and passes on details about the user, such as job title, company affiliation, and level of purchasing authority. These "attributes" travel with a user's identity and can be selectively exposed based on the user's preferences and the needs of participating organizations. The challenge for a federated identity is to provide access while simultaneously protecting the privacy of the user. Because these identities are authenticated across and among external "domains of trust," business partners are assured that their enterprise resources are protected from unauthorized users. The benefits to users include increased convenience and productivity, broader access to information and services, and control over what personal information is shared and with whom.

66.16 Authorization

Following a successful implementation of IM including authentication, password management, password management self-service, and workflow, organizations will want to move into centralized or decentralized authorization and access control, or role-based access control (RBAC). This function is supported by product suites providing identity and access management. The functionality builds from the central baseline module core to most products and utilizes the central database and interfaces to central directory services such as LDAP or Microsoft Active Directory (AD), with real-time interfaces to human resources (HR) systems for implementing new access, managing access requirements change (organizational changes), and, most importantly, immediate revocation when users are terminated.

Authorization is based on the need to know or minimal access based on the user's role within the organization. It enables synchronization across the enterprise and the storing of not just a user's identity within a central data store but also the assignment of a role or a group within the organization, granting access to information, transactions, privileges, and capabilities across the enterprise. This is particularly important with regard to the instant removal of perimeter access and managing employee terminations, contractors, and disgruntled employees. Supporting processes must be automated to the extent possible and integrated with other HR, IT, and business processes, manual and electronic. It is also important to implement checks and balances in the form of reports and cross-checking. Solutions should be centrally managed and decentralized to accommodate local area networks (LANs) and distributed one-off applications.

66.17 Laws and Regulations

Faced with a long and growing list of regulations affecting IT security, most organizations currently rank compliance among their top concerns. In a recent survey of 250 security executives—conducted for RSA by an independent firm—a large percentage of respondents said regulatory compliance had a greater impact on their company's awareness of security issues than actual security threats such as viruses, hacking, and identity theft. The new legislation and regulations hold organizations accountable for protecting the confidentiality and privacy of personal information entrusted to them by customers and business partners. Other measures require companies to document financial decisions and transactions, including who took part in related online activities. Still other directives govern the use of digital signatures as valid and binding substitutes for handwritten signatures, thereby eliminating paperwork and maintaining end-to-end electronic processes. More laws and regulations are being passed all the time, and the existing ones continue to evolve. Legal experts predict another decade of expanding, evolving, and fine-tuning of laws and regulations regarding the protection of information, customer and personal privacy, and accounting and financial practices, as well as other requirements for information security, protection, and privacy. While most laws do not specify the technologies that should be used to achieve compliance—preferring instead that organizations identify and adopt best practices themselves—it is becoming increasingly clear that IM/IAM solutions provide a strong foundation for supporting compliance goals.

The primary applicable laws and regulations driving the need for IM are discussed later in this chapter. These laws and regulations are forcing companies to invest heavily in information security and privacy solutions, particularly IM and IAM. Below are some definitions of the common legislation and regulation referenced in this chapter.

- *Health Insurance Portability and Accountability Act* (*HIPAA*)—This broad legislation establishes privacy and security standards designed to protect patient identities and sensitive health and treatment information.
- *Gramm-Leach-Bliley*—This legislation applies to financial services firms operating in the United States and is designed to protect consumers' financial information from unauthorized access.
- *Sarbanes–Oxley Act* (*SOX*)—This legislation applies to all public companies in the United States; the Act sets forth auditing standards designed to ensure the integrity of the IT systems of publicly traded companies.
- *U.S. Patriot Act Customer Identification Program*—This program requires financial services firms operating in the United States to obtain, verify, and record information that identifies each individual or entity opening an account.

As a general guidance, security organizations should meet compliance needs by first documenting their security processes and controls using the ISO 17799 standard to baseline security best practices. Then, they must invest in four critical activities that align enterprise security needs and regulatory requirements:

- Enhance segregation of duties with identity and access management (IAM).
- Improve configuration and change management of regulated systems using security and configuration management tools.
- Increase activity auditing on key databases and applications, especially related to user access.
- Improve data security for personal information through encryption and content monitoring and filtering.

66.18 Avoid Regulatory Distraction

Regulatory compliance is mandatory, but companies should not allow it to derail their core security programs. Most organizations are using regulatory pressure to fund needed security projects and integrate security more tightly with business units. It is the excuse security professionals have been waiting for to force business integration. However, some organizations are distracted by reporting, ongoing audits, and putting out the fires of remediation. It is important for these companies to focus on *getting* secure first, then worry about *showing* that the organization is secure. Protect customer data and then document it. Most of the current regulatory burden is the result of increased reporting requirements and audit activities, particularly due to Sarbanes–Oxley, Section 404, and its extensive documentation and audits. In the case of a control deficiency, the company's CEO will not go to jail under Sarbanes–Oxley unless he or she perpetuated fraud by trying to cover up the problem.

Compliance changes priorities, but it should not reduce security. Security departments need to manage compliance reporting and remediation without losing focus on top security concerns. Not all auditors are experienced in IT and may make unreasonable requests, which should be discussed with their management. Company management should be notified when generating compliance reports interferes with core security operations and could hurt the business. Not every enterprise should implement all facets of a complete IM solution, such as self-service password reset, user provisioning, extranet access management, single sign-on, directory consolidation, and role management. The IM project team should be armed with the necessary facts by gathering the metrics that justify investment in and phasing implementation of the project.

Compliance with enterprise policies, as well as with regulations such as the Gramm-Leach-Bliley Financial Services Modernization Act of 1999, the U.S. Health Insurance Portability and Accountability Act (HIPAA), and the U.S. Public Company Accounting Reform and Investor Protection Act of 2002 (Sarbanes–Oxley), is bringing identity management practices to the forefront of many enterprises' information security agendas. Privacy enforcement, separation of duties, and need-to-know access policies are at the center of these regulations, although these are access-control best practices and are not considered to be new requirements for a mature information security program.

Another information security program best practice is to have a security administration review process that requires the production access-control infrastructure be reviewed quarterly, semiannually, or annually; therefore, companies should review their access-control policies to ensure that they have the appropriate policies (for example, users must be uniquely identified to enterprise IT resources) and to determine the values (such as 30, 90, or 180 days) for policy compliance metrics (for example, passwords that allow access to confidential information or applications that can affect the financial position of the enterprise must be changed every 30 days).

66.19 Privacy and Fraud

To add further complexity, the more extensive capture and use of identity information required for electronic authentication also raises customer privacy concerns. Gartner believes that new customer authentication requirements will continue to generate federal laws and regulations regarding new unanticipated risks for businesses. These risks include not only direct hits to an enterprise's bottom line, if the enterprise miscalculates the appropriate level of authentication required for new applications, but also a legal liability if certain customer identity information has not been adequately protected or if its use has not been authorized. Perhaps the biggest obstacles for enterprises are those that are most difficult to quantify: winning the confidence of customers so they share their identity information and engage in the significant types of transactions that harness the potential of E-business and make the online experience convenient enough to keep customers coming back.

Consumer mistrust contributes to the ongoing pursuit of IM solutions and infrastructures for organizations. While the growth tends to be slow and cautious, it continues to gain momentum throughout the industry. The technology is complex in that it must operate across large complex heterogeneous domains, but the implementation itself is also complex, for many reasons. Organizations typically fight against centralized corporate control. Separate business units within an entity or even further distributed administrative groups serving up a small application will not be able to establish an ROI for joining the enterprisewide IM infrastructure.

Many organizations have established either a wait-and-see attitude or a proceed slowly approach to IM/IAM. Using IM for compliance to laws and regulations can establish consumer confidence and serve as a marketing and sales benefit for enterprises that are early adopters or who have automated the tools necessary for a successful IM implementation. Everyone today is aware of ongoing media accounts of the loss of personal information that was in the hands of trusted business partners or even employees. The issue of identity and privacy theft will continue to be core to decisions regarding investments and moving to E-business and IM/IAM.

In response to the growing online world, IM/IAM solutions must address the misuse of online identities to commit crimes. Weak and penetrable passwords offer the greatest risk for intrusion by impersonating legitimate users for the purpose of committing online crimes. Identity theft of information stored on corporate servers is a second area of vulnerability. Compromised confidential identity information has the potential to greatly harm an organization's financial solvency, as well as its branding. Information in this category includes Social Security numbers, birth dates, credit card numbers, etc. The individual whose identity has been compromised may suffer financial losses, ruined credit, loss of professional reputation, or even arrest and conviction for crimes someone else has committed. For an enterprise, the direct and indirect costs of such security breaches may include exposure of high-value information and trade secrets, disruption of mission-critical business processes, adverse publicity, and the loss of customer and investor confidence.

66.20 The Concept and Value of Trust Relationships

Enterprises must define customer identity protection standards, including how initial customer registration, verification, and enrollment should be conducted and how identity queries and issues should be handled. While password reset and identity verification are standard features of call center and contact center services, enterprises will need to reevaluate or include new customer identity management and protection procedures and training as new transactional capabilities and channels are introduced. Customer authentication and the collection, use, and access to customer identity information often occur outside the enterprise. Enterprises must ensure consistent authentication and customer identity protection standards for business affiliates that are responsible for part of the customer engagement or fulfillment process, as well as for other business partners and service providers. Enterprises should develop contracts that stipulate:

- How authentication technologies and supporting processes should be implemented and maintained
- How employees should or should not access applications and systems that contain customer identity information
- How identity information can be used or disclosed
- Noncompliance penalties

Contractual agreements that create obligations for the confidentiality and protection of customer information with business partners and service providers are required under recent privacy legislation, such as the Financial Modernization Act or HIPAA. Chains of trust can be created by ensuring that business partners and service providers adhere to authentication standards and the confidentiality of customer information via contracts. The integrity of the ongoing process with regard to other legislation and regulations, such as Sarbanes–Oxley, should be maintained by requiring business partners to provide SAS70 audit reports, at a minimum, annually.

66.21 ISO 17799 as a Baseline

For information security, ISO 17799 is a recognized global standard for best practices. Although it is not perfect, it is an excellent tool for benchmarking security programs and evaluating them over time for regulatory compliance. It is not possible to officially certify against the current ISO 17799 type 1; however, any reputable security consultant or auditor can measure a company's level of compliance and provide an official report. Type 2 provides certification but has not received final approval. Using ISO 17799 for internal self-audits allows a company to justify its choice of security policies to external auditors. Organizations with an effective security program should already be compliant with most, if not all, of ISO 17799. In some cases, they may have alternative security controls not included in the standard that provide equal or greater security. This is a good thing but nevertheless should be documented. Following security best practices and documenting and testing using ISO 17799 will allow a company to meet the majority of regulatory requirements for information security. IM/IAM covers many technologies related to user management, but two categories are most useful for compliance: User provisioning is used to document who has access to which systems and in what roles. Application-specific, role-based access control tools integrate with major applications such as SAP and dramatically enhance role analysis and access control enforcement. Although other areas of IM/IAM are useful and enhance information security, these two categories provide the most immediate compliance benefits while forming a foundation for future compliance needs. They help document rights with regard to systems which is useful for generating compliance reports and identifying segregation of duties. They can build audit logs of accesses and privilege changes, identify and disable inactive accounts, and adjust privileges and access as employees change job roles.

66.22 Audits and Monitoring

While audits and monitoring are not recognized and advertised features of IM/IAM systems, the process certainly adds intrinsic value to security and compliance projects. Most laws and regulations require volumes of audit logs. This is a challenge for all organizations. It has been recognized and acknowledged for decades that process integrity can be demonstrated through the process of auditing and logging. Audits of security, administration, and system management functions will keenly scrutinize their audit and monitoring processes. Because the audit and monitoring process is fairly common to all security policies and programs; technologists, vendors, standards bodies, etc. have been working on this common challenge for some time. Many products and technologies are evolving for compliance and for good security practices.

Because the IM/IAM project provides a centralized authoritative source for the granting of access and privileges, it is a perfect place to audit the overall process. It is not enough to just collect the logs; companies actually have to do something with them. They need to develop and document supporting processes and, for today's emerging and evolving laws and regulations, must consider separation and segregation of duties; for example, your security administrator who is adding and managing accounts and user IDs should not be the one to audit reports of that process. Companies must also archive the logs and establish, document, and test a process for retrieval. This is particularly important for forensics and litigation purposes. Legal departments across industries are pondering this issue long and hard. What are the required retention periods for Sarbanes–Oxley? How about HIPAA? What about, in general, for compliance to internal security policies? What do the customers require? What is a company contractually obligated to do? What do the company's business partners require? What are the company's outsourcing partners obligated to provide? And the list of such questions continues.

With new audit and logging requirements as the driver, it is no surprise that new products are emerging to help address the problem. Middleware products are available that integrate with storage technology to actually ensure that a user can find the proverbial needle-in-the-haystack e-mail message for discovery and litigation.

66.23 Conclusion

Significant potential gains from implementing an enterprisewide centralized and decentralized IM/IAM project can be expected. Many of the benefits are directly related to cost savings and process improvements.

An additional benefit of an IM/IAM implementation is the compliance gains achieved from an enterprise IM/IAM that is already compliant with ISO 17799, HIPAA, or Sarbanes–Oxley, for example. Each successive application or project does not have to solve this problem time and again. A challenge is to ensure that the IM/IAM implementation remains compliant over time. Of course, a company's trusty auditors can help with that problem.

67

Blended Threat Analysis: Passwords and Policy

Daniel D. Houser

67.1 Executive Summary

Although many organizations have aggressive password controls in place, adopting the most restrictive and "secure" password policy does not always serve the needs of the business. In fact, excessive password policies can cause unintended business and security problems. This chapter focuses on the blended threat of password attacks, documents the approach taken by this project, and the specific password policy modeling, research, and analysis performed to determine an optimum password policy. Additionally, analysis of password and authentication attacks is detailed, with compensating controls. Appropriate compensating controls are recommended for increasing password and access control strength, focusing on high-impact, low-cost measures.

67.2 Overview

The purpose of this chapter is to provide research and analysis of password attacks and the estimated effect of predicted changes to password composition. This analysis includes both password policy controls, which directly affect the strength of the password (e.g., password length, history, and age), and external controls, which indirectly affect the strength of the password (e.g., user awareness training, encryption, screen savers). This chapter details the approach, analysis, findings, and recommendations for specific tactical and strategic changes to internal and external password policy.

67.3 Objectives

Given a Model architecture and policy as a baseline,

1. Determine if there is a "best" password policy that provides a balanced position to avoid the most severe and likely password attacks. If so, what might this be?
2. Determine the most likely password attacks, and those with the greatest impact. Provide a weighted risk value of comparative password components to reflect both likelihood and impact.
3. Given the weighted, ranked list of password attacks, determine the most effective security controls (external to password policy) to reduce the effectiveness, likelihood, or impact of these attacks.
4. Provide a recommendation for password policy and security controls to negate likely password and authentication attacks.

67.4 Scope

The scope of this chapter includes the analysis of password components and likely attacks against passwords and password repositories. Specifically out of scope is any empirical research in a live environment, such as analysis of existing passwords, password cracking exercises, or audits of specific controls. Although very useful, this was not included in the first round of this research. See the section entitled "Further Studies" for details on the next phases of this study, and what specific issues are to be studied.

67.5 History

> …the design of the [password selection] advice given to users, and of the system-level enforcement which may complement this, are important problems which involve subtle questions of applied psychology to which the answers are not obvious.
>
> **Yan et al. 2000, p. 2**

Strong passwords have evolved over the past 40 years as security officers and system administrators have sought to control the single greatest component of systems security that is entirely in the users' hands to protect. Controls have been added to best practice over time, until we have achieved quite a large grouping of controls for a single security component, perhaps more than any other discrete security component in most systems. These controls include such measures as:

- Expiring passwords
- Password complexity
- Increased password length
- Randomly generated passwords
- Password history
- Minimum password age
- Password storage encryption
- Password transmission encryption

- Password hashing
- Password hashing with salt
- Shadow password files
- Challenge-response systems
- Event-driven password changes
- Regular password audits
- User password training
- "Moonlight mouse-pad" audits
- Ctrl-Alt-Delete password interface
- Interface password masking
- Multi-factor authentication
- Failed log-in account lockout
- Rigorous authentication logging
- Password expiry reminders
- Pronounceable random passwords
- Single Sign-on

As could be predicted when dealing with a human-based system, introducing many of these controls produced unintended consequences in user behavior, resulting in further controls being added to resolve the unintended behavior. Forcing regular password changes induced users to reuse passwords, so password history was added as an additional control. However, adding password history begets password minimum age, as a short password history caused users seeking the path of least resistance to recycle passwords quickly and arrive again at their favorite password. Human nature being what it is, humans in our systems will react to security controls with a mixture of stubbornness, defiance, compliance, and altruism, and this is certainly true of password controls.

While over time more password controls have been added to counter undesirable user behavior, Moore's law and publicly available cryptography have made serious inroads against password files, to the point that most typical user password files can be "cracked" in one to three days. However, discussions of password cracking are pure and clean mathematics, and straightforward compared with the intricacies of human psychology.

It is no longer sufficient to keep piling on additional password controls, as the Law of Diminishing Returns has started to cause password controls to reach a saturation point (see Exhibit 67.1). Once 15–20 password controls are in place, adding further controls may frustrate users into bypassing controls (e.g., writing down their passwords), thus decreasing the overall security of the system instead of increasing it. The need to achieve balance in password policy was the spark that initiated this study.

67.6 Analysis Approach

The analysis for this project proceeds from the assertion, supported by the information security body of knowledge, that the "best" security controls are not those that are most successful against a single specific attack, but those controls that are most effective in concert against both the most likely and devastating attacks. Thus, the most effective password policy is not the one that is most resistant to cracking, or the one most resistant to guessing, or the best defense against user disclosure. Rather, the most effective password policy is the one that provides a balanced approach to defeat the most likely password attacks and most devastating attacks. If one chooses to ignore this blended approach, and to create password controls that are extremely resistant to password cracking, then one ignores the significant role that human beings play in password security. However, one cannot ignore the threat of cracking attacks on

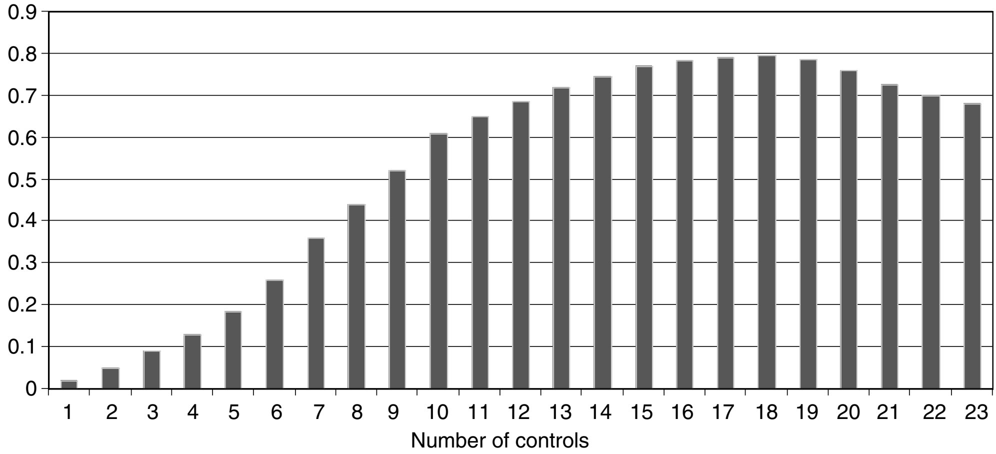

EXHIBIT 67.1 Effectiveness of password controls.

passwords by solely focusing on controls that minimize disclosure. Thus, the goal of the analysis is to estimate the blended effectiveness of security controls against a blended range of attacks.

The modeling used relies on a combination of a methodology for effective estimation, using Bayesian modeling as well as the overlapping compensating control methodology espoused by information security guru Peter Tippett, Ph.D., CTO and founder of TruSecure. Additionally, Bruce Schneier's Attack Tree modeling was used to determine the likelihood of specific attacks against passwords.

Password and behavioral research was consulted, along with the consensus opinion of several credentialed information security professionals. Where research data and empirical evidence were not available, groups of credentialed information security engineers and analysts were convened (90 percent holding CISSP credentials). Extensive Bayesian modeling and Attack Tree modeling were performed and reviewed with these groups to drive out estimations of discrete attacks and control effectiveness.

Because much of the modeling involved base assumptions of probability and uncertainty, the results are not based on statistical information. Rather, a base security stance is presumed, which represents the likelihood of a specific attack against a system as 10 percent likely. Given this likelihood, specific password controls are added or subtracted, and their *relative* protection is estimated using mathematical modeling.

To provide an example of this analysis, presume that the likelihood of a given house being robbed is 10 percent per year, and steel doors are added to the house. The doors are judged to be 90 percent effective against burglars. One could reasonably state that the addition of the doors has reduced the risk of robbery by approximately 90 percent, and the likelihood of the house being robbed in any given year is now roughly 10 percent × 10 percent = 1 percent. Although the original 10 percent may not be a true and accurate representation, the important component of the analysis is the *relative* reduction in risk (90 percent reduction), and not the ability to state an absolute (1 percent). Even if the original number is off by a factor of 10, the compensating control (steel doors) could still be stated as approximately 90 percent effective. Further, if three more security measures are added to the house, which are each 50 percent effective, the likelihood of attack is now reduced to approximately (1 percent × 50 percent × 50 percent × 50 percent) = 0.125 percent. Although the assessment of the relative strength is by no means an exact science, overall the analysis should provide reasonable assurance of the effectiveness of security controls applied in isolation or in concert.

67.6.1 Numerical Precision

Finally, a necessary word on the numerical precision expressed in this report. Without this explanation, the numbers will infuriate, frustrate, and challenge those of us who enjoy a numerical-based world.

One of the challenges in achieving a balanced estimation of effective password policy is resolving the tremendous difference in scales when comparing extremely unlikely events with likely events. We are conditioned as information security professionals to express risk in terms of "high," "medium," and "low" risk. Password disclosure is nearly certain, and password cracking is very unlikely. There might be a tendency to call one highly likely, and the other highly unlikely. Unfortunately, terms such as "highly likely" and "highly unlikely" do not capture the relative difference in the two ends of the scale that encompasses several orders of magnitude. As an example, consider the scale of hot to cold that TV news meteorologists use to describe weather patterns. Although "hot" and "cold" can accurately describe March weather in Miami and Thunder Bay, the temperature of the surface of the sun cannot be legitimately expressed on the same scale with such a crude measurement as "very hot" because the scale does not begin to describe the magnitude of the value. The same is true of security vulnerabilities and exploits with a blended threat. Some events are likely; some are relatively unlikely; and some are really, really darn unlikely, which starts to twist language to the point of obscurity when attempting to convey 50 percent and 0.00005 percent in a coarse-grained scale.

To convert between the three very disparate scales of probability, mathematical representations of likelihood are used and calculated, resulting in numbers that can appear to have a great deal of precision, when in fact they do not. This is an unfortunate, but necessary, side effect of comparing between very different scales. Although the analysis does not provide accuracy to a stated level of numerical precision, it is still important to note the relative likelihood on the different scales, to keep perspective. Otherwise, if using a five-point scale or intangible values such as "high, medium, low," the results would be entirely skewed, making a highly unlikely event (0.001 percent) appear to occur with the same frequency as an unlikely event (20 percent). For this perceived numerical madness, the author apologizes to mathematicians and statisticians everywhere, but forges ahead because he finds it useful to have granular measurements.

67.7 Model Architecture

An analysis relying on relative security controls is meaningless without a reference point, so a Model architecture was established, based on a synthesis of best practice password policies for a "strong password." This synthesis of policy was established from large U.S. banking, finance, healthcare, and manufacturing corporations, and higher education. As Microsoft Windows is the dominant corporate desktop environment, a corporate "strong password" policy will likely be enforced through Microsoft's Active Directory strong password enforcement (PASSFILT.DLL), so this played heavily in the establishment of the model policy.

This model policy provides for:

- Passwords must be a minimum of eight characters (Microsoft PASSFILT requires six characters).
- Passwords must be changed every 60 days.
- Passwords cannot be based on dictionary words.
- Passwords must be comprised of sufficient complexity, such that three of the following four are used:
  - Lower-case alphabet: a, b, c, …, y, z
  - Upper-case alphabet: A, B, C, …, Y, Z
  - Numerals: 0, 1, 2, …, 8, 9
  - Special characters: !, @, #, $, _, *, \
- Passwords cannot contain the username or any part of the full name for the associated account.
- Password history of 15 is enforced.
- Passwords must be kept for a minimum of one day.
- Passwords must be encrypted in storage and transit.

- Passwords must be hashed, never employing reversible encryption.
- Passwords must not be written down or shared.
- Passwords are disabled for an hour after the fifth incorrect log-in attempt.

67.8 Findings

67.8.1 Methodology

Initial analysis was performed using Bayesian mathematical modeling for three basic types of attacks: (1) password cracking, (2) password guessing, and (3) password disclosure. In this initial Bayesian analysis, only inner-password controls are presumed; that is, those controls that are inherent in the composition and governance of the password itself—length, composition, age, history. The effectiveness of extra password controls (e.g., hashing, shadow files, protection from Trojans, protocol analyzers, and keyboard loggers) is addressed later.

Password cracking would include cryptographic and brute-force attacks against password files, applying massive amounts of computing power to overwhelm the cryptographic protection of the passwords, typically in a remote or offline mode. *Password guessing* would include users attempting to guess the passwords to specific accounts, based on analysis and conjecture, and would typically be conducted through the password interface in an online mode. *Password disclosure* would include users sharing password credentials, or writing down passwords such that they are discoverable by an attacker.

For all password composition analysis (cracking, guessing, and disclosure), the same values were used for the password policy changes. Baselines were established for each environment, and the methodology described above was implemented. For this analysis, the "baseline" does not refer to the model policy provided above. The "baseline" is used in this portion of the analysis to indicate a password policy against which an attack would be 100 percent effective, to rate relative effectiveness of inner-password controls.

A simple table (see Exhibit 67.2) was established to categorize password controls, and should be referred to for the remainder of the Bayesian analysis. When the analysis refers to a password of medium age and medium length, it indicates that the password cannot be older than 60 days, with a minimum length of eight characters.

67.8.2 Password Cracking

Mathematical modeling was used for this analysis, based on input from nine senior information security engineers (CISSPs) who arrived at agreed effectiveness of password controls to thwart cracking. The assumption was that these would have all controls inherent in the baseline environment, and were based on the professional and considered opinion of user password behavior, keeping in mind published and well-documented user behavior with regard to passwords. This data was used to drive the model based on the combinatorial analysis established by Dr. Peter Tippett to analyze systems with overlapping and complementary security controls, described in the "Approach" section above.

EXHIBIT 67.2 Reference Policy Password Controls

	Baseline[a]	Low	Medium	High
Age	30 days	30 days	60 days	90 days
Complexity	PIN	Alpha only	Alphanumeric	3 of 4 (alpha, mixed case, numeric, special)
Length	4	6	8	12
History	None	5	10	20

[a] The Baseline was established as a presumed attack that is 100 percent effective, and is used as the relative scoring offset for the rest of the values.

EXHIBIT 67.3 Effectiveness of Password Controls against Cracking Attacks

	Baseline[a]	Low	Medium	High
Age	Age is agreed to be irrelevant for preventing password cracking because most passwords can be cracked in a few days			
Complexity	0	66 percent	75 percent	85 percent
Length	0	75 percent	80 percent	80 percent
History	0	10 percent	17 percent	30 percent

[a] The Baseline was established as a presumed attack that is 100 percent effective, and is used as the relative scoring offset for the rest of the values.

Exhibit 67.3 documents the aggregate considered opinion of these professionals with regard to the effectiveness of each password control (the inverse of probability of attack).

It was agreed by all assessment participants that 12-character passwords are onerous enough that it will cause user behavior to negate the effectiveness of the additional length, by selecting passwords that are largely based on dictionary words, and are thus likely to be compromised by a dictionary attack. The statistical likelihood of a straight dictionary attack succeeding is 7 percent (±3 percent) (Morris and Thompson 1979; Yan et al. 2000; Shaffer 2002).

Note that the effectiveness of the controls is measured against the baseline of 0 percent effectiveness, which is a nonexpiring four-digit PIN. While most password crackers can readily crack alphanumeric passwords, they are relatively strong compared with pure PIN passwords, although they are still expected to be compromised. Again, the important component is the *relative* effectiveness of the compensating control, and not the absolute effectiveness.

Once the effectiveness of password components against a cracking attack has been estimated, the overall *relative* effectiveness of password policy as a deterrent to password cracking can also be estimated utilizing the overlapping controls method. Thus, the estimated likelihood of any given cracking attack succeeding, based on password policy controls, is demonstrated in Exhibit 67.4.

In Exhibit 67.4, "current" denotes the Model architecture password policy. If this is your current policy, migrating to a "weaker" policy creates a significant decrease in effectiveness against password cracking attacks. Likelihood is not based on an annualized attack, but on the success of any given attack against a given password, *relative* to an attack against the baseline password of a four-digit PIN. By

EXHIBIT 67.4 Reference Policy Password Controls

Compromised	2.63%	5.16%	3.38%	4.38%	5.16%	5.63%	5.83%	6.87%	7.50%
Length	Medium								
Complexity	High			Medium			Low		
History	H	M	L	H	M	L	H	M	L
Compromised	2.10% {current}	4.13%	2.70%	3.50%	4.13%	4.50%	4.67%	5.50%	6.00%
Length	High								
Complexity	High			Medium			Low		
History	H	M	L	H	M	L	H	M	L
Compromised	2.10%	4.13%	2.70%	3.50%	4.13%	4.50%	4.67%	5.50%	6.00%

referencing Exhibit 67.4, it can be determined that, relative to "weaker" password policies, the Model architecture password policy shows one of the strongest defenses against password cracking.

It should be noted that, due to the presence of LANMAN legacy passwords on most corporate networks from legacy Windows 95 and Windows 98 machines, it was the consensus of the assessment team that nearly any Windows password file, once obtained, will unconditionally be compromised. The numbers in Exhibit 67.4 should then be considered a scenario where there are no LANMAN passwords in the environment.

67.8.3 Password Guessing

The empirical information for user behavior based on password guessing is not as clear-cut because it falls largely on user behavior. Traditional mathematical analysis of the password space (Fites and Kratz 1993, pp. 8–10; see Exhibit 67.5) falls short for our purposes, because it presumes that passwords are evenly distributed throughout the password space. However, that is true only of cryptographic systems with pseudo-random distribution. Human beings are notoriously poor at distributing passwords throughout the available password space, and tend to quite often pick common dictionary words. Analysis by a banking group in 2000 discovered that roughly 4 percent of online banking users in the study chose the *same password*, and that the top 20 passwords comprised roughly 10 percent of the entire passwords chosen. Thus, password guessers trying the most popular password (presuming they knew it) would expect to successfully compromise 40 of every 1000 accounts by simply attempting a single log-in per account.

While users traditionally select weak passwords, our Model architecture policy (see above) provides some obfuscation of the password and protection against guessing by requiring complex passwords. While a user may be known to be a die-hard Green Bay Packers fan, actually guessing his password of "#1CheeZHead" is not nearly as easy as it seems, due to all the permutations caused by capitalization, numerals, and punctuation.

To develop an analytical model in this space, the base assumption was created that users would be able to guess passwords for known persons after roughly 1000 attempts, or a 0.1 percent chance of password discovery. Referring back above to our Model architecture password policy, which permits five guesses per hour, this equates to 1920 guesses during a two-week vacation ($5 \times 24 \times 16$). A thousand guesses is not nearly as difficult a deterrent as it seems, because (on average) 500 guesses would be necessary to guess a password with a 0.1 percent chance of discovery. A persistent guesser would be expected to compromise such a password after 4.2 days. However, it is unlikely that an attacker would make such an

EXHIBIT 67.5 Mathematical Analysis of Password Composition

Fites and Kratz provide some outstanding theoretical password information in their text, on pages 6 to 7.
Given:
L = length of time a password is valid
T = time interval
G = number of guesses possible in the (T) time interval
A = number of possible characters each position in the password can contain
M = password length
P = password space

1. The password space is easily calculated as $P = M^A$.
2. The likelihood N of guessing the password is approximately $N = (L \times G)/P$.
3. The necessary password space P to ensure a certain maximum probability of guessing a password is (by solving for P) $P = (L \times G)/N$.
4. The length (M) necessary for the password is $M = (\log P)/(\log A)$.

Unfortunately, this great theoretical proof is useless as a practical exercise because it presumes that passwords are evenly distributed throughout the password space. Unfortunately, many people will pick the same dictionary password ("password"), and very few, if any, will pick the password "EMoJ@Wj0qd3)!9e120)." In fact, many password studies have shown that many users will pick the same password.

exhaustive search, and could do so while remaining unnoticed. A less risky attack would be to attempt three password guesses per hour during the workday, which would typically go undetected. Presuming this attack was made against a password with a 0.1 percent chance of discovery, this "low and slow" attack would permit an attacker to guess the password in an average of 20.8 days. Again, this would take great persistence, as well as some personal risk, because the attempt cannot be made offline.

Bayesian analysis was performed using several assumptions based on research and analysis. Guessing attempts are more likely to be sensitive to changes in password history than cracking, as users are far more likely to repeat passwords or use predictable patterns with a low history. That is, it is presumed that users are far more likely to choose passwords of Dogsled1, Dogsled2, Dogsled3, and Dogsled4 if history is only 4, while this behavior is less likely with a history of 10, 15, or 20. Because of this, low history passwords were treated as nearly trivial to guess, particularly if attackers are presumed to have some prior knowledge of the individual or an old, expired password. Due to user behavior, long passwords (e.g., 12 characters in length) were also deemed somewhat ineffective, as the use of multiple dictionary words dramatically increases at this length. However, complexity was treated as the most significant password component control, due to the relative strength of complex passwords (7TigerS!) compared with alpha passwords (tigers).

The same values for password composition were used for password guessing as password cracking (see Exhibit 67.2).

Based on the scale in Exhibit 67.2 and the analysis approach detailed above, the model detailing estimated likelihood of password guessing is provided in Exhibit 67.6.

As with previous examples, "current" in Exhibit 67.6 provides a reference value against the PASSFILT.DLL based Model architecture, showing an organization with similar policies to the Model architecture policy and how relatively effective its policy is as a deterrent to password guessing.

Examining Exhibit 67.6, presuming an attacker made an effort to guess a password, the Model architecture password policy (medium length and age, high complexity and history) affords a fairly strong level of security, presumed to be at 0.1 percent likelihood of compromise. The most effective attack would be against a password of high age and low complexity, history, and length, which is relatively 40 percent likely. The most rigorous password combination is estimated as 90 percent more effective than the Model architecture policy, at 0.01 percent likelihood of compromise from a guessing attack.

67.8.4 Password Disclosure

Password disclosure has an inverse relationship to the previous two models. Very strong password controls encourage users to write down their passwords, while lax controls that make guessing and cracking easier make disclosure relatively uncommon.

The analysis of password disclosure was significantly aided by solid research to provide guidance, as several empirical studies of user behavior have been conducted where specific tests were performed to determine user likelihood to write down passwords. Although not empirical, an additional survey conducted by Rainbow in 2003 (Armstrong et al. 2003; Fisher 2003) determined the following startling information:

- 9 percent of users always write down passwords.
- 55 percent of users write down passwords at least once.
- 45 percent of users do not write down passwords.
- 80 percent of users indicate that password complexity (mixed case, numeric, special character) encourages them to write down passwords.
- 40 percent of users admit they share accounts and passwords with others.

These numbers match closely with the information provided in empirical studies (Zviran and Haga 1993; Yan et al. 2000; Tippett 2003), which showed (on average) that users were 400 percent more likely to write down complex and random passwords than low complexity passwords that they had chosen on their

own. Published workspace "mouse-pad" audits[1] concur with this information, and typically discover 33–65 percent of user workspaces with at least one password written down (Shaffer 2002; Tippett 2003).

Because of the solid behavioral information in this area, the range of values for likelihood of disclosure was set to a minimum of 9 percent disclosure, and a maximum of 55 percent. That is, an environment with the most user-friendly password policy (e.g., no history, password expiry, length, or complexity requirement) will still incur 9 percent of users who will always write down their passwords. On the other hand, the strictest password policy will cause 55 percent of users to write down passwords, and only 45 percent of users will comply with the policy to not write down their passwords. Password complexity and age are the two most significant documented causes for disclosure of passwords, while low history is presumed to cause users to select repetitive passwords, which they would therefore be less inclined to write down. Length is also a significant modifier, but less effective a control than age and complexity. Because the Model architecture password policy is a very strict policy, it is presumed that the gap between this model policy and the most restrictive policy is 10 percent, so the Model architecture's value for compliance was arbitrarily set at 55 percent (45 percent likelihood of disclosure).

Based on published moonlight audit2 statistics and observation of user behavior, passwords written down are presumed to be discoverable, so the study presumes that users who write down their passwords will not utilize effective physical security to protect their documented passwords. This, in short, is the "Yellow Sticky" attack, looking for passwords jotted on self-adhesive tabs and stuck where "no one will find them."[2]

Because password factors do not seem to be related to the likelihood for users to share accounts, it was not factored into the disclosure scoring model. However, it will be discussed later when the weighted scoring is detailed.

The same values for password composition were used in the prior two models (see Exhibit 67.2).

Based on the scale in Exhibit 67.2 and the analysis approach detailed above, the model detailing estimated likelihood of password disclosure is detailed in Exhibit 67.7.

Based on the forecasted model, an attacker who decided to obtain passwords at a typical workstation in the Model architecture (denoted as "current" in Exhibit 67.7) would find a password 45 percent of the time.

67.8.5 Weighted Risk Analysis

To this point in the study, all probabilities have been discussed as vulnerabilities, with the presumed likelihood of attack at 100 percent. That is, the 45 percent likelihood above that an attacker would discover a password is only true if the likelihood of an attack is 100 percent. However, attacks are rarely 100 percent likely. In actuality, it is the *vulnerability* of the password that is 45 percent, and the risk to the password is significantly lower, as all passwords are not under constant attack.

The weighted risk analysis seeks to provide a blended score for each password policy position, such that all three attacks (crack, guess, and disclose) are viewed in the aggregate. To accomplish this, a base assumption was made about the likelihood of each of these attacks, which is shown in Exhibit 67.8.

These probabilities were discussed with over 30 Information Security professionals in group and individual meetings, and with several CSO and CISOs. While several professionals thought the numbers could be adjusted slightly, no one disagreed with the numbers or thought they were substantially out of line. In fact, the most consistent point of contention is that the password cracking attack might be too high, and that the password disclosure attack was too low and might be higher. It was the consensus of information security professionals polled that, by and large, the only cracking attack that occurs on the majority of secured networks in a given year are those employed by "Attack and Penetration" (A&P)

[1] A "moonlight" or "mouse-pad" audit is an after-hours audit of user workspace to make an observation of disclosed passwords in and around the user's workstation, typically looking under mouse-pads by moonlight—hence the name.

[2] I suspect this is the same dominant gene that causes people in the United States to buy key holders that look like rocks, home safes that look like cans of oil or hairspray, and swim at the beach with complete confidence that no one would suspect their wallet and keys are stashed in their shoes lying beside their beach towels.

Note: Disclosure indicates likelihood of passwords being written down. Excludes likelihood of attack.

EXHIBIT 67.8 Probability of Attack

Attack	Attacks per Year	Daily Probability
Cracking	1	0.274 percent
Guessing	3.5	0.959 percent
Disclosure	3.5	0.959 percent

teams. The perversely logical consensus was that, because cracking attacks by A&P teams are typically devastatingly effective, there cannot be too many actual cracking attacks, or the incidence of systems compromise would be significantly higher. In unsecured networks where script kiddies and hackers regularly exploit boxes, root and 0wN servers, the cracking incidence is much higher, but those poor hapless administrators probably do not read articles like this. For you, the enlightened reader, the assumption is that you care deeply about the security of your network and have controls in place to prevent and detect widespread compromises of systems. For most systems with appropriate levels of security controls in place, it was the consensus of the professionals polled that, on average, one malicious crack occurs per year, and one crack of curiosity occurs per year, without an exploit of the knowledge gained.

This author chose to leave attack incident numbers as stated above because several attacks with a similar *modus operandus* as disclosure are, in fact, the compromise of an unlocked terminal, without a disclosure of the password. Because password disclosure is also the single greatest modifier that is divergent from the Model architecture password policy, the analysts were careful to not exaggerate the likelihood of a disclosure attack and thus skew the data, choosing to err on the side of caution. The reason the cracking likelihood was not reduced is explained below.

While the likelihood of an attack has now been estimated, the impact of an attack has not, and that is where additional empirical data from research provides a helpful guide. Conventional wisdom would indicate that guessing and disclosure are far more likely to compromise unprivileged accounts, and password cracking is far more likely to compromise all accounts, including super-users (e.g., root, admin, SA). Thus, conventional wisdom would take the position that cracking would be more likely to yield catastrophic compromises by exposing extremely sensitive accounts, while guessing and disclosure typically yield end-user passwords of less consequence.

Interestingly enough, conventional wisdom does not match empirical data. Most cracking reports (including several case studies from the SANS Reading Room) detail that 99 percent of passwords were cracked, except for the supervisor/root/admin passwords, which were set to very strong passwords that would have taken longer than the password reset age to crack. This concurs with several engagements the author has had in other organizations where password testing using cracking tools was performed. Because the systems administrator knew that life would be hell if someone compromised his account, his password was more likely to be incredibly tough to crack, and impossible to guess. “But wait!” you cry; it is common for A&P activities to find a few easily cracked super-user passwords that show up on some hosts. These compromised administrator passwords are also typically ones where the super-user’s ID matches the password, or is some trivial or default password. However, this does not reinforce conventional wisdom, as these passwords are also trivial to guess. Administrators have also been known to share passwords or assign domain administrator privileges to groups for unauthorized reasons, which equate to disclosing an administrative password. On the whole, empirical data would support the position that cracking yields a rich bounty of user accounts, but is no more likely to expose super-user credentials than password guessing or disclosure.

Bowing to the fact that root passwords can be cracked, and may cause a significant compromise, this author has left the probability of a cracking attack artificially higher than actually anticipated, to create a weighting multiplier for successful cracking that may disclose a root or super-user password.

Using the classic model of (Risk = Incidence × Vulnerability), the weighted score is expressed as the sum of the risk of all attacks. For each cell of the model, corresponding to each password policy position, the risk is then estimated as:

$$(\mathrm{CV} \times \mathrm{CL}) + (\mathrm{GV} \times \mathrm{GL}) + (\mathrm{DV} \times \mathrm{DL})$$

where:

CV = cracking vulnerability
CL = cracking likelihood
GV = guessing vulnerability
GL = guessing likelihood
DV = disclosure vulnerability
DL = disclosure likelihood

This weighted score yields the data in Exhibit 67.9.

As with previous figures, the "current" label in Exhibit 67.9 (0.44 percent) shows the reference point provided by the Model architecture largely based on PASSFILT.DLL. The data in Exhibit 67.9 should in no way be used to determine actual likelihood of password compromise, because the methodology is only concerned with the *relative* risk of password controls, and not absolute statements of likelihood. Quite frankly, one's mileage may vary, and one is encouraged to plug in one's own numbers into the formulas to determine modifiers for one's environment, policy, and unique circumstances.

Using the relative comparison in Exhibit 67.9, the results of this analysis would seem to show several interesting points, including:

- The Model architecture password policy, although stated as a "strong" policy, is only 17 percent better than the *weakest* possible password policy in this model, largely due to the tendency for a strict password policy to drive users to disclose their passwords.
- The "best" security policy is one that has the following composition:
  — A six-character alphabetic password with low history and a 30-day expiry.
- The "best" policy would provide a 61 percent improvement over the Model architecture "Strong Password" policy.

However, the author and consulted analysts cannot, in good conscience, recommend a password policy with such a low password history, and therefore recommend a password policy comprised of the following:

$$\text{An eight} - \text{character alphabetic password with } 30 - \text{day or } 60 - \text{day expiry,}$$
$$\text{and a strong password history } (20+)$$

This recommendation provides an estimated 30 percent improvement over current password policy by reducing the likelihood of users writing down passwords, while blocking the user tendency to recycle passwords due to low history. Moving from a six-character password to eight characters makes password cracking using LANMAN hashes slightly more difficult than a six-character password.

67.8.6 Password Attack Tree Analysis

While the analysis of cracking, guessing, and disclosure concerned password policy controls, the second phase of analysis concerns the likelihood of specific attacks against passwords that utilize external controls to mitigate the risk of compromise. To conduct this analysis, Bruce Schneier's landmark Attack Trees methodology was utilized to estimate the most likely attacks on passwords within the Model architecture environment. For a brief and entertaining overview of Attack Trees, the reader is encouraged to view Dr. Schneier's presentation online, at http://www.schneier.com/paper-attacktrees-ddj-ft.html.

History	H	M	L	H	M	L	H	M	L	H	M	L	H	M	L	H	M	L	H	M	L	H	M	L	H	M	L
Compromised	0.29	0.31	0.31	0.41	0.44	0.41	0.36	0.43	0.49	0.38	0.37	0.26	0.41	0.39	0.32	0.34	0.36	0.40	0.45	0.45	0.30	0.44	0.46	0.31	0.29	0.32	0.32

The initial approach was to determine all viable attack vectors against passwords and, to a larger extent, authenticated sessions. From an initial list of 88 attacks, several were combined into nearly identical attack vectors, yielding 70 unique attacks that were enumerated. These were then classified into two major categories: (1) attacks that yield cleartext passwords (or bypass authentication altogether), and (2) attacks that yield a password component that must be cracked, reverse-engineered, or otherwise requires significant analysis to yield a cleartext password.

Once attacks were detailed, four attack factors were determined for each attack: (1) sophistication of the attack, (2) cost to the attacker, (3) likelihood of the attack, and (4) impact of the attack. The attack factors are detailed in Exhibit 67.10.[3]

Upon first glance, some of the factors appear redundant, because it appears that the following relationship is true:

$$\frac{\text{Cost}}{\text{Sophistication}} \approx \frac{1}{\text{Likelihood}}$$

However, the relationship is not direct as expressed. For example, an attack against an unlocked workstation is both low cost and low sophistication, and a medium likelihood. By the same token, force (such as extortion) is also low cost and low sophistication, but an unlikely attack, at least in the United States. The complete Attack Trees can be found in Exhibit 67.10.

After all attack factors were calculated, compared, and analyzed, a score was generated to capture both the likelihood and impact of the attack. The scoring algorithm is detailed at the bottom of Exhibit 67.11. This provides a score that addresses both the likelihood and the impact, to provide a blended analysis of the attack risk.

As a result of the Attack Tree analysis, the following were determined to be the 12 most likely, high-risk attacks, in order:

1. Social engineering
2. Unlocked host screen
3. Host password file tamper/replace
4. Administrator collusion
5. Administrator bribe/extortion
6. Host malware/virus
7. Unlocked client screen
8. Spoofed password reset
9. Client shoulder surf/password disclosure
10. Force
11. Copying host password file (ciphertext acquisition)
12. Host session hijacking

In Exhibit 67.12, specific compensating controls are detailed for these high-risk attacks, focusing on those controls that provide the best return on investment (ROI) in risk mitigation; that is, those that provided the most significant risk mitigation for estimated implementation cost. The intent of Exhibit 67.12 is to convey the most likely compensating controls for each of the top 12 password and authentication risks identified.

[3] The attack factors are referenced to typical environments in the United States at the time of publication, and are not necessarily applicable in all regions for all times. For example, high crime rates and political unrest will significantly increase the likelihood of kidnapping, extortion, and other physical attacks as means for obtaining administrative passwords.

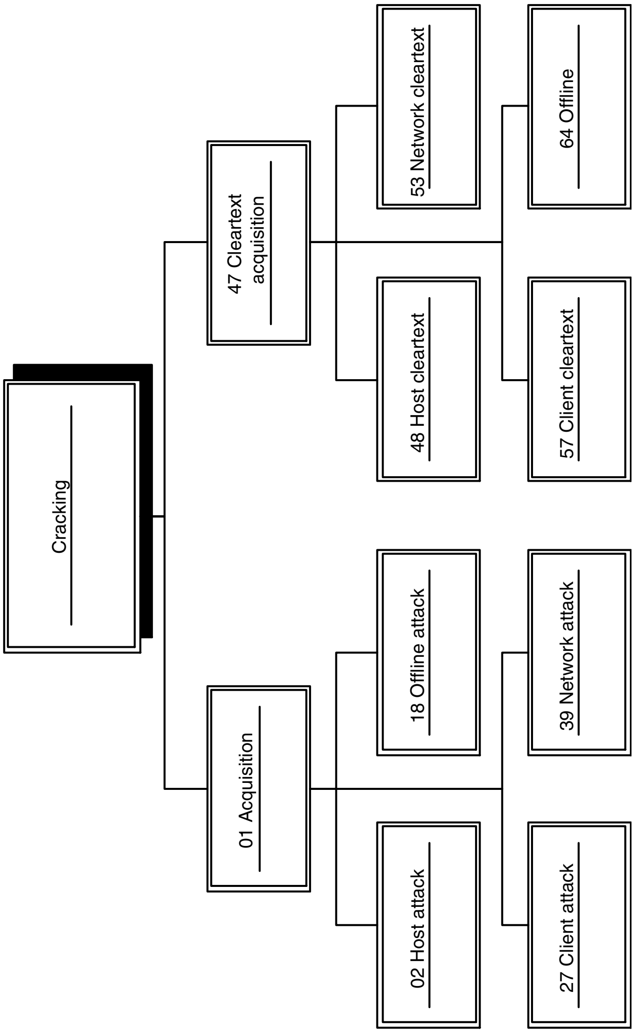

EXHIBIT 67.10 Attack trees.

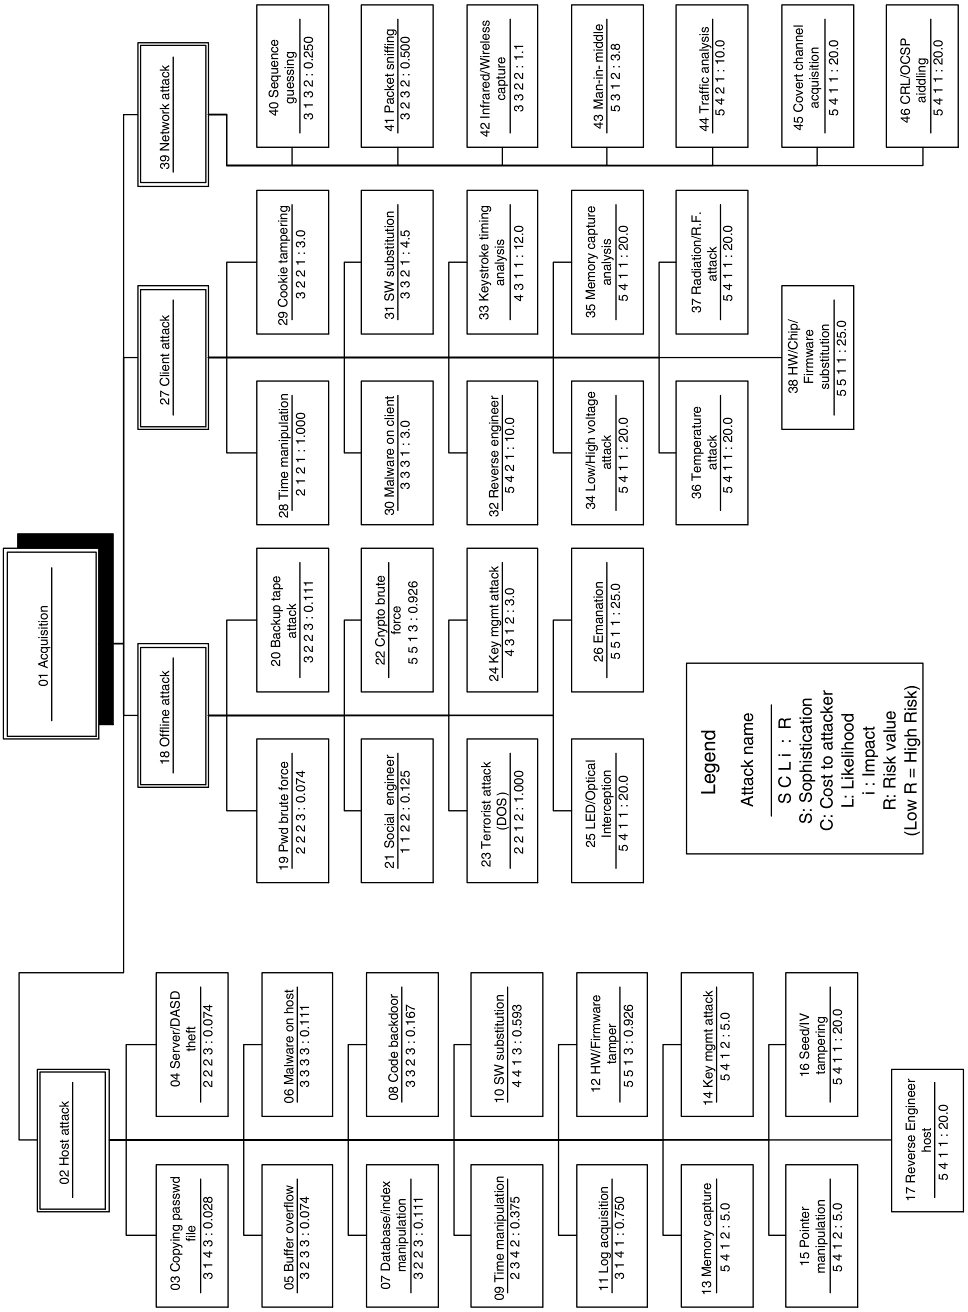

EXHIBIT 67.10 (continued)

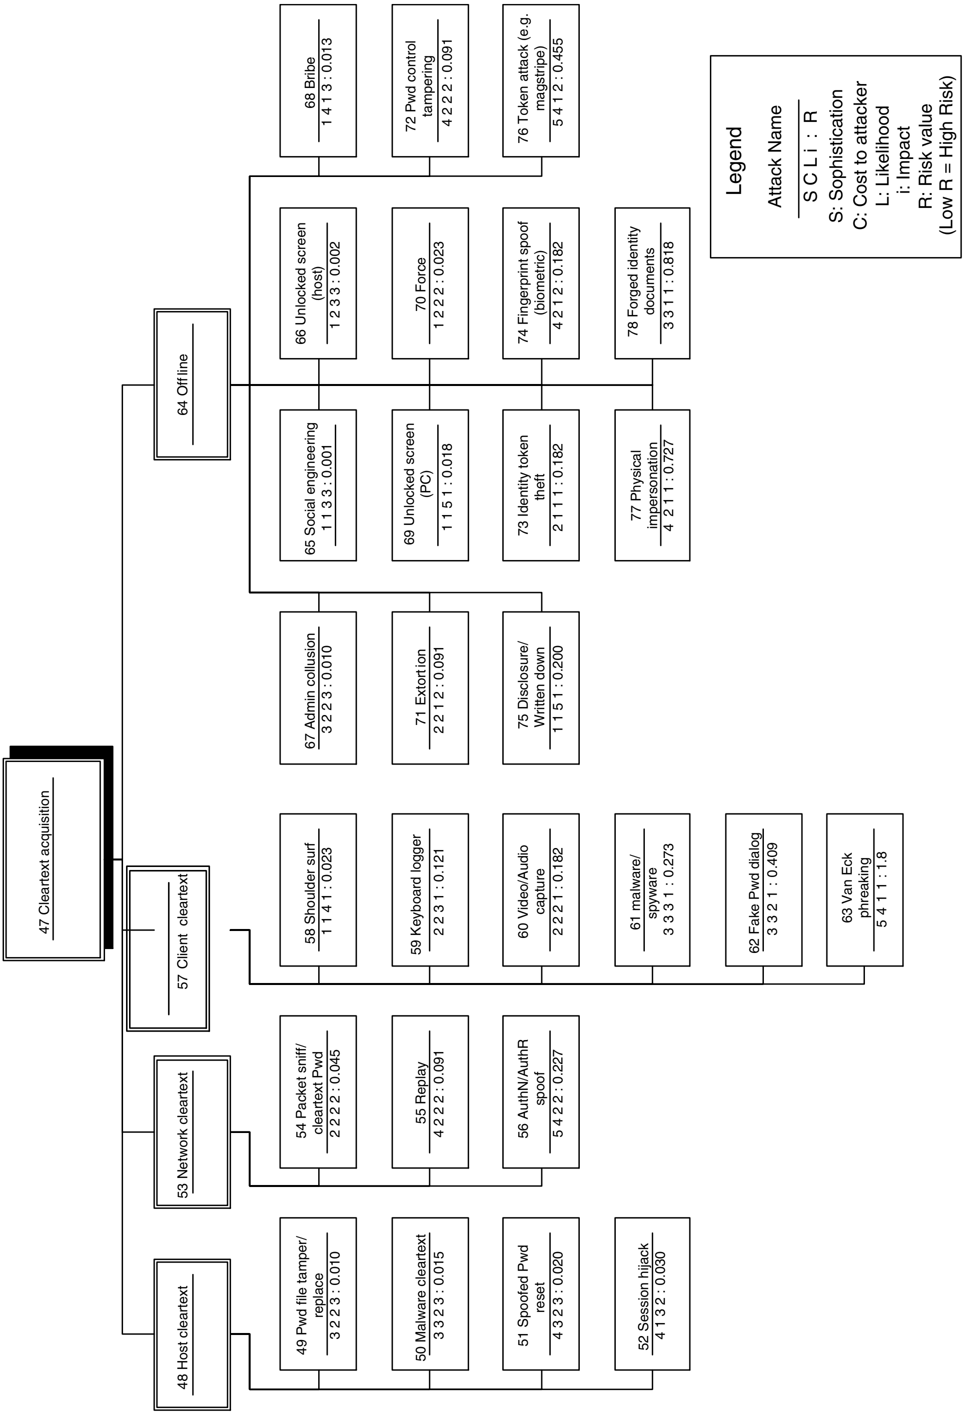

EXHIBIT 67.10 (continued)

EXHIBIT 67.11 Attack Tree Analysis: Attack Factors

S = Sophistication
1 No special tools required, easily accomplished
2 Some special tools required, but are easily acquired
3 Custom tools and software development required
4 Extensive customized tools and specialized knowledge required
5 Significant effort and expertise required; highly sophisticated attack
C = Cost
1 Very low/zero cost
2 Low cost, easily affordable
3 Medium cost
4 High cost
5 Very high cost
L = Likelihood
1 Very unlikely
2 Unlikely
3 Probable
4 Likely
5 Very likely
I = Impact
1 Low impact: single user password
2 High impact: large group of passwords
3 Very high impact: root compromise
C = Cleartext
0 Encrypted password acquisition
1 Cleartext password acquisition
Risk formula
$\text{Risk} = (S \times C)/(L \times ii) * (1 + (10 \times C))$
Lowest number = highest risk
Thus, the cost to the attacker is divided by the likelihood times the impact squared (1, 3, 9). A cleartext attack is 11 times more risk than one that yields cleartext.

67.9 Observations

Conventional wisdom has long held that password cracking is devastatingly effective, and the best attack vector for compromising all passwords. Although cracking is no less effective, this study has been able to show that password guessing can be nearly as effective, while requiring no special tools or access beyond a log-in console.

Disclosure is even more effective; a routine search of several offices and cubicles after hours has a very low probability of being detected, and will almost certainly turn up a log-in password. Cracking is a much more sophisticated attack, typically requiring special access to grab a password file, or sniff a packet from the network. Again, while cracking is no less effective, password guessing and password disclosure are more significant threats in a typical corporate environment and should be recognized in the tuning of password policy.

67.10 Recommendations[4]

For corporate environments with policies similar to the Model architecture, the following recommendations are suggested:

[4] Your mileage may vary, and any adoption of significant changes to controls should follow your own analysis.

EXHIBIT 67.12 High-Risk Attacks and Mitigation

The following are the high-risk attacks, as determined from the Attack Tree analysis, with compensating controls, listed in perceived order of effectiveness. Recommended security controls are marked with an asterisk.

Social Engineering
* Awareness training, end users
  Focused awareness training: admins
* Assessment/mitigation of admin segregation of duties

Unlocked Host Screen
* Audit/remediation, screen saver use
* Mandatory one-minute screen saver for hosts
* All servers in data center (lab lockdown)
  Host multi-factor authentication
  Zoned physical security in data center
* Regular security patrols

Host Password File Tamper/Replace
* All servers in data center (lab lockdown)
* Host-based integrity checking (e.g., Tripwire)
  Host intrusion detection systems (HIDS)
  Centralized authentication/authorization server
* Beefed-up change control
  Secure centralized logging
  Zoned physical security in data center
  Host multi-factor authentication

Admin Collusion/Bribery
* Assessment/mitigation of admin segregation of duties
  Secure centralized logging
  Admin periodic drug testing
  Admin periodic credit checks
* Mandatory two-week vacation for those with more than two weeks per year
  Host-based intrusion detection
* Job families
* Admin background checks prior to hire or promotion to admin status
* Drug testing of all administrators prior to hire or promotion to admin

Host Malware/Virus
* Server-based anti-virus
* Host-based integrity check (e.g., Tripwire)
* Least privilege assessment for services and applications
* All servers in data center (lab lockdown)
  Host-based intrusion detection
  Beefed-up change control
  Segregated network zones (e.g., VLANs)
  Assessment/mitigation of admin segregation of duties

Unlocked Client Screen
  Client-based multi-factor authentication
* 100 percent of clients with security template
  Eliminate Windows 95/98/ME
* Reduce screensaver to 1 ten-minute lockout ("sweet spot" endorsed by TruSecure)
* User awareness training

Spoofed Password Reset
  Client-based multi-factor authentication
* Risk analysis/mitigation of password reset procedure
  Encrypt password reset credentials (employee number, address, date of birth, etc.)
* ID admin awareness training
  One-time password

Shoulder Surfing/Password Written Down
  Client multi-factor authentication
* User awareness training
  Low password complexity

EXHIBIT 67.12 (continued)

Force
* Assessment/mitigation of admin segregation of duties
* Duress codes for building access
Admin periodic drug testing prior to hire
Admin periodic credit checks prior to hire
andatory two-week vacation for those with more than two weeks per year
* Job families
Admin background checks prior to hire/promotion to admin status
Host-based intrusion detection

Copying Host Password File (ciphertext)
* All servers in data center (lab lockdown)
* Host-based integrity checking (e.g., Tripwire)
Host intrusion detection
Centralized authentication/authorization server
*Beefed-up change control
Secure logging
Zoned physical security in data center
Host multi-factor authentication

Host Session Hijacking
* Evaluation/mitigation to ensure three-tier environment (presentation, app, data)
* Evaluation/mitigation existing state tracking and session management
Dynamic Web pages
Challenge/response state tracking
* Evaluation/mitigation of cookie handling, encryption

- Based on the Bayesian analysis of password policy, one should consider the following password policy:
  - An eight-character alphabetic password with 30-day expiry and strong password history
- Based on the Attack Tree analysis, and estimation of the ROI to execute mitigating controls for the 12 most likely attack vectors, the following steps are presented as likely measures that should be undertaken to increase the security of access controls to meet the most significant password/authentication threats:
  - Migrate 100 percent of clients to an OS using a security template/hardened OS
  - Conduct drug testing and background checks of all administrators prior to hire or if they are promoted to admin status
  - Network segmentation ensuring lab servers, production servers, and user space (cubicle-land) are in different networks and security zones; air gap labs and firewall off production networks from user space
  - Assessment, gap analysis, and mitigation of admin segregation of duties
  - Enforce complete screensaver use for all users (ten minutes)
  - User awareness training
  - Audit and perform gap analysis of change control
  - Provide duress codes for building access
  - Host-based integrity checking (e.g., Tripwire)
  - ID admin awareness training
  - Review and market referencing of jobs and job families
  - Least privilege assessment for services and applications
  - Mandatory one-minute screen saver for hosts
  - Mandatory two-week vacation for those with more than two weeks per year
  - Risk analysis of password reset procedure
  - Server-based anti-virus

  - Eliminate LAN Manager authentication by enforcing NTLMv2 authentication and retiring all workstations older than Windows 2000
  - Create process to include security representation on all development projects of significant cost or risk

  This list may not meet your needs. The reader is encouraged to study Exhibit 67.12, and select one to three mitigating controls for each threat, based on their environment, budget, risk tolerance, and maturity of their security program.

- Annual password audits should be performed by independent or internal auditors. The purpose of this audit is to determine and report on the effectiveness of end-user training in the selection of strong passwords. The four most significant factors in selecting this team:
  - Technical competence
  - No administrative access or CIRT responsibilities
  - No access to source code
  - Independence

The author recommends this assessment be conducted using the latest version of L4, the product formerly known as L0phtCrack, as L4 now supports the ability to suppress the display of passwords from the auditor, as well as storage of passwords. This state should be guaranteed to ensure that passwords are not exposed.

67.11 Summary

Passwords and passphrases have been with us for several thousands of years in various formats and contexts, and have always been open to compromises of one sort or another. Although passwords are often vilified as an evil necessity that must be replaced with multi-factor authentication, it is difficult to envision a future where passwords have no place. It seems likely that we will be living with passwords in legacy systems for decades to come, and that password protection will continue to be both a mainstay of security practitioners, as well as the thorn in their side.

It is likely this study both challenged and frustrated the reader because the information debunks conventional wisdom, and appears to be blasphemy at first glance. However, it is difficult to get past these five issues:

1. Users will disclose passwords a minimum of 6000 times per year in an organization with 10,000 users and a mandatory 60-day password reset.
2. Many existing password policies rely on no empirical evidence, but rather groupthink and consensus of best practice without formal study.
3. The likelihood of password disclosure is so significant that password policies and user awareness training must be tuned to drive down disclosure as much as possible.
4. User awareness training is even more important in light of disclosure statistics.
5. Moore's law[5] and weak password constructs on legacy systems have created an environment where password files, once obtained, are nearly certain to be compromised, so password controls to prevent cracking are nearly worthless.

In this environment, we must fundamentally change our approach to password policy and password protection. To be most effective, password policies will need to protect against guessing and disclosure, and will only be able to defeat cracking by denying attackers the files and packets containing passwords so they cannot be cracked.

[5] The price point for hard drives has reached $100 for 200-GB IDE drives, which means the price point for a terabyte is now at $500 for the average consumer. Pre-computing UNIX salted hashed passwords is now possible on a $1000 machine, enabling dictionary attacks to defeat salted hash in near-real-time. For several months, a 64-processor Beowulf cluster was hosted on the Internet for the sole purpose of cracking submitted passwords and returning them in near-real-time.

67.12 Further Studies

While several of the components of this study are based on empirical research, much of the information was based on expert opinion and Bayesian analysis. While appropriate where no data exists, a field study of actual password use is recommended to validate some of the assertions in this chapter. Primarily, it is recommended that further studies pursue:

- Collection of password files and associated policies governing the password controls. Crack the password files, and compare the cracking times and successful percentage of compromised passwords with the policies used to protect the passwords. Determine if a "strong" password policy has any effect on the ability to crack passwords.
- Further, once the previous item is complete, perform analysis on how cracked passwords deviate from minimal password requirements to determine:
  - The distribution of password length from minimal standards (length 8, 9, 10, etc.)
  - The deviation in composition from minimal standards; for example, if alphanumeric is required, what is the tendency to select a dictionary word plus a single digit?
  - In an alphanumeric password, what is the most commonly selected digit?
  - What, if any, is the distribution of digits in the password (first ordinal, final ordinal, middle between two dictionary words)?
  - Does the selection and position of numerals in fact weaken the password space due to significantly reduced availability of numerals (0 to 9) over alphabetics (A to Z, a to z)?
  - If mixed case is required, what tendency, if any, is there to capitalize first ordinal, final ordinal, and both first and final ordinal?
  - How prevalent is hacker replacement (1337 h4x0R) of letters?
  - How often are dictionary words used?
  - What percentage of passwords selected appear in the top 100/1000 password lists?
  - How many of the passwords were identical?
  - What was the prevalence of userID = password?
- Analyze the results for subsequent determination of *actual* keyspace used by users, as compared with policy.
- Attempt to validate or update the models in this chapter with the analysis of actual password selection and the ability to guess and crack the passwords.

Enhancing Security through Biometric Technology

Stephen D. Fried

68.1 Introduction

The U.S. Immigration and Naturalization Service has begun a program that will allow frequent travelers to the United States to bypass the personal interview and inspection process at selected major airports, by taking electronic readings of the visitor's hand to positively identify the traveler. A similar system is in use at the U.S./Canada border that uses fingerprints and voice recognition to identify people crossing the border.

In 1991, Los Angeles County installed a system that uses fingerprint identification to reduce fraudulent and duplicate claims in the county's welfare system. The county saved more than $5 million in the first six months of use.

Casinos from Las Vegas to Atlantic City use face recognition systems to spot gambling cheats, card counters, and criminals in an attempt to reduce losses and protect their licenses.

All these systems have one thing in common: they all use *biometrics* to provide for enhanced security of people, locations, or financial interests. Biometrics is becoming one of the fastest growing segments of the security field and has gained a great deal of popularity both in the popular press and within the security profession. The use of biometrics—how it works, how it is used, and how effective it can be—is the subject of this chapter.

68.2 Biometrics Basics

From its Greek origins, the term "biometrics" literally means "the measurement of life." In more practical usage, biometrics is the science of measuring and analyzing biological information. The use of biometrics involves taking the measurements of various aspects of living (typically human) beings, making analytical judgments on those measurements, and taking appropriate action based on those judgments. Most typically, those judgments help to accurately identify the subject of the measurement. For example, law enforcement officials use the biometric of fingerprints to identify criminals. If the fingerprints of a suspect correspond to the collected at a crime scene, the suspect may be held for further questioning. If the fingerprints do not, the suspect may be set free. In another example, security cameras can scan the faces in the crowd at a football stadium, then match the scanned images against a database of individuals known to be associated with terrorism. If one of the faces in the crowd matches a face in the database, police can take action to take that person into custody. Such a system was used at the 2001 Super Bowl in Tampa Bay, Florida. The system identified 19 individuals in the crowd with criminal records.

Security professionals already have a wide variety of identification and authentication options available to them, including ID badges, passwords, PINs, and smart cards. So why is biometrics different, and why is it considered by many to be the "best" method for accurate identification and authentication? The answer comes from the nature of identification and authentication. Both these processes are based on the concept of *uniqueness*. They assume that there is some unique aspect to an individual that can be isolated and used to positively identify that individual. However, current forms of identification and authentication all suffer from the same fallacy: the "unique" property they measure is artificially attached to the individual. User IDs and passwords are assigned to users and must be remembered by the user. ID badges or tokens are given to users who must then carry them in their possession. Certificate forms of authentication, such as driver's licenses, passports, or X.509 public key certificates are assigned to a person by some authority that attests to the matching between the name on the certificate and the picture or public key the certificate contains. None of these infallibly identify or authenticate the named individual. They can all be fooled or "spoofed" in some form or another.

Biometrics approaches the uniqueness problem in a different way. Instead of artificially attaching some type of uniqueness to the subject, the uniqueness is determined through an intrinsic quality that the subject already possesses. Characteristics such as fingerprints, retina patterns, hand geometry, and DNA are something almost all people already possess and are all naturally unique. It is also something that is with the person at all times and thus available whenever needed. A user cannot forget his finger or leave his voice at home. Biometric traits also have an intrinsic strength in their uniqueness. A person cannot choose a weak biometric in the same way he can choose a weak password or PIN. For very high-security applications, or situations where an extremely high assurance level for identification or authentication is required, this built-in uniqueness gives biometrics the edge it needs over its traditional identification and authentication counterparts.

68.3 How Does Biometrics Work?

Although the physiology behind biometrics is quite complex, the process of using biometric measurements in an application is relatively simple. The first step is to determine the specific biometric *characteristic* that must be measured. This is more a function of practicality, personal preference, and user attitude than a strict technology question. The different factors that go into selecting an appropriate biometric measurement are discussed later in this chapter.

Once the specific characteristic to be measured has been determined, a reading of that biometric is taken through some mechanical or technical means. The specific means will be based on the biometric characteristic selected, but biometric readings are generally taken by either (1) photographing or scanning an image of the characteristic, or (2) measuring the characteristic's life signs within the subject. Once the reading is taken, it needs to be modified into a form that makes further comparison easier. Storing the entire scanned or read image for thousands of people would take up large amounts of storage space, and using the whole image for comparison is inefficient. In reality, only a small portion of the entire image contains significant information that is needed for accurate comparison. These significant bits are called *match points*. By identifying and gathering only the match points, biometric measurements can be made accurately and data storage requirements can be significantly reduced.

The match points are collected into a standard format called a *template*. The template is used for further comparison with other templates stored in the system or collected from users. Templates are stored for later retrieval and comparison in whatever data storage system the biometric application is using. Later, when a user needs to be identified or authenticated, another biometric reading is taken of the subject. The template is extracted from this new scan and compared with one or more templates stored in the database. The existence or absence of a matching template will trigger an appropriate response by the system.

68.4 Biometric Traits

All biometric systems are based on one of three different types of human traits. *Genotypic* traits are those that are defined by the genetic makeup of the individual. Examples of genotypic traits are facial geometry, hand geometry, and DNA patterns. It is interesting to note that genotypic traits found between identical twins or clones are very similar and often difficult to use as a distinguishing characteristic to tell the two apart.

Randotypic traits are those traits that are formed early in the development of the embryo. Many of the body features that humans possess take on certain patterns during this stage of development, and those patterns are distributed randomly throughout the entire population. This makes duplication highly improbable and, in some cases, impossible. Examples of randotypic traits are fingerprints, iris patterns, and hand-vein patterns.

Behavioral traits are those aspects of a person that are developed through training or repeated learning. As humans develop, they learn certain modes of behavior that they carry throughout their lives. Interestingly, behavioral traits are the one type of biometric trait that can be altered by a person through re-training or behavior modification. Examples of behavioral traits include signature dynamics and keyboard typing patterns.

68.5 Common Uses for Biometrics

The science and application of biometrics has found a variety of uses for both security and non-security purposes. *Authentication* of individuals is one of the most popular uses. For example, hand scanners can be used to authenticate people who try to access a high-security building. The biometric reading taken of the subject is then compared against the single record belonging to that individual in the database. When used in this form, biometric authentication is often referred to as *positive matching* or *one-to-one matching*.

Very often, all that is needed is basic *identification* of a particular subject out of a large number of possible subjects. Police in the London borough of Newham use a system of 140 cameras mounted throughout the borough to scan the faces of people passing through the district. Those faces are compared against a database of known criminals to see if any of them are wandering around Newham's streets. In this particular use, the biometric system is performing *negative matching* or *one-to-many matching*. Unlike the single-record lookup used in positive matching, each sample face scanned by the Newham cameras is compared against all the records in the police database looking for a possible match. In effect, the system is trying to show that a particular face is not in the database (and, presumably, not an identified criminal).

Fraud prevention is another common use for biometrics. When a user goes through biometric authentication to access a system, that user's identity is then associated with every event, activity, and transaction that the user performs. If a fraudulent transaction is discovered or the system becomes the subject of an investigation or audit, an audit trail of that user's actions can be produced, confirming or refuting their involvement in the illicit activity. If the personnel using the system are made aware of the ID tagging and audit trails, the use of biometrics can actually serve as a deterrent to prevent fraud and abuse.

Biometrics can also be used as a basic *access control* mechanism to restrict access to a high-security area by forcing the identification of individuals before they are allowed to pass. Biometrics is generally used for identification only in a physical security access control role. In other access control applications, biometrics is used as an authentication mechanism. For example, users might be required to biometrically authenticate themselves before they are allowed to view or modify classified or proprietary information. Normally, even in physical access control, it is not efficient to search the database for a match when the person can identify himself (by stating his name or presenting some physical credential) and have the system quickly perform positive matching.

A less security-oriented use of biometrics is to improve an organization's *customer service*. A supermarket can use facial recognition to identify customers at the checkout line. Once customers are identified, they can be given the appropriate "frequent-shopper" discounts, have their credit cards automatically charged, and have their shopping patterns analyzed to offer them more personally targeted sales and specials in the future—all without the customer needing to show a Shopper's Club card or swipe a credit card. Setting aside the privacy aspect of this type of use (for now), this personalized customer service application can be very desirable for consumer-oriented companies in highly competitive markets.

68.6 Biometric Measurement Factors

As with any process involving measurement, mechanical reproduction, and analysis, here there are many factors that contribute to the success or failure of the process. All of these factors fall into two general categories: *properties of the characteristics measured* and *properties of the measurement process*.

68.6.1 Characteristic Properties

The most important requirement for determining if a particular characteristic is suitable for biometric measurement is *uniqueness*. The specific characteristic must be measurably unique for each individual in the subject population. As a corollary, the characteristic must be able to produce comparison points that are unique to the particular individual being measured. This uniqueness property is essential, as two people possessing identical characteristics may be able to fool the measurement system into believing one is the other.

The characteristic must also be *universal*, existing in all individuals in the population being measured. This may sound easy at first, because everyone has fingerprints, everyone has DNA, and everyone has a voice. Or do they? When establishing a biometric measurement system, security practitioners need to account for the fact that there will be some part of the measured population that does not have a particular characteristic. For example, people lose fingers to accidents and illness and some people cannot speak. For these people, fingerprint analysis or voice recognition will not work as a valid biometric mechanism. If the number of people in a particular population lacking these qualities is very small, alternate procedures can be set up to handle these cases. If the number is relatively large, an alternative biometric method, or even an altogether different security mechanism, should be considered.

When considering a particular biometric with respect to universality, the security practitioner must also take cultural considerations into account. A measurement system tuned to a specific target population may not perform well with other racial, ethnic, or gender groups. For example, suppose a company uses a voice recognition system that requires users to speak several standard words in order to get an accurate voiceprint. If the system is tuned to clearly understand words spoken by New Yorkers (where the system is used), an employee with a deep southern U.S. accent transferring into the area might have difficulty being recognized when speaking the standard words. Likewise, some cultures have customs regarding the touching of objects and health concerns regarding the shared use of the same device (like a hand scanner or a fingerprint reader). When setting up a biometric system that requires the user to touch or physically interact with the reading device, these types of considerations need to be addressed.

Another important property for a biometric characteristic is *permanence*. The characteristic must be a permanent part of the individual and the individual must not be able to remove or alter the characteristic without causing grave personal harm or danger. This permanence property also applies over time. The characteristic must not change significantly over time or it will make any pattern matching inaccurate. This aspect has several interesting ramifications. For example, the physiology of young children changes quite rapidly during their growing years, so voice or facial characteristics measured when they are young may be invalid just a few years later. Likewise, elderly people who have their physical characteristics damaged through surgery or accidental injury may take an unusually long time to heal, again rendering any physical measurements inaccurate, at least for a time. Pregnancy causes a woman's blood vessels in the back of the eye to change, thereby requiring re-enrollment if retinal scanning is being used. Finally, handwritten signature patterns change over time as people age, or in relation to the number of documents they need to sign on a regular basis. These situations will lead to a higher number of false rejections on the part of the biometric system. To avoid these types of problems it may be advantageous to periodically reestablish a baseline measurement for each individual in the system.

In addition to permanence, the characteristic must be *unalterable*. It should be impossible for a person to change the characteristic without causing an error condition in the biometric system or presenting harm or risk to the subject. For example, it is impossible to change a person's DNA. And while it is theoretically possible to give someone new fingerprints (through skin grafts or digit transplant), most people would consider that too extreme and dangerous to be considered a strong threat for most applications.

It is important that the characteristic has the *ability to be captured or otherwise recognized* by some type of recording device. The characteristic must be measurable by a standard (perhaps specialized) input device that can convert that characteristic (and its match points) to a form that is readable and understandable by human or technical means.

The final important property of any biometric characteristic is that it *can be authenticated*. The characteristic for an individual must be able to be matched against similar characteristics found in other subjects and a definitive positive or negative match must be able to be made based on the measurement and match points presented.

68.6.2 Measurement Properties

The previous section dealt with properties of the various biological characteristics used in biometrics. However, a large part of the success or failure of a biometric system lies in the measurement and analysis process. One of the most important aspects of the process is *accuracy*. As with any monitoring or surveillance system, it is critically important that the biometric system takes accurate measurements and creates an accurate representation of the characteristic in question. Likewise, the template that the system produces from the measurement must accurately depict the characteristic in question and allow the system to perform accurate comparisons with other templates.

The system's ability to produce templates and use these templates in a later evaluation must be *consistent over time*. The measurement process must be able to accurately measure and evaluate the characteristic over an indefinite (although not necessarily infinite) period of time. For example, if an employee enrolls in a face-scanning system on the first day of work, that scanning system should be able to accurately verify that employee throughout the entire length of employment (even accounting for aging, growth or removal of facial hair, and the occasional broken nose).

Because biometric systems are based on examinations of human characteristics, it is important that the system *verify the source of the characteristic*, as opposed to simply checking the characteristic's features or match points. For example, if the system is measuring facial geometry, can holding a picture of the subject's face up to the camera fool it into believing the image is from a real person? If a fingerprint system is used, does the system check to see if the finger is attached to a living person? (This is not as far-fetched as one may think!) Checking for traits like body heat, blood flow, movement, and vocal intonation can help the system distinguish between the real article and a mechanical reproduction.

Finally, the measurement system should work to reduce the influence of *environmental factors* that may play into the accuracy of the biometric readings. An example of this would be the accurate placement of face scanners so that sunlight or glare does not affect the cameras. Fingerprint systems should employ mechanisms to ensure the print reader does not become smudged or laden with dirt, thus affecting its ability to take accurate measurements. The accuracy of a voice matching system might be compromised if it is operated in a crowded or noisy public environment. All these factors work against a successful biometric operation, and all should be considered and dealt with early in the planning phases.

68.7 Biometric Measurement

Although the science and technology behind biometrics has improved greatly in recent years, it is not foolproof. Absolute, 100-percent error-free accuracy of the measurements taken by biometric devices, and of the comparisons made between biometric characteristics, is neither realistic nor to be expected. Therefore, implementers of a biometric system need to understand the limitations of the technology and take the appropriate steps to mitigate any possible error-causing conditions. Biometric systems, like all security systems, must be "tuned" based on the particular needs of the installation and must account for real-world variations in use and operating environment.

68.7.1 Measurement Characteristics

The process of comparing biometric templates to determine if they are similar (and how far that similarity extends) is called *matching*. The matching process results in a *score* that indicates how well (or how poorly) the presented template compares against a template found in the database. For every biometric system there is a particular *threshold* that must be met for the system to issue a "pass" result. If the score produced for that match falls above the threshold, the template is accepted. If the score falls below the threshold, the template is rejected. The threshold value is typically set by the system's administrators or operators and is tunable, depending on the degree of sensitivity the operator desires.

Ironically, the template produced by a user during normal system use and the template stored in the system for that user should rarely result in a completely identical match. There is always some degree of change (however small) between user "sessions" in biometric systems, and that degree of change should be accounted for in the system's overall threshold tuning. The detection of a completely identical match between a presented template and a stored template (e.g., if an intruder obtains a digitized copy of the reader output and subsequently bypasses the reader by feeding the copy into the matching process) may be an indication of tampering or the use of mechanically reproduced biometric characteristics.

68.7.2 Error-Producing Factors

The process of initially measuring a person's characteristics, creating a template, and storing that template in a system is called *enrollment*. During the enrollment process, the system "learns" the biometric characteristic of the subject. This learning process may involve taking several readings of the characteristic under different conditions. As the system gets more experience with the subject, it learns the various ways that the characteristic can be presented and refines the template stored for that user. It then uses that information during actual operation to account for variations in the way the characteristic is presented.

The performance of the enrollment process can have a large impact on the overall accuracy of the system. It is vitally important that enrollment take place not only under ideal conditions (e.g., in a quiet room with good lighting), but also perhaps under less than optimal conditions (e.g., with added background noise or subdued lighting). A well-performed enrollment increases the accuracy of the comparisons made by the system during normal use and will greatly reduce the likelihood of inaccurate readings. If errors are introduced into the enrollment process, they can lead to errors in verifying the user during later system operation or, in extreme conditions, allow for an imposter to be accepted by the system.

Not all the errors introduced into a biometric system are due to mechanical failures or technical glitches. The users of the systems themselves cause many of the problems encountered by biometric systems. Humans are able to easily adapt to new and different situations and learn new modes of behavior much more easily than machines. How a biometric system handles that change will play an important part in its overall effectiveness.

For example, when a biometric system is first put into operation, users might be unsure of how to accurately present their characteristic to the system. How should they hold their head in order to get an accurate eye scan? How do they place their fingers on the reader so an accurate fingerprint reading can be taken? This initial inexperience (and possible discomfort) with the system can lead to a large number of inaccurate readings, along with frustration among the user population. The natural reaction on the part of users will be to blame the system for the inaccuracies when, in fact, it is the user who is making the process more difficult.

As time passes and users become more familiar with the system, they will become conditioned to presenting their information in a way that leads to more accurate measurements. This conditioning will occur naturally and subconsciously as they learn how to "present" themselves for measurement. In effect, the users learn how to be read by the system. This has the effect of speeding up the throughput rate of the system and causing fewer false readings.

User behavior and physiology play a part in the process as well. As humans move through their days, weeks, and months, they experience regular cycles in their physiology and psychology. Some people are more alert and attentive early in the day and show visible signs of fatigue as the day progresses. Others do not reach their physical peak until midday or even the evening. Seasonal changes cause associated physiological changes in some people, and studies have shown that many people grow depressed during the winter months due to the shorter days. Fatigue or stress can also alter a person's physiological makeup. These cyclical changes can potentially affect any biometric reading that may take place.

The *importance of a transaction* also affects user behavior and attitude toward having biometric readings taken. People are much more willing to submit to biometric sampling for more important, critical, sensitive, or valuable transactions. Even nontechnical examples show this to be true. The average person will take more time and care signing a $100,000 check than a $10 check.

68.7.3 Error Rates

With any biometric system there are statistical error rates that affect the overall accuracy of the system. The *False Rejection Rate* (FRR) is the rate at which legitimate system users are rejected and categorized as invalid users. False rejection is also known as a *Type I Error* or a *False Negative*. The general formula for calculating the False Rejection Rate is:

$$\text{False Rejection Rate} = \text{NFR/NEIA} \quad \text{(for identification systems)}$$

or

$$\text{False Acceptance Rate} = \text{NFR/NEVA} \quad \text{(for authentication systems)}$$

where:

NFR = Number of false rejections
NEIA = Number of enrollee identification attempts
NEVA = Number of enrollee verification attempts

The *False Acceptance Rate* (FAR) is the rate at which nonlegitimate users are accepted by the system as legitimate and categorized as valid users. False acceptance is also known as a *Type II Error* or a *False Positive*. The general formula for calculating the False Acceptance Rate is:

$$\text{False Acceptance Rate} = \text{NFR/NEVA} \quad \text{(for authentication systems)}$$

or

$$\text{False Rejection Rate} = \text{NFA/NIVA} \quad \text{(for authentication systems)}$$

where:

NFA = Number of false acceptances
NEIA = Number of imposter identification attempts
NEVA = Number of imposter verification attempts

The final statistic that should be known about any biometric system is the *Crossover Error Rate* (CER), also known as the *Equal Error Rate* (EER). This is the point where the False Rejection Rate and the False Acceptance Rate are equal over the size of the population. That is, the system is tuned such that the rate of false negatives and the rate of false positives produced by the system are approximately equal. Ideally, the goal is to tune the system to get the Crossover Error Rate as low as possible so as to produce both the fewest false negatives and false positives. However, there are no absolute rules on how to do this, and changes made to the sensitivity of the system affect both factors. Tuning the system for stricter identification in an attempt to reduce false positives will lead to more false negatives, as questionable measurements taken by the system will lean toward rejection rather than acceptance. Likewise, if you tune the system to be more accepting of questionable readings (e.g., in an effort to improve customer service), you increase the likelihood of more false positive readings.

Finally, for every biometric system there is a *Failure To Enroll* rate, or FTE. The FTE is the probability that a given user will be unable to enroll in the system. This can be due to errors in the system or because the user's biometric characteristic is not unique enough or is difficult to measure. Users who are unable to provide biometric data (e.g., amputees or those unable to speak) are generally not counted in a system's FTE rate.

68.8 Implementation Issues

Like any other automated system that employs highly technological methods, the technology used in biometric systems only plays one part in the overall effectiveness of that system. The other equally important piece is how that technology is implemented in the system and how the users interact with the technology. State-of-the-art technology is of little use if it is implemented poorly or if the users of the system are resistant (or even hostile) to its use.

One important factor is the relative *autonomy of the users* of a biometric system. This refers to the ability of the users to resist or refuse to participate in a system that uses biometric identification. Generally, company employees (or those bound by contractual obligation) can be persuaded or coerced into using the system as a condition of their employment or contract. Although they may resist or protest, they have little recourse or alternative. On the other hand, members of the general public have the ability to opt out of participation in a biometric system that they feel is intrusive or infringes too much on their personal privacy. Each of these users has the power make a "risk-versus-gain" decision and decide whether or not to participate in the system.

Some users will resist using a biometric system that they feel is too *physically intrusive on their person*. Some biometric technologies (e.g., retina scans or fingerprint readings) are more physically imposing on users. Other technologies, such as voice recognition or facial recognition, are more socially acceptable because they impose less of a personal proximity risk and do not require the user to physically touch anything. As previously stated, cultural aspects pertaining to personal touch or capturing of personal images also play an important part in the issue of intrusiveness. In general, the more physically intrusive a particular biometric technology is, the more users will resist its use and it may also produce higher error rates because uncomfortable users will not become as conditioned to properly presenting themselves for measurement.

The *perception of the user* as to *how the system is being used* also plays an important part in the system's effectiveness. Users want to understand the motivation behind its use. Is the system owner looking to catch "bad guys"? If this is the case, users may feel like they are all potential suspects in the owner's eyes and will not look kindly upon this attempt to "catch" one of them. On the other hand, if the system is being used (and advertised) as a way to protect the people using the system and to prevent unauthorized personnel from entering the premises and harming innocent people, that use may be more readily acceptable to the user population and alter their attitudes toward its use.

Particular technologies themselves might be at issue with users. The use of fingerprints has most often been associated with criminal behavior. Even if a system owner implements a fingerprint scanning system for completely benign purposes, the users of that system may feel as if they are being treated like criminals and resist its use. *Ease of use* is always a factor in the proper operation of a biometric system. Is enrollment performed quickly and does it require minimal effort? Are special procedures needed to perform the biometric measurement, or can the measurements be taken while the user is performing some other activity? How long do users have to wait after taking the measurements to learn if they have passed or failed the process? Proper end-user operational and ergonomic planning can go a long way toward ensuring lower error rates and higher user satisfaction.

In these days of heightened awareness concerning privacy and the security of personal information, it is no wonder that many potential system implementers and users alike have *concerns over the privacy aspects* of the use of biometrics. With most other identification methods, the system gathers information about the person in question, such as name, identification number, height, weight, age, etc. With biometric applications, however, the system maintains information of the person in question, such as fingerprint patterns or voice patterns. This type of information is truly "personal" in the most literal sense, and many users are uncomfortable sharing that level of personal detail. More than any other technology, biometrics has the ability to capture and record some of the most essentially private information a person possesses.

Many are also concerned with the storage of their personal information. Where will it be stored, how will it be used, and (most importantly) who will have access to it? In effect, the biometric system is storing the very essence of the individual, a characteristic that can uniquely identify that person. If unauthorized individuals were to get hold of that information, they could use it to their advantage or to the victim's detriment. The loss or compromise of stored biometric information presents an opportunity for the truest form of identity theft.

For example, suppose "Joe Badguy" was able to get hold of a user's template used for fingerprint identification. He may be able to use that template to masquerade as that user to the system, or perhaps feed that template into another system to gain access elsewhere. He may even alter the template for a legitimate user and substitute his own template data. At that point, Joe Badguy can present his fingerprints to the system and be correctly identified as "Jane Innocent, authorized user."

Biometrics also *reduces the possibility of anonymity* in the personal lives of its users. Despite the universal use of credit cards in the global economy, many people still prefer to use cash for many transactions because it allows them to retain their anonymity. It is much more difficult to track the flow of cash than it is to trace credit card records. Taking the earlier example of the store using face recognition to help customers speed through the checkout line, suppose the system also stores the items a customer purchases in its database along with the biometric data for that customer. An intruder to that system (or even a trusted insider) will be able to discover potentially embarrassing or compromising information that the subject would rather not make public (e.g., the purchase of certain medications that might be indicative of an embarrassing health condition). By using biometrics to associate people with purchases, you reduce the ability for people to act anonymously—one of the basic tenets of a free society.

A large privacy problem with information systems in general is the issue of *secondary use*. This is the situation where information gathered for one purpose is used (or sold to a third party) for an entirely different purpose. Secondary use is not peculiar to biometric systems per se, but because of the very personal nature of the information stored in a biometric database, the potential for identity fraud is even greater. While a user might give grudging approval to have his face used as part of a system for authenticating ATM transactions (after all, that is the trade-off for convenient access to money), that user might not consent to sharing that same biometric characteristic information with a local retailer.

Finally, there is the issue of *characteristic replacement*. When a person has his credit card stolen, the bank issues that person a new card and cancels the old one. When a computer user forgets his password, a system administrator will cancel the old password and assign a new one to the user. In these two processes, when credentials become compromised (through loss or theft), some authority will invalidate the old credential and issue a new (and different) one to the user. Unfortunately, it is not that easy with biometric systems. If a person has their fingerprints stolen they can't call the doctor and get new fingers! And despite advances in cosmetic surgery, getting a new face because the old image has been compromised is beyond the reach of most normal (or sane) people. The use of biometric systems presents unique challenges to security, because compromise of the data in the system can be both unrecoverable and potentially catastrophic to the victim.

When designing the security for a biometrics-based system, the security professional should use all the tools available in the practitioner's toolbox. This includes such time-honored strategies as defense-in-depth, strong access control, separation and rotation of duties, and applying the principle of least privilege to restrict who has access to what parts of the system. Remember that biometric systems store the most personal information about their users, and thus require that extra attention be paid to their security.

EXHIBIT 68.1 Biometric Technologies by Characteristic Type

Trait Type	Biometric
Rantotypic	Fingerprints
	Eye scanning
	Vein patterns
Genotypic	Facial recognition
	DNA matching
	Hand geometry
	Voice and speech recognition
Behavioral	Signature analysis
	Keystroke dynamics

68.9 Biometric Technologies

The different types of biometric technologies available today can be divided among the three types of biometric traits found in humans. Exhibit 68.1 lists the most common biometric technologies and the trait types with which each is associated.

68.9.1 Fingerprints

Fingerprints are the most popular and most widely used biometric characteristic for identification and authentication. Fingerprints are formed in the fetal stage (at approximately five months) and remain constant throughout a person's lifetime. The human finger contains a large number of ridges and furrows on the surface of the fingertips. Deposits of skin oil or amino acids on the fingers leave the prints on a particular surface. Those prints can be extracted from the surface and analyzed.

- *How it works*. In fingerprint scanning systems, the user places a finger on a small optical or silicon surface the size of a postage stamp for two or three seconds. There are two different types of finger-scanning technology. The first is an *optical scan*, which uses a visual image of a finger. The second uses a *generated electrical field* to electronically capture an image of a finger.
- *Match points used*. The patterns of ridges and furrows in each print are extracted for analysis. Ridge and furrow patterns are classified in four groups: *arch* (which are very rare), *tented arch*, *whorl*, and *loop* (which is the most common). When a line stops or splits, it is called a "minutia." It is the precise pattern and location of the ridges, furrows, and minutiae that give a fingerprint its uniqueness. Most European courts require 16 minutiae for a positive match and a few countries require more. In the United States, the testimony of a fingerprint expert is sufficient to legally establish a match, regardless of the number of matching minutiae, although a match based on fewer than ten matching points will face a strong objection from the defense.
- *Storage requirements*. Fingerprint systems store either the entire image of the finger or a representation of the match points for comparison. The U.S. Federal Bureau of Investigation stores digitized images at a resolution of 500 pixels per inch with 256 gray levels. With this standard, a single 1.5-square-inch fingerprint image uses approximately 10 megabytes of data per fingerprint card. To save space, many fingerprint storage systems store only information about the ridges, furrows, and minutiae rather than the entire image. The storage requirement for these systems is typically 250 to 1000 bytes per image.
- *Accuracy*. Fingerprint scanning systems tend to exhibit more false negatives (i.e., failure to recognize a legitimate user) than false positives. Most fingerprint systems on the market use a variety of methods to try to detect the presentation of false images. For example, someone might attempt to use latent print residue on the sensor just after a legitimate user accesses the system or even try to use a finger that is no longer connected to its original owner. To combat this, many sensors use special measurements to determine whether a finger is live, and not made of man-made materials (like latex or plastic). Measurements for blood flow, blood-oxygen level, humidity, temperature, pulse, or skin conductivity are all methods of combating this threat.

68.9.2 Eye Scanning

The human eye contains some of the most unique and distinguishing characteristics for use in biometric measurement. The two most common forms of eye-based biometrics are *iris recognition* and *retina recognition*.

- *How it works*. The process of scanning a person's iris consists of analyzing the colored tissue that surrounds the pupil. The scans use a standard video camera and will work from a distance of 2 to 18 inches away, even if the subject is wearing glasses. The iris scan typically takes three- to five seconds. In contrast, retinal scanning analyses the blood vessels found at the back of the eye. Retinal scanning involves the use of a low-intensity green light source that bounces off the user's retina and is then read by the scanner to analyze the patterns. It does, however, require the user to remove glasses, place his eye close to the reading device, and focus at length on a small green light. The user must keep his head still and his eye focused on the light for several seconds, during which time the device will verify the user's identity. Retina scans typically take from ten to twelve seconds to complete.

- *Match points used.* There are more than 200 usable match points in the iris, including rings, furrows, and freckles. Retina scans measure between 400 and 700 different points in order to make accurate templates.
- *Storage requirements.* Typical template size for an iris scan is between 256 and 512 bytes. Most retina scans can be stored in a much smaller template, typically 96 bytes.
- *Accuracy.* The uniqueness of eyes among humans makes eye scanning a very strong candidate for biometric use. This uniqueness even exists between the left and right eyes of the same person. There is no known way to replicate a retina, and a retina from a dead person deteriorates extremely rapidly. The likelihood of a false positive using eye scan technology is extremely low, and its relative speed and ease of use make it an effective choice for security and identification applications. The primary drawbacks to eye scanning as a biometric are the social and health concerns among users needing to be scanned. People are generally uncomfortable allowing something to shine directly into their eyes and are concerned about the residual health effects that may result. This problem is more pronounced among users of retina scanning systems, where the exposure to the scanning light is longer.

68.9.3 Vein Patterns

Vein pattern recognition uses the unique pattern of surface and subcutaneous veins on the human body, most notably around the human hand.

- *How it works.* A special camera and infrared sensor take an image of veins in the palm, wrist, or back of the hand. The image is then digitized into a template and used for comparison.
- *Match points used.* The images show the tree patterns in the veins that are unique to each person, and the veins and other subcutaneous features present large, robust, stable, and largely hidden patterns.
- *Storage requirements.* The template produced from a vein scanner is approximately 250 bytes.
- *Accuracy.* The unique pattern of vein distribution is highly stable and stays the same throughout a person's life into old age. In that respect, vein patterns provide a highly stable biometric for identification. With respect to social acceptability, vein recognition does not have many of the criminal implications that fingerprinting has. Finally, vein patterns are not subject to temporary damage that fingerprints often suffer from through normal use, such as weekend gardening or masonry work. Despite this, vein scanning has not seen the widespread deployment that some of the other biometric measurements have seen.

68.9.4 Facial Recognition

Facial recognition technology involves analyzing certain facial characteristics, storing them in a database, and using them to identify users accessing systems. Humans have a natural ability to recognize a single face with uncanny accuracy, but until relatively recently it has proven extremely difficult to develop a system to handle this task automatically. Recent advances in scientific research and computing power have made facial recognition a powerful and accurate choice for biometric security.

- *How it works*. Facial recognition is based on the principle that there are features of the human face that change very little over a person's lifetime, including the upper sections of eye sockets, the area around cheek bones, and the sides of the mouth. In a typical facial recognition system, the user faces a camera at a distance of one to two feet for three to four seconds. There are several different types of facial recognition. *Eigenface*, developed at MIT, utilizes two-dimensional gray-scale images representing the distinct facial characteristics. Most faces can be reconstructed using 100 to 125 eigenfaces that are converted to numerical coefficients. During analysis, the "live" face will be analyzed using the same process and the results matched against the stored coefficients. The *Feature Analysis* method measures dozens of facial features from different parts of the face. Feature analysis is more forgiving of facial movement or varying camera angles than the Eigenface method. Another alternative, *Neural Network Mapping* systems, compares both the live image and the stored image against each other and conducts a "vote" on whether there is a match. The algorithm can modify the weight it gives to various features during the process to account for difficult lighting conditions or movement of facial features. Finally, *Automatic Face Processing* uses the distances between easily acquired features such as the eyes, the end of nose, and the corners of the mouth.
- *Match points used*. The specific match points used depend on the type of scanning methodology employed. Almost all methods take measurements of facial features as a function of the distance between them or in comparison with "standardized" faces.
- *Storage requirements*. Template size varies based on the method used. One-to-one matching applications generally use templates in the 1 to 2-Kb range. One-to-many applications can use templates as small as 100 bytes.
- *Accuracy*. Many companies marketing facial scanning technology claim accuracy rates as high as 98 to 99 percent. However, a recent U.S. Department of Defense study found that most systems have an accuracy rate of only 50 to 60 percent. Despite this, the ease of use and the lack of need for direct user interaction with scanning devices make facial scanning an attractive method for many applications.

68.9.5 DNA Matching

Perhaps no type of biometric has received more press in recent times than DNA matching. Applications as widely diverse as criminal investigation, disaster victim identification, and child safety have all looked to DNA matching for assistance. The basic hereditary substance found in all living cells is called deoxyribonucleic acid, or DNA. This DNA is created during embryonic development of living creatures and is copied to every cell in the body.

- *How it works*. The majority of DNA molecules are identical for all humans. However, about three million pairs of each person's DNA molecules (called *base pairs*) vary from person to person. When performing DNA analysis, scientists first isolate the DNA contained in a given sample. Next, the DNA is cut into short fragments that contain identical repeat sequences of DNA known as VNTR. The fragments are then sorted by size and compared to determine a DNA match.
- *Match points used*. Once the VNTR fragments are isolated, they are put through statistical analysis. For example, for any VNTR "locus" of a given length, there may be many people in a population who have a matching VNTR of that length. However, when combined with other samples of VNTR loci, the combination of all those samples becomes a statistically unique pattern possessed only by that person. Using more and more loci, it becomes highly unlikely (statistically) that two unrelated people would have a matching DNA profile.
- *Storage requirements*. DNA matching information can be stored in physical form (using special x-ray film) or in electronic form using a specialized database. Many governments around the world are starting to develop large DNA databases with hundreds of thousands of unique DNA

profiles. Because each system stores the DNA template information in its own format, exact sizing requirements are difficult to determine. Note, however, that storing DNA templates is different from storing a person's actual DNA, a medical practice that is gaining in popularity.

- *Accuracy.* Using even four VNTR loci, the probability of finding two people with a DNA match is around one in five million. FBI analysis uses 13 loci on average, making the odds of a match less than one in 100 billion. This makes DNA matching one of the most accurate forms of biometric analysis. However, due to its complexity, DNA analysis is strictly a laboratory science. It is not yet a "consumer marketplace" technology.

68.9.6 Hand Geometry

The process of hand geometry analysis uses the geometric shape and configuration of the features of the hand to conduct identification and authentication. With the exception of fingerprints, individual hand features do not have sufficiently unique information to provide positive identification. However, several features, when taken in combination, provide enough match points to make biometric use possible.

- *How it works.* A user places a hand, palm down, on a large metal surface. On that surface are five short metal contacts, called "guidance pegs." The guidance pegs help the user align the hand on the metal surface for improved accuracy. The device "reads" the hand's properties and records the various match points. Depending on the system, the scan can take a two-dimensional or three-dimensional image. Features such as scars, dirt, and fingernails can be disregarded because these "features" change rapidly over a person's lifetime. Typical hand scans take from two to four seconds.
- *Match points used.* Hand scanning systems typically record 90 to 100 individual hand characteristics, including the length, width, thickness, skin transparency, and surface area of the hand, including the fingers. These features, as well as the relationship each has to each other (e.g., distance, relative size, etc.), are recorded and stored.
- *Storage requirements.* Hand geometry templates can be stored in a relatively small amount of storage, as little as nine bytes. This makes it ideal for applications where memory storage is at a premium, such as smart cards.
- *Accuracy.* The accuracy of hand geometry systems is fairly high, making it a historically popular biometric method. It also has a fairly high acceptance value among users, and current implementations are easy to use. However, hand geometry systems are typically used for authentication purposes, as one-to-many identification matching becomes increasingly more difficult as the size of the database becomes larger. In addition, the equipment can be expensive and difficult to integrate into existing environments.

68.9.7 Voice and Speech Recognition

There are several different varieties of voice-based biometrics. These include *speaker verification*, where patterns in a person's speech are analyzed to positively identify the speaker, and speech recognition, which identifies words as they are spoken, irrespective of the individual performing the speaking. Because there is no direct correlation between the speaker and the speech in speech recognition systems, they are *not* useful for identification or authentication. Finally, *voiceprint systems* record a human voice and create an analog or digital representation of the acoustic information present in the speaker's voice.

- *How it works.* A user is positioned near a microphone or telephone receiver so that his voice can be captured and analyzed. The user is prompted to recite a phrase according to one of several scenarios:
  - *Text-dependent systems* require the user to recite a specific set of predefined words or phrases.

  - *Text-independent systems* request that the user speak any words or phrases of their choice. These systems use voiceprints to measure the user's speech.
  - *Text-prompted systems* require the user to recite random words that are supplied by the system.

- The user's voice is digitized by the system and a model template is produced and used for later comparisons. Typical recognition time in voice-based systems is four to six seconds.
- *Match points used.* Each word or phrase spoken into the system is divided into small segments consisting of syllables or phonemes (or small phonetic units), each of which contains several dominant frequencies. These dominant frequencies are fairly consistent over the entire length of the segment. In turn, each of these segments has several (three to five) dominant tones that are captured and converted to a digital format. This digital information is then transferred to a master table. The combined table of tones for all the segments creates the user's unique voiceprint.
- *Storage requirements.* Voiceprint templates vary considerably in size, depending on the application and the quality of voice information required by the system. Storage size can range from 300 to 500 bytes, all the way up to 5000 to 10,000 bytes. This is not particularly well-suited for applications where the storage or analysis system has low memory or storage capacity.
- *Accuracy.* Most voice recognition systems have a high degree of accuracy. The better ones not only analyze the user's voiceprint, but also check for liveliness in an attempt to verify if the voice is original or a mechanical reproduction. Because the system requires no special training on the part of the user, acceptance and convenience satisfaction are high among users. However, external factors such as ambient noise and the fidelity of the recording can negatively affect the accuracy of the process.

68.9.8 Signature Analysis

Probably the least controversial of all the biometric processes is the use of signature analysis. This is because the process of producing a signature, as well as the social and legal implications of accepting one, are well-established in almost all modern societies. Unlike eye scans or fingerprinting, there is almost no social stigma attached to the use of signature-based biometric systems. From a security standpoint, the use of signatures constitutes a deliberate act; they are never given out by accident. Other biometric information, such as eye scans, fingerprints, and DNA, can all be obtained without the user's knowledge. In contrast, a person must deliberately provide his or her signature.

- *How it works.* A user "signs" her name on a special tablet. Rather than using ink to record pen strokes, the tablet uses a special sensor to record the movement of a stylus to simulate the creation of a signature. There are two different types of signature analysis. *Signature comparison* examines the physical features found within the signature, including such characteristics as letter size, spacing, angles, strokes, and slant. Unfortunately, signature comparison systems can be easier to fool because they are susceptible to the use of mechanical reproductions or the handiwork of experienced forgers. In contrast, *dynamic signature verification* goes one step further; in addition to checking the physical features within the signature, it also accounts for the process of creating the signature. Dynamic signature verification systems take into account the changes in speed, timing, pressure, and acceleration that occur as a person signs his or her name. Where an experienced forger can faithfully recreate the look of a victim's signature, only the originator of a signature can repeatedly produce similar penstrokes every time. The typical verification time for a signature biometric system is four to six seconds.
- *Match points used.* The specific match points used vary from vendor to vendor. The most common systems store a digitized graphic representation of the signature as well as the variable pen movement and pressure information recorded during the signature process.

- *Storage requirements*. Most signature analysis systems store templates of approximately 1500 bytes. Some vendors claim that through compression and optimization techniques the template can be reduced to approximately 200 bytes.
- *Accuracy*. Overall, signature analysis systems possess only moderate accuracy, particularly when compared with other types of biometric indicators. This is perhaps due to the wide range of variability with which signature systems must deal. Such factors as fatigue, illness, impatience, and weather all affect how a person signs his or her name in any given instance.

68.9.9 Keystroke Dynamics

One of the most desirable aspects for a potential biometric system is to gather user input without requiring the user to alter his work process or (in the best case) even be aware that the biometric is being measured. To that end, the use of *keystroke dynamics analysis* comes closest to being as unobtrusive on the end user as possible. Measuring keystroke dynamics involves monitoring users as they type on a keyboard and measuring the speed, duration, latencies, errors, force, and intervals of the individual keystrokes. Most computer users can repeatedly type certain known patterns (such as their user ID or a standard phrase) with a consistency that can be repeated and measured, thus making it a natural for biometric use.

- *How it works*. A user types a passphrase into the keyboard. The phrase is one that is previously known to the user and is typically standardized for each user. The system scans the keyboard at a rate of 1000 times per second and records a number of different measurements to create a template. Input time varies, depending on the length of the passphrase, and verification time is typically less than five seconds.
- *Match points used*. The system separates the keystrokes into a series of *digraphs* (two adjacent keystrokes) or *trigraphs* (three adjacent keystrokes). The relationship between each key in the digraph/trigraph is captured and analyzed to create the template for that session. Two aspects of key timing are particularly important: the *dwell time* or *duration* (the amount of time a particular key is held down) and the *flight time* or *latency* (the amount of time between key presses).
- *Storage requirements*. The storage requirements for keystroke dynamics systems depend on the size of the passphrase used and the number of measurements taken per digraph.
- *Accuracy*. The overall accuracy of keystroke-based biometric systems can be highly variable, depending on the method of measurement used and the type of input requested from the user. In a system that uses structured text (i.e., passphrases supplied by the system), rather than allowing the user to supply his own passphrase, accuracy rates of 90 percent or more have been achieved. However, several factors can affect the accuracy, including the user's typing proficiency and even the use of a different keyboard.

68.9.10 Combining Technologies

The choice of which biometric system to use is very much based on the particular security need, the cost and feasibility of implementing a particular method, and the ease with which the measure can be installed and used. However, each different biometric technology has its limitations. When looking to create a high-security environment, it may be advantageous to use a time-honored security strategy: *defense-in-depth*. The concept of defense-in-depth is to place many layers or barriers between a potential attacker and a potential target. Each layer complements and enhances the layer before it, requiring an attacker to jump multiple (and difficult) hurdles to get to the target.

Defense-in-depth can also be applied to biometrics. One method of accomplishing this is through the use of *layering*. The concept behind layering is to use biometric technology in conjunction with other traditional forms of identification and authentication. For example, to gain access to a building, a visitor might have to both show a photo ID card and pass a fingerprint scan. Because photo IDs are not foolproof (despite the use of modern anti-counterfeit techniques like holographic seals and watermarks), the confidence in the accuracy of the process is enhanced by the use of fingerprints to verify that the person on the card and the person at the door are the same.

Another way of providing defense-in-depth is through *multimodal* use of biometrics. In a multimodal installation, two (or more) biometric technologies are used in parallel and the user must pass through each to be successfully identified. For example, a user might need to pass both an iris scan and a voice identification test in order to be admitted into a classified area. Multimodal use of biometrics has a couple of advantages. First, it allows the use of biometric technologies that may have higher error rates because the supplemental biometric in use will pick up any error slack. Put another way, one biometric technology may have a 10-percent error rate and another may have a 12-percent error rate. By themselves, each of these rates may be too high for practical use. But when combined, the two technologies together may have an error rate of only 1.5 percent. This may be much more acceptable for the potential user. In addition, the use of multiple biometrics allows for more variation in any single measurement. For example, voice recognition systems may have difficulty with scratchy voices (due to a cold), and other biometrics may have difficulty due to altered body features (e.g., scars, bruises, etc.). Multimodal use allows for more variation in body characteristics while still retaining a high overall level of assurance in the biometric process.

68.10 Biometric Standards

There are more than 200 vendors developing or marketing biometric equipment and systems. As in any other industry where so many different products and specifications exist, this has led to a situation where there are numerous "standards" for biometric products and measurement, and there are just as many methods of storing, retrieving, and processing biometric information. To rectify the situation and make products and systems more compatible with each other, there have been several efforts to standardize biometric interfaces and processes.

The largest effort is the *Biometric Application Program Interface*, or *BioAPI*. The BioAPI Consortium, a group of more than 90 organizations developing biometric systems and applications, developed the BioAPI. The BioAPI provides applications with a standardized way of interfacing with a broad range of biometric technologies. By using the BioAPI, developers can integrate their biometric systems in a technology-independent and platform-independent manner. For example, developers of finger scanning hardware will be able to integrate their systems with any computing platform, as long as both follow the BioAPI specification. The BioAPI specification is currently in version 1.1 and has been released into the public domain. An open source reference implementation is also available for developers to use for modeling and testing their products.

While the BioAPI addresses the standardization of biometric technology interfaces, the *Common Biometric Exchange File Format*, or *CBEFF*, is concerned with defining a common format for the storage and exchange of biometric templates. Very often, biometric applications will use their own proprietary or platform-specific formats for data storage. Unfortunately, this makes the passing of biometric data between applications or platforms difficult. The CBEFF addresses this issue by defining a platform-independent and biometric-independent format for the storage and exchange of biometric templates between systems and applications. The CBEFF is being promoted by the National Institute of Standards and Technology (NIST) and is gaining wide support as a useful standard.

68.11 Conclusion

There was a time when the use of biometric technology was restricted to classified military installations and science-fiction movies. The very notion of using biological traits to identify, authenticate, and track a person seemed too far advanced for "normal" people to consider. However, the day is now here where everyday use of biometrics is not only possible, it is happening everywhere: in office buildings and supermarkets, on computer networks and in banks, on street corners, and at football stadiums. The reduction in cost and the large gains in feasibility and reliability have forced system owners and security professionals alike to consider the use of biometrics in addition to, or even as a replacement for, traditional user identification and authentication systems. Even end users have become more and more accepting of biometrics in their everyday lives, and that trend will only continue into the future. The day is not far off when keyboards will have fingerprint readers built in to replace passwords, ATM machines will use iris scans instead of PINs, and hand scanners will replace ID badges in the office. Whatever the future holds, one thing is certain: biometrics is here to stay and getting more popular. Successful (and informed) security professionals must learn how to plan for, implement, and use biometric technology as part of their ever-growing security toolbox.

69

Single Sign-On for the Enterprise

Ross A. Leo

Corporations everywhere have made the functional shift from the mainframe-centered data processing environment to the client/server configuration. With this conversion have come new economies, a greater variety of operational options, and a new set of challenges. In the mainframe-centric installation, systems management was often the administrative twin of the computing complex itself: the components of the system were confined to one area, as were those who performed the administration of the system. In the distributed client/server arrangement, those who manage the systems are again arranged in a similar fashion. This distributed infrastructure has complicated operations, even to the extent of making the simple act of logging in more difficult.

Users need access to many different systems and applications to accomplish their work. Getting them set up to do this simply and easily is frequently time-consuming, requiring coordination between several individuals across multiple systems. In the mainframe environment, switching between these systems and applications meant returning to a main menu and making a new selection. In the client/server world, this can mean logging in to an entirely different system. New loginid, new password, and both very likely different than the ones used for the previous system—the user is inundated with these, and the problem of keeping them un-confused to prevent failed log-in attempts. It was because of this and related problems that the concept of the *Single Sign-On*, or SSO, was born.

69.1 Evolution

Given the diversity of computing platforms, operating systems, and access control software (and the many loginids and passwords that go with them), having the capability to log on to multiple systems once and simultaneously through a single transaction would seem an answer to a prayer. Such a prayer is one offered by users and access control administrators everywhere. When the concept arose of a method to accomplish this, it became clear that integrating it with the different forms of system access control would pose a daunting challenge with many hurdles.

In the days when applications software ran on a single platform, such as the early days of the mainframe, there was by default only a single login that users had to perform. Whether the application was batch oriented or interactive, the user had only a single loginid and password combination to remember. When the time came for changing passwords, the user could often make up his own. The worst thing to face was the random password generator software implemented by some companies that served up number/letter combinations. Even then, there was only one of them.

The next step was the addition of multiple computers of the same type on the same network. While these machines did not always communicate with each other, the user had to access more than one of them to fulfill all data requirements. Multiple systems, even of the same type, often had different rules of use. Different groups within the data processing department often controlled these disparate systems and sometimes completely separate organizations with the same company. Of course, the user had to have a different loginid and password for each one, although each system was reachable from the same terminal.

Then, the so-called "departmental computer" appeared. These smaller, less powerful processors served specific groups in the company to run unique applications specific to that department. Examples include materials management, accounting and finance applications, centralized word-processing, and shop-floor applications. Given the limited needs of these areas, and the fact that they frequently communicated electronically internal to themselves, tying these systems together on the same network was unnecessary. This state of affairs did not last long.

It soon became obvious that tying these systems together, and allowing them to communicate with each other over the network would speed up the information flow from one area to another. Instead of having to wait until the last week of the month to get a report through internal mail, purchasing records could be reconciled weekly with inventory records for materials received the same week from batched reports sent to purchasing. This next phase in the process of information flow did not last long either.

As systems became less and less batch oriented and more interactive, and business pressures to record the movement of goods, services, and money mounted, more rapid access was demanded. Users in one area needed direct access to information in another. There was just one problem with this scenario—and it was not a small one.

Computers have nearly always come in predominantly two different flavors: the general-purpose machines and specific-use machines. Initially called "business processing systems" and "scientific and engineering systems," these computers began the divergence from a single protocol and single operating system that continues today. For a single user to have access to both often required two separate networks because each ran on a different protocol. This of course meant two different terminals on that user's desk. That all the systems came from the same manufacturer was immaterial: the systems could not be combined on the same wire or workstation.

The next stage in the evolution was to hook in various types of adapters, multiple screen "windowed" displays, protocol converters, etc. These devices sometimes eliminated the second terminal. Then came the now-ubiquitous personal computer, or "PC" as it was first called when it was introduced by IBM on August 12, 1981. Within a few short years, adapters appeared that permitted this indispensable device to connect and display information from nearly every type of larger host computer then in service. Another godsend had hit the end user!

This evolution has continued to the present day. Most proprietary protocols have gone the way of the woolly Mammoth, and have resolved down to a precious few, nearly all of them speaking TCP/IP in some form. This convergence is extremely significant: the basic method of linking all these different computing platforms together with a common protocol on the same wire exists.

The advent of Microsoft Windows pushed this convergence one very large step further. Just as protocols had come together, so too the capability of displaying sessions with the different computers was materializing. With refinement, the graphical user interface ("GUI"—same as gooey) enabled simultaneous displays from different hosts. Once virtual memory became a reality on the PC, this pushed this envelope further still by permitting simultaneous active displays and processing.

Users were getting capabilities they had wanted and needed for years. Now impossible tasks with impossible deadlines were rendered normal, even routine. But despite all the progress that had been made, the real issue had yet to be addressed. True to form, users were grateful for all the new toys and the ease of use they promised… until they woke up and found that none of these innovations fixed the thing they had complained most and loudest about: multiple loginids and passwords.

So what is single sign-on?

69.2 What Single Sign-On Is: The Beginning

Beginning nearly 50 years ago, system designers realized that a method of tracking interaction with computer systems was needed, and so a form of identification—the loginid—was conceived. Almost simultaneously with this came the password—that sometimes arcane companion to the loginid that authenticates, or confirms the identity of, the user. And for most of the past five decades, a single loginid and its associated password was sufficient to assist the user in gaining access to virtually all the computing power then available, and to all the applications and systems that user was likely to use. Yes, those were the days… simple, straightforward, and easy to administer. And now they are all but gone, much like the club moss, the vacuum tube, and MS/DOS (perhaps).

Today's environment is more distributed in terms of both geography and platform. Although some will dispute, the attributes differentiating one operating system from another are being obscured by both network access and graphical user interfaces (the ubiquitous GUI). Because not every developer has chosen to offer his or her particular application on every computing platform (and networks have evolved to the point of being seemingly oblivious to this diversity), users now have access to a broader range of tools spread across more platforms, more transparently than at any time in the past. And yet all is not paradise.

Along with this wealth of power and utility comes the same requirement as before: to identify and authenticate the user. But now this must be done across all these various systems and platforms, and (no surprise) they all have differing mechanisms to accomplish this. The result is that users now have multiple loginids, each with its own unique password, quite probably governed by its equally unique set of rules. The CISSP knows that users complain bitterly about this situation, and will often attempt to circumvent it by whatever means necessary. To avoid this, the CISSP had to find a solution. To facilitate this, and take advantage of a marketing opportunity, software vendors saw a vital need, and thus the single sign-on (SSO) was conceived to address these issues.

Exhibit 69.1 shows where SSO was featured in the overall security program when it first appeared. As an access control method, SSO addressed important needs across multiple platforms (user identification and authentication). It was frequently regarded as a "user convenience" that was difficult and costly to implement, and of questionable value in terms of its contribution to the overall information protection and control structure.

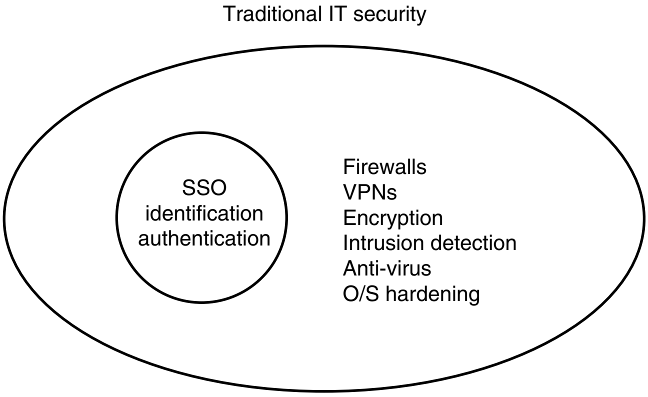

EXHIBIT 69.1 Single sign-on: in the beginning.

69.3 The Essential Problem

In simplest terms, too many loginids and passwords, and a host of other user access administration issues. With complex management structures requiring a geographically dispersed matrix approach to oversee employee work, distributed and often very different systems are necessary to meet operational objectives and reporting requirements.

In the days of largely mainframe-oriented systems, a problem of this sort was virtually nonexistent. Standards were made and enforcement was not complex. In these days, such conditions carry the same mandate for the establishment and enforcement of various system standards. Now, however, such conditions, and the systems arising in them, are of themselves not naturally conducive to this.

As mentioned above, such systems have different built-in systems for tracking user activity. The basic concepts are similar: audit trail, access control rule sets, Access Control Lists (ACLs), parameters governing system privilege levels, etc. In the end, it becomes apparent that one set of rules and standards, while sound in theory, may be exceedingly difficult to implement across all platforms without creating unmanageable complexity. It is however the "Holy Grail" that enterprise-level user administrators seek.

Despite the seeming simplicity of this problem, it represents only the tip of a range of problems associated with user administration. Such problems exist wherever the controlling access of users to resources is enforced: local in-house, remote WAN nodes, remote dial-in, and Web-based access.

As compared with Exhibit 69.1, Exhibit 69.2 illustrates how SSO has evolved into a broader scope product with greater functionality. Once considered merely a "user convenience," SSO has been more tightly integrated with other, more traditional security products and capabilities. This evolution has improved SSO's image measurably, but has not simplified its implementation.

In addition to the problem mentioned above, the need for this type of capability manifests itself in a variety of ways, some of which include:

1. As the number of entry points increases (Internet included), there is a need to implement improved and auditable security controls.
2. The management of large numbers of workstations is dictating that some control be placed over how they are used to avoid viruses, limit user-introduced problems, minimize help desk resources, etc.
3. As workstations have become electronic assistants, there has likewise arisen a need for end users to be able to use various workstations along their work path to reach their electronic desktop.
4. The proliferation of applications has made getting to all the information that is required too difficult, too cumbersome, or too time-consuming, even after passwords are automated.

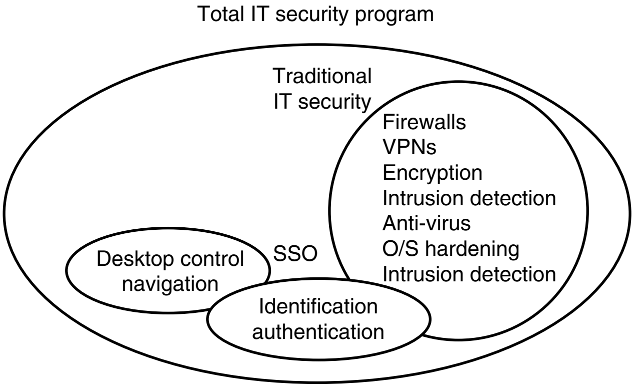

EXHIBIT 69.2 The evolution of SSO.

5. The administration of security needs to move from an application focus to a global focus to improve compliance with industry guidelines and to increase efficiency.

69.4 Mechanisms

The mechanisms used to implement SSO have varied over time. One method uses the Kerberos product to authenticate users and resources to each other through a "ticketing" system, tickets being the vehicle through which authorization to systems and resources is granted. Another method has been shells and scripting: primary authentication to the shell, which then initiated various platform-specific scripts to activate account and resource access on the target platforms.

For those organizations not wanting to expend the time and effort involved with a Kerberos implementation, the final solution was likely to be a variation of the shell-and-script approach. This had several drawbacks. It did not remove the need to set up user accounts individually on each platform. It also did not provide password synchronization or other management features. Shell-and-scripting was a half-step at best, and although it simplified user login, that was about the extent of the automation it facilitated. That was "then."

Today, different configuration approaches and options are available when implementing an SSO platform, and the drawbacks of the previous attempts have largely been well-addressed. Regardless, from the security engineering perspective, the design and objectives (i.e., the problem one is trying to solve) for the implementation plan must be evaluated in a risk analysis, and then mitigated as warranted. In the case of SSO, the operational concerns should also be evaluated, as discussed below.

One form of implementation allows one login session, which concludes with the user being actively connected to the full range of their authorized resources until logout. This type of configuration allows for reauthentication based on time (every … minutes or hours) or can be event driven (i.e., system boundary crossing).

One concern with this configuration is resource utilization. This is because a lot of network traffic is generated during login, directory/ACL accesses are performed, and several application/system sessions are established. This level of activity will degrade overall system performance substantially, especially if several users engage their login attempts simultaneously. Prevention of session loss (due to inactivity timeouts) would likely require an occasional "ping" to prevent this, if the feature itself cannot be deactivated. This too consumes resources with additional network traffic.

The other major concern with this approach would be that "open sessions" would exist, regardless of whether the user is active in a given application or not. This might make possible "session stealing" should the data stream be invaded, penetrated, or rerouted.

Another potential configuration would perform the initial identification/authentication to the network service, but would not initialize access to a specific system or application until the user explicitly requests it (i.e., double-click the related desktop icon). This would reduce the network traffic level, and would invoke new sessions only when requested. The periodic reauthentication would still apply.

69.4.1 What Single Sign-On Provides

SSO products have moved beyond simple end-user authentication and password management to more complex issues that include addressing the centralized administration of endpoint systems, the administration of end users through a role-based view that allows large populations of end users to be affected by a single system administration change (e.g., adding a new application to all office workers), and the monitoring of end users' usage of sensitive applications.

The next section describes many of the capabilities and features that an ideal single sign-on product might offer. Some of the items that mention cost refer expressly to the point being made, and not to the software performing the function. The life-cycle cost of a product such as that discussed here can and does vary widely from one installation to the next. The extent of such variation is based on many factors, and is well beyond the scope of this discussion.

A major concern with applying the SSO product to achieve the potential economies is raised when consideration is given to the cost of the product, and comparing it to the cost of how things were done pre-SSO, and contrasting this with the cost of how things will be done post-SSO, the cost of putting SSO in, and all other dollars expended in the course of project completion.

By comparing the before-and-after expenditures, the ROI (return on investment) for installing the SSO can be calculated and used as part of the justification for the project. It is recommended that this be done using equivalent formulas, constraints, and investment/ROI objectives the enterprise applies when considering any project. When the analysis and results are presented (assuming they favor this undertaking), the audience will have better insight into the soundness of the investment in terms of real costs and real value contribution. Such insight fosters endorsement, and favors greater acceptance of what will likely be a substantial cost and lengthy implementation timeline.

Regardless, it is reasonably accurate to say that this technology is neither cheap to acquire nor to maintain. In addition, as with any problem-solution set, the question must be asked, "Is this problem worth the price of the solution?" The next section discusses some of the features to assist in making such a decision.

69.4.2 Internal Capability Foundation

Having GUI-based central administration offers the potential for simplified user management, and thus possibly substantial cost-savings in reduced training, reduced administrative effort, and lower life-cycle cost for user management. This would have beneath it a logging capability that, based on some DBMS engine and a set of report generation tools, would enhance and streamline the data reduction process for activity reporting and forensic analysis derived through the SSO product.

The basic support structure must include direct (standard customary login) and Web-based access. This would be standard, especially now that the Internet has become so prolific and also since an increasing number of applications are using some form of Web-enabled/aware interface. This means that the SSO implementation would necessarily limit the scope or depth of the login process to make remote access practical, whether direct dial-up or via the Web.

One aspect of concern is the intrusiveness of the implementation. Intrusiveness is the extent to which the operating environment must be modified to accommodate the functionality of the product. Another is the retrofitting of legacy systems and applications. Installation of the SSO product on the various platforms in the enterprise would generally be done through APIs to minimize the level of custom code.

Not surprisingly, most SSO solutions vendors developed their product with the retrofit of legacy systems in mind. For example, the Platinum Technologies (now CA) product AutoSecure SSO supported RACF, ACF2, and TopSecret—all of which are access control applications born and bred in the legacy systems world. It also supports Windows NT, Novell, and TCP/IP network-supported systems. Thus, it covers the range from present day to legacy.

69.4.3 General Characteristics

The right SSO product should provide all the required features and sustain itself in an enterprise production environment. Products that operate in an open systems distributed computing environment, complete with parallel network servers, are better positioned to address enterprise needs than more narrow NOS-based SSO products.

It is obvious then that SSO products must be able to support a fairly broad array of systems, devices, and interfaces if the promise of this technology is to be realized. Given that, it is clear some environments will require greater modification than others; that is, the SSO configuration is more complex and modifies the operating environment to a greater extent. Information derived through the following questions will assist in pre-implementation analysis:

1. Is the SSO nonintrusive; that is, can it manage access to all applications, without a need to change the applications in any way?
2. Does the SSO product dictate a single common logon and password across all applications?
3. What workstations are supported by the SSO product?
4. On what operating systems can SSO network servers operate?
5. What physical identification technologies are supported (e.g., Secure-ID card)?
6. Are dial-up end users supported?
7. Is Internet access supported? If so, are authentication and encryption enforced?
8. Can the SSO desktop optionally replace the standard desktop to more closely control the usage of particular workstations (e.g., in the production area)?
9. Can passwords be automatically captured the first time an end user uses an endpoint application under the SSO product's control?
10. Can the look of the SSO desktop be replaced with a custom site-specific desktop look?
11. How will the SSO work with the PKI framework already installed?

69.4.4 End-User Management Facilities

These features and options include the normal suite of functions for account creation, password management, etc. The performance of end-user identification and authentication is obvious. Password management includes all the normal features: password aging, histories, and syntax rules. To complete the picture, support for the wide variety of token-type devices (Secure-ID cards), biometric devices, and the like should be considered, especially if remote end users are going to be using the SSO product. At the very least, optional modules providing this support should exist and be available.

Some additional attributes that should be available are:

- *Role-based privileges*. This functionality makes it possible to administer a limited number of roles that are in turn shared by a large population of end users. This would not necessarily have any effect on individual users working outside the authority scope of that role.
- *Desktop control*. This allows the native desktop to be replaced by an SSO-managed desktop, thereby preventing end users from using the workstation in such a way as to create support problems (e.g., introducing unauthorized software). This capability is particularly important in areas where workstations are shared by end users (e.g., production floor).
- *Application authorization*. This ensures that any launched application is registered and cleared by the SSO product and records are kept of individual application usage.

- *Mobile user support.* This capability allows end users to reach their desktop, independent of their location or the workstation they are using. It should also include configuring the workstation to access the proper domain server and bringing the individual's preferences to the workstation before launching applications.

69.4.5 Application Management Facilities

Application management in the context of SSO refers to the treatment of an application in a manner similar to how it manages or treats users. As shown in Exhibit 69.2, the evolved state of SSO has moved beyond the simplistic identification/authentication of users, and now encompasses certain aspects of application management. This management capability relates to the appearance of user desktops and navigation through application menus and interfaces rather than with the maintenance and upgrading of application functionality.

Context management ensures that when multiple sessions that relate to a common subject are simultaneously active, each session is automatically updated when another related session changes position (e.g., in a healthcare setting, the lab and pharmacy sessions must be on the same patient if the clinician is to avoid mixing two patients' records when reaching a clinical decision).

Application monitoring is particularly useful when it is desirable to monitor the usage of particular rows of information in an application that is not programmed to provide that type of information (e.g., access to particular constituents' records in a government setting).

Application positioning is a feature that relates to personalized yet centrally controlled desktops. This allows configuration of an end-user start-up script to open an application (possibly chosen from a set of options) on initialization, and specify even what screen is loaded.

One other feature that binds applications together is application fusing. This allows applications to operate in unison such that the end user is only aware of a single session. The view to the end user can range from a simple automated switching between applications up to and including creating an entirely new view for the end user.

69.4.6 Endpoint Management Facilities

Endpoint administration is an essential component of an SSO product because, without it, administration is forced to input the same information twice; once in the SSO and once in the endpoint each time a change is made to the SSO database. Two methods of input into the endpoint should be supported: (1) API-based agents to update endpoint systems that support an API, and (2) session animation agents to update endpoint systems that do not support an API. Services provided by the SSO to accomplish this administrative goal should include:

- *Access control.* This is the vehicle used by end users to gain access to applications and, based on each application's capabilities, to define to the application the end user's privileges within it. Both API-based and session-based applications should be supported.
- *Audit services.* These should be made available through an API to endpoint applications that wish to publish information into the SSO product's logging system.
- *Session encryption.* This feature ensures information is protected from disclosure and tampering as it moves between applications and end users. This capability should be a requirement in situations where sensitive applications only offer cleartext facilities.

69.4.7 Mobile Users

The capability for end users to use any available workstation to reach information sources is mandatory in environments where end users are expected to function in a number of different locations. Such users would include traveling employees, healthcare providers (mobile nurses, physicians, and technicians), consultants, and sales staff. In the highly mobile workforce of today's world, it is unlikely that a product not offering this feature would be successful.

Another possible feature would facilitate workstation sharing; that is, the sharing of the device by multiple simultaneous users, each one with their own active session separate from all others. This capability would entail the use of a form of screen swapping so that loginids and passwords would not be shared. When the first user finishes his session, rather than log out, he locks the session, a hot-key combination switches to the next open login screen, and the second user initiates his session, etc.

When investigating the potential needs in this regard, the questions to ask yourself and the vendors of such products should include:

1. Can a workstation in a common area be shared by many end users (e.g., production floor)?
2. If someone wants to use a workstation already in use by another end user, can the SSO product gracefully close the existing end user's applications (including closing open documents) and turn control over to the new end user?
3. Can end users adjust the organization of their desktop, and if so, does it travel with them, independent of the workstation they use?
4. Can individual applications preferences travel with the end user to other workstations (e.g., MS Word preferences)?
5. Can the set of available applications be configured to vary based on the entry point of the end user into the network?
6. If a Novell end user is logging in at a workstation that is assigned to a different Novell domain, how does the end user get back to his or her domain?
7. Given that Windows 95 and Windows NT rely on a locally stored password for authentication, what happens when the end user logs onto another workstation?
8. Is the date and time of the last successful sign-on shown at the time the end user signs on to highlight unauthorized sign-ons?
9. Is the name of the logged in end user prominently displayed to avoid inadvertent use of workstations by other end users?

69.4.8 Authentication

Authentication ensures that users are who are who they claim to be. It also ensures that all processes and transactions are initiated only by authorized end users. User authentication couples the loginid and the password, providing an identifier for the user, a mechanism for assigning access privileges, and an auditing "marker" for the system against which to track all activity, such as file accesses, process initiation, and other actions (e.g., attempted logons). Thus, through the process of authentication, one has the means to control and track the "who" and the "what."

The SSO products take this process and enable it to be used for additional services that enhance and extend the applications of the loginid/password combination. Some of these applications provide a convenience for the user that also improves security: the ability to lock the workstation just before stepping away briefly means the user is more likely to do it, rather than leave his workstation open for abuse by another. Some are extensions of audit tools: display of last login attempt, and log entry of all sign-ons. These features are certainly not unique to SSO, but they extend and enhance its functionality, and thus make it more user friendly.

As part of a Public Key Infrastructure (PKI) installation, the SSO should have the capability to support digital certificate authentication. Through a variety of methods (token, password input, biometrics possibly), the SSO supplies a digital certificate for the user that the system then uses as both an authenticator and an access privilege "license" in a fashion similar to the Kerberos ticket. The vital point here is not how this functionality is actually performed (that is another lengthy discussion), but that the SSO supports and integrates with a PKI, and that it uses widely recognized standards in doing so.

It should noted, however, that any SSO product that offers less than the standard suite of features obtainable through the more common access control programs should *not* be considered. Such a product may be offered as an alternative to the more richly featured SSO products on the premise that "simpler is better." Simpler is not better in this case because it means reduced effectiveness.

To know whether the candidates measure up, an inquiry should be made regarding these aspects:

1. Is authentication done at a network server or in the workstation?
2. Is authentication done with a proven and accepted standard (e.g., Kerberos)?
3. Are all sign-on attempts logged?
4. After a site-specified number of failed sign-on attempts, can all future sign-on attempts be unconditionally rejected?
5. Is an inactivity timer available to lock or close the desktop when there is a lack of activity for a period of time?
6. Can the desktop be easily locked or closed when someone leaves a workstation (e.g., depression of single key)?
7. Is the date and time of the last successful sign-on shown at the time the end user signs on to highlight unauthorized sign-ons?

69.4.9 Encryption

Encryption ensures that information that flows between the end users and the security server(s) and endpoint applications they access is not intercepted through spying, line-tapping, or some other method of eavesdropping. Many SSO products encrypt traffic between the end user and the security server but let cleartext pass between the end user and the endpoint applications, causing a potential security gap to exist. Some products by default encrypt all traffic between workstation and server, some do not, and still others provide this feature as an option that is selectable at installation.

Each installation is different in its environment and requirements. The same holds true when it comes to risks and vulnerabilities. Points to cover that address this include:

- Is all traffic between the workstation and the SSO server encrypted?
- Can the SSO product provide encryption all the way to the endpoint applications (e.g., computer room) without requiring changes to the endpoint applications?
- Is the data stream encrypted using an accepted and proven standard algorithm (e.g., DES, Triple DES, IDEA, AES, or other)?

69.4.10 Access Control

End users should only be presented with the applications they are authorized to access. Activities required to launch these applications should be carefully evaluated because many SSO products assume that only API-based endpoint applications can participate, or that the SSO is the owner of a single password that all endpoint applications must comply with. These activities include automatically inputting and updating application passwords when they expire.

Exhibit 69.3 shows how the SSO facilitates automatic login and acquisition of all resources to which a user is authorized. The user logs into the authentication server (centrally positioned on the network). This then validates the user and his access rights. The server then sends out the validated credentials and activates the required scripts to log the user in and attach his resources to the initiated session.

While it is certainly true that automatically generated passwords might make the user's life easier, current best practice is to allow users to create and use their own passwords. Along with this should be a rule set governing the syntax of those passwords; for example, no dictionary words, a combination of numbers and

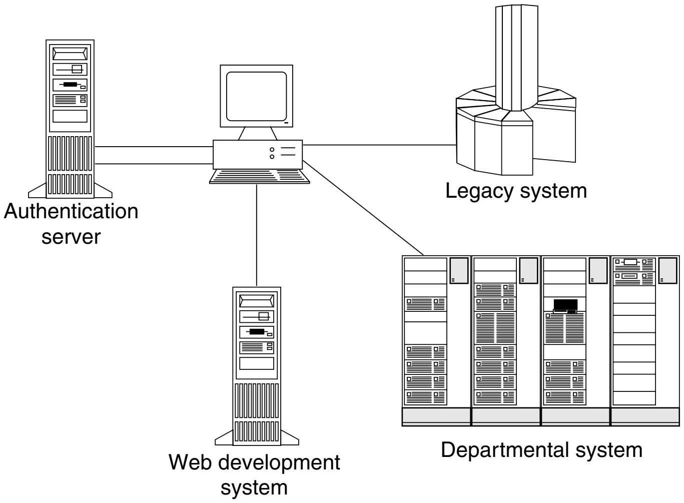

EXHIBIT 69.3 Automated login.

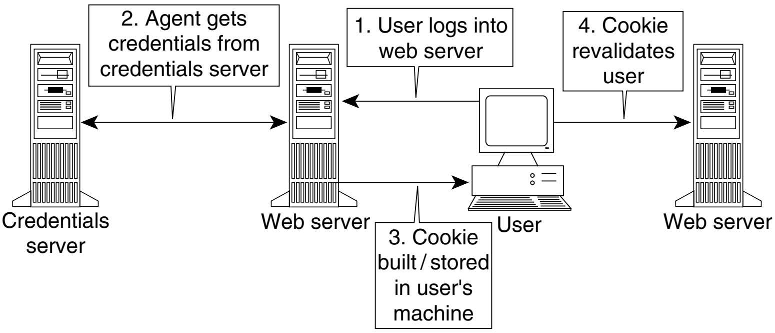
letters, a mixture of case among the letters, no repetition within a certain number of password generations, proscribed use of special characters (#, $, &, ?, %, etc.), and other rules. The SSO should support this function across all intended interfaces to systems and applications.

Exhibit 69.4 shows how the SSO facilitates login over the World Wide Web (WWW) by making use of cookies—small information packets shipped back and forth over the Web. The user logs into the initial Web server (1), which then activates an agent that retrieves the user's credentials from the credentials server (2). This server is similar in function to a name server or an LDAP server, except that this device provides authorization and access privileges information specifically. The cookie is then built and stored in the user's machine (3), and is used to revalidate the user each time a page transition is made.

This process is similar to verification of application-level privileges inside a DBMS. While moving within the database system, each time the user accesses a new region or transaction, access privileges must be reverified to ensure correct authorization. Page transitions on the Web equate to new regions or transactions within the DBMS.

In this area, the following points should be covered:

1. Can all applications, regardless of platform, be nonintrusively supported (i.e., without changing them, either extensively or at all)?



2. Agent gets credentials from credentials server
1. User logs into web server
4. Cookie revalidates user
Credentials server
Web server
User
Web server
3. Cookie built / stored in user's machine

EXHIBIT 69.4 SSO: Web with cookies.

2. What types of adapters are available to mechanize the application launching process without having to adjust the individual applications? Are API-based, OLE-based, DDE-based, scripting-based, and session-simulation adapters available?
3. Are all application activations and deactivations logged?
4. When application passwords expire, does the SSO product automatically generate new expired one-time passwords or are users able to select and enter their own choices?
5. When an application is activated, can information be used to navigate to the proper position in the application (e.g., order entry application is positioned to the order entry screen)?
6. Can the application activation procedure be hidden from the end user, or does the end user have to see the mechanized process as it progresses?
7. Are inactivity timers available to terminate an application when there is a lack of activity for a period of time?

69.4.11 Application Control

Application control limits end users' use of applications in such a way that only particular screens within a given application are visible, only specific records can be requested, and particular uses of the applications can be recorded for audit purposes, transparently to the endpoint applications so no changes are needed to the applications involved.

As a way in which user navigation is controlled, this is another feature that can assist with enhancing the overall security posture of an installation. Again, this would be as an adjunct feature—not the key method. The determination of the usefulness of this capability can be made through the following questions.

1. Can applets be incorporated into the desktop's presentation space (e.g., list of major accounts)?
2. Can applet information (e.g., particular account) be used to navigate to the proper position within an application (e.g., list of orders outstanding for a particular customer)?
3. Can each application's view be adjusted to show only the information that is appropriate for a particular end user?
4. Can the SSO product log end users' activities inside applications (e.g., which accounts have been accessed)?
5. Can application screens be enhanced with new capabilities without having to change the applications themselves (e.g., additional validation of input as it is captured)?
6. Can the SSO product log attempt to reach areas of applications that go beyond permitted areas (e.g., confidential patient information)?
7. Can multiple applications be fused into a single end-user session to eliminate the need for end users to learn each application?
8. Can applications be automatically coordinated such that end-user movement in one application (e.g., billing) automatically repositions subordinate application sessions (e.g., current orders, accounts receivable)?

69.4.12 Administration

The centralized administration capabilities offered by the SSO are—if not the main attraction—the "Holy Grail" mentioned earlier. The management (creation, modification, deletion) of user accounts and resource profiles through an SSO product can streamline and simplify this function within an organization or enterprise. The power of the administration tools is key because the cost of administering a large population of end users can easily overshadow the cost of the SSO product itself.

The product analysis should take the following attributes into consideration:

1. Does the SSO product allow for the central administration of all endpoint systems? (That is, changes to the central administration database are automatically reflected in endpoint systems.)
2. Is administration done at an "end-user" or a "role within the enterprise" level? (This is a critical element because an end-user focus can result in disproportional administration effort.)
3. Does each workstation have to be individually installed? If so, what is the estimated time required?
4. Can end users' roles in the organization be easily changed (to deal with people that perform mixed roles)?
5. Is the desktop automatically adjusted if the end user's roles are changed, or does the desktop view have to be adjusted manually?
6. Can an administrator see a list of active end users by application?
7. Can an administrator access all granted passwords to specific endpoint applications?
8. Does the product gracefully deal with network server failures?

69.4.13 Services for Desktop-Aware Applications

In cases where it is possible to modify existing endpoint applications, the ability for them to cooperatively share responsibilities with the desktop is very attractive. What is required is a published desktop API and associated services.

The circumstance can and does arise where the end user wants to customize a standard product in the enterprise suite for his own use in a way that affects only him and does not change the basic application itself. Such customization may include display formats, scripts, and processes relating to specific tasks the individual user wants or needs to use in conjunction with the server-supplied application. Through the supplied API, the user can make the custom changes necessary without impediment, and this allows other users to proceed without affecting them or their workstations.

In such cases, the user wanting the changes may require specific access and other controls to lock out other users. An example might be one where the user requiring the changes works on sensitive or restricted information, and others in the same area do not, and are not permitted access to such. This then may necessitate the use of access controls embedded in the scripts used to change his desktop to meet his additional security needs.

That being the case, the API should provide the capability to access the SSO, and perform the access/privilege checking, without the user (the one making the localized changes) having any direct access to the SSO access/privilege database. This should likewise be true to facilitate the logging of access attempts, transactions, and data access authorizations to track the use of the local workstation. To determine the existence of this facility in the SSO, questions should be asked regarding such services, APIs, and related capabilities, such as:

1. Can desktop-aware applications interrogate end-user permissions managed by the SSO product?
2. Can desktop-aware applications make use the SSO product's logging facilities for their own use?
3. Do API services exist that enable desktop customization?
4. Do these APIs facilitate this without compromising overall system integrity by providing "back-door" access to the resident security information database?

69.4.14 Reliability and Performance

Given that an SSO product is, by necessity, positioned between the end users and the applications they need access to get their jobs done, it has a very high visibility within the enterprise and any unexpected reliability or performance problems can have serious consequences. This issue points directly back at the original business case made to justify the product.

Concerns with regard to reliability and performance generally focus on the additional layering of one software upon another ("yet another layer"), the interfaces between the SSO and other access control programs it touches, the complexity of these interactions, etc. One aspect of concern is the increased latency introduced by this new layer. The time from power-on to login screen has steadily increased over the years, and the addition of the SSO may increase it yet again. This can exacerbate user frustration.

The question of reliability arises when considering the interaction between the SSO and the other security front ends. The complexity of the interfaces, if very great, may lead to increased service problems; the more complex the code, the more likely failure is to result more frequently. This may manifest itself by passwords and changes in them losing synchronization, not being reliably passed, or privilege assignment files not being updated uniformly or rapidly. Such problems as these call into question whether SSO was such a good idea, even if it truly was. Complex code is costly to maintain, and the SSO is nothing if not complex. Even the best programming can be rendered ineffective or, worse yet, counterproductive if it is not implemented properly.

An SSO product requires more of this type of attention than most because of its feature-rich complexity. It is clear that the goal of SSO is access control, and in that regard achieves the same goals of confidentiality, integrity, and availability as any other access control system does. SSO products are designed to provide more functionality, but in so doing can adversely affect the environments in which they are installed. If they do, the impacts will most likely appear against factors of reliability, integrity, and performance; and if large enough, the impacts will negate the benefits the SSO provides elsewhere.

69.5 Requirements

This section presents the contents of a requirements document that the Georgia Area RACF Users Group (GARUG) put together regarding things it would like to see in an SSO application.

69.5.1 Objectives

The focus of this list is to present a set of functional requirements for the design and development of a trusted single sign-on and security administration product. It is the intention that this be used by security practitioners to determine the effectiveness of the security products they may be reviewing.

It contains many requirements that experienced security users feel are very important to the successful protection of multi-platform systems. It also contains several functional requirements that may not be immediately available at this time. Having said that, the list can be used as a research and development tool because the requirements are being espoused by experienced, working security practitioners in response to real-world problems.

This topic was brought to the forefront by many in the professional security community, and the GARUG members that prepared this list in response. This is not a cookbook to use in the search for security products. In many ways, this list is visionary, which is to say that many of the requirements stated here do not exist. But just because they do not exist now does not deter their inclusion now. As one member noted, "If we don't ask for it, we won't get it."

69.5.2 Functional Requirements

The following is a listing of the functional requirements of an ideal security product on the market. The list also includes many features that security practitioners want to see included in future products. The requirements are broken down in four major categories: security administration management, identification and authorization, access control, and data integrity/confidentiality/encryption. Under each category the requirements are listed in most critical to least critical order.

69.5.3 Assumptions

There are three general assumptions that follow throughout this document.

1. All loginids are unique; no two loginids can be the same. This prevents two users from having the same loginid.
2. The vendor should provide the requisite software to provide functionality on all supported platforms.
3. All vendor products are changing. All products will have to work with various unlike platforms.

69.5.4 Security Administration Management

69.5.4.1 Single Point of Administration

All administration of the product should be done from a single point. This enables an administrator to provide support for the product from any one platform device.

69.5.4.2 Ability to Group Users

The product should enable the grouping of like users where possible. These groups should be handled the same way individual users are handled. This will enable more efficient administration of access authority.

69.5.4.3 Ability to Enforce Enterprise/Global Security Rules

The product should provide the ability to enforce security rules over the entire enterprise, regardless of platform. This will ensure consistent security over resources on all protected platforms.

69.5.4.4 Audit Trail

All changes, modifications, additions, and deletions should be logged. This ensures that all security changes are recorded for review at a later time.

69.5.4.5 Ability to Recreate

Information logged by the system should be able to be used to “back out” changes to the security system. Example: used to recreate deleted resources or users. This enables mass changes to be “backed out” of production or enables mass additions or changes to be made based on logged information.

69.5.4.6 Ability to Trace Access

The product should enable the administrator to be able to trace access to systems, regardless of system or platform.

69.5.4.7 Scoping and Decentralization of Control

The product should be able to support the creation of spans of control so that administrators can be excluded from or included in certain security control areas within the overall security setup. This enables an administrator to decentralize the administration of security functions based on the groups, nodes, domains, and enterprises over which the decentralized administrator has control.

69.5.4.8 Administration for Multiple Platforms

The product should provide for the administration of the product for any of the supported platforms. This enables the administrator to support the product for any platform of his or her choice.

69.5.4.9 Synchronization across All Entities

The product should be synchronizing security data across all entities and all platforms. This ensures that all security decisions are made with up-to-date security information.

69.5.4.10 Real-Time and Batch Update

All changes should be made online/real-time. The ability to batch changes together is also important to enable easy loading or changing of large numbers of security resources or users.

69.5.4.11 Common Control Language across All Platforms

The product should feature a common control language across all serviced platforms so that administrators do not have to learn and use different commands on different platforms.

69.5.4.12 One Single Product

The product should be a single product—not a compendium of several associated products. Modularity for the sake of platform-to-platform compatibility is acceptable and favored.

69.5.4.13 Flexible Cost

The cost of the product should be reasonable. Several cost scenarios should be considered, such as per seat, CPU, site licensing, and MIPS pricing. Pricing should include disaster recovery scenarios.

69.5.4.14 Physical Terminal/Node/Address Control

The product should have the ability to restrict or control access on the basis of a terminal, node, or network address. This ability will enable users to provide access control by physical location.

69.5.4.15 Release Independent/Backward Compatible

All releases of the product should be backward compatible or release independent. Features of new releases should coexist with current features and not require a total reinstallation of the product. This ensures that the time and effort previously invested in the prior release of the product is not lost when a new release is installed.

69.5.4.16 Software Release Distribution

New releases of the product should be distributed via the network from a single distribution server of the administrator's choice. This enables an administrator to upgrade the product on any platform without physically moving from platform to platform.

69.5.4.17 Ability to Do Phased Implementation

The product should support a phased implementation to enable administrators to implement the product on individual platforms without affecting other platforms. This will enable installation on a platform-by-platform basis if desired.

69.5.4.18 Ability to Interface with Application/Database/Network Security

The product should be able to interface with existing application, database, or network security by way of standard security interfaces. This will ensure that the product will mesh with security products already installed.

69.5.4.19 SQL Reporting

The product should have the ability to use SQL query and reporting tools to produce security setup reports/queries. This feature will enable easy access to security information for administrators.

69.5.4.20 Ability to Create Security Extract Files

The product should have a feature to produce an extract file of the security structure and the logging/violation records. This enables the administrator to write his or her own reporting systems via SAS or any other language.

69.5.4.21 Usage Counter per Application/Node/Domain/Enterprise

The product should include an internal counter to maintain the usage count of each application, domain, or enterprise. This enables an administrator to determine which applications, nodes, domains, or enterprises are being used and to what extent they are being used.

69.5.4.22 Test Facility

The product should include a test facility to enable administrators to test security changes before placing them into production. This ensures that all security changes are fully tested before being placed into production.

69.5.4.23 Ability to Tag Enterprise/Domain/Node/Application

The product should be able to add a notation or "tag" an enterprise/domain/node/application in order to provide the administrator with a way identify the entity. This enables the administrator to denote the tagged entity and possibly perform extra or nonstandard operations on the entity based on that tag.

69.5.4.24 Platform Inquiries

The product should support inquiries to the secured platforms regarding the security setup, violations, and other logged events. This will enable an administrator to inquire on security information without having to sign on/log on.

69.5.4.25 Customize in Real-Time

It is important to have a feature that enables the customization of selected features (those features for which customization is allowed) without reinitializing the product. This feature will ensure that the product is available for 24-hour, seven-day-a-week processing.

69.5.4.26 GUI Interface

The product should provide a user interface via a Windows-like user interface. The interface may vary slightly between platforms (i.e., Windows, OS/2, X-Windows, etc.) but should retain the same functionality. This facilitates operating consistency and lowers operator and user training requirements.

69.5.4.27 User-Defined Fields

The product should have a number of user customizable/user-defined fields. This enables a user to provide for informational needs that are specific to his or her organization.

69.5.5 Identification and Authorization

69.5.5.1 Support RACF Pass Ticket Technology

The product should support IBM's RACF Pass Ticket technology, ensuring that the product can reside in an environment using Pass Ticket technology to provide security identification and authorization.

69.5.5.2 Support Password Rules (i.e., Aging, Syntax, etc.)

All common password rules should be supported:

- Use or non-use of passwords
- Password length rules
- Password aging rules
- Password change intervals
- Password syntax rules
- Password expiration warning message
- Save previous passwords
- Password uniqueness rules

- Limited number of logons after a password expires
- Customer-defined rules

69.5.5.3 Logging of All Activity Including Origin/Destination/Application/Platform

All activity should be logged, or able to be logged, for all activities. The logging should include the origin of the logged item or action, the destination, the application involved, and the platform involved. This enables the administrator to provide a concise map of all activity on the enterprise. The degree of logging should be controlled by the administrator.

69.5.5.4 Single Revoke/Resume for All Platforms

The product should support a single revoke or resume of a loginid, regardless of the platform. This ensures that users can be revoked or resumed with only one command from one source or platform.

69.5.5.5 Support a Standard Primary loginid Format

The administrator should define all common loginid syntax rules. The product should include features to translate unlike loginids from different platforms so that they can be serviced. This enables the product to handle loginids from systems that support different loginid syntax that cannot be supported natively.

69.5.5.6 Auto Revoke after X Attempts

Users should be revoked from system access after a specified number of invalid attempts. This threshold should be set by the administrator. This ensures that invalid users are prevented from retrying sign-ons indefinitely.

69.5.5.7 Capture Point of Origin Information, Including Caller ID/Phone Number for Dial-In Access

The product should be able to capture telephone caller ID (ANI) information if needed. This will provide an administrator increased information that can be acted upon manually or via an exit to provide increased security for chosen ports.

69.5.5.8 Authorization Server Should Be Portable (Multi-platform)

The product should provide for the authentication server to reside on any platform that the product can control. This provides needed portability if there is a need to move the authentication server to another platform for any reason.

69.5.5.9 Single Point of Authorization

All authorizations should be made a single point (i.e., an authentication server). The product should not need to go to several versions of the product on several platforms to gain the needed access to a resource. This provides not only a single point of administration for the product, but also reduced network security traffic.

69.5.5.10 Support User Exits/Options

The product should support the addition of user exits, options, or application programming interfaces (APIs) that could be attached to the base product at strategically identified points of operation. The points would include sign-on, sign-off, resource access check, etc. The enables an administrator or essential technical support personnel to add exit/option code to the package to provide for specific security needs above and beyond the scope of the package.

69.5.5.11 Ensure loginid Uniqueness

The product should ensure that all loginids are unique; no two loginids can be the same. This prevents two users from having the same loginid.

69.5.5.12 Source Sign-On Support

The product should support sign-ons from a variety of sources. These sources should include LAN/WAN, workstations, portables (laptops and notebooks), dial-in, and dumb terminals. This would ensure that all potential login sources are enabled to provide login capability and facilitate support for legacy systems.

69.5.5.13 Customizable Messages

The product should support the use of customized security messages. The will enable an administrator to customize messages to fit the needs of his or her organization.

69.5.6 Access Control

69.5.6.1 Support Smart Card Tokens

The product should support the use of the common smart card security tokens (i.e., SecureID cards) to enable their use on any platform. The enables the administrator to provide for increased security measures where they are needed for access to the systems.

69.5.6.2 Ability to Support Scripting—Session Manager Menus

The product should support the use of session manager scripting. This enables the use of a session manager script in those sites and instances where they are needed or required.

69.5.6.3 Privileges at the Group and System Level

The product should support administration privileges at a group level (based on span of control) or on the system level. This enables the product to be administered by several administrators without the administrators' authority overlapping.

69.5.6.4 Default Protection Unless Specified

The product should provide for the protection of all resources and entities as the default unless the opposite of protection for only those resources profiled is specified. The enables each organization to determine the best way to install the product based on is own security needs.

69.5.6.5 Support Masking/Generics

The product should support security profiles containing generic characters that enable the product to make security decisions based on groups of resources as opposed to individual security profiles. The enables the administrator to provide security profiles over many like-named resources with the minimum amount of administration.

69.5.6.6 Allow Delegation within Power of Authority

The product should allow an administrator to delegate security administration authority to others at the discretion of the administrator within his or her span of authority. An administrator would have the ability to give some of his or her security authority to another administrator for backup purposes.

69.5.7 Data Integrity/Confidentiality/Encryption

69.5.7.1 No Cleartext Passwords (Net or DB)—Dumb Terminal Exception

At no time should any password be available on the network or in the security database in clear, human-readable form. The only exception is the use of dumb terminals where the terminal does not support encryption techniques. This will ensure the integrity of the users' passwords in all cases with the exception of dumb terminals.

69.5.7.2 Option to Have One or Distributed Security DBs

The product should support the option of having a single security database or several distributed security databases on different platforms. This enables an administrator to use a distributed database on a platform that may be sensitive to increased activity rather than a single security database. The administrator will control who can and if they can update distributed databases.

69.5.7.3 Inactive User Timeout

All users who are inactive for a set period during a session should be timed out and signed off of all sessions. This ensures that a user who becomes inactive for whatever reason does not compromise the security of the system by providing an open terminal to a system. This feature should be controlled by the administrator and have two layers:

1. At the session manager/screen level
2. At the application/platform level

69.5.7.4 Inactive User Revoke

All users who have not signed on within a set period should be revoked. This period should be configurable by the administrator. This will ensure that loginids are not valid if not used within a set period of time.

69.5.7.5 Ability to Back Up Security DBs to Choice of Platforms/Media

The product should be able to back up its security database to a choice of supported platforms or storage media. This enables the user to have a variety of destinations available for the security database backup.

69.5.7.6 Encryption should Be Commercial Standard (Presently DES)

The encryption used in the product should be standard. That standard is presently DES but could change as new encryption standards are made. This will ensure that the product will be based on a tested, generally accepted encryption base.

69.5.7.7 Integrity of Security DB(s)

The database used by the product to store security information and parameters should be protected from changes via any source other than the product itself. Generic file edit tools should not be able to view or update the security database.

69.5.7.8 Optional Application Data Encryption

The product should provide the optional ability to interface to encrypted application data if the encryption techniques are provided. This enables the product to interact with encrypted data from existing applications.

69.5.7.9 Failsoft Ability

The product should have the ability to perform at a degraded degree without access to the security database. This ability should rely on administrator input on an as-needed basis to enable a user to sign on, access resources, and sign off. This enables the product to at least work in a degraded mode in an emergency in such a fashion that security is not compromised.

69.6 Conclusion

Single sign-on (SSO) can indeed be the answer to an array of user administration and access control problems. For the user, it might be a godsend. It is, however, not a straightforward or inexpensive solution. As with other so-called “enterprise security solutions,” there remain the problems of scalability and phasing-in. There is generally no half-step to be taken in terms of how such a technology as this is rolled out. It is of course possible to limit it to a single platform, but that negates the whole point of doing SSO in the first place.

Like all solutions, SSO must have a real problem that it addresses. Initially regarded as a solution looking for a problem, SSO has broadened its scope to address more than simply the avalanche of loginids and passwords users seem to acquire in their systems travels. This greater functionality can provide much needed assistance and control in managing the user, his access rights, and the trail of activity left in his wake. This however comes at a cost.

Some significant observations made by others regarding SSO became apparent from an informal survey conducted by this author. The first is that it can be very expensive, based mostly on the scope of the implementation. The second is that it can be a solution looking for a problem—meaning that it sounds like a "really neat" technology (which it is) that proffers religion on some. This "religion" tends to be a real cause for concern in the manager or CIO over the IT function, for reasons that are well-understood. When the first conjoins with the second, the result is frequently substantial project scope creep—usually a very sad story with an unhappy ending in the IT world.

The third observation was more subtle, but more interesting. Although several vendors still offer an SSO product as an add-on, the trend appears to be more toward SSO slowly disappearing as a unique product. Instead, this capability is being included in platform or enterprise IT management solution software such as Tivoli (IBM) and Unicenter-TNG (Computer Associates). Given the fact that SSO products support most of the functions endemic to PKI, the other likelihood in the author's opinion is that SSO will be subsumed into the enterprise PKI solution and thus become a "feature" rather than a "product."

It does seem certain that this technology will continue to mature and improve, and eventually become more widely used. As more and more experience is gained in implementation endeavors, the files of "lessons learned" will grow large with many painful implementation horror stories. Such stories often arise from "bad products badly constructed." Just as often, they arise from poorly managed implementation projects. SSO will suffer, and has, from the same bad rap—partially deserved, partially not. The point here is: do your homework, select the right tool for the right job, plan your work carefully, and execute thoroughly. It will probably still be difficult, but one might actually get the results one wants.

In the mystical and arcane practice of information security, many different tools and technologies have acquired that rarified and undeserved status known as "panacea." In virtually no case has any one of them fully lived up to this unreasonable expectation, and the family of products providing the function known as "single sign-on" is no exception.

70
Centralized Authentication Services (RADIUS, TACACS, DIAMETER)

Bill Stackpole

Got the telecommuter, mobile workforce, VPN, multi-platform, dial-in user authentication blues? Need a centralized method for controlling and auditing external accesses to your network? Then RADIUS, TACACS, or DIAMETER may be just what you have been looking for. Flexible, inexpensive, and easy to implement, these centralized authentication servers improve remote access security and reduce the time and effort required to manage remote access server (RAS) clients.

RADIUS, TACACS, and DIAMETER are classified as authentication, authorization, and accounting (AAA) servers. The Internet Engineering Task Force (IETF) chartered an AAA Working Group in 1998 to develop the authentication, authorization, and accounting requirements for network access. The goal was to produce a base protocol that supported a number of different network access models, including traditional dial-in network access servers (NAS), Mobile-IP, and roaming operations (ROAMOPS). The group was to build upon the work of existing access providers such as Livingston Enterprises.

Livingston Enterprises originally developed RADIUS (Remote Authentication Dial-In User Service) for their line of network access servers (NAS) to assist timeshare and Internet service providers with billing information consolidation and connection configuration. Livingston based RADIUS on the IETF distributed security model and actively promoted it through the IETF Network Access Server Requirements Working Group in the early 1990s. The client/server design was created to be open and extensible so it could be easily adapted to work with other third-party products. At this writing, RADIUS version 2 was a proposed IETF standard managed by the RADIUS Working Group.

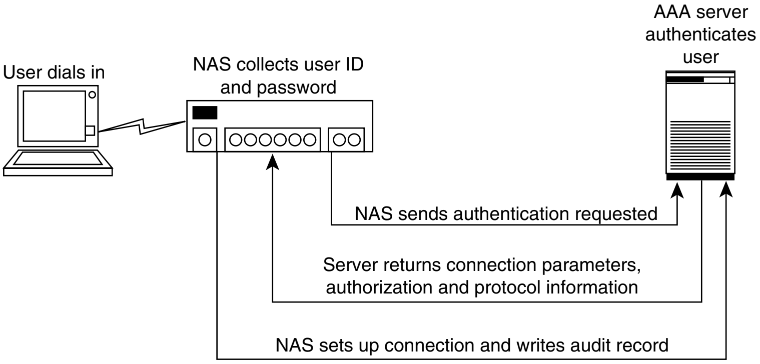
The origin of the Terminal Access Controller Access Control System (TACACS) daemon used in the early days of ARPANET is unknown. Cisco Systems adopted the protocol to support AAA services on its products in the early 1990s. Cisco extended the protocol to enhance security and support additional types of authentication requests and response codes. They named the new protocol TACACS+. The current version of the TACACS specification is a proposed IETF Standard (RFC 1492) managed by the Network Working Group. It was developed with the assistance of Cisco Systems.

Pat Calhoun (Sun Laboratories) and Allan Rubens (Ascend Communications) proposed the DIAMETER AAA framework as a draft standard to the IETF in 1998. The name DIAMETER is not an acronym but rather a play on the RADIUS name. DIAMETER was designed from the ground up to support roaming applications and to overcoming the extension limitations of the RADIUS and TACACS protocols. It provides the base protocols required to support any number of AAA extensions, including NAS, Mobile-IP, host, application, and Web-based requirements. At this writing, DIAMETER consisted of eight IETF draft proposals, authored by twelve different contributors from Sun, Microsoft, Cisco, Nortel, and others. Pat Calhoun continues to coordinate the DIAMETER effort.

70.1 AAA 101: Key Features of an AAA Service

The key features of a centralized AAA service include (1) a distributed (client/server) security model, (2) authenticated transactions, (3) flexible authentication mechanisms, and (4) an extensible protocol. Distributed security separates the authentication process from the communications process, making it possible to consolidate user authentication information into a single centralized database. The network access devices (i.e., an NAS) are the clients. They pass user information to an AAA server and act upon the response(s) the server returns. The servers receive user connection requests, authenticate the user, and return to the client NAS the configuration information required to deliver services to the user. The returned information may include transport and protocol parameters, additional authentication requirements (i.e., callback, SecureID), authorization directives (i.e., services allowed, filters to apply), and accounting requirements (Exhibit 70.1).

Transmissions between the client and server are authenticated to ensure the integrity of the transactions. Sensitive information (e.g., passwords) is encrypted using a shared secret key to ensure confidentiality and



AAA server authenticates user
User dials in
NAS collects user ID and password
NAS sends authentication requested
Server returns connection parameters, authorization and protocol information
NAS sets up connection and writes audit record

EXHIBIT 70.1 Key features of a centralized AAA service.

prevent passwords and other authentication information from being monitored or captured during transmission. This is particularly important when the data travels across public carrier (e.g., WAN) links.

AAA servers can support a variety of authentication mechanisms. This flexibility is a key AAA feature. User access can be authenticated using PAP (Password Authentication Protocol), CHAP (Challenge Handshake Authentication Protocol), the standard UNIX login process, or the server can act as a proxy and forward the authentication to other mechanisms like a Microsoft domain controller, a Novell NDS server, or a SecureID ACE server. Some AAA server implementations use additional mechanisms such as calling number identification (caller ID) and callback to further secure connections.

Because technology changes so rapidly, AAA servers are designed with extensible protocols. RADIUS, DIAMETER, and TACACS use variable-length attribute values designed to support any number of new parameters without disturbing existing implementations of the protocol. DIAMETER's framework approach provides additional extensibility by standardizing a transport mechanism (framework) that can support any number of customized AAA modules.

From a management perspective, AAA servers provide some significant advantages, including:

- Reduced user setup and maintenance times because users are maintained on a single host
- Fewer configuration errors because formats are similar across multiple access devices
- Less security administrator training requirements because there is only one system syntax to learn
- Better auditing because all login and authentication requests come through a single system
- Reduced help desk calls because the user interface is consistent across all access methods
- Quicker proliferation of access information because information only needs to be replicated to a limited number of AAA servers
- Enhanced security support through the use of additional authentication mechanisms (i.e., SecureID)
- Extensible design makes it easy to add new devices without disturbing existing configurations

70.2 RADIUS: Remote Authentication Dial-In User Service

RADIUS is by far the most popular AAA service in use today. Its popularity can be attributed to Livingston's decision to open the distribution of the RADIUS source code. Users were quick to port the service across multiple platforms and add customized features, many of which Livingston incorporated as standard features in later releases. Today, versions of the RADIUS server are available for every major operating system from both freeware and commercial sources, and the RADIUS client comes standard on NAS products from every major vendor.

A basic RADIUS server implementation references two configuration files. The client configuration file contains the address of the client and the shared secret used to authenticate transactions. The user file contains the user identification and authentication information (e.g., userID and password) as well as connection and authorization parameters. Parameters are passed between the client and server using a simple five-field format encapsulated into a single UDP packet. The brevity of the format and the efficiency of the UDP protocol (no connection overhead) allow the server to handle large volumes of requests efficiently. However, the format and protocol also have a downside. They do not lend themselves well to some of today's diverse access requirements (i.e., ROAMOPS), and retransmissions are a problem in heavy load or failed node scenarios.

70.2.1 Putting the AA in RADIUS: Authentications and Authorizations

RADIUS has eight standard transaction types: access-request, access-accept, access-reject, accounting-request, accounting-response, access-challenge, status-server, and status-client. Authentication is accomplished by decrypting a NAS access-request packet, authenticating the NAS source, and validating the access-request parameters against the user file. The server then returns one of three authentication responses: access-accept, access-reject, or access-challenge. The latter is a request for additional authentication information such as a one-time password from a token or a callback identifier.

Authorization is not a separate function in the RADIUS protocol but simply part of an authentication reply. When a RADIUS server validates an access request, it returns to the NAS client all the connection attributes specified in the user file. These usually include the data link (i.e., PPP, SLIP) and network (i.e., TCP/IP, IPX) specifications, but may also include vendor-specific authorization parameters. One such mechanism automatically initiates a Telnet or rlogin session to a specified host. Other methods include forcing the port to a specific IP address with limited connectivity, or applying a routing filter to the access port.

70.2.2 The Third A: Well, Sometimes Anyway!

Accounting is a separate function in RADIUS and not all clients implement it. If the NAS client is configured to use RADIUS accounting, it will generate an Accounting-Start packet once the user has been authenticated, and an Accounting-Stop packet when the user disconnects. The Accounting-Start packet describes the type of service the NAS is delivering, the port being used, and user being serviced. The Accounting-Stop packet duplicates the Start packet information and adds session information such as elapsed time, bytes inputs and outputs, disconnect reason, etc.

70.2.3 Forward Thinking and Other Gee-Whiz Capabilities

A RADIUS server can act as a proxy for client requests, forwarding them to servers in other authentication domains. Forwarding can be based on a number of criteria, including a named or number domain. This is particularly useful when a single modem pool is shared across departments or organizations. Entities are not required to share authentication data; each can maintain its own RADIUS server and service proxied requests from the server at the modem pool. RADIUS can proxy both authentication and accounting requests. The relationship between proxies can be distributed (one-to-many) or hierarchical (many-to-one), and requests can be forwarded multiple times. For example, in Exhibit 70.2, it is perfectly permissible for the "master" server to forward a request to the user's regional server for processing.

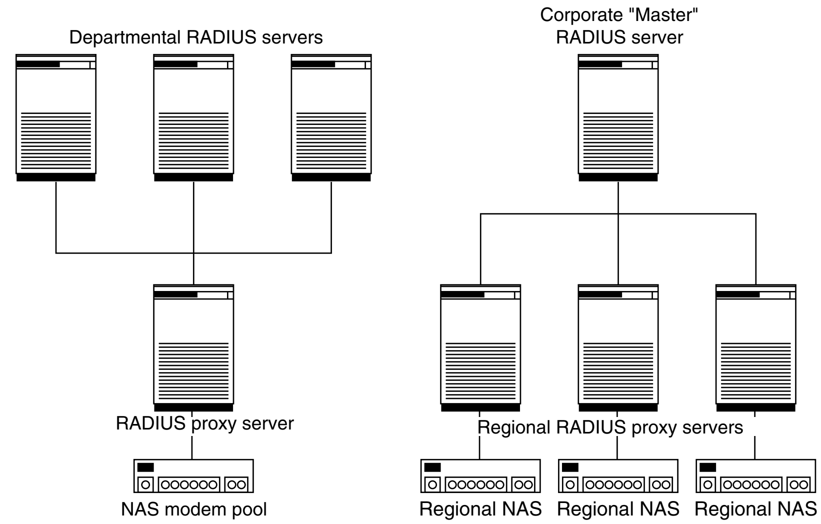
Most RADIUS clients have the ability to query a secondary RADIUS server for redundancy purposes, although this is not required. The advantage is continued access when the primary server is off line. The disadvantage is the increase in administration required to synchronize data between the servers.

Most RADIUS servers have a built-in database connectivity component. This allows accounting records to be written directly into a database for billing and reporting purposes. This is preferable to processing a flat text accounting "detail" file. Some server implementations also include database access for authentication purposes. Novell's implementation queries NDS, NT versions query the PDC, and several vendors are working on LDAP connectivity.

70.2.4 It Does Not Get Any Easier than This. Or Does It?

When implementing RADIUS, it is important to remember that the source code is both open and extensible. The way each AAA, proxy, and database function is implemented varies considerably from vendor to vendor. When planning a RADIUS implementation, it is best to define one's functional requirements first and then choose NAS components and server software that support them. Here are a few factors to consider:

- *What accesses need to be authenticated*? External accesses via modem pools and VPN servers are essential, but internal accesses to critical systems and security control devices (i.e., routers, firewalls) should also be considered.



Departmental RADIUS servers
Corporate "Master" RADIUS server
RADIUS proxy server
Regional RADIUS proxy servers
NAS modem pool
Regional NAS
Regional NAS
Regional NAS

EXHIBIT 70.2 "Master" server forwards a request on to the user's regional server for processing.

- *What protocols need to be supported*? RADIUS can return configuration information at the datalink, network, and transport levels. Vendor documentation as well as the RADIUS RFCs and standard dictionary file are good sources of information for evaluating these parameters.
- *What services are required*? Some RADIUS implementations require support for services such as Telnet, rlogin, and third-party authentication (i.e., SecureID), which often require additional components and expertise to implement.
- *Is proxy or redundancy required*? When NAS devices are shared across management or security domains, proxy servers are usually required and it is necessary to determine the proxy relationships in advance. Redundancy for system reliability and accessibility is also an important consideration because not all clients implement this feature.

Other considerations might include:

- Authorization, accounting, and database access requirements
- Interfaces to authentication information in NDS, X.500, or PDC databases
- The RADIUS capabilities of existing clients
- Support for third-party Mobile-IP providers like iPass
- Secure connection support (i.e., L2TP, PPTP)

Client setup for RADIUS is straightforward. The client must be configured with the IP address of the server(s), the shared secret (encryption key), and the IP port numbers of the authentication and accounting services (the defaults are 1645 and 1646, respectively). Additional settings may be required by the vendor.

The RADIUS server setup consists of the server software installation and three configuration files:

1. The dictionary file is composed of a series of Attribute/Value pairs the server uses to parse requests and generate responses. The standard dictionary file supplied with most server software contains the attributes and values found in the RADIUS RFCs. One may need to add vendor-specific attributes, depending upon one's NAS selection. If any modifications are made, double-check that none of the attribute Names or Values are duplicated.

2. The client file is a flat text file containing the information the server requires to authenticate RADIUS clients. The format is the client name or IP address, followed by the shared secret. If names are used, the server must be configured for name resolution (i.e., DNS). Requirements for the length and format of the shared secret vary, but most UNIX implementations are eight characters or less. There is no limitation on the number of clients a server can support.
3. The user file is also a flat text file. It stores authentication and authorization information for all RADIUS users. To be authenticated, a user must have a profile consisting of three parts: the *username*, a list of authentication *check items*, and a list of *reply items*. A typical entry would look like the one displayed in Exhibit 70.3. The first line contains the user's name and a list of check items separated by commas. In this example, John is restricted to using one NAS device (the one at 10.100.1.1). The remaining lines contain reply items. Reply items are separated by commas at the end of each line. String values are put in quotes. The final line in this example contains an authorization parameter that applies a packet filter to this user's access.

The check and reply items contained in the user file are as diverse as the implementations, but a couple of conventions are fairly common. Username prefixes are commonly used for proxy requests. For example, usernames with the prefix CS/would be forwarded to the computer science RADIUS server for authentication. Username suffixes are commonly used to designate different access types. For example, a user name with a %vpn suffix would indicate that this access was via a virtual private network (VPN). This makes it possible for a single RADIUS server to authenticate users for multiple NAS devices or provide different reply values for different types of accesses on the same NAS.

The DEFAULT user parameter is commonly used to pass authentication to another process. If the username is not found in the user file, the DEFAULT user parameters are used to transfer the validation to

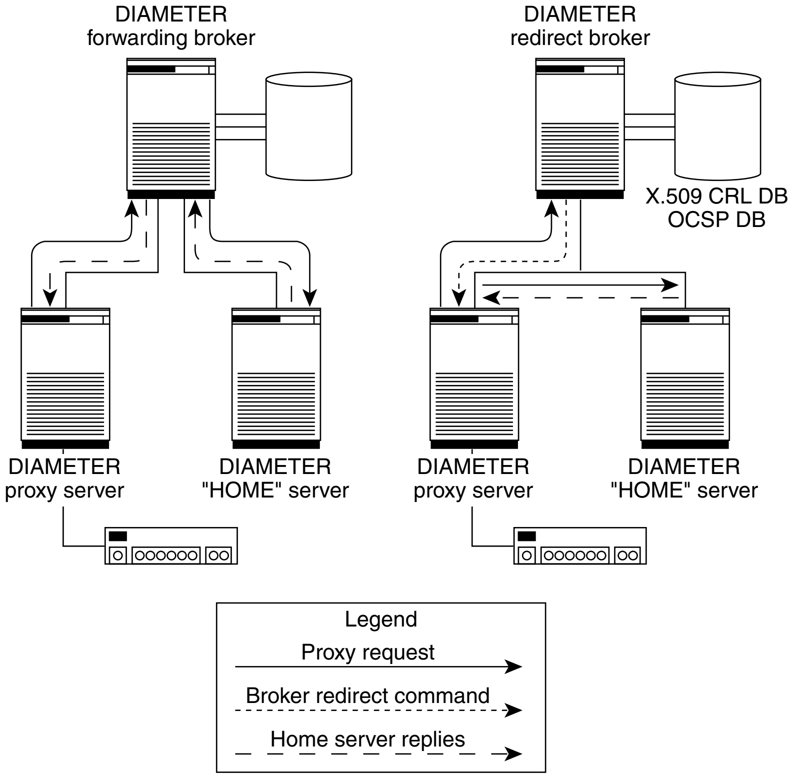


EXHIBIT 70.3 DIAMETER uses a broker proxy server.

another mechanism. On UNIX, this is typically the */etc/passwd* file. On NT, it can be the local user database or a domain controller. Using secondary authentication mechanisms has the advantage of expanding the check items RADIUS can use. For example, UNIX and NT groups can be checked as well as account activation and date and time restriction.

Implementations that use a common NAS type or one server for each NAS type have fairly uncomplicated user files, but user file contents can quickly become quite convoluted when NAS devices and access methods are mixed. This not only adds complexity to the management of the server, but also requires more sophistication on the part of users.

70.2.5 Stumbling Blocks, Complexities, and Other RADIUS Limitations

RADIUS works well for remote access authentication but is not suitable for host or application authentication. Web servers may be the first exception. Adding a RADIUS client to a Web server provides a secure method for authenticating users across open networks. RADIUS provides only basic accounting facilities with no facilities for monitoring nailed-up circuits or system events. User-based rather than device-based connection parameters are another major limitation of RADIUS. When a single RADIUS server manages several different types of NAS devices, user administration is considerably more complex. Standard RADIUS authentication does not provide facilities for checking a user's group membership, restricting access by date or time of day, or expiring a user's account on a given date. To provide these capabilities, the RADIUS server must be associated with a secondary authentication service.

Overall, RADIUS is an efficient, flexible, and well-supported AAA service that works best when associated with a secondary authentication service like NDS or NT where additional account restrictions can be applied. The adoption of RADIUS version 2 as an IETF standard will certainly ensure its continued success and importance as a good, general-purpose authentication, authorization, and accounting service.

70.3 TACACS: Terminal Access Controller Access Control System

What is commonly referred to today as TACACS actually represents two evolutions of the protocol. The original TACACS, developed in the early ARPANet days, had very limited functionality and used the UDP transport. In the early 1990s, the protocol was extended to include additional functionality and the transport changed to TCP. To maintain backward compatibility, the original functions were included as subsets of the extended functions. The new protocol was dubbed XTACACS (Extended TACACS). Virtually all current TACACS daemons are based on the extended protocol as described in RFC1492.

Cisco Systems adopted TACACS for its AAA architecture and further enhanced the product by separating the authentication, authorization, and accounting functions and adding encryption to all NAS-server transmissions. Cisco also improved the extensibility of TACACS by permitting arbitrary length and content parameters for authentication exchanges. Cisco called its version TACACS + but, in reality, TACACS + bares no resemblance to the original TACACS and packet formats are not backward compatible. Some server implementations support both formats for compatibility purposes. The remainder of this section is based on TACACS + because it is the proposed IETF standard.

TACACS + servers use a single configuration file to control server options, define users and attribute/value (AV) pairs, and control authentication and authorization actions. The options section specifies the settings of the service's operation parameters, the shared secret key, and the accounting file name. The remainder of the file is a series of user and group definitions used to control authentication and authorization actions. The format is "*user = username*" or "*group = groupname*," followed by one or more AV pairs inside curly brackets.

The client initiates a TCP session and passes a series of AV pairs to the server using a standard header format followed by a variable length parameter field. The header contains the service request type (authentication, authorization, or accounting) and is sent in the clear. The entire parameter field is encrypted for confidentiality. TACACS' variable parameter field provides for extensibility and site-specific customization, while the TCP protocol ensures reliable delivery. However, the format and protocol also increase communications overhead, which can impact the server's performance under heavy load.

70.3.1 A 1: TACACS Authentication

TACACS authentication has three packet types: Start, Continue, and Reply. The client begins the authentication with a Start packet that describes the type of authentication to be performed. For simple authentication types such as PAP, the packet may also contain the userID and password. The server responds with a Reply. Additional information, if required, is passed with client Continue and server Reply packets. Transactions include login (by privilege level) and password change using various authentication protocols (i.e., CHAP, PAP, PPP, etc.). Like RADIUS, a successful TACACS authentication returns attribute-value (AV) pairs for connection configuration. These can include authorization parameters or they can be fetched separately.

70.3.2 A 2: TACACS Authorization

Authorization functions in TACACS consist of Request and Response AV pairs used to:

- Permit or deny certain commands, addresses, services or protocols
- Set user privilege level
- Invoke input and output packet filters
- Set access control lists (ACLs)
- Invoke callback actions
- Assign a specific network address

Functions can be returned as part of an authentication transaction or an authorization-specific request.

70.3.3 A 3: TACACS Accounting

TACACS accounting functions use a format similar to authorization functions. Accounting functions include Start, Stop, More, and Watchdog. The Watchdog function is used to validate TCP sessions when data is not sent for extended periods of time. In addition to the standard accounting data supported by RADIUS, TACACS has an event logging capability that can record system level changes in access rights or privilege. The reason for the event as well as the traffic totals associated with it can also be logged.

Take Another Look (and Other Cool Capabilities)

TACACS authentication and authorization processes are considerably enhanced by two special capabilities: recursive lookup and callout. Recursive lookup allows connection, authentication, and authorization information to be spread across multiple entries. AV pairs are first looked up in the user entry. Unresolved pairs are then looked up in the group entry (if the user is a member of a group) and finally assigned the default value (if one is specified). TACACS + permits groups to be embedded in other groups, so recursive lookups can be configured to encompass any number of connection requirements. TACACS + also supports a callout capability that permits the execution of user-supplied programs. Callout can be used to dynamically alter the authentication and authorization processes to accommodate any number of requirements—a considerably more versatile approach than RADIUS' static configurations. Callout can be used to interface TACACS + with third-party authentication mechanisms (i.e., Kerberos and SecureID), pull parameters from a directory or database, or write audit and accounting records.

TACACS, like RADIUS, can be configured to use redundant servers and because TACACS uses a reliable transport (TCP); it also has the ability to detect failed nodes. Unlike RADIUS, TACACS cannot be configured to proxy NAS requests, which limits its usefulness in large-scale and cross-domain applications.

70.3.4 Cisco, Cisco, Cisco: Implementing TACACS

There are a number of TACACS server implementations available, including two freeware versions for UNIX, a Netware port, and two commercial versions for NT, but the client implementations are Cisco, Cisco, Cisco. Cisco freely distributes the TACACS and TACACS+source code, so features and functionality vary considerably from one implementation to another. CiscoSecure is generally considered the most robust of the commercial implementations and even supports RADIUS functions. Once again, be sure to define functional requirements before selecting NAS components and server software. If your shop is Cisco-centric, TACACS is going to work well; if not, one might want to consider a server product with both RADIUS and TACACS+capabilities.

Client setup for TACACS on Cisco devices requires an understanding of Cisco's AAA implementation. The AAA function must be enabled for any of the TACACS configuration commands to work. The client must be configured with the IP address of the server(s) and the shared secret encryption key. A typical configuration would look like this:

```
aaa new-model
tacacs-server key <your key here>
tacacs-server host <your primary TACACS server
IP address here >
tacacs-server host <your secondary TACACS server
IP address here >
```

followed by port-specific configurations. Different versions of Cisco IOS support different TACACS settings. Other NAS vendors support a limited subset of TACACS+commands.

TACACS server setup consists of the server software installation and editing the options, authentication, and authorization entries in the configuration files. Comments may be placed anywhere in the file using a pound sign (#) to start the line. In the following example, Jane represents a dial-in support contractor, Bill a user with multiple access methods, and Dick an IT staff member with special NAS access.

```
# The default authentication method will use the
local UNIX
# password file, default authorization will be
permitted for
# users without explicit entries and accounting
records will be
# written to the /var/adm/tacacs file.
default authentication=file /etc/passwd
default authorization=permit
     accounting file=/var/adm/tacacs
# Contractors, vendors, etc.
user=jane {
name="Jane Smith"
global=cleartext "Jane'sPassword"
expires="May 10 2000"
service=ppp
protocol=ip {
     addr=10.200.10.64
inacl=101
outacl=102
}
}
# Employees with "special" requirements
user=bill {
name="Bill Jones"
arap=cleartext "Apple_ARAP_Password"
pap=cleartext "PC_PAP_Password"
default service=permit
    }
user=dick {
name="Dick Brown"
member=itstaff
# Use the service parameters from the default user
default service=permit
# Permit Dick to access the exec command using
connection access list 4
service=exec {
    acl=4
}
# Permit Dick to use the telnet command
to everywhere but 10.101.10.1
cmd=telnet {
    deny 10\.101\.10\.1
    permit.*
}
    }
# Standard Employees use these entries
user=DEFAULT {
service=ppp {
    # Disconnect if idle for 5 minutes
    idletime=5
    # Set maximum connect time to one hour
    timeout=60
}
protocol=ip {
    addr-pool=hqnas
}
    }
# Group Entries
group=itstaff {
# Staff uses a special password file
login=file /etc/itstaff_passwds
    }
```

Jane's entry sets her password to "Jane'sPassword" for all authentication types, requires her to use PPP, forces her to a known IP, and applies both inbound and outbound extended IP access control lists (a.k.a. IP filters). It also contains an account expiration date so the account can be easily enabled and disabled. Bill's entry establishes different passwords for Apple and PAP logins, and assigns his connection the default service parameters. Dick's entry grants him access to the NAS executive commands, including Telnet, but restricts their use by applying a standard IP access control list and an explicit **deny** to the host at 10.101.10.1. Bill and Dick's entries also demonstrate TACACS' recursive lookup feature. The server first looks at user entry for a password, then checks for a group entry. Bill is not a member of any group, so the default authentication method is applied. Dick, however, is a member of "itstaff," so the server validates the group name and looks for a password in the group entry. It finds the **login** entry and authenticates Dick using the /etc/itstaff_passwds file. The default user entry contains AV pairs specifying the use of PPP with an idle timeout of five minutes and a maximum session time of one hour.

In this example, the UNIX /etc/password and /etc/group files are used for authentication, but the use of other mechanisms is possible. Novell implementations use NDS, NT versions use the domain controller, and CiscoSecure support LDAP and several SQL-compatible databases.

70.3.5 Proxyless, Problems, and Pitfalls: TACACS Limitations

The principle limitation of TACACS + may well be its lack of use. While TACACS + is a versatile and robust protocol, it has few server implementations and even fewer NAS implementations. Outside of Cisco, this author was unable to find any custom extensions to the protocol or any vendor-specific AV pairs. Additionally, TACACS' scalability and performance are an issue. Unlike RADIUS' single-packet UDP design, TACACS uses multiple queries over TCP to establish connections, thus incurring overhead that can severely impact performance. TACACS + servers have no ability to proxy requests so they cannot be configured in a hierarchy to support authentication across multiple domains. CiscoSecure scalability relies on regional servers and database replication to scale across multiple domains. While viable, the approach assumes a single management domain, which may not always be the case.

Overall, TACACS + is a reliable and highly extensible protocol with existing support for Cisco's implementation of NAS-based VPNs. Its "outcalls" capability provides a fairly straightforward way to customize the AAA functions and add support for third-party products. Although TACACS + supports more authentication parameters than RADIUS, it still works best when associated with a secondary authentication service like NDS or an NT domain. The adoption of TACACS + as an IETF standard and its easy extensibility should improve its adoption by other NAS manufactures. Until then, TACACS + remains a solid AAA solution for Cisco-centric environments.

70.4 DIAMETER: Twice RADIUS?

DIAMETER is a highly extensible AAA framework capable of supporting any number of authentication, authorization, or accounting schemes and connection types. The protocol is divided into two distinct parts: the Base Protocol and the Extensions. The DIAMETER Base Protocol defines the message format, transport, error reporting, and security services used by all DIAMETER extensions. DIAMETER Extensions are modules designed to conduct specific types of authentication, authorization, or accounting transactions (i.e., NAS, Mobile-IP, ROAMOPS, and EAP). The current IETF draft contains definitions for NAS requests, Mobile-IP, secure proxy, strong security, and accounting, but any number of other extensions are possible.

DIAMETER is built upon the RADIUS protocol but has been augmented to overcome inherent RADIUS limitations. Although the two protocols do not share a common data unit (PDU), there are sufficient similarities to make the migration from RADIUS to DIAMETER easier. DIAMETER, like RADIUS, uses a UDP transport but in a peer-to-peer rather than client/server configuration. This allows servers to initiate requests and handle transmission errors locally. DIAMETER uses reliable transport extensions to reduce retransmissions, improve failed node detection, and reduce node congestion. These enhancements reduce latency and significantly improve server performance in high-density NAS and hierarchical proxy configurations. Additional improvements include:

- Full support for roaming
- Cross-domain, broker-based authentication
- Full support for the Extensible Authentication Protocol (EAP)

- Vendor-defined attributes-value pairs (AVPs) and commands
- Enhanced security functionality with replay attack protections and confidentiality for individual AVPs

70.4.1 There Is Nothing Like a Good Foundation

The DIAMETER Base Protocol consists of a fixed-length (96 byte) header and two or more attribute-value pairs (AVPs). The header contains the message type, option flags, version number, and message length, followed by three transport reliability parameters (see Exhibit 70.4).

AVPs are the key to DIAMETER's extensibility. They carry all DIAMETER commands, connection parameters, and authentication, authorization, accounting, and security data. AVPs consist of a fixed-length header and a variable-length data field. A single DIAMETER message can carry any number of AVPs, up to the maximum UDP packet size of 8192 bytes. Two AVPs in each DIAMETER message are mandatory. They contain the message Command Code and the sender's IP address or host name. The message type or the Extension in use defines the remaining AVPs. DIAMETER reserves the first header byte and the first 256 AVPs for RADIUS backward compatibility.

70.4.2 A Is for the Way You Authenticate Me

The specifics of a DIAMETER authentication transaction are governed by the Extension in use, but they all follow a similar pattern. The client (i.e., a NAS) issues an authentication request to the server containing the AA-Request Command, a session-ID, and the client's address and host name followed by the user's name and password and a state value.

The session-ID uniquely identifies this connection and overcomes the problem in RADIUS with duplicate connection identifiers in high-density installations. Each connection has its own unique session with the server. The session is maintained for the duration of the connection and all transactions related to the connection use the same session-ID. The state AVP is used to track the state of multiple transaction authentication schemes such as CHAP or SecureID.

The server validates the user's credentials and returns an AA-Answer packet containing either a Failed-AVP or the accompanying Result-Code AVP or the authorized AVPs for the service being provided (i.e., PPP parameters, IP parameters, routing parameters, etc.). If the server is not the HOME server for this user, it will forward (proxy) the request.

70.4.3 Proxy on Steroids!

DIAMETER supports multiple proxy configurations, including the two RADIUS models and two additional Broker models. In the hierarchical model, the DIAMETER server forwards the request directly to the user's HOME server using a session-based connection. This approach provides several advantages over the standard RADIUS implementation. Because the proxy connection is managed separately from the client connection, failed node and packet retransmissions are handled more efficiently and the hop can be secured with enhanced security like IPSec. Under RADIUS the first server in the authentication chain must know the CHAP shared secret, but DIAMETER's proxy scheme permits the authentication to take place at the HOME server. As robust as DIAMETER's hierarchical model is, it still is not suitable for many roaming applications.

EXHIBIT 70.4 DIAMETER Base Protocol Packet Format

Type – Flags – Version		Message Length
	Node Identifier	
Next Send		Next Received
	AVPs …	

EXHIBIT 70.5 A Typical Entry

User Name	Attribute = Value

John	Password = "1secret9," NAS-IP-Address = 10.100.1.1
	Service-Type = Framed-User
	Framed-Protocol = PPP,
	Framed-IP-Address = 10.200.10.1
	Framed-IP-Netmask = 255.255.255.0
	Filter-Id = "firewall"

DIAMETER uses a Broker proxy server to support roaming across multiple management domains. Brokers are employed to reduce the amount of configuration information that needs to be shared between ISPs within a roaming consortium. The Broker provides a simple message routing function. In DIAMETER, two routing functions are provided: either the Broker forwards the message to the HOME server or provides the keys and certificates required for the proxy server to communicate directly with the HOME server (see Exhibit 70.5).

70.4.4 *A Two Brute*: DIAMETER Authorization

Authorization transactions can be combined with authentication requests or conducted separately. The specifics of the transaction are governed by the Extension in use but follow the same pattern and use the same commands as authentications. Authorization requests must take place over an existing session; they cannot be used to initiate sessions but they can be forwarded using a DIAMETER proxy.

70.4.5 Accounting for Everything

DIAMETER significantly improves upon the accounting capabilities of RADIUS and TACACS + by adding event monitoring, periodic reporting, real-time record transfer, and support for the ROAMOPS Accounting Data Interchange Format (ADIF). DIAMETER accounting is authorization-server directed. Instructions regarding how the client is to generate accounting records is passed to the client as part of the authorization process. Additionally, DIAMETER accounting servers can force a client to send current accounting data. This is particularly useful for connection troubleshooting or to capture accounting data when an accounting server experiences a crash. Client writes and server polls are fully supported by both DIAMETER proxy models.

For efficiency, records are normally batch transferred but for applications like ROAMOPS where credit limit checks or fraud detection are required, records can be generated in real-time. DIAMETER improves upon standard connect and disconnect accounting with a periodic reporting capability that is particularly useful for monitoring usage on nailed-up circuits. DIAMETER also has an event accounting capability like TACACS + that is useful for recording service-related events like failed nodes and server reboots.

70.4.6 Security, Standards, and Other Sexy Stuff

Support for strong security is a standard part of the DIAMETER Base Protocol. Many applications, like ROAMOPS and Mobile-IP, require sensitive connection information to be transferred across multiple domains. Hop-by-hop security is inadequate for these applications because data is subject to exposure at each interim hop. DIAMETER's Strong Proxy Extension overcomes the problem by encrypting sensitive data in S/MIME objects and encapsulating them in standard AVPs.

Got the telecommuter, mobile workforce, VPN, multi-platform, dial-in user authentication blues? One does not need to! AAA server solutions like RADIUS, TACACS, and DIAMETER can chase those blues away. With a little careful planning and a few hours of configuration, one can increase security, reduce administration time, and consolidate one's remote access venues into a single, centralized, flexible, and scalable solution. That should put a smile on one's face.

71

An Introduction to Secure Remote Access

Christina M. Bird

In the past decade, the problem of establishing and controlling remote access to corporate networks has become one of the most difficult issues facing network administrators and information security professionals. As information-based businesses become a larger and larger fraction of the global economy, the nature of "business" itself changes. "Work" used to take place in a well-defined location—such as a factory, an office, or a store—at well-defined times, between relatively organized hierarchies of employees. But now, "work" happens everywhere: all over the world, around the clock, between employees, consultants, vendors, and customer representatives. An employee can be productive working with a personal computer and a modem in his living room, without an assembly line, a filing cabinet, or a manager in sight.

The Internet's broad acceptance as a communications tool in business and personal life has introduced the concept of remote access to a new group of computer users. They expect the speed and simplicity of Internet access to translate to their work environment as well. Traveling employees want their private network connectivity to work as seamlessly from their hotel room as if they were in their home office. This increases the demand for reliable and efficient corporate remote access systems, often within organizations for whom networking is tangential at best to the core business.

The explosion of computer users within a private network—now encompassing not only corporate employees in the office, but also telecommuters, consultants, business partners, and clients—makes the design and implementation of secure remote access even tougher. In the simplest local area networks (LANs), all users have unrestricted access to all resources on the network. Sometimes, granular access control is provided at the host computer level, by restricting log-in privileges. But in most real-world environments, access to different kinds of data—such as accounting, human resources, or research & development—must be restricted to limited groups of people. These restrictions may be provided by physically isolating resources on the network or through logical mechanisms (including router access control lists and stricter firewall technologies). Physical isolation, in particular, offers considerable protection to network resources, and sometimes develops without the result of a deliberate network security strategy.

Connections to remote employees, consultants, branch offices, and business partner networks make communications between and within a company extremely efficient; but they expose corporate networks and sensitive data to a wide, potentially untrusted population of users, and a new level of vulnerability. Allowing non-employees to use confidential information creates stringent requirements for data classification and access control. Managing a network infrastructure to enforce a corporate security policy for non-employees is a new challenge for most network administrators and security managers. Security policy must be tailored to facilitate the organization's reasonable business requirements for remote access. At the same time, policies and procedures help minimize the chances that improved connectivity will translate into compromise of data confidentiality, integrity, and availability on the corporate network.

Similarly, branch offices and customer support groups also demand cost-effective, robust, and secure network connections.

This chapter discusses general design goals for a corporate remote access architecture, common remote access implementations, and the use of the Internet to provide secure remote access through the use of virtual private networks (VPNs).

71.1 Security Goals for Remote Access

All remote access systems are designed to establish connectivity to privately maintained computer resources, subject to appropriate security policies, for legitimate users and sites located away from the main corporate campus. Many such systems exist, each with its own set of strengths and weaknesses. However, in a network environment in which the protection of confidentiality, data integrity, and availability is paramount, a secure remote access system possesses the following features:

- Reliable authentication of users and systems
- Easy-to-manage granular control of access to particular computer systems, files, and other network resources
- Protection of confidential data
- Logging and auditing of system utilization
- Transparent reproduction of the workplace environment
- Connectivity to a maximum number of remote users and locations
- Minimal costs for equipment, network connectivity, and support

71.1.1 Reliable Authentication of Remote Users/Hosts

It seems obvious, but it is worth emphasizing that the main difference between computer users in the office and remote users is that remote users are not there. Even in a small organization, with minimal security requirements, many informal authentication processes take place throughout the day. Co-workers recognize each other, and have an understanding about who is supposed to be using particular systems throughout the office. Similarly, they may provide a rudimentary access control mechanism if they pay attention to who is going in and out of the company's server room.

In corporations with higher security requirements, the physical presence of an employee or a computer provides many opportunities—technological and otherwise—for identification, authentication, and access control mechanisms to be employed throughout the campus. These include security guards, photographic employee ID cards, keyless entry to secured areas, among many other tools.

When users are not physically present, the problem of accurate identification and authentication becomes paramount. The identity of network users is the basis for assignment of all system access privileges that will be granted over a remote connection. When the network user is a traveling salesman

1500 miles away from corporate headquarters, accessing internal price lists and databases—a branch office housing a company's research and development organization—or a business partner with potential competitive interest in the company, reliable verification of identity allows a security administrator to grant access on a need-to-know basis within the network. If an attacker can present a seemingly legitimate identity, then that attacker can gain all of the access privileges that go along with it.

A secure remote access system supports a variety of strong authentication mechanisms for human users, and digital certificates to verify identities of machines and gateways for branch offices and business partners.

71.1.2 Granular Access Control

A good remote access system provides flexible control over the network systems and resources that may be accessed by an off-site user. Administrators must have fine-grain control to grant access for all appropriate business purposes while denying access for everything else. This allows management of a variety of access policies based on trust relationships with different types of users (employees, third-party contractors, etc.). The access control system must be flexible enough to support the organization's security requirements and easily modified when policies or personnel change. The remote access system should scale gracefully and enable the company to implement more complex policies as access requirements evolve.

Access control systems can be composed of a variety of mechanisms, including network-based access control lists, static routes, and host system- and application-based access filters. Administrative interfaces can support templates and user groups, machines, and networks to help manage multiple access policies. These controls can be provided, to varying degrees, by firewalls, routers, remote access servers, and authentication servers. They can be deployed at the perimeter of a network as well as internally, if security policy so demands.

The introduction of the remote access system should not be disruptive to the security infrastructure already in place in the corporate network. If an organization has already implemented user- or directory-based security controls (e.g., based on Novell's Netware Directory Service or Windows NT domains), a remote access system that integrates with those controls will leverage the company's investment and experience.

71.1.3 Protection of Confidential Data

Remote access systems that use public or semi-private network infrastructure (including the Internet and the public telephone network) provide lots of opportunities for private data to fall into unexpected hands. The Internet is the most widely known public network, but it is hardly the only one. Even private Frame Relay connections and remote dial-up subscription services (offered by many telecommunications providers) transport data from a variety of locations and organizations on the same physical circuits. Frame Relay sniffers are commodity network devices that allow network administrators to examine traffic over private virtual circuits, and allow a surprising amount of eavesdropping between purportedly secure connections. Reports of packet leaks on these systems are relatively common on security mailing lists like *BUGTRAQ* and *Firewall-Wizards.*

Threats that are commonly acknowledged on the Internet also apply to other large networks and network services. Thus, even on nominally private remote access systems—modem banks and telephone lines, cable modem connections, Frame Relay circuits—security-conscious managers will use equipment that performs strong encryption and per-packet authentication.

71.1.4 Logging and Auditing of System Utilization

Strong authentication, encryption, and access control are important mechanisms for the protection of corporate data. But sooner or later, every network experiences accidental or deliberate disruptions, from system failures (either hardware or software), human error, or attack. Keeping detailed logs of system utilization helps to troubleshoot system failures.

If troubleshooting demonstrates that a network problem was deliberately caused, audit information is critical for tracking down the perpetrator. One's corporate security policy is only as good as one's ability to associate users with individual actions on the remote access system—if one cannot tell who did what, then one cannot tell who is breaking the rules.

Unfortunately, most remote access equipment performs rudimentary logging, at best. In most cases, call level auditing—storing username, start time, and duration of call—is recorded, but there is little information available about what the remote user is actually *doing*. If the corporate environment requires more stringent audit trails, one will probably have to design custom audit systems.

71.1.5 Transparent Reproduction of the Workplace Environment

For telecommuters and road warriors, remote access should provide the same level of connectivity and functionality that they would enjoy if they were physically in their office. Branch offices should have the same access to corporate headquarters networks as the central campus. If the internal network is freely accessible to employees at work, then remote employees will expect the same degree of access. If the internal network is subject to physical or logical security constraints, then the remote access system should enable those constraints to be enforced. If full functionality is not available to remote systems, priority must be given to the most business-critical resources and applications, or people will not use it.

Providing transparent connectivity can be more challenging than it sounds. Even within a small organization, personal work habits differ widely from employee to employee, and predicting how those differences might affect use of remote access is problematic. For example, consider access to data files stored on a UNIX file server. Employees with UNIX workstations use the Network File Service (NFS) protocol to access those files. NFS requires its own particular set of network connections, server configurations, and security settings in order to function properly. Employees with Windows-based workstations probably use the Server Message Bus (SMB) protocol to access the same files. SMB requires its own set of configuration files and security tuning. If the corporate remote access system fails to transport NFS and SMB traffic as expected, or does not handle them at all, remote employees will be forced to change their day-to-day work processes.

71.1.6 Connectivity to Remote Users and Locations

A robust and cost-effective remote access system supports connections over a variety of mechanisms, including telephone lines, persistent private network connections, dial-on-demand network connections, and the Internet. This allows the remote access architecture to maintain its usefulness as network infrastructure evolves, whether or not all connectivity mechanisms are being used at any given time.

Support for multiple styles of connectivity builds a framework for access into the corporate network from a variety of locations: hotels, homes, branch offices, business partners, and client sites, domestic or international. This flexibility also simplifies the task of adding redundancy and performance tuning capabilities to the system.

The majority of currently deployed remote access systems, at least for employee and client-to-server remote connectivity, utilize TCP/IP as their network protocol. A smaller fraction continues to require support for IPX, NetBIOS/NetBEUI, and other LAN protocols; even fewer support SNA, DECNet, and older services. TCP/IP offers the advantage of support within most modern computer operating systems; most corporate applications either use TCP/IP as their network protocol, or allow their traffic to be encapsulated over TCP/IP networks. This chapter concentrates on TCP/IP-based remote access and its particular set of security concerns.

71.1.7 Minimize Costs

A good remote access solution will minimize the costs of hardware, network utilization, and support personnel. Note, of course, that the determination of appropriate expenditures for remote access, reasonable return on investment, and appropriate personnel budgets differs from organization to organization, and depends on factors including sensitivity to loss of resources, corporate expertise in network and security design, and possible regulatory issues depending on industry.

In any remote access implementation, the single highest contribution to overall cost is incurred through payments for persistent circuits, be they telephone capacity, private network connections, or access to the Internet. Business requirements will dictate the required combination of circuit types, typically based on the expected locations of remote users, the number of LAN-to-LAN connections required, and expectations for throughput and simultaneous connections. One-time charges for equipment, software, and installation are rarely primary differentiators between remote access architectures, especially in a high-security environment. However, to fairly judge between remote access options, as well as to plan for future growth, consider the following components in any cost estimates:

- One-time hardware and software costs
- Installation charges
- Maintenance and upgrade costs
- Network and telephone circuits
- Personnel required for installation and day-to-day administration

Not all remote access architectures will meet an organization's business requirements with a minimum of money and effort, so planning in the initial stages is critical.

At the time of this writing, Internet access for individuals is relatively inexpensive, especially compared to the cost of long-distance telephone charges. As long as home Internet access cost is based on a monthly flat fee rather than per-use calculations, use of the Internet to provide individual remote access, especially for traveling employees, will remain economically compelling. Depending on an organization's overall Internet strategy, replacing private network connections between branch offices and headquarters with secured Internet connections may result in savings of one third to one half over the course of a couple of years. This huge drop in cost for remote access is often the primary motivation for the evaluation of secure virtual private networks as a corporate remote access infrastructure. But note that if an organization does not already have technical staff experienced in the deployment of Internet networks and security systems, the perceived savings in terms of ongoing circuit costs can easily be lost in the attempt to hire and train administrative personnel.

It is the security architect's responsibility to evaluate remote access infrastructures in light of these requirements. Remote access equipment and service providers will provide information on the performance of their equipment, expected administrative and maintenance requirements, and pricing. Review pricing on telephone and network connectivity regularly; the telecommunications market changes rapidly and access costs are extremely sensitive to a variety of factors, including geography, volume of voice/data communications, and the likelihood of corporate mergers.

A good remote access system is scalable, cost-effective, and easy to support. Scalability issues include increasing capacity on the remote access servers (the gateways into the private network), through hardware and software enhancements; increasing network bandwidth (data or telephone lines) into the private network; and maintaining staff to support the infrastructure and the remote users. If the system will be used to provide mission-critical connectivity, then it needs to be designed with reliable, measurable throughput and redundancy from the earliest stages of deployment. Backup methods of remote access will be required from *every* location at which mission-critical connections will originate.

Remember that not every remote access system necessarily possesses (or requires) each of these attributes. Within any given corporate environment, security decisions are based on preexisting policies, perceived threat, potential losses, and regulatory requirements—and remote access decisions, like all else, will be specific to a particular organization and its networking requirements. An organization supporting a team of 30 to 40 traveling sales staff, with a relatively constant employee population, has minimal requirements for flexibility and scalability—especially since the remote users are all trusted employees and only one security policy applies. A large organization with multiple locations, five or six business partners, and a sizable population of consultants probably requires different levels of remote access. Employee turnover and changing business conditions also demand increased manageability from the remote access servers, which will probably need to enforce multiple security policies and access control requirements simultaneously.

71.2 Remote Access Mechanisms

Remote access architectures fall into three general categories: (1) remote user access via analog modems and the public telephone network; (2) access via dedicated network connections, persistent or on-demand; and (3) access via public network infrastructures such as the Internet.

71.2.1 Telephones

Telephones and analog modems have been providing remote access to computer resources for the past two decades. A user, typically at home or in a hotel room, connects her computer to a standard telephone outlet and establishes a point-to-point connection to a network access server (NAS) at the corporate location. The NAS is responsible for performing user authentication, access control, and accounting, as well as maintaining connectivity while the phone connection is live. This model benefits from low end-user cost (phone charges are typically very low for local calls, and usually covered by the employer for long-distance tolls) and familiarity. Modems are generally easy to use, at least in locations with pervasive access to phone lines. Modem-based connectivity is more limiting if remote access is required from business locations, which may not be willing to allow essentially unrestricted outbound access from their facilities.

But disadvantages are plentiful. Not all telephone systems are created equal. In areas with older phone networks, electrical interference or loss of signal may prevent the remote computer from establishing a reliable connection to the NAS. Even after a connection is established, some network applications (particularly time-sensitive services such as multimedia packages and applications that are sensitive to network latency) may fail if the rate of data throughput is low. These issues are nearly impossible to resolve or control from corporate headquarters.

Modem technology changes rapidly, requiring frequent and potentially expensive maintenance of equipment. And network access servers are popular targets for hostile action because they provide a single point of entrance to the private network—a gateway that is frequently poorly protected.

71.2.2 Dedicated Network Connections

Branch office connectivity—network connections for remote corporate locations—and business partner connections are frequently met using dedicated private network circuits. Dedicated network connections are offered by most of the major telecommunications providers. They are generally deemed to be the safest way of connecting multiple locations because the only network traffic they carry “belongs” to the same organization.

Private network connections fall into two categories: dedicated circuits and Frame Relay circuits. Dedicated circuits are the most private, as they provide an isolated physical circuit for their subscribers (hence, the name). The only data on a dedicated link belongs to the subscribing organization. An attacker can subvert a dedicated circuit infrastructure only by attacking the telecommunications provider itself. This offers substantial protection. But remember that telco attacks are the oldest in the hacker lexicon—most mechanisms that facilitate access to voice lines work on data circuits as well because the physical infrastructure is the same. For high-security environments, such as financial institutions, strong authentication and encryption are required even over private network connections.

Frame Relay connections provide private bandwidth over a shared physical infrastructure by encapsulating traffic in frames. The frame header contains addressing information to get the traffic to its destination reliably. But the use of shared physical circuitry reduces the security of Frame Relay connections relative to dedicated circuits. Packet leak between frame circuits is well-documented, and devices that eavesdrop on Frame Relay circuits are expensive but readily available. To mitigate these risks, many vendors provide Frame Relay-specific hardware that encrypts packet payload, protecting it against leaks and sniffing but leaving the frame headers alone.

The security of private network connections comes at a price, of course—subscription rates for private connections are typically two to five times higher than connections to the Internet, although discounts for high-volume use can be significant. Deployment in isolated areas is challenging if telecommunications providers fail to provide the required equipment in those areas.

71.2.3 Internet-Based Remote Access

The most cost-effective way to provide access into a corporate network is to take advantage of shared network infrastructure whenever feasible. The Internet provides ubiquitous, easy-to-use, inexpensive connectivity. However, important network reliability and security issues must be addressed.

Internet-based remote user connectivity and wide area networks are much less expensive than in-house modem banks and dedicated network circuits, both in terms of direct charges and in equipment maintenance and ongoing support. Most importantly, ISPs manage modems and dial-in servers, reducing the support load and upgrade costs on the corporate network/telecommunications group.

Of course, securing private network communications over the Internet is a paramount consideration. Most TCP/IP protocols are designed to carry data in cleartext, making communications vulnerable to eavesdropping attacks. Lack of IP authentication mechanisms facilitates session hijacking and unauthorized data modification (while data is in transit). A corporate presence on the Internet may open private computer resources to denial-of-service attacks, thereby reducing system availability. Ongoing development of next-generation Internet protocols, especially IPSec, will address many of these issues. IPSec adds per-packet authentication, payload verification, and encryption mechanisms to traditional IP. Until it becomes broadly implemented, private security systems must explicitly protect sensitive traffic against these attacks.

Internet connectivity may be significantly less reliable than dedicated network links. Troubleshooting Internet problems can be frustrating, especially if an organization has typically managed its wide area network connections in-house. The lack of any centralized authority on the Internet means that resolving service issues, including packet loss, higher than expected latency, and loss of packet exchange between backbone Internet providers, can be time-consuming. Recognizing this concern, many of the national Internet service providers are beginning to offer “business class” Internet connectivity, which provides service level agreements and improved monitoring tools (at a greater cost) for business-critical connections.

Given mechanisms to ensure some minimum level of connectivity and throughput, depending on business requirements, VPN technology can be used to improve the security of Internet-based remote access. For the purposes of this discussion, a VPN is a group of two or more privately owned and managed computer systems that communicates “securely” over a public network (see Exhibit 71.1).

Security features differ from implementation to implementation, but most security experts agree that VPNs include encryption of data, strong authentication of remote users and hosts, and mechanisms for hiding or masking information about the private network topology from potential attackers on the public network. Data in transmission is encrypted between the remote node and the corporate server, preserving data confidentiality and integrity. Digital signatures verify that data has not been modified. Remote users and hosts are subject to strong authentication and authorization mechanisms, including one-time password generators and digital certificates. These help to guarantee that only appropriate personnel can access and modify corporate data. VPNs can prevent private network addresses from being propagated over the public network, thus hiding potential target machines from attackers attempting to disrupt service.

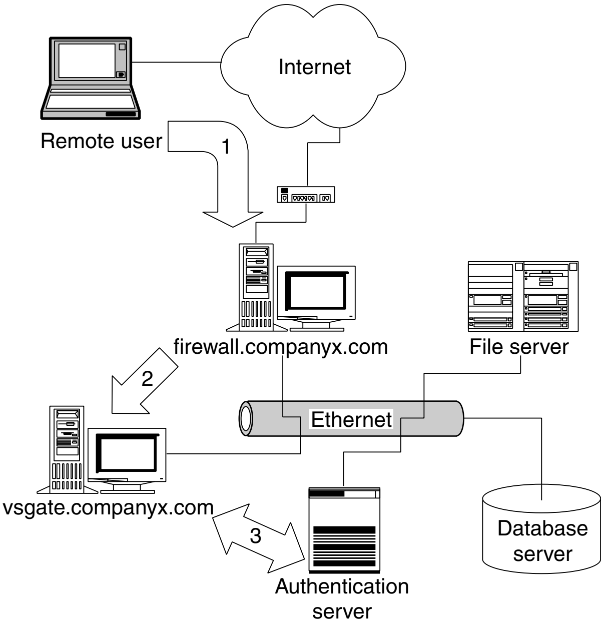

EXHIBIT 71.1 Remote user VPN.

In most cases, VPN technology is deployed over the Internet (see Exhibit 71.2), but there are other situations in which VPNs can greatly enhance the security of remote access. An organization may have employees working at a business partner location or a client site, with a dedicated private network circuit back to the home campus. The organization may choose to employ a VPN application to connect its own employees back into their home network—protecting sensitive data from potential eavesdropping on the

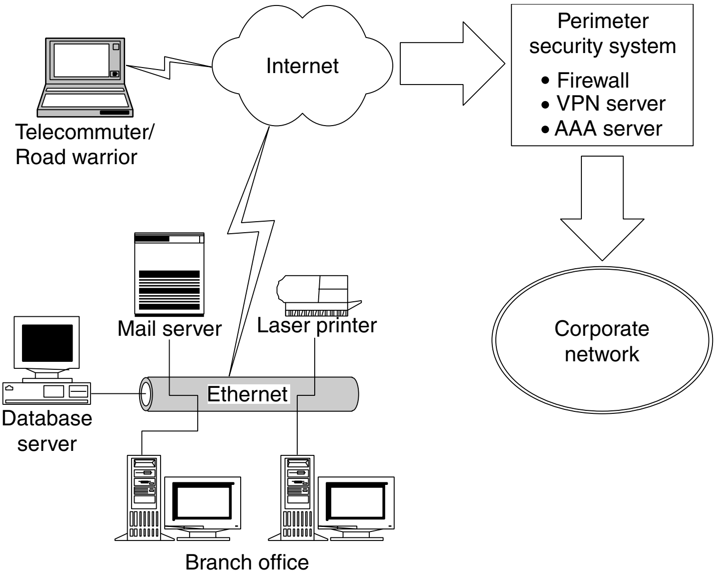

EXHIBIT 71.2 Intranet WAN over VPN.

business partner network. In general, whenever a connection is built between a private network and an entity over which the organization has no administrative or managerial control, VPN technology provides valuable protection against data compromise and loss of system integrity.

When properly implemented, VPNs provide granular access control, accountability, predictability, and robustness at least equal to that provided by modem-based access or Frame Relay circuits. In many cases, because network security has been a consideration throughout the design of VPN products, they provide a higher level of control, auditing capability, and flexibility than any other remote access technology.

71.3 Virtual Private Networks

The term "virtual private network" is used to mean many different things. Many different products are marketed as VPNs, but offer widely varying functionality. In the most general sense, a VPN allows remote sites to communicate as if their networks were directly connected. VPNs also enable multiple independent networks to operate over a common infrastructure. The VPN is implemented as part of the system's networking. That is, ordinary programs like Web servers and e-mail clients see no difference between connections across a physical network and connections across a VPN.

VPN technologies fall into a variety of categories, each designed to address distinct sets of concerns. VPNs designed for secure remote access implement cryptographic technology to ensure the confidentiality, authenticity, and integrity of traffic carried on the VPN. These are sometimes referred to as secure VPNs or crypto VPNs. In this context, private suggests confidentiality and has specific security implications: namely, that the data will be encoded so as to be unreadable, and unmodified, by unauthorized parties.

Some VPN products are aimed at network service providers. These service providers—including AT&T, UUNET, and MCI/Sprint, to name only a few—built and maintain large telecommunications networks, using infrastructure technologies like Frame Relay and ATM. The telecom providers manage large IP networks based on this private infrastructure. For them, the ability to manage multiple IP networks using a single infrastructure might be called a VPN. Some network equipment vendors offer products for this purpose and call them VPNs.

When a network service provider offers this kind of service to an enterprise customer, it is marketed as equivalent to a private, leased-line network in terms of security and performance. The fact that it is implemented over an ATM or Frame Relay infrastructure does not matter to the customer, and is rarely made apparent. These so-called VPN products are designed for maintenance of telecom infrastructure, not for encapsulating private traffic over public networks like the Internet, and are therefore addressing a different problem. In this context, the private aspect of a VPN refers only to network routing and traffic management. It does not imply the use of security mechanisms such as encryption or strong authentication.

Adding further confusion to the plethora of definitions, many telecommunications providers offer subscription dial-up services to corporate customers. These services are billed as "private network access" to the enterprise computer network. They are less expensive for the organization to manage and maintain than in-house access servers because the telecom provider owns the telephone circuits and network access equipment.

But let the buyer beware. Although the providers tout the security and privacy of the subscription services, the technological mechanisms provided to help guarantee privacy are often minimal. The private network points-of-presence in metropolitan areas that provide local telephone access to the corporate network are typically co-located with the provider's Internet access equipment, sometimes running over the same physical infrastructure. Thus, the security risks are often equivalent to using a bare-bones Internet connection for corporate access, often without much ability for customers to monitor security configurations and network utilization. Two years ago, the services did not encrypt private traffic. After much criticism, service providers are beginning to deploy cryptographic equipment to remedy this weakness.

Prospective customers are well-advised to question providers on the security and accounting within their service. The security considerations that apply to applications and hardware employed within an organization apply to network service providers as well, and are often far more difficult to evaluate. Only someone familiar with a company's security environment and expectations can determine whether or not they are supported by a particular service provider's capabilities.

71.4 Selecting A Remote Access System

For organizations with small, relatively stable groups of remote users (whether employees or branch offices), the cost benefits of VPN deployment are probably minimal relative to the traditional remote access methods. However, for dynamic user populations, complex security policies, and expanding business partnerships, VPN technology can simplify management and reduce expenses:

- VPNs enable traveling employees to access the corporate network over the Internet. By using remote sites' existing Internet connections where available, and by dialing into a local ISP for individual access, expensive long-distance charges can be avoided.
- VPNs allow employees working at customer sites, business partners, hotels, and other untrusted locations to access a corporate network safely over dedicated, private connections.
- VPNs allow an organization to provide customer support to clients using the Internet, while minimizing risks to the client's computer networks.

For complex security environments requiring the simultaneous support of multiple levels of access to corporate servers, VPNs are ideal. Most VPN systems interoperate with a variety of perimeter security devices, such as firewalls. VPNs can utilize many different central authentication and auditing servers, simplifying management of the remote user population. Authentication, authorization, and accounting (AAA) servers can also provide granular assignment of access to internal systems. Of course, all this flexibility requires careful design and testing—but the benefits of the initial learning curve and implementation effort are enormous.

Despite the flexibility and cost advantages of using VPNs, they may not be appropriate in some situations; for example:

1. VPNs reduce costs by leveraging existing Internet connections. If remote users, branch offices, or business partners lack adequate access to the Internet, then this advantage is lost.
2. If the required applications rely on non-IP traffic, such as SNA or IPX, then the VPNs are more complex. Either the VPN clients and servers must support the non-IP protocols, or IP gateways (translation devices) must be included in the design. The cost and complexity of maintaining gateways in one's network must be weighed against alternatives like dedicated Frame Relay circuits, which can support a variety of non-IP communications.
3. In some industries and within some organizations, the use of the Internet for transmission of private data is forbidden. For example, the federal Health Care Finance Administration does not allow the Internet to be used for transmission of patient-identifiable Medicare data (at the time of this writing). However, even within a private network, highly sensitive data in transmission may be best protected through the use of cryptographic VPN technology, especially bulk encryption of data and strong authentication/digital certificates.

71.5 Remote Access Policy

A formal security policy sets the goals and ground rules for all of the technical, financial, and logistical decisions involved in solving the remote access problem (and in the day-to-day management of all IT resources). Computer security policies generally form only a subset of an organization's overall security framework; other areas include employee identification mechanisms, access to sensitive corporate locations and resources, hiring and termination procedures, etc.

Few information security managers or auditors believe that their organizations have well-documented policy. Configurations, resources, and executive philosophy change so regularly that maintaining up-to-date documentation can be prohibitive. But the most effective security policies define expectations for the use of computing resources within the company, and for the behavior of users, operations staff, and managers on those computer systems. They are built on the consensus of system administrators, executives, and legal and regulatory authorities within the organization. Most importantly, they have clear management support and are enforced fairly and evenly throughout the employee population.

Although the anatomy of a security policy varies from company to company, it typically includes several components.

- A concisely stated *purpose* defines the security issue under discussion and introduces the rest of the document.

EXHIBIT 71.3 Sample Remote Access Policy

Purpose of Policy: To define expectations for use of the corporate remote access server (including access via the modem bank and access via the Internet); to establish policies for accounting and auditing of remote access use; and to determine the chain of responsibility for misuse of the remote access privilege.

Intended Audience: This document is provided as a guideline to all employees requesting access to corporate network computing resources from non-corporate locations.

Introduction: Company X provides access to its corporate computing environment for telecommuters and traveling employees. This remote connectivity provides convenient access into the business network and facilitates long-distance work. But it also introduces risk to corporate systems: risk of inappropriate access, unauthorized data modification, and loss of confidentiality if security is compromised. For this reason, Company X provides the following standards for use of the remote access system.

All use of the Company X remote access system implies knowledge of and compliance with this policy.

Requirements for Remote Access: An employee requesting remote access to the Company X computer network must complete the *Remote Access Agreement*, available on the internal Web server or from the Human Resources group. The form includes the following information: employee's name and log-in ID; job title, organizational unit, and direct manager; justification for the remote access; and a copy of remote user responsibilities. After completing the form, and acknowledging acceptance of the usage policy, the employee must obtain the manager's signature and send the form to the Help Desk.

NO access will be granted unless all fields are complete.

The Human Resources group will be responsible for annually reviewing ongoing remote access for employees. This review verifies that the person is still employed by Company X and that their role still qualifies them for use of the remote access system. Human Resources is also responsible for informing the IT/Operations group of employee terminations within one working day of the effective date of termination.

IT/Operations is responsible for maintaining the modem-based and Internet-based remote access systems; maintaining the user authentication and authorization servers; and auditing use of the remote access system (recording start and end times of access and user IDs for chargeback accounting to the appropriate organizational units).

Remote access users are held ultimately responsible for the use of their system accounts. The user must protect the integrity of Company X resources by safeguarding modem telephone numbers, log-in processes and start-up scripts; by maintaining their strong authentication tokens in their own possession at all times; and by NOT connecting their remote computers to other private networks at the same time that the Company X connection is active. [This provision does not include private networks maintained solely by the employee within their own home, so long as the home network does not contain independent connections to the Internet or other private (corporate) environments.] Use of another employee's authentication token, or loan of a personal token to another individual, is strictly forbidden.

Unspecified actions that may compromise the security of Company X computer resources are also forbidden. IT/Operations will maintain ongoing network monitoring to verify that the remote access system is being used appropriately. Any employee who suspects that the remote access system is being misused is required to report the misuse to the Help Desk immediately.

Violation of this policy will result in disciplinary action, up to and including termination of employment or criminal prosecution.

- The *scope* states the intended audience for the policy, as well as the chain of oversight and authority for enforcement.
- The *introduction* provides background information for the policy, and its cultural, technical, and economic motivators.
- *Usage expectations* include the responsibilities and privileges with regard to the resource under discussion. This section should include an explicit statement of the corporate ownership of the resource.
- The final component covers *system auditing and violation of policy*: an explicit statement of an employee's right to privacy on corporate systems, appropriate use of ongoing system monitoring, and disciplinary action should a violation be detected.

Within the context of remote access, the scope needs to address which employees qualify for remote access to the corporate network. It may be tempting to give access to everyone who is a "trusted" user of the local network. However, need ought to be justified on a case-by-case basis, to help minimize the risk of inappropriate access.

A sample remote access policy is included in Exhibit 71.3.

Another important issue related to security policy and enforcement is ongoing, end-user education. Remote users require specific training, dealing with the appropriate use of remote connectivity; awareness of computer security risks in homes, hotels, and customer locations, especially related to unauthorized use and disclosure of confidential information; and the consequences of security breaches within the remote access system.

72

Hacker Tools and Techniques

Ed Skoudis

Recent headlines demonstrate that the latest crop of hacker tools and techniques can be highly damaging to an organization's sensitive information and reputation. With the rise of powerful, easy-to-use, and widely distributed hacker tools, many in the security industry have observed that today is the golden age of hacking. The purpose of this chapter is to describe the tools in widespread use today for compromising computer and network security. Additionally, for each tool and technique described, the chapter presents practical advice on defending against each type of attack.

The terminology applied to these tools and their users has caused some controversy, particularly in the computer underground. Traditionally, and particularly in the computer underground, the term "hacker" is a benign word, referring to an individual who is focused on determining how things work and devising innovative approaches to addressing computer problems. To differentiate these noble individuals from a nasty attacker, this school of thought labels malicious attackers as "crackers." While hackers are out to make the world a better place, crackers want to cause damage and mayhem. To avoid the confusion often associated with these terms, in this chapter, the terms "system and security administrator" and "security practitioner" will be used to indicate an individual who has a legitimate and authorized purpose for running these tools. The term "attacker" will be used for those individuals who seek to cause damage to systems or who are not authorized to run such tools.

Many of the tools described in this chapter have dual personalities; they can be used for good or evil. When used by malicious individuals, the tools allow a motivated attacker to gain access to a network, mask the fact that a compromise occurred, or even bring down service, thereby impacting large masses of users. When used by security practitioners with proper authorization, some tools can be used to measure the security stance of their own organizations, by conducting "ethical hacking" tests to find vulnerabilities before attackers do.

72.1 Caveat

The purpose of this chapter is to explain the various computer underground tools in use today, and to discuss defensive techniques for addressing each type of tool. This chapter is *not* designed to encourage attacks. Furthermore, the tools described below are for illustration purposes only, and mention in this chapter is *not* an endorsement. If readers feel compelled to experiment with these tools, they should do so at their own risk, realizing that such tools frequently have viruses or other undocumented features that could damage networks and information systems. Curious readers who want to use these tools should conduct a through review of the source code, or at least install the tools on a separate, air-gapped network to protect sensitive production systems.

72.2 General Trends in the Computer Underground

72.2.1 The Smart Get Smarter, and the Rise of the Script Kiddie

The best and brightest minds in the computer underground are conducting probing research and finding new vulnerabilities and powerful, novel attacks on a daily basis. The ideas and deep research done by super-smart attackers and security practitioners are being implemented in software programs and scripts. Months of research into how a particular operating system implements its password scheme is being rendered in code, so even a clueless attacker (often called a "script kiddie") can conduct a highly sophisticated attack with just a point-and-click. Although the script kiddie may not understand the tools' true function and nuances, most of the attack is automated.

In this environment, security practitioners must be careful not to underestimate their adversaries' capabilities. Often, security and system administrators think of their potential attackers as mere teenage kids cruising the Internet looking for easy prey. While this assessment is sometimes accurate, it masks two major concerns. First, some of these teenage kids are amazingly intelligent, and can wreak havoc on a network. Second, attackers may not be just kids; organized crime, terrorists, and even foreign governments have taken to sponsoring cyberattacks.

72.2.2 Wide Distribution of High-Quality Tools

Another trend in the computing underground involves the widespread distribution of tools. In the past (a decade ago), powerful attack tools were limited to a core group of elites in the computer underground. Today, hundreds of Web sites are devoted to the sharing of tools for every attacker (and security practitioner) on the planet. FAQs abound describing how to penetrate any type of operating system. These overall trends converge in a world where smart attackers have detailed knowledge of undermining our systems, while the not-so-smart attackers grow more and more plentiful. To address this increasing threat, system administrators and security practitioners must understand these tools and how to defend against them. The remainder of this chapter describes many of these very powerful tools in widespread use today, together with practical defensive tips for protecting one's network from each type of attack.

72.3 Network Mapping and Port Scanning

When launching an attack across a TCP/IP network (such as the Internet or a corporate intranet), an attacker needs to know what addresses are active, how the network topology is constructed, and which services are available. A network mapper identifies systems that are connected to the target network. Given a network address range, the network mapper will send packets to each possible address to determine which addresses have machines.

By sending a simple Internet Control Message Protocol (ICMP) packet to a server (a "ping"), the mapping tool can discover if a server is connected to the network. For those networks that block incoming pings, many of the mapping tools available today can send a single SYN packet to attempt to open a connection to a server. If a server is listening, the SYN packet will trigger an ACK if the port is open, and potentially a "Port Unreachable" message if the port is closed. Regardless of whether the port is open or closed, the response indicates that the address has a machine listening. With this list of addresses, an attacker can refine the attack and focus on these listening systems.

A port scanner identifies open ports on a system. There are 65,535 TCP ports and 65,535 UDP ports, some of which are open on a system, but most of which are closed. Common services are associated with certain ports. For example, TCP Port 80 is most often used by Web servers, TCP Port 23 is used by Telnet daemons, and TCP Port 25 is used for server-to-server mail exchange across the Internet. By conducting a port scan, an attacker will send packets to each and every port. Essentially, ports are rather like doors on a machine. At any one of the thousands of doors available, common services will be listening. A port scanning tool allows an attacker to knock on every one of those doors to see who answers.

Some scanning tools include TCP fingerprinting capabilities. While the Internet Engineering Task Force (IETF) has carefully specified TCP and IP in various Requests for Comments (RFCs), not all packet options have standards associated with them. Without standards for how systems should respond to illegal packet formats, different vendors' TCP/IP stacks respond differently to illegal packets. By sending various combinations of illegal packet options (such as initiating a connection with an RST packet, or combining other odd and illegal TCP code bits), an attacker can determine what type of operating system is running on the target machine. For example, by conducting a TCP fingerprinting scan, an attacker can determine if a machine is running Cisco IOS, Sun Solaris, or Microsoft Windows 2000. In some cases, even the particular version or service pack level can be determined using this technique.

After utilizing network mapping tools and port scanners, an attacker will know which addresses on the target network have listening machines, which ports are open on those machines (and therefore which services are running), and which operating system platforms are in use. This treasure trove of information is useful to the attacker in refining the attack. With this data, the attacker can search for vulnerabilities on the particular services and systems to attempt to gain access.

Nmap, written by Fyodor, is one of the most full-featured mapping and scanning tools available today. Nmap, which supports network mapping, port scanning, and TCP fingerprinting, can be found at http://www.insecure.org/nmap.

72.3.1 Network Mapping and Port Scanning Defenses

To defend against network mapping and port scans, the administrator should remove all unnecessary systems and close all unused ports. To accomplish this, the administrator must disable and remove unneeded services from the machine. Only those services that have an absolute, defined business need should be running. A security administrator should also periodically scan the systems to determine if any unneeded ports are open. When discovered, these unneeded ports must be disabled.

72.4 Vulnerability Scanning

Once the target systems are identified with a port scanner and network mapper, an attacker will search to determine if any vulnerabilities are present on the victim machines. Thousands of vulnerabilities have been discovered, allowing a remote attacker to gain a toehold on a machine or to take complete administrative control. An attacker could try each of these vulnerabilities on each system by entering individual commands to test for every vulnerability, but conducting an exhaustive search could take years. To speed up the process, attackers use automated scanning tools to quickly search for vulnerabilities on the target.

These automated vulnerability scanning tools are essentially databases of well-known vulnerabilities with an engine that can read the database, connect to a machine, and check to see if it is vulnerable to the exploit. The effectiveness of the tool in discovering vulnerabilities depends on the quality and thoroughness of its vulnerability database. For this reason, the best vulnerability scanners support the rapid release and update of the vulnerability database and the ability to create new checks using a scripting language.

High-quality commercial vulnerability scanning tools are widely available, and are often used by security practitioners and attackers to search for vulnerabilities. On the freeware front, SATAN (the Security Administrator Tool for Analyzing Network) was one of the first widely distributed automated vulnerability scanners, introduced in 1995. More recently, Nessus has been introduced as a free, open-source vulnerability scanner available at http://www.nessus.org. The Nessus project, which is led by Renaud Deraison, provides a full-featured scanner for identifying vulnerabilities on remote systems. It includes source code and a scripting language for writing new vulnerability checks, allowing it to be highly customized by security practitioners and attackers alike.

While Nessus is a general-purpose vulnerability scanner, looking for holes in numerous types of systems and platforms, some vulnerability scanners are much more focused on particular types of systems. For example, Whisker is a full-feature vulnerability scanning tool focusing on Web server CGI scripts. Written by Rain Forest Puppy, Whisker can be found at http://www.wiretrip.net/rfp.

72.4.1 Vulnerability Scanning Defenses

As described above, the administrator must close unused ports. Additionally, to eliminate the vast majority of system vulnerabilities, system patches must be applied in a timely fashion. All organizations using computers should have a defined change control procedure that specifies when and how system patches will be kept up-to-date.

Security practitioners should also conduct periodic vulnerability scans of their own networks to find vulnerabilities before attackers do. These scans should be conducted on a regular basis (such as quarterly or even monthly for sensitive networks), or when major network changes are implemented. The discovered vulnerabilities must be addressed in a timely fashion by updating system configurations or applying patches.

72.5 Wardialing

A cousin of the network mapper and scanner, a wardialing tool is used to discover target systems across a telephone network. Organizations often spend large amounts of money in securing their network from a full, frontal assault over the Internet by implementing a firewall, intrusion detection system, and secure DMZ. Unfortunately, many attackers avoid this route and instead look for other ways into the network. Modems left on users' desktops or old, forgotten machines often provide the simplest way into a target network.

Wardialers, also known as "demon dialers," dial a series of telephone numbers, attempting to locate modems on the victim network. An attacker will determine the telephone extensions associated with the target organization. This information is often gleaned from a Web site listing telephone contacts, employee newsgroup postings with telephone contact information in the signature line, or even general employee e-mail. Armed with one or a series of telephone numbers, the attacker will enter into the wardialing tool ranges of numbers associated with the original number (for example, if an employee's telephone number in a newsgroup posting is listed as 555-1212, the attacker will dial 555-XXXX). The wardialer will automatically dial each number, listen for the familiar wail of a modem carrier tone, and make a list of all telephone numbers with modems listening.

With the list of modems generated by the wardialer, the attacker will dial each discovered modem using a terminal program or other client. Upon connecting to the modem, the attacker will attempt to identify the system based on its banner information and see if a password is required. Often, no password is required, because the modem was put in place by a clueless user requiring after-hours access and not wanting to bother using approved methods. If a password is required, the attacker will attempt to guess passwords commonly associated with the platform or company.

Some wardialing tools also support the capability of locating a repeat dial-tone, in addition to the ability to detect modems. The repeat dial-tone is a great find for the attacker, as it could allow for unrestricted dialing from a victim's PBX system to anywhere in the world. If an attacker finds a line on PBX supporting repeat dial-tone in the same local dialing exchange, the attacker can conduct international wardialing, with all phone bills paid for by the victim with the misconfigured PBX.

The most fully functional wardialing tool available today is distributed by The Hacker's Choice (THC) group. Known as THC-Scan, the tool was written by Van Hauser and can be found at http://inferno.tusculum.edu/thc. THC-Scan 2.0 supports many advanced features, including sequential or randomized dialing, dialing through a network out-dial, modem carrier and repeat dial-tone detection, and rudimentary detection avoidance capabilities.

72.5.1 Wardialing Defenses

The best defense against wardialing attacks is a strong modem policy that prohibits the use of modems and incoming lines without a defined business need. The policy should also require the registration of all modems with a business need in a centralized database only accessible by a security or system administrator.

Additionally, security personnel should conduct periodic wardialing exercises of their own networks to find the modems before the attackers do. When a phone number with an unregistered modem is discovered, the physical device must be located and deactivated. While finding such devices can be difficult, network defenses depend on finding these renegade modems before an attacker does.

72.6 Network Exploits: Sniffing, Spoofing, and Session Hijacking

TCP/IP, the underlying protocol suite that makes up the Internet, was not originally designed to provide security services. Likewise, the most common data-link type used with TCP/IP, Ethernet, is fundamentally unsecure. A whole series of attacks are possible given these vulnerabilities of the underlying protocols. The most widely used and potentially damaging attacks based on these network vulnerabilities are sniffing, spoofing, and session hijacking.

72.6.1 Sniffing

Sniffers are extremely useful tools for an attacker and are therefore a fundamental element of an attacker's toolchest. Sniffers allow an attacker to monitor data passing across a network. Given their capability to monitor network traffic, sniffers are also useful for security practitioners and network administrators in troubleshooting networks and conducting investigations. Sniffers exploit characteristics of several data-link technologies, including Token Ring and especially Ethernet.

Ethernet, the most common LAN technology, is essentially a broadcast technology. When Ethernet LANs are constructed using hubs, all machines connected to the LAN can monitor all data on the LAN segment. If userIDs, passwords, or other sensitive information are sent from one machine (e.g., a client) to another machine (e.g., a server or router) on the same LAN, all other systems connected to the LAN could monitor the data. A sniffer is a hardware or software tool that gathers all data on a LAN segment. When a sniffer is running on a machine gathering all network traffic that passes by the system, the Ethernet interface and the machine itself are said to be in "promiscuous mode."

Many commonly used applications, such as Telnet, FTP, POP (the Post Office Protocol used for e-mail), and even some Web applications, transmit their passwords and sensitive data without any encryption. Any attacker on a broadcast Ethernet segment can use a sniffer to gather these passwords and data.

Attackers who take over a system often install a software sniffer on the compromised machine. This sniffer acts as a sentinel for the attacker, gathering sensitive data that moves by the compromised system. The sniffer gathers this data, including passwords, and stores it in a local file or transmits it to the attacker. The attacker then uses this information to compromise more and more systems. The attack methodology of installing a sniffer on one compromised machine, gathering data passing that machine, and using the sniffed information to take over other systems is referred to as an island-hopping attack.

Numerous sniffing tools are available across the Internet. The most fully functional sniffing tools include sniffit (by Brecht Claerhout, available at http://reptile.rug.ac.be/~coder/sniffit/sniffit.html) and Snort (by Martin Roesch, available at http://www.clark.net/~roesch/security.html). Some operating systems ship with their own sniffers installed by default, notably Solaris (with the snoop tool) and some varieties of Linux (which ship with tcpdump). Other commercial sniffers are also available from a variety of vendors.

72.6.1.1 Sniffing Defenses

The best defense against sniffing attacks is to encrypt the data in transit. Instead of sending passwords or other sensitive data in cleartext, the application or network should encrypt the data (SSH, secure Telnet, etc.).

Another defense against sniffers is to eliminate the broadcast nature of Ethernet. By utilizing a switch instead of a hub to create a LAN, the damage that can be done with a sniffer is limited. A switch can be configured so that only the required source and destination ports on the switch carry the traffic. Although they are on the same LAN, all other ports on the switch (and the machines connected to those ports) do not see this data. Therefore, if one system is compromised on a LAN, a sniffer installed on this machine will not be capable of seeing data exchanged between other machines on the LAN. Switches are therefore useful in improving security by minimizing the data a sniffer can gather, and also help to improve network performance.

72.6.2 IP Spoofing

Another network-based attack involves altering the source address of a computer to disguise the attacker and exploit weak authentication methods. IP address spoofing allows an attacker to use the IP address of another machine to conduct an attack. If the target machines rely on the IP address to authenticate, IP spoofing can give an attacker access to the systems. Additionally, IP spoofing can make it very difficult to apprehend an attacker, because logs will contain decoy addresses and not the real source of the attack. Many of the tools described in other sections of this chapter rely on IP spoofing to hide the true origin of the attack.

72.6.2.1 Spoofing Defenses

Systems should not use IP addresses for authentication. Any functions or applications that rely solely on IP address for authentication should be disabled or replaced. In UNIX, the "**r**-commands" (**rlogin**, **rsh**, **rexec**, and **rcp**) are notoriously subject to IP spoofing attacks. UNIX trust relationships allow an administrator to manage systems using the **r**-commands without providing a password. Instead of a password, the IP address of the system is used for authentication. This major weakness should be avoided by replacing the **r**-commands with administration tools that utilize strong authentication. One such tool, secure shell (ssh), uses strong cryptography to replace the weak authentication of the **r**-commands. Similarly, all other applications that rely on IP addresses for critical security and administration functions should be replaced.

Additionally, an organization should deploy anti-spoof filters on its perimeter networks that connect the organization to the Internet and business partners. Anti-spoof filters drop all traffic coming from outside the network claiming to come from the inside. With this capability, such filters can prevent some types of spoofing attacks, and should be implemented on all perimeter network routers.

72.6.3 Session Hijacking

While sniffing allows an attacker to view data associated with network connections, a session hijack tool allows an attacker to take over network connections, kicking off the legitimate user or sharing a login. Session hijacking tools are used against services with persistent login sessions, such as Telnet, rlogin, or FTP. For any of these services, an attacker can hijack a session and cause a great deal of damage.

A common scenario illustrating session hijacking involves a machine, Alice, with a user logged in to remotely administer another system, Bob, using Telnet. Eve, the attacker, sits on a network segment between Alice and Bob (either Alice's LAN, Bob's LAN, or between any of the routers between Alice's and Bob's LANs). Exhibit 72.1 illustrates this scenario in more detail.

Using a session hijacking tool, Eve can do any of the following:

- *Monitor Alice's session.* Most session hijacking tools allow attackers to monitor all connections available on the network and select which connections they want to hijack.
- *Insert commands into the session.* An attacker may just need to add one or two commands into the stream to reconfigure Bob. In this type of hijack, the attacker never takes full control of the session. Instead, Alice's login session to Bob has a small number of commands inserted, which will be executed on Bob as though Alice had typed them.
- *Steal the session.* This feature of most session hijacking tools allows an attacker to grab the session from Alice, and directly control it. Essentially, the Telnet client control is shifted from Alice to Eve, without Bob's knowing.
- *Give the session back.* Some session hijacking tools allow the attacker to steal a session, interact with the server, and then smoothly give the session back to the user. While the session is stolen, Alice is put on hold while Eve controls the session. With Alice on hold, all commands typed by Alice are displayed on Eve's screen, but not transmitted to Bob. When Eve is finished making modifications on Bob, Eve transfers control back to Alice.

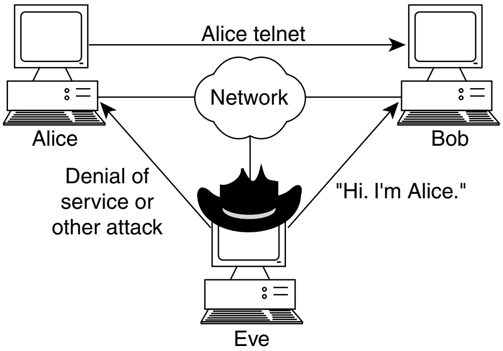

EXHIBIT 72.1 Eve hijacks the session between Alice and Bob.

For a successful hijack to occur, the attacker must be on a LAN segment between Alice and Bob. A session hijacking tool monitors the connection using an integrate sniffer, observing the TCP sequence numbers of the packets going each direction. Each packet sent from Alice to Bob has a unique TCP sequence number used by Bob to verify that all packets are received and put in proper order. Likewise, all packets going back from Bob to Alice have sequence numbers. A session hijacking tool sniffs the packets to determine these sequence numbers. When a session is hijacked (through command insertion or session stealing), the hijacking tool automatically uses the appropriate sequence numbers and spoofs Alice's address, taking over the conversation with Bob where Alice left off.

One of the most fully functional session hijacking tool available today is Hunt, written by Kra and available at http://www.cri.cz/kra/index.html. Hunt allows an attacker to monitor and steal sessions, insert single commands, and even give a session back to the user.

72.6.3.1 Session Hijacking Defenses

The best defense against session hijacking is to avoid the use of insecure protocols and applications for sensitive sessions. Instead of using the easy-to-hijack (and easy-to-sniff) Telnet application, a more secure, encrypted session tool should be used. Because the attacker does not have the session encryption keys, an encrypted session cannot be hijacked. The attacker will simply see encrypted gibberish using Hunt, and will only be able to reset the connection, not take it over or insert commands.

Secure shell (ssh) offers strong authentication and encrypted sessions, providing a highly secure alternative to Telnet and rlogin. Furthermore, ssh includes a secure file transfer capability (scp) to replace traditional FTP. Other alternatives are available, including secure, encrypted Telnet or a virtual private network (VPN) established between the source and destination.

72.7 Denial-of-Service Attacks

Denial-of-service attacks are among the most common exploits available today. As their name implies, a denial-of-service attack prevents legitimate users from being able to access a system. With E-commerce applications constituting the lifeblood of many organizations and a growing piece of the world economy, a well-timed denial-of-service attack can cause a great deal of damage. By bringing down servers that control sensitive machinery or other functions, these attacks could also present a real physical threat to life and limb. An attacker could cause the service denial by flooding a system with bogus traffic, or even purposely causing the server to crash. Countless denial-of-service attacks are in widespread use today, and can be found at http://packetstorm.securify.com/exploits/DoS. The most often used network-based denial-of-service attacks fall into two categories: malformed packet attacks and packet floods.

72.7.1 Malformed Packet Attacks

This type of attack usually involves one or two packets that are formatted in an unexpected way. Many vendor product implementations do not take into account all variations of user entries or packet types. If the software handles such errors poorly, the system may crash when it receives such packets. A classic example of this type of attack involves sending IP fragments to a system that overlap with each other (the fragment offset values are incorrectly set). Some unpatched Windows and Linux systems will crash when they encounter such packets. The teardrop attack is an example of a tool that exploits this IP fragmentation handling vulnerability. Other malformed packet attacks that exploit other weaknesses in TCP/IP implementations include the colorfully named WinNuke, Land, LaTierra, NewTear, Bonk, Boink, etc.

72.7.2 Packet Flood Attacks

Packet flood denial-of-service tools send a deluge of traffic to a system on the network, overwhelming its capability to respond to legitimate users. Attackers have devised numerous techniques for creating such floods, with the most popular being SYN floods, directed broadcast attacks, and distributed denial-of-service tools.

SYN flood tools initiate a large number of half-open connections with a system by sending a series of SYN packets. When any TCP connection is established, a three-way handshake occurs. The initiating system (usually the client) sends a SYN packet to the destination to establish a sequence number for all packets going from source to destination in that session. The destination responds with a SYN-ACK packet, which acknowledges the sequence number for packets going from source to destination, and establishes an initial sequence number for packets going the opposite direction. The source completes the three-way handshake by sending an ACK to the destination. The three-way handshake is completed, and communication (actual data transfer) can occur.

SYN floods take advantage of a weakness in TCP's three-way handshake. By sending only spoofed SYN packets and never responding to the SYN-ACK, an attacker can exhaust a server's ability to maintain state of all the initiated sessions. With a huge number of so-called half-open connections, a server cannot handle any new, legitimate traffic. Rather than filling up all of the pipe bandwidth to a server, only the server's capacity to handle session initiations needs to be overwhelmed (in most network configurations, a server's ability to handle SYNs is lower than the total bandwidth to the site). For this reason, SYN flooding is the most popular packet flood attack. Other tools are also available that flood systems with ICMP and UDP packets, but they merely consume bandwidth, so an attacker would require a bigger connection than the victim to cut off all service.

Another type of packet flood that allows attackers to amplify their bandwidth is the directed broadcast attack. Often called a smurf attack, named after the first tool to exploit this technique, directed broadcast attacks utilize a third-party's network as an amplifier for the packet flood. In a smurf attack, the attacker locates a network on the Internet that will respond to a broadcast ICMP message (essentially a ping to the network's broadcast address). If the network is configured to allow broadcast requests and responses, all machines on the network will send a response to the ping. By spoofing the ICMP request, the attacker can have all machines on the third-party network send responses to the victim. For example, if an organization has 30 hosts on a single DMZ network connected to the Internet, an attacker can send a spoofed network broadcast ping to the DMZ. All 30 hosts will send a response to the spoofed address, which would be the ultimate victim. By sending repeated messages to the broadcast network, the attacker has amplified bandwidth by a factor of 30. Even an attacker with only a 56-kbps dial-up line could fill up a T1 line (1.54 Mbps) with that level of amplification. Other directed broadcast attack tools include Fraggle and Papasmurf.

A final type of denial-of-service that has received considerable press is the distributed denial-of-service attack. Essentially based on standard packet flood concepts, distributed denial-of-service attacks were used to cripple many major Internet sites in February 2000. Tools such as Trin00, Tribe Flood Network 2000 (TFN2K), and Stacheldraht all support this type of attack. To conduct a distributed denial-of-service attack, an attacker must find numerous vulnerable systems on the Internet. Usually, a remote buffer overflow attack (described below) is used to take over a dozen, a hundred, or even thousands of machines. Simple daemon processes, called zombies, are installed on these machines taken over by the attacker. The attacker communicates with this network of zombies using a control program. The control program is used to send commands to the hundreds or thousands of zombies, requesting them to take uniform action simultaneously.

The most common action to be taken is to simultaneously launch a packet flood against a target. While a traditional SYN flood would deluge a target with packets from one host, a distributed denial-of-service attack would send packets from large numbers of zombies, rapidly exhausting the capacity of even very high-bandwidth, well-designed sites. Many distributed denial-of-service attack tools support SYN, UDP, and ICMP flooding, smurf attacks, as well as some malformed packet attacks. Any one or all of these options can be selected by the attacker using the control program.

72.7.3 Denial-of-Service Attack Defenses

To defend against malformed packet attacks, system patches and security fixes must be regularly applied. Vendors frequently update their systems with patches to handle a new flavor of denial-of-service attack.

An organization must have a program for monitoring vendor and industry security bulletins for security fixes, and a controlled method for implementing these fixes soon after they are announced and tested.

For packet flood attacks, critical systems should have underlying network architectures with multiple, redundant paths, eliminating a single point of failure. Furthermore, adequate bandwidth is a must. Also, some routers and firewalls support traffic flow control to help ease the burden of a SYN flood.

Finally, by configuring an Internet-accessible network appropriately, an organization can minimize the possibility that it will be used as a jumping-off point for smurf and distributed denial-of-service attacks. To prevent the possibility of being used as a smurf amplifier, the external router or firewall should be configured to drop all directed broadcast requests from the Internet. To lower the chance of being used in a distributed denial-of-service attack, an organization should implement anti-spoof filters on external routers and firewalls to make sure that all outgoing traffic has a source IP address of the site. This egress filtering prevents an attacker from sending spoofed packets from a zombie or other denial-of-service tool located on the network. Antispoof ingress filters, which drop all packets from the Internet claiming to come from one’s internal network, are also useful in preventing some denial-of-service attacks.

72.8 Stack-Based Buffer Overflows

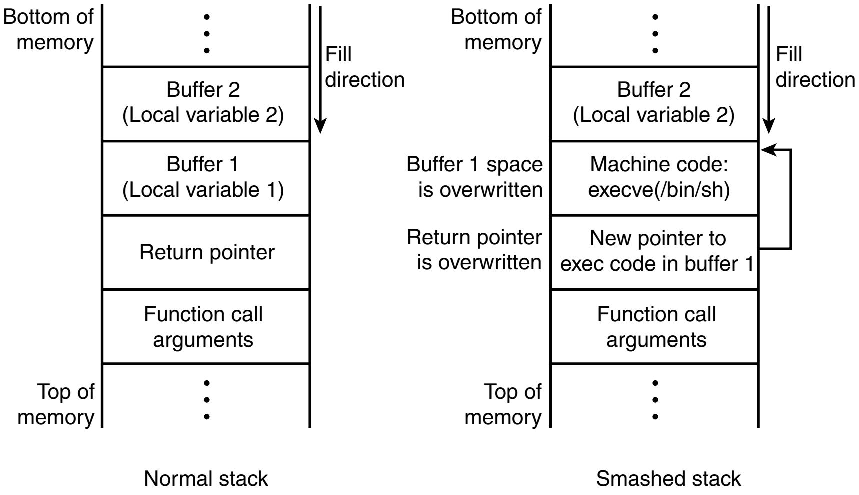
Stack-based buffer overflow attacks are commonly used by an attacker to take over a system remotely across a network. Additionally, buffer overflows can be employed by local malicious users to elevate their privileges and gain superuser access to a system. Stack-based buffer overflow attacks exploit the way many operating systems handle their stack, an internal data structure used by running programs to store data temporarily. When a function call is made, the current state of the executing program and variables to be passed to the function are pushed on the stack. New local variables used by the function are also allocated space on the stack. Additionally, the stack stores the return address of the code calling the function. This return address will be accessed from the stack once the function call is complete. The system uses this address to resume execution of the calling program at the appropriate place. Exhibit 72.2 shows how a stack is constructed.

Most UNIX and all Windows systems have a stack that can hold data and executable code. Because local variables are stored on the stack when a function is called, poor code can be exploited to overrun the boundaries of these variables on the stack. If user input length is not examined by the code, a particular variable on the stack may exceed the memory allocated to it on the stack, overwriting all variables and even the return address for where execution should resume after the function is complete. This operation, called “smashing” the stack, allows an attacker to overflow the local variables to insert executable code and another return address on the stack. Exhibit 72.2 also shows a stack that has been smashed with a buffer overflow.

The attacker will overflow the buffer on the stack with machine-specific bytecodes that consist of executable commands (usually a shell routine), and a return pointer to begin execution of these inserted commands. Therefore, with very carefully constructed binary code, the attacker can actually enter information as a user into a program that consists of executable code and a new return address. The buggy program will not analyze the length of this input, but will place it on the stack, and actually begin to execute the attacker’s code. Such vulnerabilities allow an attacker to break out of the application code, and access any system components with the permissions of the broken program. If the broken program is running with superuser privileges (e.g., SUID root on a UNIX system), the attacker has taken over the machine with a buffer overflow.

72.8.1 Stack-Based Buffer Overflow Defenses

The most thorough defenses against buffer overflow attacks is to properly code software so that it cannot be used to smash the stack. All programs should validate all input from users and other programs, ensuring that it fits into allocated memory structures. Each variable should be checked (including user input, variables from other functions, input from other programs, and even environment variables) to



Bottom of memory
Buffer 2 (Local variable 2)
Buffer 1 (Local variable 1)
Return pointer
Function call arguments
Top of memory
Fill direction
Normal stack
Bottom of memory
Buffer 2 (Local variable 2)
Buffer 1 space is overwritten
Machine code: execve(/bin/sh)
Return pointer is overwritten
New pointer to exec code in buffer 1
Function call arguments
Top of memory
Fill direction
Smashed stack

EXHIBIT 72.2 A normal stack and a stack with a buffer overflow.

ensure that allocated buffers are adequate to hold the data. Unfortunately, this ultimate solution is only available to individuals who write the programs and those with source code.

Additionally, security practitioners and system administrators should carefully control and minimize the number of SUID programs on a system that users can run and have permissions of other users (such as root). Only SUID programs with an explicit business need should be installed on sensitive systems.

Finally, many stack-based buffer overflow attacks can be avoided by configuring the systems to not execute code from the stack. Notably, Solaris and Linux offer this option. For example, to secure a Solaris system against stack-based buffer overflows, the following lines should be added:

```
/etc/system:

     set noexec_user_stack=1
     set noexec_user_stack_log=1
```

The first line will prevent execution on a stack, and the second line will log any attempt to do so. Unfortunately, some programs legitimately try to run code off the stack. Such programs will crash if this option is implemented. Generally, if the system is single purpose and needs to be secure (e.g., a Web server), this option should be used to prevent stack-based buffer overflow.

72.9 The Art and Science of Password Cracking

The vast majority of systems today authenticate users with a static password. When a user logs in, the password is transmitted to the system, which checks the password to make the decision whether to let the user log in. To make this decision, the system must have a mechanism to compare the user's input with the actual password. Of course, the system could just store all of the passwords locally and compare from this file. Such a file of cleartext passwords, however, would provide a very juicy target for an attacker. To make the target less useful for attackers, most modern operating systems use a one-way hash or encryption mechanism to protect the stored passswords. When a user types in a password, the system hashes the user's entry and compares it to the stored hash. If the two hashes match, the password is correct and the user can login.

Password cracking tools are used to attack this method of password protection. An attacker will use some exploit (often a buffer overflow) to gather the encrypted or hashed password file from a system (on a UNIX system without password shadowing, any user can read the hashed password file). After downloading the hashed password file, the attacker uses a password cracking tool to determine users' passwords. The cracking tool operates using a loop: it guesses a password, hashes or encrypts the password, and compares it to the hashed password from the stolen file. If the hashes match, the attacker has the password. If the hashes do not match, the loop begins again with another password guess.

Password cracking tools base their password guesses on a dictionary or a complete brute-force attack, attempting every possible password. Dozens of dictionaries are available online, in a multitude of languages, including English, French, German, Klingon, etc.

Numerous password-cracking tools are available. The most popular and full-functional password crackers include:

- John-the-Ripper, by Solar Designer, focuses on cracking UNIX passwords, and is available at http://www.openwall.com/john/.
- L0phtCrack, used to crack Windows NT passwords, is available at http://www.l0pht.com.

72.9.1 Password Cracking Defenses

The first defense against password cracking is to minimize the exposure of the encrypted/hashed password file. On UNIX systems, shadow password files should be used, which allow only the superuser to read the password file. On Windows NT systems, the SYSKEY feature available in NT 4.0 SP 3 and later should be installed and enabled. Furthermore, all backups and system recovery disks should be stored in physically secured locations and possibly even encrypted.

A strong password policy is a crucial element in ensuring a secure network. A password policy should require password lengths greater than eight characters, require the use of alphanumeric *and* special characters in every password, and force users to have passwords with mixed-case letters. Users must be aware of the issue of weak passwords and be trained in creating memorable, yet difficult-to-guess passwords.

To ensure that passwords are secure and to identify weak passwords, security practitioners should check system passwords on a periodic basis using password cracking tools. When weak passwords are discovered, the security group should have a defined procedure for interacting with users whose passwords can be easily guessed.

Finally, several software packages are available that prevent users from setting their passwords to easily guessed values. When a user establishes a new password, these filtering programs check the password to make sure that it is sufficiently complex and is not just a variation of the user name or a dictionary word. With this kind of tool, users are simply unable to create passwords that are easily guessed, eliminating a significant security issue. For filtering software to be effective, it must be installed on all servers where users establish passwords, including UNIX servers, Windows NT Primary and Back-up Domain Controllers, and Novell servers.

72.10 Backdoors

Backdoors are programs that bypass traditional security checks on a system, allowing an attacker to gain access to a machine without providing a system password and getting logged. Attackers install backdoors on a machine (or dupe a user into installing one for them) to ensure they will be able to gain access to the system at a later time. Once installed, most backdoors listen on special ports for incoming connections from the attacker across the network. When the attacker connects to the backdoor listener, the traditional userID and password or other forms of authentication are bypassed. Instead, the attacker can gain access to the system without providing a password, or by using a special password used only to enter the backdoor.

Netcat is an incredibly flexible tool written for UNIX by Hobbit and for Windows NT by Weld Pond (both versions are available at http://www.l0pht.com/~weld/netcat/). Among its numerous other uses, Netcat can be used to create a backdoor listener with a superuser-level shell on any TCP or UDP port. For Windows systems, an enormous number of backdoor applications are available, including Back Orifice 2000 (called BO2K for short, and available at http://www.bo2k.com) and hack-a-tack (available at http://www.hack-a-tack.com).

72.10.1 Backdoor Defenses

The best defense against backdoor programs is for system and security administrators to know what is running on their machines, particularly sensitive systems storing critical information or processing high-value transactions. If a process suddenly appears running as the superuser listening on a port, the administrator needs to investigate. Backdoors listening on various ports can be discovered using the **netstat -na** command on UNIX and Windows NT systems.

Additionally, many backdoor programs (such as BO2K) can be discovered by an anti-virus program, which should be installed on all users' desktops, as well as on servers throughout an organization.

72.11 Trojan Horses and RootKits

Another fundamental element of an attacker's toolchest is the Trojan horse program. Like the Trojan horse of ancient Greece, these new Trojan horses appear to have some useful function, but in reality are just disguising some malicious activity. For example, a user may receive an executable birthday card program in electronic mail. When the unsuspecting user activates the birthday card program and watches birthday cakes dance across the screen, the program secretly installs a backdoor or perhaps deletes the users' hard drive. As illustrated in this example, Trojan horses rely on deception — they trick a user or system administrator into running them for their (apparent) usefulness, but their true purpose is to attack the user's machine.

72.11.1 Traditional Trojan Horses

A traditional Trojan horse is simply an independent program that can be run by a user or administrator. Numerous traditional Trojan horse programs have been devised, including:

- The familiar birthday card or holiday greeting e-mail attachment described above.
- A software program that claims to be able to turn CD-ROM readers into CD writing devices. Although this feat is impossible to accomplish in software, many users have been duped into downloading this "tool," which promptly deletes their hard drives upon activation.
- A security vulnerability scanner, WinSATAN. This tool claims to provide a convenient security vulnerability scan for system and security administrators using a Windows NT system. Unfortunately, an unsuspecting user running this program will also have a deleted hard drive.

Countless other examples exist. While conceptually unglamorous, traditional Trojan horses can be a major problem if users are not careful and run untrusted programs on their machines.

72.11.2 RootKits

A RootKit takes the concept of a Trojan horse to a much more powerful level. Although the name implies otherwise, RootKits do not allow an attacker to gain "root" (superuser) access to a system. Instead, RootKits allow an attacker who already has superuser access to keep that access by foiling all attempts of an administrator to detect the invasion. RootKits consist of an entire suite of Trojan horse programs that replace or patch critical system programs. The various tools used by administrators to detect attackers on their machines are routinely undermined with RootKits.

Most RootKits include a Trojan horse backdoor program (in UNIX, the */bin/login* routine). The attacker will install a new Trojan horse version of */bin/login*, overwriting the previous version. The

RootKit */bin/login* routine includes a special backdoor userID and password so that the attacker can access the system at later times.

Additionally, RootKits include a sniffer and a program to hide the sniffer. An administrator can detect a sniffer on a system by running the **ifconfig** command. If a sniffer is running, the **ifconfig** output will contain the PROMISC flag, an indication that the Ethernet card is in promiscuous mode and therefore is sniffing. RootKit contains a Trojan horse version of **ifconfig** that does not display the PROMISC flag, allowing an attacker to avoid detection.

UNIX-based RootKits also replace other critical system executables, including **ps** and **du**. The **ps** command, emloyed by users and administrators to determine which processes are running, is modified so that an attacker can hide processes. The **du** command, which shows disk utilization, is altered so that the file space taken up by RootKit and the attacker's other programs can be masked.

By replacing programs like /bin/login, ifconfig, ps, du, and numerous others, these RootKit tools become part of the operating system itself. Therefore, RootKits are used to cover the eyes and ears of an administrator. They create a virtual world on the computer that appears benign to the system administrator, when in actuality, an attacker can log in and move around the system with impunity. RootKits have been developed for most major UNIX systems and Windows NT. A whole variety of UNIX RootKits can be found at http://packetstorm.securify.com/UNIX/penetration/rootkits, while an NT RootKit is available at http://www.rootkit.com.

A recent development in this arena is the release of kernel-level RootKits. These RootKits act at the most fundamental levels of an operating system. Rather than replacing application programs such as /bin/login and ifconfig, kernel-level RootKits actually patch the kernel to provide very low-level access to the system. These tools rely on the loadable kernel modules that many new UNIX variants support, including Linux and Solaris. Loadable kernel modules let an administrator add functionality to the kernel on-the-fly, without even rebooting the system. An attacker with superuser access can install a kernel-level RootKit that will allow for the remapping of execution of programs.

When an administrator tries to run a program, the Trojanized kernel will remap the execution request to the attacker's program, which could be a backdoor offering access or other Trojan horse. Because the kernel does the remapping of execution requests, this type of activity is very difficult to detect. If the administrator attempts to look at the remapped file or check its integrity, the program will appear unaltered, because the program's image is unaltered. However, when executed, the unaltered program is skipped, and a malicious program is substituted by the kernel. Knark, written by Creed, is a kernel-level RootKit that can be found at http://packetstorm.securify.com/UNIX/penetration/rootkits.

72.11.3 Trojan Horses and RootKit Defenses

To protect against traditional Trojan horses, user awareness is key. Users must understand the risks associated with downloading untrusted programs and running them. They must also be made aware of the problems of running executable attachments in e-mail from untrusted sources.

Additionally, some traditional Trojan horses can be detected and eliminated by anti-virus programs. Every end-user computer system (and even servers) should have an effective and up-to-date anti-virus program installed.

To defend against RootKits, system and security administrators must use integrity checking programs for critical system files. Numerous tools are available, including the venerable Tripwire, that generate a hash of the executables commonly altered when a RootKit is installed. The administrator should store these hashes on a protected medium (such as a write-protected floppy disk) and periodically check the veracity of the programs on the machine with the protected hashes. Commonly, this type of check is done at least weekly, depending on the sensitivity of the machine. The administrator must reconcile any changes discovered in these critical system files with recent patches. If system files have been altered, and no patches were installed by the administrator, a malicious user or outside attacker may have installed a

RootKit. If a RootKit is detected, the safest way to ensure its complete removal is to rebuild the entire operating system and even critical applications.

Unfortunately, kernel-level RootKits cannot be detected with integrity check programs because the integrity checker relies on the underlying kernel to do its work. If the kernel lies to the integrity checker, the results will not show the RootKit installation. The best defense against the kernel-level RootKit is a monolithic kernel that does not support loadable kernel modules. On critical systems (such as firewalls, Internet Web servers, DNS servers, mail servers, etc.), administrators should build the systems with complete kernels without support for loadable kernel modules. With this configuration, the system will prevent an attacker from gaining root-level access and patching the kernel in real-time.

72.12 Overall Defenses: Intrusion Detection and Incident Response Procedures

Each of the defensive strategies described in this chapter deals with particular tools and attacks. In addition to employing each of those strategies, organizations must also be capable of detecting and responding to an attack. These capabilities are realized through the deployment of intrusion detection systems (IDSs) and the implementation of incident response procedures.

IDSs act as burglar alarms on the network. With a database of known attack signatures, IDSs can determine when an attack is underway and alert security and system administration personnel. Acting as early warning systems, IDSs allow an organization to detect an attack in its early stages and minimize the damage that may be caused.

Perhaps even more important than IDSs, documented incident response procedures are among the most critical elements of an effective security program. Unfortunately, even with industry-best defenses, a sufficiently motivated attacker can penetrate the network. To address this possibility, an organization must have procedures defined in advance describing how the organization will react to the attack. These incident response procedures should specify the roles of individuals in the organization during an attack. The chain of command and escalation procedures should be spelled out in advance. Creating these items during a crisis will lead to costly mistakes.

Truly effective incident response procedures should also be multidisciplinary, not focusing only on information technology. Instead, the roles, responsibilities, and communication channels for the Legal, Human Resources, Media Relations, Information Technology, and Security organizations should all be documented and communicated. Specific members of these organizations should be identified as the core of a Security Incident Response Team (SIRT), to be called together to address an incident when one occurs. Additionally, the SIRT should conduct periodic exercises of the incident response capability to ensure that team members are effective in their roles.

Additionally, with a large number of organizations outsourcing their information technology infrastructure by utilizing Web hosting, desktop management, e-mail, data storage, and other services, the extension of the incident response procedures to these outside organizations can be critical. The contract established with the outsourcing company should carefully state the obligations of the service provider in intrusion detection, incident notification, and participation in incident response. A specific service-level agreement for handling security incidents and the time needed to pull together members of the service company's staff in a SIRT should also be agreed upon.

72.13 Conclusions

While the number and power of these attack tools continues to escalate, system administrators and security personnel should not give up the fight. All of the defensive strategies discussed throughout this chapter boil down to doing a thorough and professional job of administering systems: know what is running on the system, keep it patched, ensure appropriate bandwidth is available, utilize IDSs, and prepare a Security Incident Response Team. Although these activities are not easy and can involve a great deal of effort, through diligence, an organization can keep its systems secured and minimize the chance of an attack. By employing intrusion detection systems and sound incident response procedures, even those highly sophisticated attacks that do get through can be discovered and contained, minimizing the impact on the organization. By creating an effective security program with sound defensive strategies, critical systems and information can be protected.

73

A New Breed of Hacker Tools and Defenses

Ed Skoudis

The state-of-the-art in computer attack tools and techniques is rapidly advancing. Yes, we still face the tried-and-true, decades-old arsenal of traditional computer attack tools, including denial-of-service attacks, password crackers, port scanners, sniffers, and RootKits. However, many of these basic tools and techniques have seen a renaissance in the past couple of years, with new features and underlying architectures that make them more powerful than ever. Attackers are delving deep into widely used protocols and the very hearts of our operating systems. In addition to their growing capabilities, computer attack tools are becoming increasingly easy to use. Just when you think you have seen it all, a new and easy-to-use attack tool is publicly released with a feature that blows your socks off. With this constant increase in the sophistication and ease of use in attack tools, as well as the widespread deployment of weak targets on the Internet, we now live in the golden age of hacking.

The purpose of this chapter is to describe recent events in this evolution of computer attack tools. To create the best defenses for our computers, one must understand the capabilities and tactics of one's adversaries. To achieve this goal, this chapter describes several areas of advance among attack tools, including distributed attacks, active sniffing, and kernel-level RootKits, along with defensive techniques for each type of attack.

73.1 Distributed Attacks

One of the primary trends in the evolution of computer attack tools is the movement toward distributed attack architectures. Essentially, attackers are harnessing the distributed power of the Internet itself to improve their attack capabilities. The strategy here is pretty straightforward, perhaps deceptively so given the power of some of these distributed attack tools. The attacker takes a conventional computer attack and splits the work among many systems. With more and more systems collaborating in the attack, the attacker's chances for success increase. These distributed attacks offer several advantages to attackers, including:

- They may be more difficult to detect.
- They usually make things more difficult to trace back to the attacker.
- They may speed up the attack, lowering the time necessary to achieve a given result.
- They allow an attacker to consume more resources on a target.

So, where does an attacker get all of the machines to launch a distributed attack? Unfortunately, enormous numbers of very weak machines are readily available on the Internet. The administrators and owners of such systems do not apply security patches from the vendors, nor do they configure their machines securely, often just using the default configuration right out of the box. Poorly secured computers at universities, companies of all sizes, government institutions, homes with always-on Internet connectivity, and elsewhere are easy prey for an attacker. Even lowly skilled attackers can take over hundreds or thousands of systems around the globe with ease. These attackers use automated vulnerability scanning tools, including homegrown scripts and freeware tools such as the Nessus vulnerability scanner (http://www.nessus.org), among many others, to scan large swaths of the Internet. They scan indiscriminately, day in and day out, looking to take over vulnerable systems. After taking over a suitable number of systems, the attackers will use these victim machines as part of the distributed attack against another target.

Attackers have adapted many classic computer attack tools to a distributed paradigm. This chapter explores many of the most popular distributed attack tools, including distributed denial-of-service attacks, distributed password cracking, distributed port scanning, and relay attacks.

73.1.1 Distributed Denial-of-Service Attacks

One of the most popular and widely used distributed attack techniques is the distributed denial-of-service (DDoS) attack. In a DDoS attack, the attacker takes over a large number of systems and installs a remotely controlled program called a zombie on each system. The zombies silently run in the background awaiting commands. An attacker controls these zombie systems using a specialized client program running on one machine. The attacker uses one client machine to send commands to the multitude of zombies, telling them to simultaneously conduct some action. In a DDoS attack, the most common action is to flood a victim with packets. When all the zombies are simultaneously launching packet floods, the victim machine will be suddenly awash in bogus traffic. Once all capacity of the victim's communication link is exhausted, no legitimate user traffic will be able to reach the system, resulting in a denial of service.

The DDoS attack methodology was in the spotlight in February 2000 when several high-profile Internet sites were hit with the attack. DDoS tools have continued to evolve, with new features that make them even nastier. The latest generation of DDoS attacks includes extensive spoofing capabilities, so that all traffic from the client to the zombies and from the zombies to the target has a decoy source address. Therefore, when a flood begins, the investigators must trace the onslaught back, router hop by router hop, from the victim to the zombies. After rounding up some of the zombies, the investigators must still trace from the zombies to the client, across numerous hops and multiple Internet service providers (ISPs). Furthermore, DDoS tools are employing encryption to mask the location of the zombies. In early generations of DDoS tools, most of the client software included a file with a list of network addresses for the zombies. By discovering such a client, an investigation team could quickly locate and eradicate the zombies. With the latest generation of DDoS tools, the list of network addresses at the client is strongly encrypted so that the client does not give away the location of the zombies.

73.1.2 Defenses against Distributed Denial-of-Service Attacks

To defend against any packet flood, including DDoS attacks, one must ensure that critical network connections have sufficient bandwidth and redundancy to eliminate simple attacks. If a network connection is mission critical, one should have at least a redundant T1 connection because all lower connection speeds can easily be flooded by an attacker.

While this baseline of bandwidth eliminates the lowest levels of attackers, one must face the fact that one will not be able to buy enough bandwidth to keep up with attackers who have installed zombies on a hundred or thousand systems and pointed them at your system as a target. If one's system's availability on the Internet is critical to the business, one must employ additional techniques for handling DDoS attacks. From a technological perspective, one may want to consider traffic shaping tools, which can help manage the number of incoming sessions so that one's servers are not overwhelmed. Of course, a large enough cadre of zombies flooding one's connection could even overwhelm traffic shapers. Therefore, one should employ intrusion detection systems (IDSs) to determine when an attack is underway. These IDSs act as network burglar alarms, listening to the network for traffic that matches common attack signatures stored in the IDS database. From a procedural perspective, one should have an incident response team on stand-by for such alarms from the IDS. For mission-critical Internet connections, one must have the cell phone and pager numbers for one's ISP's own incident response team. When a DDoS attack begins, one's incident response team must be able to quickly and efficiently marshal the forces of the ISP's incident response team. Once alerted, the ISP can deploy filters in their network to block an active DDoS attack upstream.

73.1.3 Distributed Password Cracking

Password cracking is another technique that has been around for many years and is now being leveraged in distributed attacks. The technique is based on the fact that most modern computing systems (such as UNIX and Windows NT) have a database containing encrypted passwords used for authentication. In Windows NT, the passwords are stored in the SAM database. On UNIX systems, the passwords are located in the /etc/passwd or /etc/shadow files. When a user logs on to the system, the machine asks the user for a password, encrypts the value entered by the user, and compares the encrypted version of what the user typed with the stored encrypted password. If they match, the user is allowed to log in.

The idea behind password cracking is simple: steal an encrypted password file, guess a password, encrypt the guess, and compare the result to the value in the stolen encrypted password file. If the encrypted guess matches the encrypted password, the attacker has determined the password. If the two values do not match, the attacker makes another guess. Because user passwords are often predictable combinations of user IDs, dictionary words, and other characters, this technique is often very successful in determining passwords.

Traditional password cracking tools automate the guess-encrypt-compare loop to help determine passwords quickly and efficiently. These tools use variations of the user ID, dictionary terms, and brute-force guessing of all possible character combinations to create their guesses for passwords. The better password-cracking tools can conduct hybrid attacks, appending and prepending characters in a brute-force fashion to standard dictionary words. Because most passwords are simply a dictionary term with a few special characters tacked on at the beginning or end, the hybrid technique is extremely useful. Some of the best traditional password-cracking tools are L0phtCrack for Windows NT passwords (available at http://www.l0pht.com) and John the Ripper for a variety of password types, including UNIX and Windows NT (available at http://www.openwall.com).

When cracking passwords, speed rules. Tools that can create and check more password guesses in less time will result in more passwords recovered by the attacker. Traditional password cracking tools address this speed issue by optimizing the implementation of the encryption algorithm used to encrypt the guesses. Attackers can gain even more speed by distributing the password-cracking load across numerous computers. To more rapidly crack passwords, attackers will simultaneously harness hundreds or thousands of systems located all over the Internet to churn through an encrypted password file.

To implement distributed password cracking, an attacker can use a traditional password-cracking tool in a distributed fashion by simply dividing up the work manually. For example, consider a scenario in which an attacker wants to crack a password file with ten encrypted passwords. The attacker could break the file into ten parts, each part containing one encrypted password, and then distribute each part to one of ten machines. Each machine runs a traditional password-cracking tool to crack the one encrypted password assigned to that system. Alternatively, the attacker could load all ten encrypted passwords on each of the machines and configure each traditional password-cracking tool to guess a different set of passwords, focusing on a different part of a dictionary or certain characters in a brute-force attack.

Beyond manually splitting up the work and using a traditional password-cracking tool, several native distributed password-cracking tools have been released. These tools help to automate the spreading of the workload across several machines and coordinate the computing resources as the attack progresses. Two of the most popular distributed password-cracking tools are Mio-Star and Saltine Cracker, both available at http://packetstorm.securify.com/distributed.

73.1.3.1 Defenses against Distributed Password Cracking.

The defenses against distributed password cracking are really the same as those employed for traditional password cracking: eliminate weak passwords from your systems. Because distributed password cracking speeds up the cracking process, passwords need to be even more difficult to guess than in the days when nondistributed password cracking ruled. One must start with a policy that mandates users to establish passwords that are greater than a minimum length (such as greater than nine characters) and include numbers, letters, and special characters in each password. Users must be aware of the policy; thus, an awareness program emphasizing the importance of difficult-to-guess passwords is key. Furthermore, to help enforce a password policy, one may want to deploy password-filtering tools on one's authentication servers. When a user establishes a new password, these tools check the password to make sure it conforms to the password policy. If the password is too short, or does not include numbers, letters, and special characters, the user will be asked to select another password. The passfilt.dll program included in the Windows NT Resource Kit and the passwd+ program on UNIX systems implement this type of feature, as do several third-party add-on authentication products. One also may want to consider the elimination of standard passwords from very sensitive environments, using token-based access technologies.

Finally, security personnel should periodically run a password-cracking tool against one's own users' passwords to identify the weak ones before an attacker does. When weak passwords are found, there should be a defined and approved process for informing users that that they should select a better password. Be sure to get appropriate permissions before conducting in-house password-cracking projects to ensure that management understands and supports this important security program. Not getting management approval could negatively impact one's career.

73.1.4 Distributed Port Scanning

Another attack technique that lends itself well to a distributed approach is the port scan. A port is an important concept in the Transmission Control Protocol (TCP) and the User Datagram Protocol (UDP), two protocols used by the vast majority of Internet services. Every server that receives TCP or UDP traffic from a network listens on one or more ports. These ports are like little virtual doors on a machine, where packets can go in or come out. The port numbers serve as addresses on a system where the packets should be directed. While an administrator can configure a network service to listen on any port, the most common services listen on well-known ports, so that client software knows where to send the packets. Web servers usually listen on TCP port 80, while Internet mail servers listen on TCP port 25. Domain Name Servers listen for queries on UDP port 53. Hundreds of other ports are assigned to various services in RFC 1700, a document available at http://www.ietf.org/rfc.html.

Port scanning is the process of sending packets to various ports on a target system to determine which ports have listening services. It is similar to knocking on the doors of the target system to see which ones are open. By knowing which ports are open on the target system, the attacker has a good idea of the services running on the machine. The attacker can then focus an attack on the services associated with these open ports. Furthermore, each open port on a target system indicates a possible entry point for an attacker. The attacker can scan the machine and determine that TCP port 25 and UDP port 53 are open. This result tells the attacker that the machine is likely a mail server and a DNS server. While there are a large number of traditional port-scanning tools available, one of the most powerful (by far) is the Nmap tool, available at http://www.insecure.org.

Because a port scan is often the precursor to a more in-depth attack, security personnel often use IDS tools to detect port scans as an early-warning indicator. Most IDSs include specific capabilities to recognize port scans. If a packet arrives from a given source going to one port, followed by another packet from the same source going to another port, followed by yet another packet for another port, the IDS can quickly correlate these packets to detect the scan. This traffic pattern is shown on the left-hand side of Exhibit 73.1, where port numbers are plotted against source network address. IDSs can easily spot such a scan, and ring bells and whistles (or send an e-mail to an administrator).

Now consider what happens when an attacker uses a distributed approach for conducting the scan. Instead of a barrage of packets coming from a single address, the attacker will configure many systems to participate in the scan. Each scanning machine will send only one or two packets and receive the results. By working together, the scanning machines can check all of the interesting ports on the target system and send their result to be correlated by the attacker. An IDS looking for the familiar pattern of the traditional port scan will not detect the attack. Instead, the pattern of incoming packets will appear more random, as shown on the right side of Exhibit 73.1. In this way, distributed scanning makes detection of attacks more difficult.

Of course, an IDS system can still detect the distributed port scan by focusing on the destination address (i.e., the place where the packets are going) rather than the source address. If a number of systems suddenly sends packets to several ports on a single machine, an IDS can deduce that a port scan is underway. But the attacker has raised the bar for detection by conducting a distributed scan. If the distributed scan is conducted over a longer period of time (e.g., a week or a month), the chances of evading an IDS are quite good for an attacker. Distributed port scans are also much more difficult to trace back to an attacker because the scan comes from so many different systems, none of which are owned by the attacker.

Several distributed port-scanning tools are available. An attacker can use the descriptively named Phpdis-tributedportscanner, which is a small script that can be placed on Web servers to conduct a scan. Whenever attackers take over a PHP-enabled Web server, they can place the script on the server and use it to scan other systems. The attacker interacts with the individual scanning scripts running on the various Web servers using HTTP requests. Because everything is Web based, distributed port scans are quite

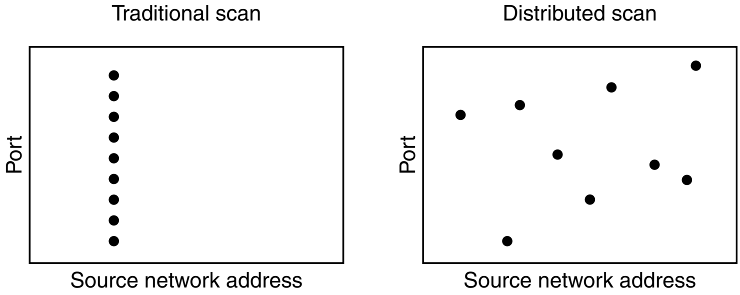


EXHIBIT 73.1 Traditional scans versus distributed scans.

simple to run. This scanning tool is available at http://www.digitaloffense.net:8000/phpDistributedPortScanner/. Other distributed port scanners tend to be based on a client/server architecture, such as Dscan (available at http://packetstorm.securify.com/distributed) and SIDEN (available at http://siden.sourceforge.net).

73.1.4.1 Defenses against Distributed Scanning

The best defense against distributed port scanning is to shut off all unneeded services on one's systems. If a machine's only purpose is to run a Web server that communicates via HTTP and HTTPS, the system should have only TCP port 80 and TCP port 443 open. If one does not need a mail server running on the same machine as the Web server, one should configure the system so that the mail server is deactivated. If the X Window system is not needed on the machine, turn it off. All other services should be shut off, which would close all other ports. One should develop a secure configuration document that provides a step-by-step process for all system administrators in an organization for building secure servers.

Additionally, one must ensure that IDS probes are kept up-to-date. Most IDS vendors distribute new attack signatures on a regular basis—usually once a month. When a new set of attack signatures is available, one should quickly test it and deploy it on the IDS probes so they can detect the latest batch of attacks.

73.1.5 Relay Attacks

A final distributed attack technique involves relaying information from machine to machine across the Internet to obscure the true source of the attack. As one can expect, most attackers do not want to get caught. By setting up extra layers of indirection between an attacker and the target, the attacker can avoid being apprehended. Suppose an attacker takes over half a dozen Internet-accessible machines located all over the world and wants to attack a new system. The attacker can set up packet redirector programs on the six systems. The first machine will forward any packets received on a given port to the second system. The second system would then forward them to the third system, and so on, until the new target is reached. Each system acts as a link in a relay chain for the attacker's traffic. If and when the attack is detected, the investigation team will have to trace the attack back through each relay point before finding the attacker.

Attackers often set up relay chains consisting of numerous systems around the globe. Additionally, to further foil investigators, attackers often try to make sure there is a great change in human language and geopolitical relations between the countries where the links of the relay chain reside. For example, the first relay may be in the United States, while the second may be in China. The third could be in India, while the fourth is in Pakistan. Finally, the chain ends in Iran for an attack against a machine back in the United States. At each stage of the relay chain, the investigators would have to contend with dramatic shifts in human language, less-than-friendly relations between countries, and huge law enforcement jurisdictional issues.

Relay attacks are often implemented using a very flexible tool called Netcat, which is available for UNIX at http://www.l0pht.com/users/10pht/nc110.tgz, and for Windows NT at http://www.l0pht.com/~weld/netcat/. Another popular tool for creating relays is Redir, located at http://oh.verio.com/~sammy/hacks.

73.1.5.1 Defenses against Relay Attacks

Because most of the action in a relay attack occurs outside an organization's own network, there is little one can do to prevent such attacks. One cannot really stop attackers from bouncing their packets through a bunch of machines before being attacked. One's best bet is to make sure that systems are secure by applying security patches and shutting down all unneeded services. Additionally, it is important to cooperate with law enforcement officials in their investigations of such attacks.

73.2 Active Sniffing

Sniffing is another, older technique that is being rapidly expanded with new capabilities. Traditional sniffers are simple tools that gather traffic from a network. The user installs a sniffer program on a computer that captures all data passing by the computer's network interface, whether it is destined for that machine or another system. When used by network administrators, sniffers can capture errant packets to help troubleshoot the network. When used by attackers, sniffers can grab sensitive data from the network, such as passwords, files, e-mail, or anything else transmitted across the network.

73.2.1 Traditional Sniffing

Traditional sniffing tools are passive; they wait patiently for traffic to pass by on the network and gather the data when it arrives. This passive technique works well for some network types. Traditional Ethernet, a popular technology used to create a large number of local area networks (LANs), is a broadcast medium. Ethernet hubs are devices used to create traditional Ethernet LANs. All traffic sent to any one system on the LAN is broadcast to all machines on the LAN. A traditional sniffer can therefore snag any data going between other systems on the same LAN. In a traditional sniffing attack, the attacker takes over one system on the LAN, installs a sniffer, and gathers traffic destined for other machines on the same LAN. Some of the best traditional sniffers include Snort (available at http://www.snort.org) and Sniffit (available at http://reptile.rug.ac.be/~coder/sniffit/sniffit.html).

One of the commonly used defenses against traditional sniffers is a switched LAN. Contrary to an Ethernet hub, which acts as a broadcast medium, an Ethernet switch only sends data to its intended destination on the LAN. No other system on the LAN is able to see the data because the Ethernet switch sends the data to its appropriate destination and nowhere else. Another commonly employed technique to foil traditional sniffers is to encrypt data in transit. If the attackers do not have the encryption keys, they will not be able to determine the contents of the data sniffed from the network. Two of the most popular encryption protocols are the Secure Socket Layer (SSL), which is most often used to secure Web traffic, and Secure Shell (SSH), which is most often used to protect command-line shell access to systems.

73.2.2 Raising the Ante with Active Sniffing

While the defenses against passive sniffers are effective and useful to deploy, attackers have developed a variety of techniques for foiling them. These techniques, collectively known as active sniffing, involve injecting traffic into the network to allow an attacker to grab data that should otherwise be unsniffable. One of the most capable active sniffing programs available is Dsniff, available at http://www.monkey.org/~dugsong/dsniff/. One can explore Dsniff's various methods for sniffing by injecting traffic into a network, including MAC address flooding, spurious ARP traffic, fake DNS responses, and person-in-the-middle attacks against SSL.

73.2.2.1 MAC Addresses Flooding

An Ethernet switch determines where to send traffic on a LAN based on its media access control (MAC) address. The MAC address is a unique 48-bit number assigned to each Ethernet card in the world. The MAC address indicates the unique network interface hardware for each system connected to the LAN. An Ethernet switch monitors the traffic on a LAN to learn which plugs on the switch are associated with which MAC addresses. For example, the switch will see traffic arriving from MAC address AA:BB:CC:DD:EE:FF on plug number one. The switch will remember this information and send data destined for this MAC address only to the first plug on the switch. Likewise, the switch will autodetect the MAC addresses associated with the other network interfaces on the LAN and send the appropriate data to them.

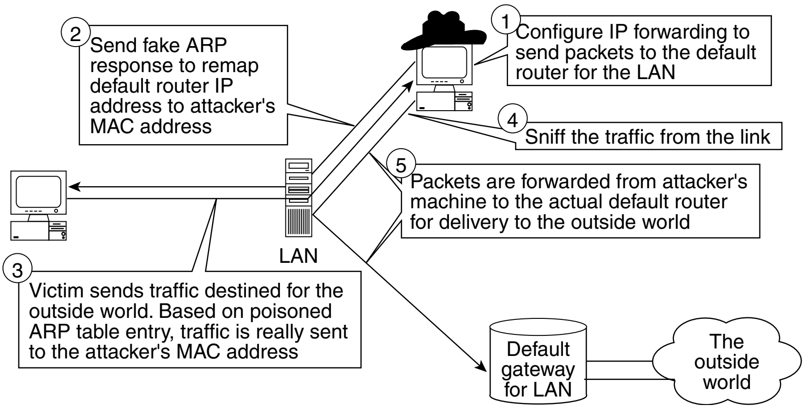
One of the simplest, active sniffing techniques involves flooding the LAN with traffic that has bogus MAC addresses. The attacker uses a program installed on a machine on the LAN to generate packets with random MAC addresses and feed them into the switch. The switch will attempt to remember all of the MAC addresses as they arrive. Eventually, the switch's memory capacity will be exhausted with bogus MAC addresses. When their memory fills up, some switches fail into a mode where traffic is sent to all machines connected to the LAN. By using MAC flooding, therefore, an attacker can bombard a switch so that the switch will send all traffic to all machines on the LAN. The attacker can then utilize a traditional sniffer to grab the data from the LAN.

73.2.2.2 Spurious ARP Traffic

While some switches fail under a MAC flood in a mode where they send all traffic to all systems on the LAN, other switches do not. During a flood, these switches remember the initial set of MAC addresses that were autodetected on the LAN, and utilize those addresses throughout the duration of the flood. The attacker cannot launch a MAC flood to overwhelm the switch. However, an attacker can still undermine such a LAN by injecting another type of traffic based on the Address Resolution Protocol (ARP).

ARP is used to map Internet Protocol (IP) addresses into MAC addresses on a LAN. When one machine has data to send to another system on the LAN, it formulates a packet for the destination's IP address; however, the IP address is just a configuration setting on the destination machine. How does the sending machine with the packet to deliver determine which hardware device on the LAN to send the packet to? ARP is the answer. Suppose a machine on the LAN has a packet that is destined for IP address 10.1.2.3. The machine with the packet will send an ARP request on the LAN, asking which network interface is associated with IP address 10.1.2.3. The machine with this IP address will transmit an ARP response, saying, in essence, "IP Address 10.1.2.3 is associated with MAC address AA:BB:CC:DD:EE:FF." When a system receives an ARP response, it stores the mapping of IP address to MAC address in a local table, called the ARP table, for future reference. The packet will then be delivered to the network interface with this MAC address. In this way, ARP is used to convert IP addresses into MAC addresses so that packets can be delivered to the appropriate network interface on the LAN. The results are stored in a system's ARP table to minimize the need for additional ARP traffic on the LAN.

ARP includes support for a capability called the "gratuitous ARP." With a gratuitous ARP, a machine can send an ARP response although no machine sent an ARP request. Most systems are thirsty for ARP entries in their ARP tables, to help improve performance on the LAN. In another form of active sniffing, an attacker utilizes faked gratuitous ARP messages to redirect traffic for sniffing a switched LAN, as shown in Exhibit 73.2. For the exhibit, the attacker's machine on the LAN is indicated by a black hat.



1 Configure IP forwarding to send packets to the default router for the LAN
2 Send fake ARP response to remap default router IP address to attacker's MAC address
3 Victim sends traffic destined for the outside world. Based on poisoned ARP table entry, traffic is really sent to the attacker's MAC address
4 Sniff the traffic from the link
5 Packets are forwarded from attacker's machine to the actual default router for delivery to the outside world
LAN
Default gateway for LAN
The outside world

EXHIBIT 73.2 Active sniffing in a switched environment using gratuitous ARP messages. (Reprinted with permission. *CounterHack: A Step by Step Guide to Computer Attacks and Effective Defenses*. Copyright 2002, Prentice Hall PTR.)

The steps of this attack, shown in Exhibit 73.2, are:

1. The attacker activates IP forwarding on the attacker's machine on the LAN. Any packets directed by the switch to the black-hat machine will be redirected to the default router for the LAN.
2. The attacker sends a gratuitous ARP message to the target machine. The attacker wants to sniff traffic sent from this machine to the outside world. The gratuitous ARP message will map the IP address of the default router for the LAN to the MAC address of the attacker's own machine. The target machine accepts this bogus ARP message and enters it into its ARP table. The target's ARP table is now poisoned with the false entry.
3. The target machine sends traffic destined for the outside world. It consults its ARP table to determine the MAC address associated with the default router for the LAN. The MAC address it finds in the ARP table is the attacker's address. All data for the outside world is sent to the attacker's machine.
4. The attacker sniffs the traffic from the line.
5. The IP forwarding activated in Step 1 redirects all traffic from the attacker's machine to the default router for the LAN. The default router forwards the traffic to the outside world. In this way, the victim will be able to send traffic to the outside world, but it will pass through the attacker's machine to be sniffed on its way out.

This sequence of steps allows the attacker to view all traffic to the outside world from the target system. Note that, for this technique, the attacker does not modify the switch at all. The attacker is able to sniff the switched LAN by manipulating the ARP table of the victim. Because ARP traffic and the associated MAC address information are only transmitted across a LAN, this technique only works if the attacker controls a machine on the same LAN as the target system.

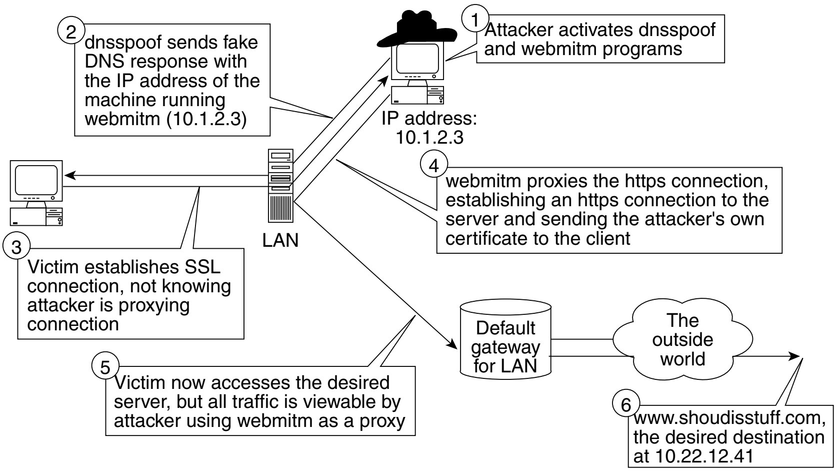
73.2.2.3 Fake DNS Responses.

A technique for injecting packets into a network to sniff traffic beyond a LAN involves manipulating the Domain Name System (DNS). While ARP is used on a LAN to map IP addresses to MAC addresses on a LAN, DNS is used across a network to map domain names into IP addresses. When a user types a domain name into some client software, such as entering www.skoudisstuff.com into a Web browser, the user's system sends out a query to a DNS server. The DNS server is usually located across the network on a different LAN. Upon receiving the query, the DNS server looks up the appropriate information in its configuration files and sends a DNS response to the user's machine that includes an IP address, such as 10.22.12.41. The DNS server maps the domain name to IP address for the user.

Attackers can redirect traffic by sending spurious DNS responses to a client. While there is no such thing as a gratuitous DNS response, an attacker that sits on any network between the target system and the DNS server can sniff DNS queries from the line. Upon seeing a DNS query from a client, the attacker can send a fake DNS response to the client, containing an IP address of the attacker's machine. The client software on the users' machine will send packets to this IP address, thinking that it is communicating with the desired server. Instead, the information is sent to the attacker's machine. The attacker can view the information using a traditional sniffer, and relay the traffic to its intended destination.

73.2.2.4 Person-in-the-Middle Attacks against SSL

Injecting fake DNS responses into a network is a particularly powerful technique when it is used to set up a person-in-the-middle attack against cryptographic protocols such as SSL, which is commonly used for secure Web access. Essentially, the attacker sends a fake DNS response to the target so that a new SSL session is established through the attacker's machine. As highlighted in Exhibit 73.3, the attacker uses a specialized relay tool to set up two cryptographic sessions: one between the client and the attacker, and the other between the attacker and the server. While the data moves between these sessions, the attacker can view it in cleartext.



1 Attacker activates dnsspoof and webmitm programs
2 dnsspoof sends fake DNS response with the IP address of the machine running webmitm (10.1.2.3)
IP address: 10.1.2.3
4 webmitm proxies the https connection, establishing an https connection to the server and sending the attacker's own certificate to the client
LAN
3 Victim establishes SSL connection, not knowing attacker is proxying connection
Default gateway for LAN
The outside world
5 Victim now accesses the desired server, but all traffic is viewable by attacker using webmitm as a proxy
6 www.shoudisstuff.com, the desired destination at 10.22.12.41

EXHIBIT 73.3 Injecting DNS responses to redirect and capture SSL traffic. (Reprinted with permission. *CounterHack: A Step by Step Guide to Computer Attacks and Effective Defenses*. Copyright 2002, Prentice Hall PTR.)

The steps shown in Exhibit 73.3 include:

1. The attacker activates Dsniff's dnsspoof program, a tool that sends fake DNS responses. Additionally, the attacker activates another Dsniff tool called "webmitm," an abbreviation for Web Monkey-in-the-Middle. This tool implements a specialized SSL relay.
2. The attacker observes a DNS query from the victim machine and sends a fake DNS response. The fake DNS response contains the IP address of the attacker's machine.
3. The victim receives the DNS response and establishes an SSL session with the IP address included in the response.
4. The webmitm tool running on the attacker's machine established an SSL session with the victim machine, and another SSL session with the actual Web server that the client wants to access.
5. The victim sends data across the SSL connection. The webmitm tool decrypts the traffic from the SSL connection with the victim, displays it for the attacker, and encrypts the traffic for transit to the external Web server. The external Web server receives the traffic, not realizing that a person-in-the-middle attack is occurring.

While this technique is quite effective, it does have one limitation from the attacker's point of view. When establishing the SSL connection between the victim and the attacker's machine, the attacker must send the victim an SSL digital certificate that belongs to the attacker. To decrypt all data sent from the target, the attacker must use his or her own digital certificate, and not the certificate from the actual destination Web server. When the victim's Web browser receives the bogus certificate from the attacker, it will display a warning message to the user. The browser will indicate that the certificate it was presented by the server was signed by a certificate authority that is not trusted by the browser. The browser then gives the user the option of establishing the connection by simply clicking on a button labeled "OK" or "Connect." Most users do not understand the warning messages from their browsers and will continue the connection without a second thought. The browser will be satisfied that it has established a secure connection because the user told it to accept the attacker's certificate. After continuing the connection, the attacker will be able to gather all traffic from the SSL session. In essence, the attacker relies on the fact that trust decisions about SSL certificates are left in the hands of the user.

The same basic technique works against the Secure Shell (SSH) protocol used for remote command-shell access. Dsniff includes a tool called sshmitm that can be used to set up a person-in-the-middle attack against SSH. Similar to the SSL attack, Dsniff establishes two SSH connections: one between the victim and the attacker, and another between the attacker and the destination server. Also, just as the Web browser complained about the modified SSL certificate, the SSH client will complain that it does not recognize the public key used by the SSH server. The SSH client will still allow the user, however, to override the warning and establish the SSH session so the attacker can view all traffic.

73.2.2.5 Defenses against Active Sniffing Techniques

Having seen how an attacker can grab all kinds of useful information from a network using sniffing tools, how can one defend against these attacks? First, whenever possible, encrypt data that gets transmitted across the network. Use secure protocols such as SSL for Web traffic, SSH for encrypted log-in sessions and file transfer, S/MIME for encrypted e-mail, and IPSec for network-layer encryption. Users must be equipped to apply these tools to protect sensitive information, both from a technology and an awareness perspective.

It is especially important that system administrators, network managers, and security personnel understand and use secure protocols to conduct their job activities. Never telnet to firewall, routers, sensitive servers, or public key infrastructure (PKI) systems! It is just too easy for an attacker to intercept one's password, which telnet transmits in cleartext. Additionally, pay attention to those warning messages from the browser and SSH client. Do not send any sensitive information across the network using an SSL session created with an untrusted certificate. If the SSH client warns that the server public key mysteriously changed, there is need to investigate.

Additionally, one really should consider getting rid of hubs because they are just too easy to sniff through. Although the cost may be higher than hubs, switches not only improve security, but also improve performance. If a complete migration to a switched network is impossible, at least consider using switched Ethernet on critical network segments, particularly the DMZ.

Finally, for networks containing very sensitive systems and data, enable port-level security on your switches by configuring each switch port with the specific MAC address of the machine using that port to prevent MAC flooding problems and fake ARP messages. Furthermore, for extremely sensitive networks, such as Internet DMZs, use static ARP tables on the end machines, hard coding the MAC addresses for all systems on the LAN. Port security on a switch and hard-coded ARP tables can be very difficult to manage because swapping components or even Ethernet cards requires updating the MAC addresses stored in several systems. For very sensitive networks such as Internet DMZs, this level of security is required and should be implemented.

73.3 The Proliferation of Kernel-Level RootKits

Just as attackers are targeting key protocols such as ARP and DNS at a very fundamental level, so too are they exploiting the heart of our operating systems. In particular, a great deal of development is underway on kernel-level RootKits. To gain a better understanding of kernel-level RootKits, one should first analyze their evolutionary ancestors, traditional RootKits.

73.3.1 Traditional RootKits

A traditional RootKit is a suite of tools that allows an attacker to maintain superuser access on a system. Once an attacker gets root-level control on a machine, the RootKit lets the attacker maintain that access. Traditional RootKits usually include a backdoor so the attacker can access the system, bypassing normal security controls. They also include various programs to let the attacker hide on the system. Some of the most fully functional traditional RootKits include Linux RootKit 5 (lrk5) and T0rnkit, which runs on Solaris and Linux. Both of these RootKits, as well as many others, are located at http://packetstorm.securify.com/UNIX/penetration/rootkits.

Traditional RootKits implement backdoors and hiding mechanisms by replacing critical executable programs included in the operating system. For example, most traditional RootKits include a replacement for the /bin/login program, which is used to authenticate users logging into a UNIX system. A RootKit version of /bin/login usually includes a backdoor password, known by the attacker, that can be used for root-level access of the machine. The attacker will write the new version of /bin/login over the earlier version, and modify the timestamps and file size to match the previous version.

Just as the /bin/login program is replaced to implement a backdoor, most RootKits include Trojan horse replacement programs for other UNIX tools used by system administrators to analyze the system. Many traditional RootKits include Trojan horse replacements for the ls command (which normally shows the contents of a directory). Modified versions of ls will hide the attacker's tools, never displaying their presence. Similarly, the attackers will replace netstat, a tool that shows which TCP and UDP ports are in use, with a modified version that lies about the ports used by an attacker. Likewise, many other system programs will be replaced, including ifconfig, du, and ps. All of these programs act like the eyes and ears of a system administrator. The attacker utilizes a traditional RootKit to replace these eyes and ears with new versions that lie about the attacker's presence on the system.

To detect traditional RootKits, many system administrators employ file system integrity checking tools, such as the venerable Tripwire program available at http://www.tripwire.com. These tools calculate cryptographically strong hashes of critical system files (such as /bin/login, ls, netstat, ifconfig, du, and ps) and store these digital fingerprints on a safe medium such as a write-protected floppy disk. Then, on a periodic basis (usually daily or weekly), the integrity-checking tool recalculates the hashes of the executables on the system and compares them with the stored values. If there is a change, the program has been altered, and the system administrator is alerted.

73.3.2 Kernel-Level RootKits

While traditional RootKits replace critical system executables, attackers have gone even further by implementing kernel-level RootKits. The kernel is the heart of most operating systems, controlling access to all resources, such as the disk, system processor, and memory. Kernel-level RootKits modify the kernel itself, rather than manipulating application-level programs like traditional RootKits. As shown on the left side of Exhibit 73.4, a traditional RootKit can be detected because a file system integrity tool such as Tripwire can rely on the kernel to let it check the integrity of application programs. When the application programs are modified, the good Tripwire program utilizes the good kernel to detect the Trojan horse replacement programs.

A kernel-level RootKit is shown on the right-hand side of Exhibit 73.4. While all of the application programs are intact, the kernel itself is rotten, facilitating backdoor access by the attacker and lying to the administrator about the attacker's presence on the system. Some of the most powerful kernel-level RootKits include Knark for Linux available at http://packetstorm.securify.com/UNIX/penetration/rootkits, Plasmoid's Solaris kernel-level RootKit available at http://www.infowar.co.uk/thc/slkm-1.0.html, and a Windows NT kernel-level RootKit available at http://www.rootkit.com.

While a large number of kernel-level RootKits have been released with a variety of features, the most popular capabilities of these tools include:

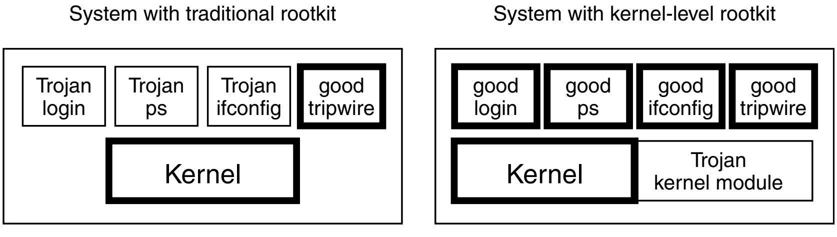


EXHIBIT 73.4 Traditional and kernel-level RootKits.

- *Execution redirection*. This capability intercepts a call to run a certain application and maps that call to run another application of the attacker's choosing. Consider a scenario involving the UNIX /bin/login routine. The attacker will install a kernel-level RootKit and leave the /bin/login file unaltered. All execution requests for /bin/login (which occur when anyone logs in to the system) will be mapped to the hidden file /bin/backdoorlog in. When a user tries to login, the /bin/backdoorlogin program will be executed, containing a backdoor password allowing for root-level access. However, when the system administrator runs a file integrity checker such as Tripwire, the standard /bin/login routine is analyzed. Only execution is redirected; one can look at the original file /bin/login and verify its integrity. This original routine is unaltered, so the Tripwire hash will remain the same.
- *File hiding*. Many kernel-level RootKits let an attacker hide any file in the file system. If any user or application looks for the file, the kernel will lie and say that the file is not present on the machine. Of course, the file is still on the system, and the attacker can access it when required.
- *Process hiding*. In addition to hiding files, the attacker can use the kernel-level RootKit to hide a running process on the machine.

Each of these capabilities is quite powerful by itself. Taken together, they offer an attacker the ability to completely transform the machine at the attacker's whim. The system administrator will have a view of the system created by the attacker, with everything looking intact. But in actuality, the system will be rotten to the core, quite literally. Furthermore, detection of kernel-level RootKits is often rather difficult because all access to the system relies on the attacker-modified kernel.

73.3.2.1 Kernel-Level RootKit Defenses

To stop attackers from installing kernel-level RootKits (or traditional RootKits, for that matter), one must prevent the attackers from gaining superuser access on one's systems in the first place. Without superuser access, an attacker cannot install a kernel-level RootKit. One must configure systems securely, disabling all unneeded services and applying all relevant security patches. Hardening systems and keeping them patched are the best preventative means for dealing with kernel-level RootKits.

Another defense involves deploying kernels that do not support loadable kernel modules (LKMs), a feature of some operating systems that allows the kernel to be dynamically modified. LKMs are often used to implement kernel-level RootKits. Linux kernels can be built without support for kernel modules. Unfortunately, Solaris systems up through and including Solaris 8 do not have the ability to disable kernel modules. For critical Linux systems, such as Internet-accessible Web, mail, DNS, and FTP servers, one should build the kernels of such systems without the ability to accept LKMs. One will have eliminated the vast majority of these types of attacks by creating nonmodular kernels.

73.4 Conclusions

The arms race between computer defenders and computer attackers continues to accelerate. As attackers devise methods for widely distributed attacks and burrow deeper into our protocols and operating systems, we must work even more diligently to secure our systems. Do not lose heart, however. Sure, the defensive techniques covered in this chapter can be a lot of work. However, by carefully designing and maintaining systems, one can maintain a secure infrastructure.

74

Hacker Attacks and Defenses

Ed Skoudis

Computer attackers continue to hone their techniques, getting ever better at undermining our systems and networks. As the computer technologies we use advance, these attackers find new and nastier ways to achieve their goals—unauthorized system access, theft of sensitive data, and alteration of information. This chapter explores some of the recent trends in computer attacks and presents tips for securing your systems. To create effective defenses, we need to understand the latest tools and techniques our adversaries are throwing at our networks. With that in mind, we will analyze four areas of computer attack that have received significant attention in the past year or so: wireless LAN attacks, active and passive operating system fingerprinting, worms, and sniffing backdoors.

74.1 Wireless LAN Attacks (War Driving)

In the past year, a very large number of companies have deployed wireless LANs, using technology based on the IEEE 802.11b protocol, informally known as *Wi-Fi*. Wireless LANs offer tremendous benefits from a usability and productivity perspective: a user can access the network from a conference room, while sitting in an associate's cubicle, or while wandering the halls. Unfortunately, wireless LANs are often one of the least secure methods of accessing an organization's network. The technology is becoming very inexpensive, with a decent access point costing less than U.S.$200 and wireless cards for a laptop or PC costing below U.S.$100. In addition to affordability, setting up an access point is remarkably simple (if security is ignored, that is). Most access points can be plugged into the corporate network and configured in a minute by a completely inexperienced user. Because of their low cost and ease of (insecure) use, wireless LANs are in rapid deployment in most networks today, whether upper management or even IT personnel realize or admit it. These wireless LANs are usually completely unsecure because the inexperienced employees setting them up have no idea of or interest in activating security features of their wireless LANs.

In our consulting services, we often meet with CIOs or Information Security Officers to discuss issues associated with information security. Given the widespread use of wireless LANs, we usually ask these upper-level managers what their organization is doing to secure its wireless infrastructure. We are often given the answer, “We don’t have to worry about it because we haven’t yet deployed a wireless infrastructure.” After hearing that stock answer, we conduct a simple wireless LAN assessment (with the CIO’s permission, of course). We walk down a hall with a wireless card, laptop, and wireless LAN detection software. Almost always we find renegade, completely unsecure wireless networks in use that were set up by employees outside of formal IT roles. The situation is similar to what we saw with Internet technology a decade ago. Back then, we would ask corporate officers what their organizations were doing to secure their Internet gateways. They would say that they did not have one, but we would quickly discover that the organization was laced with homegrown Internet connectivity without regard to security.

74.1.1 Network Stumbling, War Driving, and War Walking

Attackers have taken to the streets in their search for convenient ways to gain access to organizations’ wireless networks. By getting within a few hundred yards of a wireless access point, an attacker can detect its presence and, if the access point has not been properly secured, possibly gain access to the target network. The process of searching for wireless access points is known in some circles as *network stumbling*. Alternatively, using an automobile to drive around town looking for wireless access points is known as *war driving*. As you might guess, the phrases *war walking* and even *war biking* have been coined to describe the search for wireless access points using other modes of transportation. I suppose it is only a matter of time before someone attempts *war hanggliding*.

When network stumbling, attackers set up a rig consisting of a laptop PC, wireless card, and antenna for discovering wireless access points. Additionally, a global positioning system (GPS) unit can help record the geographic location of discovered access points for later attack. Numerous software tools are available for this task as well. One of the most popular is NetStumbler (available at www.netstumbler.com), an easy-to-use GUI-based tool written by Marius Milner. NetStumbler runs on Windows systems, including Win95, 98, and 2000, and a PocketPC version called *Mini-Stumbler* has been released. For UNIX, several war-driving scripts have been released, with Wi-scan (available at www.dis.org/wl/) among the most popular.

This wireless LAN discovery process works because most access points respond, indicating their presence and their services set identifier (SSID) to a broadcast request from a wireless card. The SSID acts like a name for the wireless access point so that users can differentiate between different wireless LANs in close proximity. However, the SSID provides no real security. Some users think that a difficult-to-guess SSID will get them extra security. They are wrong. Even if the access point is configured not to respond to a broadcast request for an SSID, the SSIDs are sent in cleartext and can be intercepted.

In a recent war-driving trip in a taxi in Manhattan, an attacker discovered 455 access points in one hour. Some of these access points had their SSIDs set to the name of the company using the access point, gaining the attention of attackers focusing on juicy targets.

After discovering target networks, many attackers will attempt to get an IP address on the network, using the Dynamic Host Configuration Protocol (DHCP). Most wireless LANs freely give out addresses to anyone asking for them. After getting an address via DHCP, the attacker will attempt to access the LAN itself. Some LANs use the Wired Equivalent Privacy (WEP) protocol to provide cryptographic authentication and confidentiality. While WEP greatly improves the security of a wireless LAN, it has some significant vulnerabilities that could allow an attacker to determine an access point's keys. An attacker can crack WEP keys by gathering a significant amount of traffic (usually over 500 MB) using a tool such as Airsnort (available at airsnort.shmoo.com/).

74.1.2 Defending against Wireless LAN Attacks

So, how do you defend against wireless LAN attacks in your environment? There are several levels of security that you could implement for your wireless LAN, ranging from totally unsecure to a strong level of protection. Techniques for securing your wireless LAN include:

- *Set the SSID to an obscure value*. As described above, SSIDs are not a security feature and should not be treated as such. Setting the SSID to an obscure value adds very little from a security perspective. However, some access points can be configured to prohibit responses to SSID broadcast requests. If your access point offers that capability, you should activate it.
- *Use MAC address filtering*. Each wireless card has a unique hardware-level address called the media access control (MAC) address. A wireless access point can be configured so that it will allow traffic only from specific MAC addresses. While this MAC filtering does improve security a bit, it is important to note that an attacker can spoof wireless card MAC addresses.
- *Use WEP, with periodic rekeying*. While WEP keys can be broken using Airsnort, the technology significantly improves the security of a wireless LAN. Some vendors even support periodic generation of new WEP keys after a given timeout. If an attacker does crack a WEP key, it is likely that they break the old key, while a newer key is in use on the network. If your access points support dynamic rotating of WEP keys, such as Cisco's Aironet security solution, activate this feature.
- *Use a virtual private network* (*VPN*). Because SSID, MAC, and even WEP solutions have various vulnerabilities as highlighted above, the best method for securing wireless LANs is to use a VPN. VPNs provide end-to-end security without regard to the unsecured wireless network used for transporting the communication. The VPN client encrypts all data sent from the PC before it gets sent into the air. The wireless access point simply collects encrypted streams of bits and forwards them to a VPN gateway before they can get access to the internal network. In this way, the VPN ensures that all data is strongly encrypted and authenticated before entering the internal network.

Of course, before implementing these technical solutions, you should establish specific policies for the use of wireless LANs in your environment. The particular wireless LAN security policies followed by an organization depend heavily on the need for security in that organization. The following list, which I wrote with John Burgess of Predictive Systems, contains recommended security policies that could apply in many organizations. This list can be used as a starting point, and pared down or built up to meet specific needs.

- All wireless access points/base stations connected to the corporate network must be registered and approved by the organization's computer security team. These access points/base stations are subject to periodic penetration tests and audits. Unregistered access points/ base stations on the corporate network are strictly forbidden.
- All wireless network interface cards (i.e., PC cards) used in corporate laptop or desktop computers must be registered with the corporate security team.
- All wireless LAN access must use corporate-approved vendor products and security configurations.
- All computers with wireless LAN devices must utilize a corporate-approved virtual private network (VPN) for communication across the wireless link. The VPN will authenticate users and encrypt all network traffic.

- Wireless access points/base stations must be deployed so that all wireless traffic is directed through a VPN device before entering the corporate network. The VPN device should be configured to drop all unauthenticated and unencrypted traffic.

While the policies listed above fit the majority of organizations, the policies listed below may or may not fit, depending on the technical level of employees and how detailed an organizations' security policy and guidelines are:

- The wireless SSID provides no security and should not be used as a password. Furthermore, wireless card MAC addresses can be easily gathered and spoofed by an attacker. Therefore, security schemes should not be based solely on filtering wireless MAC addresses because they do not provide adequate protection for most uses.
- WEP keys can be broken. WEP may be used to identify users, but only together with a VPN solution.
- The transmit power for access points/base stations near a building's perimeter (such as near exterior walls or top floors) should be turned down. Alternatively, wireless systems in these areas could use directional antennas to control signal bleed out of the building.

With these types of policies in place and a suitable VPN solution securing all traffic, the security of an organization's wireless infrastructure can be vastly increased.

74.2 Active and Passive Operating System Fingerprinting

Once access is gained to a network (through network stumbling, a renegade unsecured modem, or a weakness in an application or firewall), attackers usually attempt to learn about the target environment so they can hone their attacks. In particular, attackers often focus on discovering the operating system (OS) type of their targets. Armed with the OS type, attackers can search for specific vulnerabilities of those operating systems to maximize the effectiveness of their attacks.

To determine OS types across a network, attackers use two techniques: (1) the familiar, time-tested approach called active OS fingerprinting, and (2) a technique with new-found popularity, passive OS fingerprinting. We will explore each technique in more detail.

74.2.1 Active OS Fingerprinting

The Internet Engineering Task Force (IETF) defines how TCP/IP and related protocols should work. In an ever-growing list of Requests for Comment (RFCs), this group specifies how systems should respond when specific types of packets are sent to them. For example, if someone sends a TCP SYN packet to a listening port, the IETF says that a SYN ACK packet should be sent in response. While the IETF has done an amazing job of defining how the protocols we use every day should work, it has not thoroughly defined every case of how the protocols should fail. In other words, the RFCs defining TCP/IP do not handle all of the meaningless or perverse cases of packets that can be sent in TCP/IP. For example, what should a system do if it receives a TCP packet with the code bits SYN-FIN-URG-PUSH all set? I presume such a packet means to SYNchronize a new connection, FINish the connection, do this URGently, and PUSH it quickly through the TCP stack. That is nonsense, and a standard response to such a packet has not been devised.

Because there is no standard response to this and other malformed packets, different vendors have built their OSs to respond differently to such bizarre cases. For example, a Cisco router will likely send a different response than a Windows NT server for some of these unexpected packets. By sending a variety of malformed packets to a target system and carefully analyzing the responses, an attacker can determine which OS it is running.

An active OS fingerprinting capability has been built into the Nmap port scanner (available at www.insecure.org/nmap). If the OS detection capability is activated, Nmap will send a barrage of unusual packets to the target to see how it responds. Based on this response, Nmap checks a user-customizable database of known signatures to determine the target OS type. Currently, this database houses over 500 known system types.

A more recent addition to the active OS fingerprinting realm is the Xprobe tool by Fyodor Yarochkin and Ofir Arkin. Rather than manipulating the TCP code bit options like Nmap, Xprobe focuses exclusively on the Internet Control Message Protocol (ICMP). ICMP is used to send information associated with an IP-based network, such as ping requests and responses, port unreachable messages, and instructions to quench the rate of packets sent. Xprobe sends between one and four specially crafted ICMP messages to the target system. Based on a very carefully constructed logic tree on the sending side, Xprobe can determine the OS type. Xprobe is stealthier than the Nmap active OS fingerprinting capability because it sends far fewer packets.

74.2.2 Passive OS Fingerprinting

While active OS fingerprinting involves sending packets to a target and analyzing the response, passive OS fingerprinting does not send any traffic while determining a target's OS type. Instead, passive OS fingerprinting tools include a sniffer to gather data from a network. Then, by analyzing the particular packet settings captured from the network and consulting a local database, the tool can determine what OS type sent that traffic. This technique is far stealthier than active OS fingerprinting because the attacker sends no data to the target machine. However, the attacker must be in a position to analyze traffic sent from the target system, such as on the same LAN or on a network where the target frequently sends packets.

One of the best passive OS fingerprinting tools is p0f (available at www.stearns.org/p0f/), originally written by Michal Zalewski and now maintained by William Stearns. P0f determines the OS type by analyzing several fields sent in TCP and IP traffic, including the rounded-up initial time-to-live (TTL), window size, maximum segment size, don't fragment flag, window scaling option, and initial packet size. Because different OSs set these initial values to varying levels, p0f can differentiate between 149 different system types.

74.2.3 Defending against Operating System Fingerprinting

To minimize the impact an attacker can have using knowledge of your OS types, you should have a defined program for notification, testing, and implementation of system patches. If you keep your systems patched with the latest security fixes, an attacker will be far less likely to compromise your machines even if they know which OS you are running. One or more people in your organization should have assigned tasks of monitoring vendor bulletins and security lists to determine when new patches are released. Furthermore, once patches are identified, they should be thoroughly but quickly tested in a quality assurance environment. After the full functionality of the tested system is verified, the patches should be rolled into production.

While a solid patching process is a must for defending your systems, you may also want to analyze some of the work in progress to defeat active OS fingerprinting. Gaël Roualland and Jean-Marc Saffroy wrote the IP personality patch for Linux systems, available at ippersonality.sourceforge.net/. This tool allows a system administrator to configure a Linux system running kernel version 2.4 so that it will have any response of the administrator's choosing for Nmap OS detection. Using this patch, you could make your Linux machine look like a Solaris system, a Macintosh, or even an old Windows machine during an Nmap scan. Although you may not want to put such a patch onto your production systems due to potential interference with critical processes, the technique is certainly worth investigating.

To foil passive OS fingerprinting, you may want to consider the use of a proxy-style firewall. Proxy firewalls do not route packets, so all information about the OS type transmitted in the packet headers is destroyed by the proxy. Proxy firewalls accept a connection from a client, and then start a new connection to the server on behalf of that client. All packets on the outside of the firewall will have the OS fingerprints of the firewall itself. Therefore, the OS type of all systems inside the firewall will be masked. Note that this technique does not work for most packet filter firewalls because packet filters route packets and, therefore, transmit the fingerprint information stored in the packet headers.

74.3 Recent Worm Advances

A computer worm is a self-replicating computer attack tool that propagates across a network, spreading from vulnerable system to vulnerable system. Because they use one set of victim machines to scan for and exploit new victims, worms spread on an exponential basis. In recent times, we have seen a veritable zoo of computer worms with names like Ramen, L10n, Cheese, Code Red, and Nimda. New worms are being released at a dizzying rate, with a new generation of worm hitting the Internet every two to six months. Worm developers are learning lessons from the successes of each generation of worms and expanding upon them in subsequent attacks. With this evolutionary loop, we are rapidly approaching an era of super-worms. Based on recent advances in worm functions and predictions for the future, we will analyze the characteristics of the coming super-worms we will likely see in the next six months.

74.3.1 Rapidly Spreading Worms

Many of the worms released in the past decade have spread fairly quickly throughout the Internet. In July 2001, Code Red was estimated to have spread to 250,000 systems in about six hours. Fortunately, recent worms have had rather inefficient targeting mechanisms, a weakness that actually impeded their speeds. By randomly generating addresses and not taking into account the accurate distribution of systems in the Internet address space, these worms often wasted time looking for nonexistent systems or scanning machines that were already conquered.

After Code Red, several articles appeared on the Internet describing more efficient techniques for rapid worm distribution. These articles, by Nicholas C. Weaver and the team of Stuart Staniford, Gary Grim, and Roelof Jonkman, described the hypothetical Warhol and Flash worms, which theoretically could take over all vulnerable systems on the Internet in 15 minutes or even less. Warhol and Flash, which are only mathematical models and not actual worms (yet), are based on the idea of fast-forwarding through an exponential spread. Looking at a graph of infected victims over time for a conventional worm, a hockey-stick pattern appears. Things start out slowly as the initial victims succumb to the worm. Only after a critical mass of victims succumbs to the attack does the worm rapidly spread. Warhol and Flash jump past this initial slow spread by prescanning the Internet for vulnerable systems. Through automated scanning techniques from static machines, an attacker can find 100,000 or more vulnerable systems before ever releasing the worm. The attacker then loads these known vulnerable addresses into the worm. As the worm spreads, the addresses of these prescanned vulnerable systems would be split up among the segments of the worm propagating across the network. By using this initial set of vulnerable systems, an attacker could easily infect 99 percent of vulnerable systems on the Internet in less than an hour. Such a worm could conquer the Internet before most people have even heard of the problem.

74.3.2 Multi-Platform Worms

The vast majority of worms we have seen to date focused on a single platform, often Windows or Linux. For example, Nimda simply ripped apart as many Microsoft products as it could, exploiting Internet Explorer, the IIS Web server, Outlook, and Windows file sharing. While it certainly was challenging, Nimda's Windows-centric approach actually limited its spread. The security community implemented defenses by focusing on repairing Windows systems.

While single-platform worms can cause trouble, be on the lookout for worms that are far less discriminating from a platform perspective. New worms will contain exploits for Windows, Solaris, Linux, BSD, HP-UX, AIX, and other operating systems, all built into a single worm. Such worms are even more difficult to eradicate because security personnel and system administrators will have to apply patches in a coordinated fashion to many types of machines. The defense job will be more complex and require more time, allowing the worm to cause more damage.

74.3.3 Morphing and Disguised Worms

Recent worms have been relatively easy to detect. Once spotted, the computer security community has been able to quickly determine their functionalities. Once a worm has been isolated in the lab, some brilliant folks have been able to rapidly reverse-engineer each worm's operation to determine how best to defend against it.

In the very near future, we will face new worms that are far stealthier and more difficult to analyze. We will see polymorphic worms, which change their patterns every time they run and spread to a new system. Detection becomes more difficult because the worm essentially recodes itself each time it runs. Additionally, these new worms will encrypt or otherwise obscure much of their own payloads, hiding their functionalities until a later time. Reverse-engineering to determine the worm's true functions and purpose will become more difficult because investigators will have to extract the crypto keys or overcome the obfuscation mechanisms before they can really figure out what the worm can do. This time lag for the analysis will allow the worm to conquer more systems before adequate defenses are devised.

74.3.4 Zero-Day Exploit Worms

The vast majority of worms encountered so far are based on old, off-the-shelf exploits to attack systems. Because they have used old attacks, a patch has been readily available for administrators to fix their machines quickly after infection or to prevent infection in the first place. Using our familiar example, Code Red exploited systems using a flaw in Microsoft's IIS Web server that had been known for over a month and for which a patch had already been published.

In the near future, we are likely going to see a worm that uses brand-new exploits for which no patch exists. Because they are brand new, such attacks are sometimes referred to as *zero-day exploits*. New vulnerabilities are discovered practically every day. Oftentimes, these problems are communicated to a vendor, who releases a patch. Unfortunately, these vulnerabilities are all — too easy to discover, and it is only a matter of time before a worm writer discovers a major hole and first devises a worm that exploits it. Only after the worm has propagated across the Internet will the computer security community be capable of analyzing how it spreads so that a patch can be developed.

74.3.5 More Damaging Attacks

So far, worms have caused damage by consuming resources and creating nuisances. The worms we have seen to date have not really had a malicious payload. Once they take over hundreds of thousands of systems, they simply continue to spread without actually doing something nasty. Do not get me wrong; fighting Code Red and Nimda consumed much time and many resources. However, these attacks did not really do anything *beyond* simply consuming resources.

Soon, we may see worms that carry out some plan once they have spread. Such a malicious worm may be released in conjunction with a terrorist attack or other plot. Consider a worm that rapidly spreads using a zero-day exploit and then deletes the hard drives of ten million victim machines. Or, perhaps worse, a worm could spread and then transfer the financial records of millions of victims to a country's adversaries. Such scenarios are not very far-fetched, and even nastier ones could be easily devised.

74.3.6 Worm Defenses

All of the pieces are available for a moderately skilled attacker to create a truly devastating worm. We may soon see rapidly spreading, multi-platform, morphing worms using zero-day exploits to conduct very damaging attacks. So, what can you do to get ready? You need to establish both reactive and proactive defenses.

74.3.6.1 Incident Response Preparation

From a reactive perspective, your organization must establish a capability for determining when new vulnerabilities are discovered, as well as rapidly testing patches and moving them into production. As described above, your security team should subscribe to various security mailing lists, such as Bugtraq (available at www.securityfocus.com), to help alert you to such vulnerabilities and the release of patches. Furthermore, you must create an incident response team with the skills and resources necessary to discover and contain a worm attack.

74.3.6.2 Vigorously Patch and Harden Your Systems

From the proactive side, your organization must carefully harden your systems to prevent attacks. For each platform type, your organization should have documentation describing to system administrators how to build the machine to prevent attacks. Furthermore, you should periodically test your systems to ensure they are secure.

74.3.6.3 Block Unnecessary Outbound Connections

Once a worm takes over a system, it attempts to spread by making outgoing connections to scan for other potential victims. You should help stop worms in their tracks by severely limiting all outgoing connections on your publicly available systems (such as your Web, DNS, e-mail, and FTP servers). You should use a border router or external firewall to block all outgoing connections from such servers, unless there is a specific business need for outgoing connections. If you do need some outgoing connections, allow them only to those IP addresses that are absolutely critical. For example, your Web server needs to send responses to users requesting Web pages, of course. But does your Web server ever need to initiate connections to the Internet? Likely, the answer is no. So, do yourself and the rest of the Internet a favor by blocking such outgoing connections from your Internet servers.

74.3.6.4 Nonexecutable System Stack Can Help Stop Some Worms

In addition to overall system hardening, one particular step can help stop many worms. A large number of worms utilize buffer overflow exploits to compromise their victims. By sending more data than the program developer allocated space for, a buffer overflow attack allows an attacker to get code entered as user input to run on the target system. Most operating systems can be inoculated against simple stack-based buffer overflow exploits by being configured with nonexecutable system stacks. Keep in mind that nonexecutable stacks can break some programs (so test these fixes before implementing them), and they do not provide a bulletproof shield against all buffer overflow attacks. Still, preventing the execution of code from the stack will stop a huge number of both known and as-yet-undiscovered vulnerabilities in their tracks. Up to 90 percent of buffer overflows can be prevented using this technique. To create a nonexecutable stack on a Linux system, you can use the free kernel patch at www.openwall.com/linux. On a Solaris machine, you can configure the system to stop execution of code from the stack by adding the following lines to the/etc/system file:

```
set noexec_user_stack=1
set noexec_user_stack_log=1
```

On a Windows NT/2000 machine, you can achieve the same goal by deploying the commercial program SecureStack, available at www.securewave.com.

74.4 Sniffing Backdoors

Once attackers compromise a system, they usually install a backdoor tool to allow them to access the machine repeatedly. A backdoor is a program that lets attackers access the machine on their own terms.

Normal users are required to type in a password or use a cryptographic token; attackers use a backdoor to bypass these normal security controls. Traditionally, backdoors have listened on a TCP or UDP port, silently waiting in the background for a connection from the attacker. The attacker uses a client tool to connect to these backdoor servers on the proper TCP or UDP port to issue commands.

These traditional backdoors can be discovered by looking at the listening ports on a system. From the command prompt of a UNIX or Windows NT/2000/XP machine, a user can type "netstat-na" to see which TCP and UDP ports on the local machine have programs listening on them. Of course, normal usage of a machine will cause some TCP and UDP ports to be listening, such as TCP port 80 for Web servers, TCP port 25 for mail servers, and UDP port 53 for DNS servers. Beyond these expected ports based on specific server types, a suspicious port turned up by the `netstat` command could indicate a backdoor listener. Alternatively, a system or security administrator could remotely scan the ports of the system, using a port-scanning tool such as Nmap (available at www.insecure.org/nmap). If Nmap's output indicates an unexpected listening port, an attacker may have installed a backdoor.

Because attackers know that we are looking for their illicit backdoors listening on ports, a major trend in the attacker community is to avoid listening ports altogether for backdoors. You may ask, "How can they communicate with their backdoors if they aren't listening on a port?" To accomplish this, attackers are integrating sniffing technology into their backdoors to create sniffing backdoors. Rather than configuring a process to listen on a port, a sniffing backdoor uses a sniffer to grab traffic from the network. The sniffer then analyzes the traffic to determine which packets are supposed to go to the backdoor. Instead of listening on a port, the sniffer employs pattern matching on the network traffic to determine what to scoop up and pass to the backdoor. The backdoor then executes the commands and sends responses to the attacker. An excellent example of a sniffing backdoor is the Cd00r program written by FX. Cd00r is available at http://www.phenoelit.de/stuff/cd00r.c.

There are two general ways of running a sniffing backdoor, based on the mode used by the sniffer program to gather traffic: the so-called nonpromiscuous and promiscuous modes. A sniffer that puts an Ethernet interface in promiscuous mode gathers all data from the LAN without regard to the actual destination address of the traffic. If the traffic passes by the interface, the Ethernet card in promiscuous mode will suck in the traffic and pass it to the backdoor. Alternatively, a nonpromiscuous sniffer gathers traffic destined only for the machine on which the sniffer runs. Because these differences in sniffer types have significant implications on how attackers can use sniffing backdoors, we will explore nonpromiscuous and promiscuous backdoors separately below.

74.4.1 Nonpromiscuous Sniffing Backdoors

As their name implies, nonpromiscuous sniffing backdoors do not put the Ethernet interface into promiscuous mode. The sniffer sees only traffic going to and from the single machine where the sniffing backdoor is installed. When attackers use a nonpromiscuous sniffing backdoor, they do not have to worry about a system administrator detecting the interface in promiscuous mode.

In operation, the nonpromiscuous backdoor scours the traffic going to the victim machine looking for specific ports or other fields (such as a cryptographically derived value) included in the traffic. When the special traffic is detected, the backdoor wakes up and interacts with the attacker.

74.4.2 Promiscuous Sniffing Backdoors

By putting the Ethernet interface into promiscuous mode to gather all traffic from the LAN, promiscuous sniffing backdoors can make an investigation even more difficult. To understand why, consider the scenario shown in Exhibit 74.1. This network uses a tri-homed firewall to separate the DMZ and internal network from the Internet. Suppose an attacker takes over the Domain Name System (DNS) server on the DMZ and installs a promiscuous sniffing backdoor. Because this backdoor uses a sniffer in promiscuous mode, it can gather all traffic from the LAN. The attacker configures the sniffing backdoor to listen in on all traffic with a destination address of the Web server (not the DNS server) to retrieve commands from

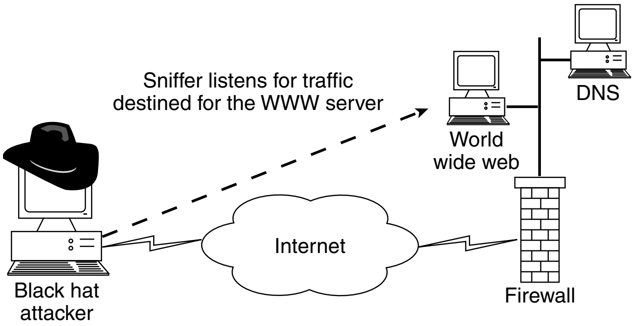

EXHIBIT 74.1 A promiscuous sniffing backdoor.

the attacker to execute. In our scenario, the attacker does not install a backdoor or any other software on the Web server. Only the DNS server is compromised.

Now the attacker formulates packets with commands for the backdoor. These packets are all sent with a destination address of the Web server (*not* the DNS server). The Web server does not know what to do with these commands, so it will either discard them or send a RESET or related message to the attacker. However, the DNS server with the sniffing backdoor will see the commands on the LAN. The sniffer will gather these commands and forward them to the backdoor where they will be executed. To further obfuscate the situation, the attacker can send all responses from the backdoor using the spoofed source address of the Web server.

Given this scenario, consider the dilemma faced by the investigator. The system administrator or an intrusion detection system complains that there is suspicious traffic going to and from the Web server. The investigator conducts a detailed and thorough analysis of the Web server. After a painstaking process to verify the integrity of the applications, operating system programs, and kernel on the Web server machine, the investigator determines that this system is intact. Yet backdoor commands continue to be sent to this machine. The investigator would only discover what is really going on by analyzing other systems connected to the LAN, such as the DNS server. The investigative process is significantly slowed down by the promiscuous sniffing backdoor.

74.4.3 Defending against Sniffing Backdoor Attacks

It is important to note that the use of a switch on the DMZ network between the Web server and DNS server does not eliminate this dilemma. As described in Chapter 11, attackers can use active sniffers to conduct ARP cache poisoning attacks and successfully sniff a switched environment. An active sniffer such as Dsniff (available at http://www.monkey.org/~dugsong/dsniff/) married to a sniffing backdoor can implement this type of attack in a switched environment.

So if a switch does not eliminate this problem, how can you defend against this kind of attack? First, as with most backdoors, system and security administrators must know what is supposed to be running on their systems, especially processes running with root or system-level privileges. Keeping up with this information is not a trivial task, but it is especially important for all publicly available servers such as systems on a DMZ. If a security or system administrator notices a new process running with escalated privileges, the process should be investigated immediately. Tools such as lsof for UNIX (available at ftp://vic.cc.purdue.edu/pub/tools/unix/lsof/) or Inzider for Windows NT/2000 (available at http://ntsecurity.nu/toolbox/inzider/) can help to indicate the files and ports used by any process. Keep in mind that most attackers will not name their backdoors “cd00r” or “backdoor,” but instead will use less obvious names to camouflage their activities. In my experience, attackers like to name their backdoors “SCSI” or “UPS” to prevent a curious system administrator from questioning or shutting off the attackers’ processes.

Also, while switches do not eliminate attacks with sniffers, a switched environment can help to limit an attacker's options, especially if it is carefully configured. For your DMZs and other critical networks, you should use a switch and hard-code all ARP entries in each host on the LAN. Each system on your LAN has an ARP cache holding information about the IP and MAC addresses of other machines on the LAN. By hard-coding all ARP entries on your sensitive LANs so that they are static, you minimize the possibility of ARP cached poisoning. Additionally, implement port-level security on your switch so that only specific Ethernet MAC addresses can communicate with the switch.

74.5 Conclusions

The computer underground and information security research fields remain highly active in refining existing methods and defining completely new ways to attack and compromise computer systems. Advances in our networking infrastructures, especially wireless LANs, are not only giving attackers new avenues into our systems, but they are also often riddled with security vulnerabilities. With this dynamic environment, defending against attacks is certainly a challenge. However, these constantly evolving attacks can be frustrating and exciting at the same time, while certainly providing job security to solid information security practitioners. While we need to work diligently in securing our systems, our reward is a significant intellectual challenge and decent employment in a challenging economy.

75

Counter-Economic Espionage

Craig A. Schiller

> Today's economic competition is global. The conquest of markets and technologies has replaced former territorial and colonial conquests. We are living in a state of world economic war, and this is not just a military metaphor—the companies are training the armies, and the unemployed are the casualties.
>
> **—Bernard Esambert,**
> **President of the French Pasteur Institute,**
> **at a Paris Conference on Economic Espionage**

The Attorney General of the United States defined economic espionage as "the unlawful or clandestine targeting or acquisition of sensitive financial, trade, or economic policy information; proprietary economic information; or critical technologies." Note that this definition excludes the collection of open and legally available information that makes up the majority of economic collection. This means that aggressive intelligence collection that is entirely open and legal may harm U.S. companies but is not considered espionage, economic or otherwise. The FBI has extended this definition to include the unlawful or clandestine targeting or influencing of sensitive economic policy decisions.

Intelligence consists of two broad categories—open source and espionage. Open-source intelligence collection is the name given to legal intelligence activities. Espionage is divided into the categories of economic and military/political/governmental; the distinction is the targets involved. A common term, *industrial espionage* was used (and is still used to some degree) to indicate espionage between two competitors. As global competitors began to conduct these activities with possible assistance from their governments, the competitor-versus-competitor nature of industrial espionage became less of a discriminator. As the activities expanded to include sabotage and interference with commerce and proposal competitions, the term *economic espionage* was coined for the broader scope.

While the examples and cases discussed in this chapter focus mainly on the United States, the issues are universal. The recommendations and types of information gathered can and should be translated for any country.

75.1 Brief History

The prosperity and success of this country are due in no small measure to economic espionage committed by Francis Cabot Lowell during the Industrial Revolution. Britain replaced costly, skilled hand labor with water-driven looms that were simple and reliable. The looms were so simple that they could be operated by a few unskilled women and children. The British government passed strict patent laws and prohibited the export of technology related to the making of cotton. A law was passed making it illegal to hire skilled textile workers for work abroad. Those workers who went abroad had their property confiscated. It was against the law to make and export drawings of the mills.

So Lowell memorized and stole the plans to a Cartwright loom, a water-driven weaving machine. It is believed that Lowell perfected the art of *spying by driving around*. Working from Edinburgh, he and his wife traveled daily throughout the countryside, including Lancashire and Derbyshire, the hearts of the Industrial Revolution. Returning home, he built a scale model of the loom. His company built its first loom in Waltham. Soon, his factories were capable of producing up to 30 miles of cloth a day.[1] This marked America's entry into the Industrial Revolution.

By the early 20th century, we had become "civilized" to the point that Henry L. Stimson, our Secretary of State, said for the record that "Gentlemen do not read other gentlemen's mail" while refusing to endorse a code-breaking operation. For a short time the U.S. Government was the only government that believed this fantasy. At the beginning of World War II, the United States found itself almost completely blind to activities inside Germany and totally dependent on other countries' intelligence services for information. In 1941 the United States recognized that espionage was necessary to reduce its losses and efficiently engage Germany. To meet this need, first the COI and then the OSS were created under the leadership of General "Wild Bill" Donovan.

It would take tremendous forces to broaden this awakening to include economic espionage.

75.2 Watershed: End of Cold War, Beginning of Information Age

In the late 1990s, two events occurred that radically changed information security for many companies. The end of the Cold War—marked by the collapse of the former Soviet Union—created a pool of highly trained intelligence officers without targets. In Russia, some continued to work for the government, some began to work in the newly created private sector, and some provided their services for the criminal element. Some did all three. The world's intelligence agencies began to focus their attention on economic targets and information war, just in time for watershed event number-two—the beginning of the information age.

John Lienhard, M.D. Anderson Professor of Mechanical Engineering and History at the University of Houston, is the voice and driving force behind the "Engines of Our Ingenuity," a syndicated program for public radio. He has said that the change of our world into an information society is not like the Industrial Revolution. No; this change is more like the change from a hunter-gatherer society to an agrarian society. A change of this magnitude happened only once or twice in all of history. Those who were powerful in the previous society may have no power in the new society. In the hunter-gatherer society, the strongest man and best hunter rules. But where is he in an agrarian society? There, the best hunter holds little or no power. During the transition to an information society, those with power in the old ways will not give it up easily. Now couple the turmoil caused by this shift with the timing of the "end" of the Cold War.

The currency of the new age is information. The power struggle in the new age is the struggle to gather, use, and control information. It is at the beginning of this struggle that the Cold War ended, making available a host of highly trained information gatherers to countries and companies trying cope with the new economy. Official U.S. acknowledgment of the threat of economic espionage came in 1996 with the passage of the Economic Espionage Act.

For the information security professional, the world has fundamentally changed. Until 1990, a common practice had been to make the cost of an attack prohibitively expensive. How do you make an attack prohibitively expensive when your adversaries have the resources of governments behind them?

Most information security professionals have not been trained and are not equipped to handle professional intelligence agents with deep pockets. Today, most business managers are incapable of fathoming that such a threat exists.

75.3 Role of Information Technology in Economic Espionage

In the 1930s, the German secret police divided the world of espionage into five roles.[2] Exhibit 75.1 illustrates some of the ways that information technology today performs these five divisions of espionage functionality.

In addition to these roles, information technology may be exploited as a target, used as a tool, used for storage (for good or bad), used as protection for critical assets as a weapon, used as a transport mechanism, or used as an agent to carry out tasks when activated.

EXHIBIT 75.1 Five Divisions of Espionage Functionality

Role	WWII Description	IT Equivalent
Collectors	Located and gathered desired information	People or IT (hardware or software) agents, designer viruses that transmit data to the Internet
Transmitters	Forwarded the data to Germany, by coded mail or shortwave radio	E-mail, browsers with convenient 128-bit encryption, FTP, applications with built-in collection and transmission capabilities (e.g., comet cursors, Real Player, Media Player, or other spyware), covert channel applications
Couriers	Worked on steamship lines and transatlantic clippers, and carried special messages to and from Germany	Visiting country delegations, partners/suppliers, temporary workers, and employees that rotate in and out of companies with CD-R/CD-RW, Zip disks, tapes, drawings, digital camera images, etc.
Drops	Innocent-seeming addresses of businesses or private individuals, usually in South American or neutral European ports; reports were sent to these addresses for forwarding to Germany	E-mail relays, e-mail anonymizers, Web anonymizers, specially designed software that spreads information to multiple sites (the reverse of distributed DoS) to avoid detection
Specialists	Expert saboteurs	Viruses, worms, DDoS, Trojan horses, chain e-mail, hoaxes, using e-mail to spread dissension, public posting of sensitive information about salaries, logic bombs, insiders sabotaging products, benchmarks, etc.

- *Target*. Information and information technology can be the target of interest. The goal of the exploitation may be to discover new information assets (breach of confidentiality), deprive one of exclusive ownership, acquire a form of the asset that would permit or facilitate reverse-engineering, corrupt the integrity of the asset—either to diminish the reputation of the asset or to make the asset become an agent—or to deny the availability of the asset to those who rely on it (denial of service).
- *Tool*. Information technology can be the tool to monitor and detect traces of espionage or to recover information assets. These tools include intrusion detection systems, log analysis programs, content monitoring programs, etc. For the bad guys, these tools would include probes, enumeration programs, viruses that search for PGP keys, etc.
- *Storage*. Information technology can store stolen or illegal information. IT can store sleeper agents for later activation.
- *Protection*. Information technology may have the responsibility to protect the information assets. The protection may be in the form of applications such as firewalls, intrusion detection systems, encryption tools, etc., or elements of the operating system such as file permissions, network configurations, etc.
- *Transport*. Information technology can be the means by which stolen or critical information is moved, whether burned to CDs, e-mailed, FTP'd, hidden in a legitimate http stream, or encoded in images or music files.
- *Agent*. Information technology can be used as an agent of the adversary, planted to extract significant sensitive information, to launch an attack when given the appropriate signal, or to receive or initiate a covert channel through a firewall.

75.4 Implications for Information Security

75.4.1 Implication 1

A major tenet of our profession has been that, because we cannot always afford to prevent information system-related losses, we should make it prohibitively expensive to compromise those systems. How does one do that when the adversary has the resources of a government behind him? Frankly, this tenet only worked on adversaries who were limited by time, money, or patience. Hackers with unlimited time on their hands—and a bevy of unpaid researchers who consider a difficult system to be a trophy waiting to be collected—turn this tenet into Swiss cheese.

This reality has placed emphasis on the onion model of information security. In the onion model you assume that all other layers will fail. You build prevention measures but you also include detection measures that will tell you that those measures have failed. You plan for the recovery of critical information, assuming that your prevention and detection measures will miss some events.

75.4.2 Implication 2

Information security professionals must now be able to determine if their industry or their company is a target for economic espionage. If their company/industry is a target, then the information security professionals should adjust their perceptions of their potential adversaries and their limits. One of the best-known quotes from the *Art of War* by Sun Tsu says, "Know your enemy." Become familiar with the list of countries actively engaging in economic espionage against your country or within your industry. Determine if any of your vendors, contractors, partners, suppliers, or customers come from these countries. In today's global economy, it may not be easy to determine the country of origin. Many companies move their global headquarters to the United States and keep only their main R&D offices in the country of origin. Research the company and its founders. Learn where and how they gained their expertise. Research any publicized accounts regarding economic espionage/intellectual property theft attributed to the company, the country, or other companies from the country. Pay particular attention to the methods used and the nature of the known targets. Contact the FBI or its equivalent and see if they can provide additional information. Do not forget to check your own organization's history with each company. With this information you can work with your business leaders to determine what may be a target within your company and what measures (if any) may be prudent.

> He who protects everything, protects nothing.
>
> **—Napoleon**

Applying the wisdom of Napoleon implies that, within the semipermeable external boundary, we should determine which information assets truly need protection, to what degree, and from what threats. Sun Tsu speaks to this need as well. It is not enough to only know your enemy.

> Therefore I say, "Know the enemy and know yourself; in a hundred battles you will never be in peril."
>
> When you are ignorant of the enemy but know yourself, your chances of winning or losing are equal.
>
> If ignorant both of your enemy and yourself, you are certain in every battle to be in peril.
>
> **—Sun Tzu, *The Art of War* (III.31–33)**

A company can "know itself" using a variation from the business continuity concept of a business impact assessment (BIA). The information security professional can use the information valuation data collected during the BIA and extend it to produce information protection guides for sensitive and critical information assets. The information protection guides tell users which information should be protected, from what threats, and what to do if an asset is found unprotected. They should tell the technical staff about threats to each information asset and about any required and recommended safeguards.

A side benefit gained from gathering the information valuation data is that, in order to gather the value information, the business leaders must internalize questions of how the data is valuable and the degrees of loss that would occur in various scenarios. This is the most effective security awareness that money can buy.

After the information protection guides have been prepared, you should meet with senior management again to discuss the overall posture the company wants to take regarding information security and counter-economic espionage. Note that it is significant that you wait until after the information valuation exercise is complete before addressing the security posture. If management has not accepted the need for security, the question about desired posture will yield damaging results.

Here are some potential postures that you can describe to management:

- *Prevent all.* In this posture, only a few protocols are permitted to cross your external boundary.
- *City wall.* A layered approach, prevention, detection, mitigation, and recovery strategies are all, in effect, similar to the walled city in the Middle Ages. Traffic is examined, but more is permitted in and out. Because more is permitted, detection, mitigation, and recovery strategies are needed internally because the risk of something bad getting through is greater.
- *Aggressive.* A layered approach, but embracing new technology, is given a higher priority than protecting the company. New technology is selected, and then security is asked how they will deal with it.
- *Edge racer.* Only general protections are provided. The company banks on running faster than the competition. "We'll be on the next technology before they catch up with our current release." This is a common position before any awareness has been effective.

75.4.3 Implication 3

Another aspect of knowing your enemy is required. As security professionals we are not taught about spycraft. It is not necessary that we become trained as spies. However, the FBI, in its annual report to congress on economic espionage, gives a summary about techniques observed in cases involving economic espionage.

Much can be learned about modern techniques in three books written about the Mossad—*Gideon's Spies* by Gordon Thomas, and *By Way of Deception*, and The *Other Side of Deception*, both by Victor Ostrovsky and Claire Hoy. These describe the Mossad as an early adopter of technology as a tool in espionage, including their use of Trojan code in software sold commercially. The books describe software known as Promis that was sold to intelligence agencies to assist in tracking terrorists; and the authors allege that the software had a Trojan that permitted the Mossad to gather information about the terrorists tracked by its customers. *By Way of Deception* describes the training process as seen by Ostrovsky.

75.4.4 Implication 4

75.4.4.1 Think Globally, Act Locally

The Chinese government recently announced that the United States had placed numerous bugging devices on a plane for President Jiang Zemin. During the customization by a U.S. company of the interior of the plane for its use as the Chinese equivalent of Air Force One, bugs were allegedly placed in the upholstery of the president's chair, in his bedroom, and even in the toilet.

When the United States built a new embassy in Moscow, the then-extant Soviet Union insisted it be built using Russian workers. The United States called a halt to its construction in 1985 when it discovered it was too heavily bugged for diplomatic purposes. The building remained unoccupied for a decade following the discovery.

The *1998 Annual Report to Congress on Foreign Economic Collection and Industrial Espionage* concluded with the following statement:

> …foreign software manufacturers solicited products to cleared U.S. companies that had been embedded with spawned processes and multithreaded tasks.

This means that foreign software companies sold products with Trojans and backdoors to targeted U.S. companies.

In response to fears about the Echelon project, in 2001 the European Union announced recommendations that member nations use open-source software to ensure that Echelon software agents are not present.

Security teams would benefit by using open-source software tools if they could be staffed sufficiently to maintain and continually improve the products. Failing that, security in companies in targeted industries should consider the origins of the security products they use. If your company knows it is a target for economic espionage, it would be wise to avoid using security products from countries actively engaged in economic espionage against your country. If unable to follow this strategy, the security team should include tools in the architecture (from other countries) that could detect extraneous traffic or anomalous behavior of the other security tools.

In this strategy you should follow the effort all the way through implementation. In one company, the corporate standard for firewall was a product of one of the most active countries engaging in economic espionage. Management was unwilling to depart from the standard. Security proposed the use of an intrusion detection system (IDS) to guard against the possibility of the firewall being used to permit undetected, unfiltered, and unreported access. The IDS was approved; but when procurement received the order, they discovered that the firewall vendor sold a special, optimized version of the same product and—without informing the security team—ordered the IDS from the vendor that the team was trying to guard against.

75.4.5 Implication 5

The system of rating computers for levels of security protection is incapable of providing useful information regarding products that might have malicious code that is included intentionally. In fact, companies that have intentions of producing code with these Trojans are able to use the system of ratings to gain credibility without merit.

It appears that the first real discovery by one of the ratings systems caused the demise of the ratings system and a cover-up of the findings. I refer to the MISSI ratings system's discovery of a potential backdoor in Checkpoint Firewall-1 in 1997. After this discovery, the unclassified X31 report[3] for this product and all previous reports were pulled from availability. The Internet site that provided them was shut down, and requestors were told that the report had been classified. The federal government had begun pulling Checkpoint Firewall-1 from military installations and replacing it with other companies' products. While publicly denying that these actions were happening, Checkpoint began correspondence with the NSA, owners of the MISSI process, to answer the findings of that study. The NSA provided a list of findings and preferred corrective actions to resolve the issue. In Checkpoint's response[4] to the NSA, they denied that the code in question, which involved SNMP and which referenced files containing IP addresses in Israel, was a backdoor. According to the NSA, two files with IP addresses in Israel "could provide access to the firewall via SNMPv2 mechanisms." Checkpoint's reply indicated that the code was dead code from Carnegie Mellon University and that the files were QA testing data that was left in the final released configuration files.

The X31 report, which I obtained through an FOIA request, contains no mention of the incident and no indication that any censorship had occurred. This fact is particularly disturbing because a report of this nature should publish all issues and their resolutions to ensure that there is no complicity between testers and the test subjects.

However, the letter also reveals two other vulnerabilities that I regard as backdoors, although the report classes them as software errors to be corrected. The Checkpoint response to some of these "errors" is to defend aspects of them as desirable. One specific reference claims that most of Checkpoint's customers prefer maximum connectivity to maximum security, a curious claim that I have not seen in their marketing material. This referred to the lack of an ability to change the implicit rules in light of the vulnerability of stateful inspection's handling of DNS using UDP, which existed in Version 3 and earlier.

Checkpoint agreed to most of the changes requested by the NSA; however, the exception is notable in that it would have required Checkpoint to use digital signatures to sign the software and data electronically to prevent someone from altering the product in a way that would go undetected. These changes would have provided licensees of the software with the ability to know that, at least initially, the software they were running was indeed the software and data that had been tested during the security review.

It is interesting to note that Checkpoint had released an internal memo nine months prior to the letter responding to the NSA claims in which they claimed nothing had ever happened.[5]

Both the ITSEC and Common Criteria security rating systems are fatally flawed when it comes to protection against software with intentional malicious code. Security companies are able to submit the software for rating and claim the rating even when the entire system has not been submitted. For example, a company can submit the assurance processes and documentation for a targeted rating. When it achieves the rating on just that portion, it can advertise the rating although the full software functionality has not been tested. For marketing types, they gain the benefit of claiming the rating without the expense of full testing. Even if the rating has an asterisk, the damage is done because many that authorize the purchase of these products only look for the rating. When security reports back to management that the rating only included a portion of the software functionality, it is portrayed as sour grapes by those who negotiated the "great deal" they were going to get. The fact is that there is no commercial push to require critical software such as operating systems and security software to include exhaustive code reviews, covert channel analysis, and to only award a rating when it is fully earned.

To make matters worse, if it appears that a company is going to get a poor rating from a test facility, the vendor can stop the process and start over at a different facility, perhaps in another country, with no penalty and no carry-over.

75.5 What Are the Targets?

The U.S. government publishes a list of military critical technologies (MCTs). A summary of the list is published annually by the FBI (see Exhibit 75.2).

There is no equivalent list for nonmilitary critical technologies. However, the government has added "targeting the national information infrastructure" to the National Security Threat List (NSTL). Targeting the national information infrastructure speaks primarily to the infrastructure as an object of potential disruption, whereas the MCT list contains technologies that foreign governments may want to acquire illegally. The NSTL consists of two tables. One is a list of issues (see Exhibit 75.3); the other is a classified list of countries engaged in collection activities against the United States. This is not the same list captured in Exhibit 75.4. Exhibit 75.4 contains the names of countries engaged in economic espionage and, as such, contains the names of countries that are otherwise friendly trading partners. You will note that the entire subject of economic espionage is listed as one of the threat list issues.

According to the FBI, the collection of information by foreign agencies continues to focus on U.S. trade secrets and science and technology products, particularly dual-use technologies and technologies that provide high profitability.

Examining the cases that have been made public, you can find intellectual property theft, theft of proposal information (bid amounts, key concepts), and requiring companies to participate in joint ventures to gain access to new country markets—then either stealing the IP or awarding the contract to an internal company with an identical proposal. Recently, a case involving HP found a planted employee sabotaging key benchmarking tests to HP's detriment. The message from the HP case is that economic

India

espionage also includes efforts beyond the collection of information, such as sabotage of the production line to cause the company to miss key delivery dates, deliver faulty parts, fail key tests, etc.

You should consider yourself a target if your company works in any of the technology areas on the MCT list, is a part of the national information infrastructure, or works in a highly competitive international business.

75.6 Who Are the Players?

75.6.1 Countries

This section is written from the published perspective of the U.S. Government. Readers from other countries should attempt to locate a similar list from their government's perspective. It is likely that two lists will exist: a "real" list and a "diplomatically correct" edition.

For the first time since its original publication in 1998, the *Annual Report to Congress on Foreign Economic Collection and Industrial Espionage 2000* lists the most active collectors of economic intelligence. The delay in providing this list publicly is due to the nature of economic espionage. To have economic espionage you must have trade. Our biggest trading partners are our best friends in the world. Therefore, a list of those engaged in economic espionage will include countries that are otherwise friends and allies. Thus the poignancy of Bernard Esambert's quote used to open this chapter.

75.6.2 Companies

Stories of companies affected by economic espionage are hard to come by. Public companies fear the effect on stock prices. Invoking the economic espionage law has proven very expensive—a high risk for a favorable outcome—and even the favorable outcomes have been inadequate considering the time, money, and commitment of company resources beyond their primary business. The most visible companies are those that have been prosecuted under the Economic Espionage Act, but there have only been 20 of those, including:

- Four Pillars Company, Taiwan, stole intellectual property and trade secrets from Avery Dennison.
- Laser Devices, Inc., attempted to illegally ship laser gun sights to Taiwan without Department of Commerce authorization.
- Gilbert & Jones, Inc., New Britain, Connecticut, exported potassium cyanide to Taiwan without the required licenses.
- Yuen Foong Paper Manufacturing Company, Taiwan, attempted to steal the formula for Taxol, a cancer drug patented and licensed by the Bristol-Myers Squibb (BMS) Company.
- Steven Louis Davis attempted to disclose trade secrets of the Gillette Company to competitors Warner-Lambert Co., Bic, and American Safety Razor Co. The disclosures were made by fax and e-mail. Davis worked for Wright Industries, a subcontractor of the Gillette Company.

- Duplo Manufacturing Corporation, Japan, used a disgruntled former employee of Standard Duplicating Machines Corporation to gain unauthorized access into a voicemail system. The data was used to compete against Standard. Standard learned of the issue through an unsolicited phone call from a customer.
- Harold Worden attempted to sell Kodak trade secrets and proprietary information to Kodak rivals, including corporations in the Peoples Republic of China. He had formerly worked for Kodak. He established his own consulting firm upon retirement and subsequently hired many former Kodak employees. He was convicted on one felony count of violating the Interstate Transportation of Stolen Property law.
- In 1977, Mitsubishi Electric bought one of Fusion Systems Corporation's microwave lamps, took it apart, then filed 257 patent actions on its components. Fusion Systems had submitted the lamp for a patent in Japan two years earlier. After 25 years of wrangling with Mitsubishi, the Japanese patent system, Congress, and the press, Fusion's board fired the company's president (who had spearheaded the fight) and settled the patent dispute with Mitsubishi a year later.
- The French are known to have targeted IBM, Corning Glass, Boeing, Bell Helicopter, Northrup, and Texas Instruments (TI). In 1991, a guard in Houston noticed two well-dressed men taking garbage bags from the home of an executive of a large defense contractor. The guard ran the license number of the van and found it belonged to the French Consul General in Houston, Bernard Guillet. Two years earlier, the FBI had helped TI remove a French sleeper agent. According to *Cyber Wars*[6] by Jean Guisnel, the French intelligence agency (the DGSE) had begun to plant young French engineers in various French subsidiaries of well-known American firms. Over the years they became integral members of the companies they had entered, some achieving positions of power in the corporate hierarchy. Guillet claims that the primary beneficiary of these efforts was the French giant electronics firm, Bull.

75.7 What Has Been Done? Real-World Examples

75.7.1 Partnering with a Company and Then Hacking the Systems Internally

In one case, very senior management took a bold step. In the spirit of the global community, they committed the company to use international partners for major aspects of a new product. Unfortunately, in selecting the partners, they chose companies from three countries listed as actively conducting economic espionage against their country. In the course of developing new products, the employees of one company were caught hacking sensitive systems. Security measures were increased but the employees hacked through them as well. The company of the offending partners was confronted. Its senior management claimed that the employees had acted alone and that their actions were not sanctioned. Procurement, now satisfied that their fragile quilt of partners was okay, awarded the accused partner company a lucrative new product partnership. Additionally, they erased all database entries regarding the issues and chastised internal employees who continued to voice suspicions. No formal investigation was launched. Security had no record of the incident. There was no information security function at the time of the incident.

When the information security function was established, it stumbled upon rumors that these events had occurred. In investigating, they found an internal employee who had witnessed the stolen information in use at the suspect partner's home site. They also determined that the offending partner had a history of economic espionage, perhaps the most widely known in the world. Despite the corroboration of the partner's complicity, line management and procurement did nothing. Procurement knew that the repercussions within their own senior management and line management would be severe because they had pressured the damaged business unit to accept the suspected partner's earlier explanation. Additionally, it would have underscored the poor choice of partners that had occurred under their care and the fatal flaw in the partnering concept of very senior management. It was impossible to extricate the company from this relationship without causing the company to collapse. IT line management would not embrace this issue because they had dealt with it before and had been stung, although they were right all along.

75.7.2 Using Language to Hide in Plain Sight

Israeli Air Force officers assigned to the Recon/Optical Company passed on technical information beyond the state-of-the-art optics to a competing Israeli company, El Op Electro-Optics Industries Ltd. Information was written in Hebrew and faxed. The officers tried to carry 75 boxes out of the plant when the contract was terminated. The officers were punished upon return to Israel—for getting caught.[7]

In today's multinational partnerships, language can be a significant issue for information security and for technical support. Imagine the difficulty in monitoring and supporting computers for five partners, each in a different language.

The *Annual Report to Congress 2000*[8] reveals that the techniques used to steal trade secrets and intellectual property are limitless. The insider threat, briefcase and laptop computer thefts, and searching hotel rooms have all been used in recent cases. The information collectors are using a wide range of redundant and complementary approaches to gather their target data. At border crossings, foreign officials have conducted excessive attempts at elicitation. Many U.S. citizens unwittingly serve as third-party brokers to arrange visits or circumvent official visitation procedures. Some foreign collectors have invited U.S. experts to present papers overseas to gain access to their expertise in export-controlled technologies. There have been recent solicitations to security professionals asking for research proposals for security ideas as a competition for awarding grants to conduct studies on security topics. The solicitation came from one of the most active countries engaging in economic espionage. Traditional clandestine espionage methods (such as agent recruitment, U.S. volunteers, and co-optees) are still employed. Other techniques include:

- Breaking away from tour groups
- Attempting access after normal working hours
- Swapping out personnel at the last minute
- Customs holding laptops for an extended period of time
- Requests for technical information
- Elicitation attempts at social gatherings, conferences, trade shows, and symposia
- Dumpster diving (searching a company's trash for corporate proprietary data)
- Using unencrypted Internet messages

To these I would add holding out the prospect of lucrative sales or contracts, but requiring the surrender or sharing of intellectual property as a condition of partnering or participation.

75.8 What Can We, as Information Security Professionals, Do?

We must add new skills and improve our proficiency in others to meet the challenge of government funded/supported espionage. Our investigative and forensic skills need improvement over the level required for nonespionage cases. We need to be aware of the techniques that have been and may be used against us. We need to add the ability to elicit information without raising suspicion. We need to recognize when elicitation is attempted and be able to teach our sales, marketing, contracting, and executive personnel to recognize such attempts. We need sources that tell us where elicitation is likely to occur. For example, at this time, the Paris Air Show is considered the number-one economic espionage event in the world.

We need to be able to raise the awareness of our companies regarding the perceived threat and real examples from industry that support those perceptions. Ensure that you brief the procurement department. Establish preferences for products from countries not active in economic espionage. When you must use a product from a country active in economic espionage, attempt to negotiate an indemnification against loss. Have procurement add requirements that partners/suppliers provide proof of background investigations, particularly if individuals will be on site.

Management and procurement should be advised that those partners with intent to commit economic espionage are likely to complain to management that the controls are too restrictive, that they cannot do their jobs, or that their contract requires extraordinary access. You should counter these objectives before they occur by fully informing management and procurement about awareness, concerns, and measures to be taken. The measures should be applied to all suppliers/partners. Ensure that these complaints and issues will be handed over to you for an official response. Treat each one individually and ask for specifics rather than generalities.

If procurement has negotiated a contract that commits the company to extraordinary access, your challenge is greater. Procurement may insist that you honor their contract. At this time you will discover where security stands in the company's pecking order. A stance you can take is, "Your negotiated contract does not and cannot relieve me of my obligation to protect the information assets of this corporation." It may mean that the company has to pay penalties or go back to the negotiating table. You should not have to sacrifice the security of the company's information assets to save procurement some embarrassment.

We need to develop sources to follow developments in economic espionage in industries and businesses similar to ours. Because we are unlikely to have access to definitive sources about this kind of information, we need to develop methods to vet the information we find in open sources. The FBI provides advanced warning to security professionals through ANSIR (Awareness of National Security Issues and Responses) systems. Interested security professionals for U.S. corporations should provide their e-mail addresses, positions, company names and addresses, and telephone and fax numbers to ansir@leo.gov. A representative of the nearest field division office will contact you. The FBI has also created InfraGard (http://www.infragard.net/fieldoffice.htm) chapters for law enforcement and corporate security professionals to share experiences and advice.[9]

InfraGard is dedicated to increasing the security of the critical infrastructures of the United States. All InfraGard participants are committed to the proposition that a robust exchange of information about threats to and actual attacks on these infrastructures is an essential element in successful infrastructure protection efforts. The goal of InfraGard is to enable information flow so that the owners and operators of infrastructures can better protect themselves and so that the U.S. Government can better discharge its law enforcement and national security responsibilities.

75.9 Barriers Encountered in Attempts to Address Economic Espionage

A country is made up of many opposing and cooperating forces. Related to economic espionage, for information security, there are two significant forces. One force champions the businesses of that country. Another force champions the relationships of that country to other countries. Your efforts to protect your company may be hindered by the effect of the opposition of those two forces. This was evident in the first few reports to Congress by the FBI on economic espionage. The FBI was prohibited from listing even the countries that were most active in conducting economic espionage. There is no place in the U.S. Government that you can call to determine if a partner you are considering has a history of economic espionage, or if a software developer has been caught with backdoors, placing Trojans, etc.

You may find that, in many cases, the FBI interprets the phrase *information sharing* to mean that you share information with them. In one instance, a corporate investigator gave an internal e-mail that was written in Chinese to the FBI, asking that they translate it. This was done to keep the number of individuals involved in the case to a minimum. Unless you know the translator and his background well, you run the risk of asking someone that might have ties to the Chinese to perform the translation. Once the translation was performed, the FBI classified the document as secret and would not give the investigator the translated version until the investigator reasoned with them that he would have to translate the document with an outside source unless the FBI relented.

Part of the problem facing the FBI is that there is no equivalent to a DoD or DoE security clearance for corporate information security personnel. There are significant issues that complicate any attempt to create such a clearance. A typical security clearance background check looks at criminal records. Background investigations may go a step further and check references, interview old neighbors, schoolmates, colleagues, etc. The most rigorous clearance checks include viewing bank records, credit records, and other signs of fiscal responsibility. They may include a psychological evaluation. They are not permitted to include issues of national origin or religion unless the United States is at war with a particular country. In those cases, the DoD has granted the clearance but placed the individuals in positions that would not create a conflict of interest. In practice, this becomes impossible. Do you share information about all countries and religious groups engaging in economic espionage, except for those to which the security officer may have ties? Companies today cannot ask those questions of its employees. Unfortunately, unless a system of clearances is devised, the FBI will always be reluctant to share information, and rightfully so.

Another aspect of the problem facing the FBI today is the multinational nature of corporations today. What exactly is a U.S. corporation? Many companies today were conceived in foreign countries but established their corporate headquarters in the United States, ostensibly to improve their competitiveness in the huge U.S. marketplace. What of U.S. corporations that are wholly owned by foreign corporations? Should they be entitled to assistance, to limited assistance, or to no assistance? If limited assistance, how are the limits determined?

Within your corporation there are also opposing and cooperating forces. One of the most obvious is the conflict between marketing/sales and information security. In many companies, sales and marketing personnel are the most highly paid and influential people in the company. They are, in most cases, paid largely by commission. This means that if they do not make the sale, they do not get paid. They are sometimes tempted to give the potential customer anything they want, in-depth tours of the plant, details on the manufacturing process, etc., in order to make the sale. Unless you have a well-established and accepted information protection guide that clearly states what can and cannot be shared with these potential customers, you will have little support when you try to protect the company.

The marketing department may have such influence that they cause your procurement personnel to abandon reason and logic in the selection of critical systems and services. A Canadian company went through a lengthy procurement process for a massive wide area network contract. An RFP was released. Companies responded. A selection committee met and identified those companies that did not meet the RFP requirements. Only those companies that met the RFP requirements were carried over into the final phase of the selection process. At this point, marketing intervened and required that procurement re-add two companies to the final selection process—companies that had not met the requirements of the RFP. These two companies purchased high product volumes from this plant. Miracle of miracles, one of the two unqualified companies won the contract.

It is one thing for the marketing department to request that existing customers be given some preference from the list of qualified finalists. It is quite another to require that unqualified respondents be given any consideration.

A product was developed in a country that conducts economic espionage operations against U.S. companies in your industry sector. This product was widely used throughout your company, leaving you potentially vulnerable to exploitation or exposed to a major liability. When the issue was raised, management asked if this particular product had a Trojan or evidence of malicious code. The security officer responded, "No, but due to the nature of this product, if it did contain a Trojan or other malicious code, it could be devastating to our company. Because there are many companies that make this kind of product in countries that do not conduct economic espionage in our industry sector, we should choose one of those to replace this one and thus avoid the risk."

Management's response was surprising. "Thank you very much, but we are going to stay with this product and spread it throughout the corporation—but do let us know if you find evidence of current backdoors and the like." One day the security team learned that, just as feared, there had indeed been a backdoor; in fact, several. The news was reported to management. Their response was unbelievable. "Well, have they fixed it?" The vendor claimed to have fixed it, but that was not the point. The point was that they had placed the code in the software to begin with, and there was no way to tell if they had replaced the backdoor with another. Management responded, "If they have fixed the problem, we are going to stay with the product, and that is the end of it. Do not bring this subject up again." In security you must raise every security concern that occurs with a product, even after management has made up its mind. To fail to do so would set the company up for charges of negligence should a loss occur that relates to that product. "Doesn't matter; do not raise this subject again."

So why would management make a decision like this? One possible answer has to do with pressure from marketing and potential sales to that country. Another has to do with embarrassment. Some vice president or director somewhere made a decision to use the product to begin with. They may even have had to fall on a sword or two to get the product they wanted. Perhaps it is because a more powerful director had already chosen this product for his site. This director may have forced the product's selection as the corporate standard so that staff would not be impacted. One rumor has it that the product was selected as a corporate standard because the individual choosing the standard was being paid a kickback by a relative working for a third-party vendor of the product. If your IT department raises the issue, it runs the risk of embarrassing one or more of these senior managers and incurring their wrath. Your director may feel intimidated enough that he will not even raise the issue.

Even closer to home is the fact that the issue was raised to your management in time to prevent the spread of the questionable product throughout the corporation. Now if the flag is raised, someone may question why it was not raised earlier. That blame would fall squarely on your director's shoulders.

Does it matter that both the vice president and the director have fiduciary responsibility for losses related to these decisions should they occur? Does it matter that their decisions would not pass the prudent man test and thus place them one step closer to being found negligent? No, it does not. The director is accepting the risk—not the risk to the corporation, but the risk that damage might occur during his watch. The vice president probably does not know about the issue or the risks involved but could still be implicated via the concept of respondent superior. The director may think he is protecting the vice president by keeping him out of the loop—the concept of plausible deniability—but the courts have already tackled that one. Senior management is responsible for the actions of those below them, regardless of whether they know about the actions.

Neither of these cases exists if the information security officer reports to the CEO. There is only a small opportunity for it to exist if the information security officer reports to the CIO. As the position sinks in the management structure, the opportunity for this type of situation increases.

The first time you raise the specter of economic espionage, you may encounter resistance from employees and management. "Our company isn't like that. We don't do anything important. No one I know has ever heard of anything like that happening here. People in this community trust one another."

Some of those who have been given evidence that such a threat does exist have preferred to ignore the threat, for to acknowledge it would require them to divert resources (people, equipment, or money) from their own initiatives and goals. They would prefer to "bet the company" that it would not occur while they are there. After they are gone it no longer matters to them.

When you raise these issues as the information security officer, you are threatening the careers of many people—from the people who went along with it because they felt powerless to do anything, to the senior management who proposed it, to the people in between who protected the concept and decisions of upper management in good faith to the company. Without a communication path to the CEO and other officers representing the stockholders, you do not have a chance of fulfilling your fiduciary liability to them.

The spy of the future is less likely to resemble James Bond, whose chief assets were his fists, than the Line X engineer who lives quietly down the street and never does anything more violent than turn a page of a manual or flick on his computer.

Insight into Intrusion Prevention Systems

Gildas Deograt-Lumy

Roy Naldo

76.1 Introduction

Intrusion in information system security simply means the attempts or actions of unauthorized entry into an IT system. This action ranges from a reconnaissance attempt to map any existence of vulnerable services, exploitation/real attack, and finally the embedding of backdoors. Such a malicious process can result in the creation of an illegal account with administrator privilege upon the victim machine. Actually, there have been several approaches or technologies designed to prevent such unwanted actions. Hence, the intrusion prevention system (IPS) is really not something new in the world of information system security. Some examples of prevention approaches or systems in existence today include anti-virus, strong authentication, cryptography, patch management, and firewalls. Anti-virus systems exist to prevent malicious programs such as viruses, worms, backdoor programs, etc. from successfully being embedded or executed within a particular system. Patch management ensures effective deployment of the latest security fixes/patches so as to prevent system vulnerabilities from successfully being exploited. Firewalls exist to prevent unwanted access to some particular systems. Cryptography exists to prevent any attempts to disclose or compromise sensitive information. Strong authentication exists to prevent any attempts to fake an identity in an effort to enter a particular system.

If prevention systems on multiple types of intrusion attempts exist, what would be new about this so-called “intrusion prevention system” that has recently arisen in the IT security marketplace? Is it really a new-breed technology able to very effectively eliminate all existing intrusion techniques, as detailed in the marketing brochures? No. The IPS is not a new technology and it is not the silver bullet in combating each and every intrusion attempt. In fact, it is just a new generation of security products aimed at combining some existing security technologies into a single measure to get the maximum benefits of these security technologies by reducing their limitations. In accordance with the multi-layered defense strategy where there is indeed no single security measure capable of combating all the intrusion attempts, an IPS has its strengths and its weaknesses. This chapter provides some insight into this area.

76.2 Basic Security Problems Overview

Know your enemy is one of the basic philosophies in information system security. It is important to look further at a so-called intrusion before looking at ways to detect and prevent it. There are many ways of breaking into a private system or network. Such action is usually not a one-shot attempt. Therefore, one can divide the intrusion life cycle into three phases: (1) reconnaissance/information gathering, (2) real attack/penetration/exploitation, and (3) proliferation. Reconnaissance is an attempt to discover as much information as possible about the target system. Most of the information being sought in this phase consists of DNS tables, opened ports, available hosts, operating system type and version, application type and version, available user accounts, etc. Information collected in this phase will determine the type of attack/exploitation/penetration in the next phase. Numerous attack techniques exist, including password brute-force attempts, buffer overflows, spoofing, directory traversals, etc. Upon a successful intrusion attempt at this phase, an intruder will usually be able to gain control of or crash the target system, causing service disruption. The third phase is one where an intruder aims to obtain sensitive or valuable information (copying confidential files, recording screen changes or keystrokes) and set up a scenario to ensure that he can come back anytime to this compromised system (backdoor, user account, modify filtering rules). This is done to use this compromised system as a stepping stone to proceed further into the private system/network premises and as an attacking machine/zombie to launch attacks against other private systems or networks. An intruder will usually attempt to delete the system or application logs, or disable the auditing configuration in an effort to eliminate traces of entry.

Today there are automatic intrusion attempts aimed at random vulnerable machines, which pose very high risk in terms of attack severity and propagation (e.g., computer worms such as NIMDA, Code Red, Slammer, and Welchia). Due to the global use of an application or system, it is now possible to cause global damage throughout the world of information systems by creating an attack program that will automatically attack a recently exposed vulnerable system and then turn this vulnerable system into another attacking machine, launching the same type of attack on other vulnerable machines. In the real world, this chain-reaction process has been shown to cause global damage, both to the Internet community and corporations, in quite a short time. The life cycle of such worms is very simple. Whenever there is exposure of system or application vulnerability along with its exploit tool, then it is just a matter of time to turn this exploit tool into an automatic attacking tool, speedily looking for and attacking vulnerable systems throughout the world. The more widely the vulnerable system is being used, the more widely this automatic attacking tool, known as a computer worm, will spread and cause damage.

Where will such intrusions likely originate? They might come from both the external and internal sides, and each side requires a different defense strategy. Defending against external intrusion usually requires a more technical approach, such as a good patch management strategy, a strict filtering policy at each gateway or WAN entry point, strong authentication for remote inbound access, etc. Moreover, the recently increased connectivity and business opportunities over the Internet and extranets expose greater risks of subversion and endanger the corporate information assets. On the other hand, internal threats require a less technical approach. Examples of internal attacks include non-company laptops belonging to consultant, contractor, or business partner, employees that lack security but are attached to the company network. They then become fertile ground for worm propagation. A low awareness level on the part of employees also makes them prone to an enticement attack, such as a virus attachment, malicious software downloads, etc. These internal threats require a strong corporate security policy, as well as a security awareness program accompanied by an effective and efficient means of implementation.

76.3 Where Are Current Defensive Approaches Lacking?

76.3.1 Preventive Approach

We need to identify the gaps both in current preventive and detective defense approaches to determine where an IPS needs to improve. There are well-known preventive approaches in existence today. A firewall is the basic step in securing an IT network. It performs traffic filtering to counter intrusion attempts into a private IT system or network. A good firewall would block all traffic except that which is explicitly allowed. In this way, corporate security policy on authorized access to IT resources that are exposed publicly and restricted access to private IT resources can be applied effectively. Advanced firewall technologies include the stateful inspection firewall and the application filtering (proxy) firewall. A stateful inspection firewall allows the traffic from authorized networks, hosts, or users to go through authorized network ports. It is able to maintain the state of a legitimate session and ensure that any improper or malicious connection will be blocked. However, a stateful inspection firewall does not check the network traffic until the application layer. For example, Welchia-infected hosts, which are authorized to access a particular network on port TCP 135, can still spread the worm infection without any difficulty. Here lies a need to have a technology capable of inspecting a packet based on more than just the network port and connection state or session. An application filtering (proxy) firewall works by rewriting both the ingress and egress connections while ensuring compliance with the standard protocol definition. It can block every connection containing a deviating protocol definition such as an unauthorized syntax or command. This particular type of firewall works effectively to prevent any application-level attack and buffer overflow. However, not all application protocols are currently supported by this type of firewall. It is limited to TCP-based applications. There are some application protocols, such as FTP, HTTP, SMTP, POP3, SQL, X11, LDAP, Telnet, etc., that are supported by this type of firewall, leaving the other application protocols to be handled at a lower level (i.e., the network level or transport level). Moreover, some applications require dynamic source or destination ports that force the firewall administrator to open a wide range of ports. Such configurations will cause greater exposure at the firewall itself.

Patch management is designed as an effective means of overcoming new vulnerabilities existing in applications such as HTTP, NETBIOS, SQL, FTP, etc. We have seen many worms in the past few years exploiting application and system vulnerabilities that are able to cause severe damage to the IT community. However, patching the systems and applications has become an unmanageable job. CERT recorded 417 vulnerabilities in the year 1999 and 4129 vulnerabilities in the year 2002. One can imagine how many vulnerability cases will arise in the years to come! Patching the system is not as simple as installing a piece of software. Various issues exist: the anti-virus tools in the patched system are disabled due to its incompatibility with the patch; the patched system becomes unstable due to incompatibility with other software in the system; the patched system remains vulnerable because the patch did not effectively close the security hole; new patches re-open the previous security hole (as in the case of the SLAMMER worm); and some business applications conflict with the new patches. Thus, there is a need to have a more effective means of protection to prevent the exploitation of system and application vulnerabilities.

Anti-virus works at the host level, preventing the execution of malicious programs such as a virus, worm, some well-known attack tool, Trojan horse, or key logger. It is a type of signature-based prevention system working at the host level. However, it can detect only known malicious programs listed in its library database. Moreover, a slight mutation or variation in a malicious program can evade the anti-virus.

76.3.2 Detective Approach

An intrusion detection system (IDS) is the other technology aimed at providing a precise detection measure on any intrusion attempt. It is designed to work both at the network level and the host level to cover the IT resources entirely. A network-based IDS is the one that covers the detection measure at the network level, while a host-based IDS is the one that covers the detection measure at the host level. Because it focuses on detection, an IDS is as good as its detection method. Now let us get some insight into the strengths and weaknesses associated with current intrusion detection techniques. Basically, there are two detection techniques that can be applied by an IDS: (1) a signature-based approach and (2) a behavior-based approach. Most IDSs today are signature based. The signature-based approach recognizes the attack characteristics and system/application vulnerabilities in a particular intrusion attempt and uses them to identify it. This approach is only as good as its signature precision. The more precise the signature, the more effective this detection approach will be. However, solely relying on this approach will not detect new (zero-day) intrusion techniques of widely spread vulnerabilities. The new intrusion technique must be identified prior to the development of a new signature. Therefore, diligent maintenance of the signature database is very critical. The other approach is behavior based. This approach applies a baseline or profile of known normal activities or behaviors and then raises alarms on any activities that deviate from this normal baseline. This approach is conceptually effective in detecting any intrusion attempts that exploit new vulnerabilities. However, in real-world practice, this approach will likely generate plenty of false alarms. The nature of an information technology system, network, or application is very dynamic. It is very difficult to profile a normal baseline due to its dynamic nature, such as a new application coming in, a system upgrade, network expansion, new IT projects, etc. Therefore, this particular detection approach is only as good as how reliable the normal baseline or profile is.

Now take a look at the current intrusion detection systems available on the market today: host-based and network-based IDSs. A host-based intrusion detection system (HIDS) is a sort of "indoor surveillance system" that examines the system integrity for any signs of intrusions. A host-based IDS usually is software installed within a monitored system and placed on business-critical systems or servers. Some of the system variables that HIDSs are likely to monitor include system logs, system processes, registry entries, file access, CPU usage, etc. One of the major limitations of an HIDS is that it can only detect intrusion attempts on the system on which it is installed. Other limitations include the fact that an HIDS will go down when the operating system goes down from an attack, it is unable to detect a network-based attack, and it consumes the resources of the monitored system, which may impact system performance. However, despite these limitations, an HIDS remains a good and strong source of evidence to prove whether or not a particular intrusion attempt at the network level is successful.

A network-based intrusion detection system (NIDS) is a sort of "outdoor surveillance system" that examines the data traffic passing throughout a particular network for any signs of intrusion. The intrusion detection system usually consists of two parts: the console and the sensor. The console is a management station that manages the incoming alerts and updates signatures on the sensor. The sensor is a monitoring agent (station) that is put onto any monitored network and raises alarms to the management station if any data traffic matches its signature databases. A NIDS is quite easy to deploy because it does not affect any existing system or application. It is also capable of detecting numerous network-based attacks, such as fragmented packet attacks, SYN floods, brute-force attempts, BIND buffer overflow attacks, IIS Unicode attacks, etc. Earlier detection of a reconnaissance type of attack by a NIDS, such as port scanning, BIND version attempt, and hosts mapping, will also help to prevent a particular intruder from launching a more severe attack attempt. However, a NIDS is more prone to false alarms compared to a HIDS. Despite its ability to detect an intrusion attempt, it cannot strongly indicate whether or not the attack was successful. Further correlation to multiple sources of information (sessions data, system logs, application logs, etc.) is still required at this level to determine if a particular attack attempt was successful or not, and to determine how far a particular attack attempt has reached.

There have been some attempts to add a prevention measure based on the detection measure performed by NIDSs. These techniques are TCP reset and firewall signaling. TCP reset is an active response from an IDS upon detecting a particular intrusion attempt, by trying to break down the intrusion session by sending a bogus TCP packet with a reset flag either to the attacker, to the victim, or to both. On the other hand, firewall signaling is a technique wherein privileged access is given to the IDS so that it can alter the filtering rules within a firewall or filtering device (like a router) to block ongoing attack attempts. A limitation regarding firewall signaling is that the firewall will, after all, create a generic blocking rule such as any based on the source IP address instead of creating a granular rule to simply drop the packet containing the particular attack signatures. This is because most firewalls do not provide signature-based (granular intrusions characteristics) blocking. With false alarm issues faced by the IDS, how far can one trust the decision of the IDS without having human intervention prior to deciding any preventive action based upon it?

An IDS is stateless. Although a signature matching method is less prone to false alarms compared to baseline matching, it still requires human intervention to filter out false alarms, validate the alerts, and evaluate the impact of a successful intrusion attempt. Every organization, depending on its business lines, will have its own network traffic characteristics due to the various applications and systems that exist today in the information technology world. Due to this variety, it is almost impossible to have common signature databases that are immune to false alarms. There will be various normal traffic that will wrongly trigger the IDS signature in each particular network. For example, a poorly made signature to detect NOOP code, which can lead to the detection of a buffer overflow attempt, may be wrongly triggered by normal FTP or HTTP traffic containing image files. Another example is the signature to watch for UDP and TCP port 65535, which is designed to look for Red worm propagation. It may be wrongly triggered by the P2P file sharing application because a P2P application might encourage its users to change their port numbers to use any number between 5001 and 65535 to avoid being blocked. In most cases, P2P users will simply choose the extreme number (i.e., 65535), which later when its traffic is passing through an IDS will wrongly trigger the Red worm signature. These examples serve to demonstrate how fine-tuning the IDS signature to filter out irrelevant signatures in order to get the most benefits of the IDS is critical and is a never-ending process due to the dynamically growing nature of the IT world. This is where human intervention is ultimately required. In addition to having the most accurate signature possible in fine-tuning the signature database, one can also consider removing an irrelevant signature. For example, one can disable a Microsoft IIS related signature if one uses only Apache Web servers throughout the network, or one might disable a BIND overflow attempt signature if one has validated that the BIND servers were well patched and immune.

In addition to the false alarms, there is yet another reason why human intervention is required. This other reason is because numerous techniques exist to elude detection by an intrusion detection system. The simple way for an intruder to elude an intrusion attempt is to launch a "snow blind" attack, which sends a large number of fake and forged intrusion attempts to a victim network in order to fill up the IDS log. Then, somewhere between these fake attempts, the intruder can simply include his real attack. Imagine if such an intrusion method creates tens of thousands of alarms. Which one of them, if any, is genuine? Having a relevant signature database in the IDS will help thwart such a method. Other methods of eluding IDS detection include obfuscation. In this method, an intruder can manipulate his attack strings in such a way that the IDS signature will not match, but yet this obfuscated attack string will still be processed as intended when it reaches the victim machine. For example, instead of sending "./../c:\winnt\system32\cmd.exe," an intruder can obfuscate it into "%2e%2e%2f%2e%2e%2fc:\winnt\system32\cmd.exe." Fragmentation is also a method that can be used to elude IDS detection. A particular attack string within a single TCP/IP packet is broken down into several fragments before being sent to the victim machine. In this way, if the IDS does not have the ability to determine these fragments and analyze them as a whole packet instead of per fragments, then it will not match the IDS signature. Yet, when it reaches the victim machine, through the normal TCP/IP stack process, it will still process the attack string as intended. There are many other variants of the above techniques to elude IDSs. Again, the above examples are to emphasize why human intervention is ultimately required in the current IDS endeavor. However, there is an approach in NIDS technology called "packet normalization," which is used to prevent the IDS from being eluded by such techniques by performing a pre-filtering phase upon each network packet before it is matched with its signature database in order to ensure that the way the IDS processes a set of network traffic for analysis is indeed the same way that a destination host will do it.

76.4 The New Terminology of IPS

Firewalls provide a prevention measure up until the application layer for some applications. However, this measure is commonly implemented only to port number and IP address while various intrusion attempts are intelligently exploiting vulnerability in applications which are opened by the firewall. Firewall signaling and TCP reset represent an effort to extend the detection measure from an IDS into a prevention measure but these fail in most cases. Therefore, a newer system trying to fill in these gaps is emerging. It is called an intrusion prevention system (IPS), a system that aims to intelligently perform earlier detection upon malicious attack attempts, policy violations, misbehaviors, and at the same time is capable of automatically blocking them effectively before they have successfully reached the target/victim system. The automatic blocking ability is required because human decisions and actions take time. In a world dominated by high-speed processing hardware and rapid communication lines, some of the security decisions and countermeasures must be performed automatically to keep up with the speed of the attacks running on top of these rapid communication lines. There are two types of intrusion prevention systems: network-based IPSs and host-based IPSs.

76.4.1 Network-Based IPS

A network-based IPS is the intrusion prevention system installed at the network gateway so that it can prevent malicious attack attempts such as Trojan horses, backdoors, rootkits, viruses, worms, buffer overflows, directory traversal, etc. from entering into the protected network at the entrance by analyzing every single packet coming through it. Technically, an IPS performs two types of functions: packet filtering and intrusion detection. The IDS part of this network-based IPS is used to analyze the traffic packets for any sign of intrusion, while the packet filtering part of it is to block all malicious traffic packets identified by the IDS part of it. Compared to existing firewall technology, a network-based IPS is simply a firewall with a far more granular knowledge base for blocking a network packet. However, the basic approach is different from that of a firewall. In a firewall, the ideal approach is to allow all legitimate traffic while blocking that, which is not specifically defined. In an IPS, it is the inverse. The IPS will allow everything except that which is specifically determined to be blocked. Compared to an IDS, an IPS is simply an IDS with an ideal and reliable blocking measure. Network-based IPSs can effectively prevent a particular attack attempt from reaching the target/victim machine. Because a network-based IPS is sort of a combination firewall and IDS within a single box, can it really replace the firewall and intrusion detection system? Are firewalls and IDSs still useful when a network-based IPS is in place? The answer is yes. Firewalls and IDSs remain useful even though a network-based IPS is in place. These three security systems can work together to provide a more solid defense architecture within a protected network. A firewall is still required to perform the first layer filtering, which allows only legitimate applications/traffic to enter a private network. Then the network-based IPS will perform the second layer filtering, which filters out the legitimate applications/traffic containing any sign of an intrusion attempt. Moreover, some current firewalls provide not just filtering features, but also features such as a VPN gateway, proxy service, and user authentication for secure inbound and outbound access, features that do not exist in current network-based IPSs. On the other hand, network-based IPSs also cannot prevent an attack inside the network behind it or one that is aimed at other internal machines within the same network. That is the reason why an IDS is still required although a network-based IPS exists in the network. An IDS is required to detect any internal attack attempts aimed at internal resources.

In addition to being able to provide basic packet filtering features such as a packet filtering firewall, a network-based IPS can also provide similar filtering mechanisms (e.g., an application filtering firewall). An application filtering firewall provides a specific application engine for each particular protocol it supports. For example, if it supports HTTP, FTP, or SQL, then it will have a specific engine for each protocol on which every packet going through an application filtering firewall will be reconstructed by the application proxy firewall and will be sent to the final destination as it was originally sent by the firewall itself. This specific engine provides knowledge to an application proxy firewall based on a particular protocol, thus allowing an application proxy firewall to drop any deviating behavior/usage of a particular protocol. Moreover, provided with this knowledge, an application proxy firewall is able to perform more granular filtering, such as disabling a specific command within a particular protocol. On the other hand, a network-based IPS also has a protocol anomaly engine wherein it is able to detect any deviating behavior of a particular protocol and is able to provide a signature to block any specific command within a particular protocol as is similar to what an application proxy firewall can provide. However, in addition to these similarities, there are some areas where an application proxy firewall excels compared to a network-based IPS. An application proxy firewall can provide address translation features while a network-based IPS cannot. With an application proxy firewall, one will also have less exposure to back-end servers because it is the firewall itself that will be exposed to the Internet while the real servers behind the firewall remain closed. This will not be the case if one is using a network-based IPS because a network-based IPS will allow a direct connection between the clients and the servers with no connection breaking mechanism such as in an application proxy firewall.

The detection approaches taken by current IPSs are quite similar to the approaches in current IDS technologies. They are signature-based, protocol anomaly and statistical/behavior-based. “Signature based” is simply a method wherein all the traffic packets are compared with a list of well-known attack patterns. Such methods can be very accurate as long as the attack string stays unchanged. However, like the problem faced by the intrusion detection system, such methods can be quite easily evaded as a simple or slight modification of the attack strings will elude the blocking in such a method. This method can effectively prevent worm propagation. Hence, it is important to consider this particular weakness when applying a pattern to a network-based IPS. Protocol anomaly detection is the method of comparing the traffic packets with the protocol standard defined in the RFC. The idea in this method is to ensure that the traffic contains protocol standards that meet the RFC guidelines. Hence, any attack attempts that possess malicious or non-standard protocol characteristics will be blocked. However, in real-world practice, this idea is not applied as expected. There are many IT products that do not respect the protocol standards drawn up in the RFC. That is why this particular method will likely generate a lot of false positives. Network IPSs also apply the behavior-based approach by defining some traffic characteristic of a specific application, such as packet length or information on a packet header and defining a threshold for some particular intrusion attempts like port scanning, password brute-force attempts, and other reconnaissance activities. It is also able to block backdoor traffic by identifying interactive traffic, such as very small network packets crossing back and forth. Other things that a network-based IPS can block include SYN flood attempts and IP spoofing, where any internal network packets sent from undefined IP addresses will simply be blocked. In addition, there is also a way for a network-based IPS to determine the operating system type of a particular host by incorporating the passive operating system and service application fingerprinting technology.

Although an IPS is able to do both the detection and prevention measures, a good IPS product would allow one to choose the different modes of operations in order to flexibly meet the particular security needs that one might have in different circumstances. At least two modes—inline and passive—must exist within a good IPS product. In inline mode, an IPS uses both its detection and prevention measures; while in passive mode, an IPS only utilizes its detection measure, which makes it work as an intrusion detection system. This passive mode is necessary when one needs to reveal the exposures in the security design, misconfigured network devices, and coordinated attacks within a particular network. This can be met by attaching the passive-mode IPS onto this particular network.

76.4.2 Host-Based IPS

A host-based IPS functions as the last line of defense. It is software-based and is installed in every host that needs to be protected. A host-based IPS usually consists of a management server and an agent. The agent is running between the application and the OS kernel. It is incorporated into a loadable kernel module if the host is a UNIX system, or a kernel driver if the host is a Windows system. It basically relies on a tight relationship with the operating system in which it is installed in order to provide robust protection. In this way, the agent can intercept system calls to the kernel, verify them against the access control lists or behavioral rules defined in the host-based IPS policy, and then decide either to allow or block access to particular resources such as disk read/write requests, network connection requests, attempts to modify the registry, or write to memory. Other features provided by a host-based IPS include being able to allow or block access based on predetermined rules, such as a particular application or user being unable to modify certain files or change certain data in the system registry. An HIPS can also have a sandbox, which prevents the mobile code or new application from accessing other objects on the system. In practice, a host-based IPS provides a good protection mechanism against known and unknown worms, key loggers, Trojan horses, rootkits, and backdoors attempting to alter system resources; and it can also prevent a malicious user with common user privilege from attempting to escalate its privileges. By having such a proactive prevention mechanism, a corporation can take a little slack in the due diligence of installing the system patches for its critical hosts.

76.4.3 Combating False Positives

A false positive is an event that occurs when a security device raises an alert or performs a prevention measure based upon a wrong interpretation. The existence of a false positive in an intrusion prevention system is much more critical than its existence in an intrusion detection system. When a false positive occurs in an IDS, no direct impact occurs unless the analyst falsely reacts by believing it was indeed a real attack attempt. However, this is not the case with IPS. When an IPS reacts wrongly upon a false positive, it will have a direct impact on users. Imagine that it is normal legitimate traffic that is identified as an attack attempt by the IPS. That traffic will be falsely blocked. Therefore, avoiding false positives is the greatest challenge for an IPS. Moreover, there is also a chance that malicious attackers will send a malicious packet using a spoofed source passing through the IPS to generate false positives, which at the end will cause a denial-of-service to the spoofed hosts if the IPS prevention rules are not carefully applied. When the block rule is used, the IPS will gracefully send TCP reset to the source; when the reject rule is used, the IPS will just drop the packet. If it is not a spoofing attack, the reject rule will "notify" the attacker that there is a security device in front of him because his system or network port can be "hanged." However, as with the IDS, there are also several ways to avoid the existence of false positives in intrusion prevention systems, and these include:

- *Fine-tuning the signature*. Having an accurate signature is the key to avoiding false alarms. One of the ways to obtain an accurate signature is to verify its relevancies. Do we need to apply a signature to watch for a IIS Unicode attack upon our Apache Web server? Do we need to apply a signature to watch for a Wu-ftpd exploit on our Windows-based FTP server? Narrowing the scope of the signatures will help in providing a more accurate signature and avoiding false alarms. Well understood network cartography and behavior in determining the profile for the protected networks are the key points to significantly reduce false positives.
- *Attacks correlation/compound detection*. Relying on more than one signature before deciding to block a particular access in order to have a more accurate detection will also help in avoiding false alarms. For example:
  - IPS will stop the X attack on FTP if it matches the A signature rule AND does not match the B protocol anomaly rule, AND if the destination host is the IIS server.
  - IPS will stop the attack if it matches the port scanning rule that came from a specific interface.
- *Mixed mode implementation*. As previously explained, there are several phases of an intrusion attempt, and each phase poses different severity levels. Therefore, applying different IPS modes upon various intrusion attempts based upon severity level can also help to avoid false positives. For example, it is better to just detect events such as port scanning instead of blocking it in order to avoid other legitimate traffic being falsely blocked by this event.

76.4.4 NIPS versus HIPS

A network-based IPS is indeed simpler to set up because it is operating system independent. In most cases, the installation of a host-based IPS requires more complex effort, such as ensuring that the business-critical application running on the protected hosts will not be affected by the host-based IPS agent, or verifying that the hardware resources in the protected host are adequate for both the business application and the host-based IPS agent. Exhibit 76.1 summarizes the strengths and weaknesses of NIPS and HIPS.

76.4.5 Applications

There are not many options for the application of a host-based IPS. HIPS must be installed on every host that needs to be protected. However, several options exist when considering the set-up of a network-based IPS. In most cases, a network-based IPS will be put at the network gateway/perimeter. It is more likely to be put at the internal side of the perimeter instead of the external side. Putting an inline IPS as the first layer of defense might impact its performance, make it vulnerable to denial-of-service, and become too noisy in terms of logging, especially when being utilized as an inline IDS at the same time. However, if the idea is to know every single external attack attempt aimed at the network, then putting the network-based IPS on the external side of the perimeter and activating it as a passive IPS, or putting an intrusion detection system on the external side, will be a more appropriate defensive solution. In addition to the network perimeter, having a network-based IPS at the DMZ side of the firewall—in particular, a VLAN or at the exit point of a VPN tunnel—can also help in providing a more intense defensive measure. One should consider putting a network-based IPS at the WAN backbone in an enterprise network in order to isolate and prevent any propagation of worms or viruses. However, it will be difficult to consider the place to put a network-based IPS in a multi gigabit speed, in a complex campus network architecture with multiple VLANs. Again, a passive IPS or IDS will be a more appropriate defensive solution in such an architecture.

EXHIBIT 76.1 Intrusion Prevention Systems

Strengths	Weaknesses
Network-Based Intrusion Prevention System	
Able to detect and prevent IP, TCP, and UDP attack in real-time	Being a single point of failure
Operating system independent	Cannot detect and prevent any encrypted attack
Does not cause server overhead as it is not installed in any protected host	May cause some impact on network performance
	May not keep up with network packets in a high-bandwidth environment
	Cannot detect and prevent an attack inside its geographical boundary
Host-Based Intrusion Prevention System	
Able to prevent an encrypted attack	Causes additional overhead to the servers/hosts where it is installed
Able to focus on application-specific attacks (operating systems, Web server, database server, etc.)	Can only detect and prevent attacks aimed at the host where it is installed
Able to detect and prevent a buffer overflow attack effectively	In an enterprise network, can be costly to deploy and cumbersome to manage
Many fewer false positives than NIPS	
Does not require additional hardware	

76.4.6 Possible Implementations of an IPS

76.4.6.1 Implementing and Exploiting an Effective Network-Based IPS

Although simpler to set up compared to a host-based IPS, further efforts are still required to get the most benefit of a network-based IPS (see Exhibit 76.2). It is essential to carefully plan the implementation of a network-based IPS because failure of proper implementation will seriously affect the entire network. Below are some critical points that should be addressed as the strategy for implementing a network-based IPS.

76.4.6.2 Purpose

The first thing to do: define the purpose of placing a network-based IPS within a particular network. One of the worthwhile purposes is to get an effective blocking response of rapidly spreading threats (e.g., virus or worm). A wildly spreading virus or worm usually poses a more static signature compared to a coordinated attack, where an attacker will likely modify his or her attack strings to avoid detection. Being able to accurately profile a virus or worm into a detection signature is good reason to utilize a network-based IPS. One other reason would be to have more granular filtering on a very sensitive and almost static network because there is no possibility of a false positive after a good fine-tuning period. For example, put a network-based IPS behind the DMZ interface of a firewall where the critical servers (such as transaction server, Internet banking servers, payment servers, etc.) are located.

76.4.6.3 Location

Bear in mind that putting a network-based IPS as the first layer of filtering, in most cases, is not suggested due to its principle of only blocking those specifically defined while allowing the rest. The first layer of filtering must have the principle of allowing those specifically defined while denying the rest. Only with this principle can an organization security policy be applied effectively. Therefore, the placement of a network-based IPS is always behind the first layer of a filtering device, which can be a filtering router or a firewall.

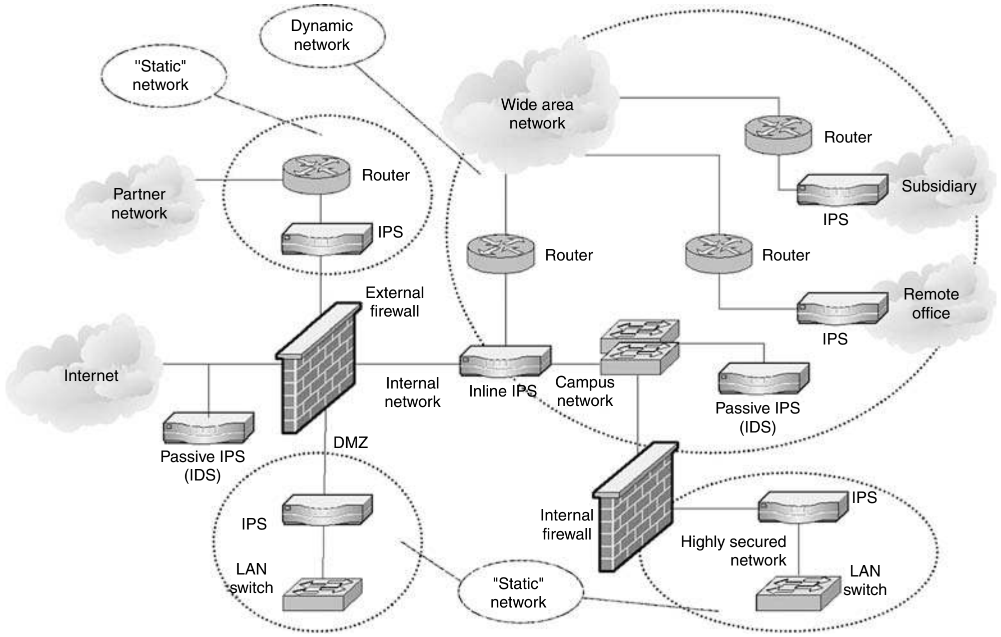

EXHIBIT 76.2 Possible implementations of IPS.

76.4.6.4 Performance Evaluation

Because it is likely to be placed at the gateway, preserving optimum network performance after the placement of a network-based IPS is essential. Bear in mind that all network traffic passing through it will be compared with every single rule applied to it. The more rules applied to it, the more likely the network performance degradation will be its trade-off. Hence, it is essential to make every single signature or rule within a network-based IPS as accurate and as meaningful as possible. In addition to network performance, it is also essential to evaluate the performance of the IPS itself. Similar to an IDS, an IPS must also maintain the TCP connection state, which in a large network with high-speed bandwidth will mean a large number of TCP connection states to maintain.

76.4.6.5 Storage Capacity

The disk capacity for storage purposes must be carefully managed to preserve loggings. In a circumstance where after or during a real attack, an attacker may try to do a "snow blind" attack at the IPS to fill up its disk in order to force the IPS administrator to delete its logs. This way, the logs containing the real attack attempted by the attacker will be deleted as well, thereby removing any chances of tracing back the attacker.

76.4.6.6 Availability

Because a disadvantage of an inline IPS is a single point of failure, an implementation inside an internal network where availability is most important, it is suggested that one install inline IPS in conjunction with a hardware fail-open box that monitors the heartbeat of the IPS (see Exhibit 76.3). So when the IPS is down, for whatever reason (e.g., system maintenance or hardware failure), it will not disrupt network service. Of course, during this period, fail-open will allow any traffic or attack attempts, such as worm propagation, to pass through the perimeter.

76.4.6.7 Management

The management of an IPS is very important and is becoming one of the biggest challenges during the implementation and operational phases. The capability to deploy standard and exception rules, the flexibility to send alerts, process logs and generate reports are the key points to manage an IPS well, This is true especially in the context of an enterprise deployment that consists of multiple IPSs processing a lot of traffic. A three-tier architecture is ideal for IPS management. It consists of an IPS device as the sensor; a management server, which includes a log and policy database; and a management console. Having such architecture will not impact the IPS performance during log processing and analysis, and provides "one-click" capability to deploy or remove standard rules.

76.4.6.8 Log Processing and Reporting

Reading and analyzing raw IPS logs is difficult and time consuming, especially when one must deal with an enormous quantity of logs generated by, for example, worm propagation. A good reporting tool helps

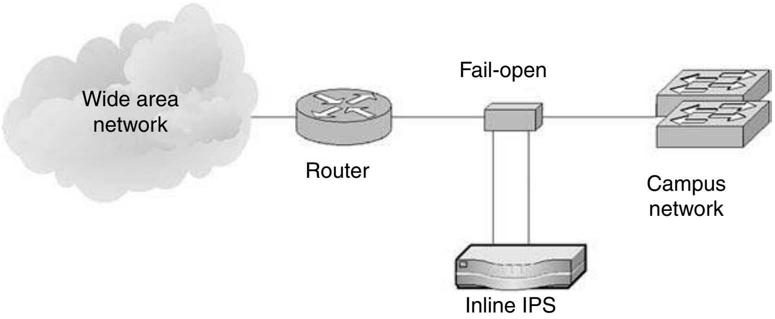

EXHIBIT 76.3 IPS in conjunction with fail-open box.

a lot—not only during the operational phase, but also during the learning process and the policy fine-tuning phase. Having a log suppression feature is very useful, especially during a major worm network infection where its propagation generates an enormous quantity of logging. With this feature, the reporting tool displays only a few log lines, instead of thousands of lines generated by the same infected host. Another important feature is the capability to generate a summary report based on the type of attack, source, destination, or timeframe.

76.4.6.9 Alert

An IPS that is able to send an alert to different system administrators using different methods, such as e-mail, pager, short message service (SMS), or executing a script or application, will provide for an efficient response time in case of attack detection and the false positive of a prevention rule. For example, when blocking an attack to or from a UNIX VLAN, the IPS informs both the IPS and UNIX administrators via e-mail. In case of a false positive, both administrators have the same level of information in real-time.

76.4.6.10 Application of the Attack Prevention Rule

Applying an active rule that prevents an attack by blocking a packet without the proper method is dangerous, due to a high probability of a denial-of-service attack by the IPS administrator. Before applying an active rule, the learning process and fine-tuning phases must be performed by the IPS administrator because enterprise internal networks are dynamic and quite often the IPS administrator has no latest update of systems documentation. Hence, ensuring the validity of systems information is very important. During this phase, the IPS administrator applies a passive rule (attack detection only) and analyzes all detected attacks. By using a profiler and contacting a related administrator, the IPS administrator can validate the detection rule.

76.5 Summary

The recent proliferation of IPS products has caused misinterpretation about their capabilities and has generated a very noisy marketplace for IPSs. In fact, an IPS is neither a security silver bullet, nor is it a new technology. It is simply a new product that combines two main security technologies: firewall/filtering and IDS. Hence, it is necessary to take the weaknesses of existing firewall and IDS technologies into consideration when evaluating an IPS. Each IPS design has its own strengths, features, and limitations. The appearance of an IPS in the security marketplace does not necessarily mean the doom for firewall and IDS technologies. In accordance with the multi-layered defense strategy, they are more complementary than dominating of each other. Depending on the objectives and provided with the appropriate security measures from these technologies, one will be able to build a solid defense architecture.

Penetration Testing

Stephen D. Fried

This chapter provides a general introduction to the subject of penetration testing and provides the security professional with the background needed to understand this special area of security analysis. Penetration testing can be a valuable tool for understanding and improving the security of a computer or network. However, it can also be used to exploit system weaknesses and attack systems and steal valuable information. By understanding the need for penetration testing, and the issues and processes surrounding its use, a security professional will be better able to use penetration testing as a standard part of the analysis toolkit.

This chapter presents penetration testing in terms of its use, application, and process. It is not intended as an in-depth guide to specific techniques that can be used to test penetration-specific systems. Penetration testing is an art that takes a great deal of skill and practice to do effectively. If not done correctly and carefully, the penetration test can be deemed invalid (at best) and, in the worst case, actually damage the target systems. If the security professional is unfamiliar with penetration testing tools and techniques, it is best to hire or contract someone with a great deal of experience in this area to advise and educate the security staff of an organization.

77.1 What is Penetration Testing?

Penetration testing is defined as a formalized set of procedures designed to bypass the security controls of a system or organization for the purpose of testing that system's or organization's resistance to such an attack. Penetration testing is performed to uncover the security weaknesses of a system and to determine the ways in which the system can be compromised by a potential attacker. Penetration testing can take several forms (which will be discussed later) but, in general, a test consists of a series of "attacks" against a target. The success or failure of the attacks, and how the target reacts to each attack, will determine the outcome of the test.

The overall purpose of a penetration test is to determine the subject's ability to withstand an attack by a hostile intruder. As such, the tester will be using the tricks and techniques a real-life attacker might use. This simulated attack strategy allows the subject to discover and mitigate its security weak spots before a real attacker discovers them.

The reason penetration testing exists is that organizations need to determine the effectiveness of their security measures. The fact that they want tests performed indicates that they believe there might be (or want to discover) some deficiency in their security. However, while the testing itself might uncover problems in the organization's security, the tester should attempt to discover and explain the underlying cause of the lapses in security that allowed the test to succeed. Simply stating that the tester was able to walk out of a building with sensitive information is not sufficient. The tester should explain that the lapse was due to inadequate attention by the guard on duty or a lack of guard staff training that would enable them to recognize valuable or sensitive information.

There are three basic requirements for a penetration test. First, the test must have a defined goal and that goal should be clearly documented. The more specific the goal, the easier it will be to recognize the success or failure of the test. A goal such as "break into the XYZ corporate network," while certainly attainable, is not as precise as "break into XYZ's corporate network from the Internet and gain access to the research department's file server." Each test should have a single goal. If the tester wishes to test several aspects of security at a business or site, several separate tests should be performed. This will enable the tester to more clearly distinguish between successful tests and unsuccessful attempts.

The test should have a limited time period in which it is to be performed. The methodology in most penetration testing is to simulate the types of attacks that will be experienced in the real world. It is reasonable to assume that an attacker will expend a finite amount of time and energy trying to penetrate a site. That time may range from one day to one year or beyond; but after that time is reached, the attacker will give up. In addition, the information being protected may have a finite useful "lifetime." The penetration test should acknowledge and accept this fact. Thus, part of the goal statement for the test should include a time limit that is considered reasonable based on the type of system targeted, the expected level of the threat, and the lifetime of the information.

Finally, the test should have the approval of the management of the organization that is the subject of the test. This is extremely important, as only the organization's management has the authority to permit this type of activity on its network and information systems.

77.2 Terminology

There are several terms associated with penetration testing. These terms are used throughout this chapter to describe penetration testing and the people and events involved in a penetration test.

The ***tester*** is the person or group who is performing the penetration test. The purpose of the tester is to plan and execute the penetration test and analyze the results for management. In many cases, the tester will be a member of the company or organization that is the subject of the test. However, a company may hire an outside firm to conduct the penetration test if it does not have the personnel or the expertise to do it itself.

An ***attacker*** is a real-life version of a tester. However, where the tester works with a company to improve its security, the attacker works against a company to steal information or resources.

An ***attack*** is the series of activities performed by the tester in an attempt to circumvent the security controls of a particular target. The attack may consist of physical, procedural, or electronic methods.

The ***subject*** of the test is the organization upon whom the penetration test is being performed. The subject can be an entire company or it can be a smaller organizational unit within that company.

A ***target*** of a penetration test is the system or organization that is being subjected to a particular attack at any given time. The target may or may not be aware that it is being tested. In either case, the target will have a set of defenses it presents to the outside world to protect itself against intrusion. It is those defenses that the penetration test is designed to test. A full penetration test usually consists of a number of attacks against a number of different targets.

Management is the term used to describe the leadership of an organization involved in the penetration test. There may be several levels of management involved in any testing effort, including the management of the specific areas of the company being tested, as well as the upper management of the company as a whole. The specific levels of management involved in the penetration testing effort will have a direct impact on the scope of the test. In all cases, however, it is assumed that the tester is working on behalf of (and sponsored by) at least one level of management within the company.

The ***penetration test*** (or, more simply, the ***test***) is the actual performance of a simulated attack on the target.

77.3 Why Test?

There are several reasons why an organization will want a penetration test performed on its systems or operations. The first (and most prevalent) is to determine the effectiveness of the security controls the organization has put into place. These controls may be technical in nature, affecting the computers, network, and information systems of the organization. They may be operational in nature, pertaining to the processes and procedures a company has in place to control and secure information. Finally, they may be physical in nature. The tester may be trying to determine the effectiveness of the physical security a site or company has in place. In all cases, the goal of the tester will be to determine if the existing controls are sufficient by trying to get around them.

The tester may also be attempting to determine the vulnerability an organization has to a particular threat. Each system, process, or organization has a particular set of threats to which it feels it is vulnerable. Ideally, the organization will have taken steps to reduce its exposure to those threats. The role of the tester is to determine the effectiveness of these countermeasures and to identify areas for improvement or areas where additional countermeasures are required. The tester may also wish to determine whether the set of threats the organization has identified is valid and whether or not there are other threats against which the organization might wish to defend itself.

A penetration test can sometimes be used to bolster a company's position in the marketplace. A test, executed by a reputable company and indicating that the subject's environment withstood the tester's best efforts, can be used to give prospective customers the appearance that the subject's environment is secure. The word "appearance" is important here because a penetration test cannot examine all possible aspects of the subject's environment if it is even moderate in size. In addition, the security state of an enterprise is constantly changing as new technology replaces old, configurations change, and business needs evolve. The "environment" the tester examines may be very different from the one the customer will be a part of. If a penetration test is used as proof of the security of a particular environment for marketing purposes, the customer should insist on knowing the details, methodology, and results of the test.

A penetration test can be used to alert the corporation's upper management to the security threat that may exist in its systems or operations. While the general knowledge that security weaknesses exist in a system, or specific knowledge of particular threats and vulnerabilities may exist among the technical staff, this message may not always be transmitted to management. As a result, management may not fully understand or appreciate the magnitude of the security problem. A well-executed penetration test can systematically uncover vulnerabilities that management was unaware existed. The presentation of concrete evidence of security problems, along with an analysis of the damage those problems can cause to the company, can be an effective wake-up call to management and spur them into paying more attention to information security issues. A side effect of this wake-up call may be that once management understands the nature of the threat and the magnitude to which the company is vulnerable, it may be more willing to expend money and resources to address not only the security problems uncovered by the test but also ancillary security areas needing additional attention by the company. These ancillary issues may include a general security awareness program or the need for more funding for security technology. A penetration test that uncovers moderate or serious problems in a company's security can be effectively used to justify the time and expense required to implement effective security programs and countermeasures.

77.4 Types of Penetration Testing

The typical image of a penetration test is that of a team of high-tech computer experts sitting in a small room attacking a company's network for days on end or crawling through the ventilation shafts to get into the company's "secret room." While this may be a glamorous image to use in the movies, in reality the penetration test works in a variety of different (and very nonglamorous) ways.

The first type of testing involves the physical infrastructure of the subject. Very often, the most vulnerable parts of a company are not found in the technology of its information network or the access controls found in its databases. Security problems can be found in the way the subject handles its physical security. The penetration tester will seek to exploit these physical weaknesses. For example, does the building provide adequate access control? Does the building have security guards, and do the guards check people as they enter or leave a building? If intruders are able to walk unchecked into a company's building, they will be able to gain physical access to the information they seek. A good test is to try to walk into a building during the morning when everyone is arriving to work. Try to get in the middle of a crowd of people to see if the guard is adequately checking the badges of those entering the building.

Once inside, check if sensitive areas of the building are locked or otherwise protected by physical barriers. Are file cabinets locked when not in use? How difficult is it to get into the communications closet where all the telephone and network communication links terminate? Can a person walk into employee office areas unaccompanied and unquestioned? All the secure and sensitive areas of a building should be protected against unauthorized entry. If they are not, the tester will be able to gain unrestricted access to sensitive company information.

While the physical test includes examining protections against unauthorized entry, the penetration test might also examine the effectiveness of controls prohibiting unauthorized exit. Does the company check for theft of sensitive materials when employees exit the facility? Are laptop computers or other portable devices registered and checked when entering and exiting the building? Are security guards trained not only on what types of equipment and information to look for, but also on how equipment can be hidden or masked and why this procedure is important?

Another type of testing examines the operational aspects of an organization. Whereas physical testing investigates physical access to company computers, networks, or facilities, operational testing attempts to determine the effectiveness of the operational procedures of an organization by attempting to bypass those procedures. For example, if the company's help desk requires each user to give personal or secret information before help can be rendered, can the tester bypass those controls by telling a particularly believable "sob story" to the technician answering the call? If the policy of the company is to "*scramble*" or demagnetize disks before disposal, are these procedures followed? If not, what sensitive information will the tester find on disposed disks and computers? If a company has strict policies concerning the authority and process required to initiate ID or password changes to a system, can someone simply claiming to have the proper authority (without any actual proof of that authority) cause an ID to be created, removed, or changed? All these are attacks against the operational processes a company may have, and all of these techniques have been used successfully in the past to gain entry into computers or gain access to sensitive information.

The final type of penetration test is the electronic test. Electronic testing consists of attacks on the computer systems, networks, or communications facilities of an organization. This can be accomplished either manually or through the use of automated tools. The goal of electronic testing is to determine if the subject's internal systems are vulnerable to an attack through the data network or communications facilities used by the subject.

Depending on the scope and parameters of a particular test, a tester may use one, two, or all three types of tests. If the goal of the test is to gain access to a particular computer system, the tester may attempt a physical penetration to gain access to the computer's console or try an electronic test to attack the machine over the network. If the goal of the test is to see if unauthorized personnel can obtain valuable research data, the tester may use operational testing to see if the information is tracked or logged when accessed or copied and determine who reviews those access logs. The tester may then switch to electronic penetration to gain access to the computers where the information is stored.

77.5 What Allows Penetration Testing to Work?

There are several general reasons why penetration tests are successful. Many of them are in the operational area; however, security problems can arise due to deficiencies in any of the three testing areas.

A large number of security problems arise due to a lack of awareness on the part of a company's employees of the company's policies and procedures regarding information security and protection. If employees and contractors of a company do not know the proper procedures for handling proprietary or sensitive information, they are much more likely to allow that information to be left unprotected. If employees are unaware of the company policies on discussing sensitive company information, they will often volunteer (sometimes unknowingly) information about their company's future sales, marketing, or research plans simply by being asked the right set of questions. The tester will exploit this lack of awareness and modify the testing procedure to account for the fact that the policies are not well-known.

In many cases, the subjects of the test will be very familiar with the company's policies and the procedures for handling information. Despite this, however, penetration testing works because often people do not adhere to standardized procedures defined by the company's policies. Although the policies may say that system logs should be reviewed daily, most administrators are too busy to bother. Good administrative and security practices require that system configurations should be checked periodically to detect tampering, but this rarely happens. Most security policies indicate minimum complexities and maximum time limits for passwords, but many systems do not enforce these policies. Once the tester knows about these security procedural lapses, they become easy to exploit.

Many companies have disjointed operational procedures. The processes in use by one organization within a company may often conflict with the processes used by another organization. Do the procedures used by one application to authenticate users complement the procedures used by other applications, or are there different standards in use by different applications? Is the access security of one area of a company's network lower than that of another part of the network? Are log files and audit records reviewed uniformly for all systems and services, or are some systems monitored more closely than others? All these are examples of a lack of coordination between organizations and processes. These examples can be exploited by the tester and used to get closer to the goal of the test. A tester needs only to target the area with the lower authentication standards, the lower access security, or the lower audit review procedures in order to advance the test.

Many penetration tests succeed because people often do not pay adequate attention to the situations and circumstances in which they find themselves. The hacker's art of social engineering relies heavily on this fact. Social engineering is a con game used by intruders to trick people who know secrets into revealing them. People who take great care in protecting information when at work (locking it up or encrypting sensitive data, for example) suddenly forget about those procedures when asked by an acquaintance at a party to talk about their work. Employees who follow strict user authentication and system change control procedures suddenly "forget" all about them when they get a call from the "Vice President of Such and Such" needing something done "right away." Does the "Vice President" himself usually call the technical support line with problems? Probably not, but people do not question the need for information, do not challenge requests for access to sensitive information even if the person asking for it does not clearly have a need to access that data, and do not compare the immediate circumstances with normal patterns of behavior.

Many companies rely on a single source for enabling an employee to prove identity, and often that source has no built-in protection. Most companies assign employee identification (ID) numbers to their associates. That number enables access to many services the company has to offer, yet is displayed openly on employee badges and freely given when requested. The successful tester might determine a method for obtaining or generating a valid employee ID number in order to impersonate a valid employee.

Many hackers rely on the anonymity that large organizations provide. Once a company grows beyond a few hundred employees, it becomes increasingly difficult for anyone to know all employees by sight or by voice. Thus, the IT and HR staff of the company need to rely on other methods of user authentication, such as passwords, key cards, or the above-mentioned employee ID number. Under such a system, employees become anonymous entities, identified only by their ID number or their password. This makes it easier to assume the identity of a legitimate employee or to use social engineering to trick people into divulging information. Once the tester is able to hide within the anonymous structure of the organization, the fear of discovery is reduced and the tester will be in a much better position to continue to test.

Another contributor to the successful completion of most penetration tests is the simple fact that most system administrators do not keep their systems up-to-date with the latest security patches and fixes for the systems under their control. A vast majority of system break-ins occur as a result of exploitation of known vulnerabilities—vulnerabilities that could have easily been eliminated by the application of a system patch, configuration change, or procedural change. The fact that system operators continue to let systems fall behind in security configuration means that testers will continuously succeed in penetrating their systems.

The tools available for performing a penetration test are becoming more sophisticated and more widely distributed. This has allowed even the novice hacker to pick up highly sophisticated tools for exploiting system weaknesses and applying them without requiring any technical background in how the tool works. Often these tools can try hundreds of vulnerabilities on a system at one time. As new holes are found, the hacker tools exploit them faster than the software companies can release fixes, making life even more miserable for the poor administrator who has to keep pace. Eventually, the administrator will miss something, and that something is usually the one hole that a tester can use to gain entry into a system.

77.6 Basic Attack Strategies

Every security professional who performs a penetration test will approach the task somewhat differently, and the actual steps used by the tester will vary from engagement to engagement. However, there are several basic strategies that can be said to be common across most testing situations.

First, do not rely on a single method of attack. Different situations call for different attacks. If the tester is evaluating the physical security of a location, the tester may try one method of getting in the building; for example walking in the middle of a crowd during the morning inrush of people. If that does not work, try following the cleaning people into a side door. If that does not work, try something else. The same method holds true for electronic attacks. If one attack does not work (or the system is not susceptible to that attack), try another.

Choose the path of least resistance. Most real attackers will try the easiest route to valuable information, so the penetration tester should use this method as well. If the test is attempting to penetrate a company's network, the company's firewall might not be the best place to begin the attack (unless, of course, the firewall was the stated target of the test) because that is where all the security attention will be focused. Try to attack lesser-guarded areas of a system. Look for alternate entry points; for example, connections to a company's business partners, analog dial-up services, modems connected to desktops, etc. Modern corporate networks have many more connection points than just the firewall, so use them to the fullest advantage.

Feel free to break the rules. Most security vulnerabilities are discovered because someone has expanded the limits of a system's capabilities to the point where it breaks, thus revealing a weak spot in the system. Unfortunately, most users and administrators concentrate on making their systems conform to the stated policies of the organization. Processes work well when everyone follows the rules, but can have unpredictable results when those rules are broken or ignored. Therefore, when performing a test attack, use an extremely long password; enter a 1000-byte URL into a Web site; sign someone else's name into a visitors log; try anything that represents abnormality or nonconformance to a system or process. Real attackers will not follow the rules of the subject system or organization—nor should the tester.

Do not rely exclusively on high-tech, automated attacks. While these tools may seem more "glamorous" (and certainly easier) to use, they may not always reveal the most effective method of entering a system. There are a number of "low-tech" attacks that, while not as technically advanced, may reveal important vulnerabilities and should not be overlooked. Social engineering is a prime example of this type of approach. The only tools required to begin a social engineering attack are the tester's voice, a telephone, and the ability to talk to people. Yet despite the simplicity of the method (or, perhaps, because of it), social engineering is incredibly effective as a method of obtaining valuable information.

"Dumpster diving" can also be an effective low-tech tool. Dumpster diving is a term used to describe the act of searching through the trash of the subject in an attempt to find valuable information. Typical information found in most Dumpsters includes old system printouts, password lists, employee personnel information, drafts of reports, and old fax transmissions. While not nearly as glamorous as running a port scan on a subject's computer, it also does not require any of the technical skill that port scanning requires. Nor does it involve the personal interaction required of social engineering, making it an effective tool for testers who may not be highly skilled in interpersonal communications.

One of the primary aims of the penetration tester is to avoid detection. The basic tenet of penetration testing is that information can be obtained from a subject without his or her knowledge or consent. If a tester is caught in the act of testing, this means, by definition, that the subject's defenses against that particular attack scenario are adequate. Likewise, the tester should avoid leaving "fingerprints" that can be used to detect or trace an attack. These fingerprints include evidence that the tester has been working in and around a system. The fingerprints can be physical (e.g., missing reports, large photocopying bills) or they can be virtual (e.g., system logs detailing access by the tester, or door access controls logging entry and exit into a building). In either case, fingerprints can be detected and detection can lead to a failure of the test.

Do not damage or destroy anything on a system unless the destruction of information is defined as part of the test and approved (in writing) by management. The purpose of a penetration test is to uncover flaws and weaknesses in a system or process—not to destroy information. The actual destruction of company information not only deprives the company of its (potentially valuable) intellectual property, but it may also be construed as unethical behavior and subject the tester to disciplinary or legal action. If the management of the organization wishes the tester to demonstrate actual destruction of information as part of the test, the tester should be sure to document the requirement and get written approval of the management involved in the test. Of course, in the attempt to "not leave fingerprints," the tester might wish to alter the system logs to cover the tester's tracks. Whether or not this is acceptable is an issue that the tester should discuss with the subject's management before the test begins.

Do not pass up opportunities for small incremental progress. Most penetration testing involves the application of many tools and techniques in order to be successful. Many of these techniques will not completely expose a weakness in an organization or point to a failure of an organization's security. However, each of these techniques may move the tester closer and closer to the final goal of the test. By looking for a single weakness or vulnerability that will completely expose the organization's security, the tester may overlook many important, smaller weaknesses that, when combined, are just as important. Real-life attackers can have infinite patience; so should the tester.

Finally, be prepared to switch tactics. Not every test will work, and not every technique will be successful. Most penetration testers have a standard "toolkit" of techniques that work on most systems. However, different systems are susceptible to different attacks and may call for different testing measures. The tester should be prepared to switch to another method if the current one is not working. If an electronic attack is not yielding the expected results, switch to a physical or operational attack. If attempts to circumvent a company's network connectivity are not working, try accessing the network through the company's dial-up connections. The attack that worked last time may not be successful this time, even if the subject is the same company. This may either be because something has changed in the target's environment or the target has (hopefully) learned its lesson from the last test. Finally, unplanned opportunities may present themselves during a test. Even an unsuccessful penetration attempt may expose the possibility that other types of attack may be more successful. By remaining flexible and willing to switch tactics, the tester is in a much better position to discover system weaknesses.

77.7 Planning the Test

Before any penetration testing can take place, a clear testing plan must be prepared. The test plan will outline the goals and objectives of the test, detail the parameters of the testing process, and describe the expectations of both the testing team and the management of the target organization.

The most important part of planning any penetration test is the involvement of the management of the target organization. Penetration testing without management approval, in addition to being unethical, can reasonably be considered "espionage" and is illegal in most jurisdictions. The tester should fully document the testing engagement in detail and get written approval from management before proceeding. If the testing team is part of the subject organization, it is important that the management of that organization knows about the team's efforts and approves of them. If the testing team is outside the organizational structure and is performing the test "for hire," the permission of management to perform the test should be included as part of the contract between the testing organization and the target organization. In all cases, be sure that the management that approves the test has the authority to give such approval. Penetration testing involves attacks on the security infrastructure of an organization. This type of action should not be approved or undertaken by someone who does not clearly have the authority to do so.

By definition, penetration testing involves the use of simulated attacks on a system or organization with the intent of penetrating that system or organization. This type of activity will, by necessity, require that someone in the subject organization be aware of the testing. Make sure that those with a need to know about the test do, in fact, know of the activity. However, keep the list of people aware of the test to an absolute minimum. If too many people know about the test, the activities and operations of the target may be altered (intentionally or unintentionally) and negate the results of the testing effort. This alteration of behavior to fit expectations is known as the Hawthorne effect (named after a famous study at Western Electric's Hawthorne factory whose employees, upon discovering that their behavior was being studied, altered their behavior to fit the patterns they believed the testers wanted to see).

Finally, during the course of the test, many of the activities the tester will perform are the very same ones that real-life attackers will use to penetrate systems. If the staff of the target organization discovers these activities, they may (rightly) mistake the test for a real attack and catch the "attacker" in the act. By making sure that appropriate management personnel are aware of the testing activities, the tester will be able to validate the legitimacy of the test.

An important ethical note to consider is that the act of penetration testing involves intentionally breaking the rules of the subject organization in order to determine its security weaknesses. This requires the tester to use many of the same tools and methods that real-life attackers use. However, real hackers sometime break the law or engage in highly questionable behavior in order to carry out their attacks. The security professional performing the penetration test is expected to draw the line between bypassing a company's security procedures and systems, and actually breaking the law. These distinctions should be discussed with management prior to the commencement of the test, and discussed again if any ethical or legal problems arise during the execution of the test.

Once management has agreed to allow a penetration test, the parameters of the test must be established. The testing parameters will determine the type of test to be performed, the goals of the tests, and the operating boundaries that will define how the test is run. The primary decision is to determine precisely what is being tested. This definition can range from broad ("test the ability to break into the company's network") to extremely specific ("determine the risk of loss of technical information about XYZ's latest product"). In general, more specific testing definitions are preferred, as it becomes easier to determine the success or failure of the test. In the case of the second example, if the tester is able to produce a copy of the technical specifications, the test clearly succeeded. In the case of the first example, does the act of logging in to a networked system constitute success, or does the tester need to produce actual data taken from the network? Thus, the specific criteria for success or failure should be clearly defined.

The penetration test plan should have a defined time limit. The time length of the test should be related to the amount of time a real adversary can be expected to attempt to penetrate the system and also the reasonable lifetime of the information itself. If the data being attacked has an effective lifetime of two months, a penetration test can be said to succeed if it successfully obtains that data within a two-month window.

The test plan should also explain any limits placed on the test by either the testing team or management. If there are ethical considerations that limit the amount of "damage" the team is willing to perform, or if there are areas of the system or operation that the tester is prohibited from accessing (perhaps for legal or contractual reasons), these must be clearly explained in the test plan. Again, the testers will attempt to act as real-life attackers and attackers do not follow any rules. If management wants the testers to follow certain rules, these must be clearly defined. The test plan should also set forth the procedures and effects of "getting caught" during the test. What defines "getting caught" and how that affects the test should also be described in the plan.

Once the basic parameters of the test have been defined, the test plan should focus on the "scenario" for the test. The scenario is the position the tester will assume within the company for the duration of the test. For example, if the test is attempting to determine the level of threat from company insiders (employees, contractors, temporary employees, etc.), the tester may be given a temporary job within the company. If the test is designed to determine the level of external threat to the organization, the tester will assume the position of an "outsider." The scenario will also define the overall goal of the test. Is the purpose of the test a simple penetration of the company's computers or facilities? Is the subject worried about loss of intellectual property via physical or electronic attacks? Are they worried about vandalism to their Web site, fraud in their electronic commerce systems, or protection against denial-of-service attacks? All these factors help to determine the test scenario and are extremely important in order for the tester to plan and execute an effective attack.

77.8 Performing the Test

Once all the planning has been completed, the test scenarios have been established, and the tester has determined the testing methodology, it is time to perform the test. In many aspects, the execution of a penetration test plan can be compared to the execution of a military campaign. In such a campaign, there are three distinct phases: reconnaissance, attack, and (optionally) occupation.

During the reconnaissance phase (often called the "discovery" phase), the tester will generally survey the "scene" of the test. If the tester is planning a physical penetration, the reconnaissance stage will consist of examining the proposed location for any weaknesses or vulnerabilities. The tester should look for any noticeable patterns in the way the site operates. Do people come and go at regular intervals? If there are guard services, how closely do they examine people entering and leaving the site? Do they make rounds of the premises after normal business hours, and are those rounds conducted at regular times? Are different areas of the site occupied at different times? Do people seem to all know one another, or do they seem to be strangers to each other. The goal of physical surveillance is to become as completely familiar with the target location as possible and to establish the repeatable patterns in the site's behavior. Understanding those patterns and blending into them can be an important part of the test.

If an electronic test is being performed, the tester will use the reconnaissance phase to learn as much about the target environment as possible. This will involve a number of mapping and surveillance techniques. However, because the tester cannot physically observe the target location, electronic probing of the environment must be used. The tester will start by developing an electronic "map" of the target system or network. How is the network laid out? What are the main access points, and what type of equipment runs the network? Are the various hosts identifiable, and what operating systems or platforms are they running? What other networks connect to this one? Is dial-in service available to get into the network, and is dial-out service available to get outside?

Reconnaissance does not always have to take the form of direct surveillance of the subject's environment. It can also be gathered in other ways that are more indirect. For example, some good places to learn about the subject are:

- Former or disgruntled employees
- Local computer shows
- Local computer club meetings
- Employee lists, organization structures
- Job application handouts and tours
- Vendors who deliver food and beverages to the site

All this information will assist the tester in determining the best type of attack(s) to use based on the platforms and services available. For each environment (physical or electronic), platform, or service found during the reconnaissance phase, there will be known attacks or exploits that the tester can use. There may also be new attacks that have not yet made it into public forums. The tester must rely on the experience gained in previous tests and the knowledge of current events in the field of information security to keep abreast of possible avenues of attack.

The tester should determine (at least preliminarily) the basic methods of attack to use, the possible countermeasures that may be encountered, and the responses that may be used to those countermeasures.

The next step is the actual attack on the target environment. The attack will consist of exploiting the weaknesses found in the reconnaissance phase to gain entry to the site or system and to bypass any controls or restrictions that may be in place. If the tester has done a thorough job during the reconnaissance phase, the attack phase becomes much easier.

Timing during the attack phase can be critical. There may be times when the tester has the luxury of time to execute an attack, and this provides the greatest flexibility to search, test, and adjust to the environment as it unfolds. However, in many cases, an abundance of time is not available. This may be the case if the tester is attempting to enter a building in between guard rounds, attempting to gather information from files during the owner's lunch hour, or has tripped a known alarm and is attempting to complete the attack before the system's intrusion response interval (the amount of time between the recognition of a penetration and the initiation of the response or countermeasure) is reached. The tester should have a good idea of how long a particular attack should take to perform and should have a reasonable expectation that it can be performed in the time available (barring any unexpected complications).

If, during an attack, the tester gains entry into a new computer or network, the tester may elect to move into the occupation phase of the attack. Occupation is the term used to indicate that the tester has established the target as a base of operations. This may be because the tester wants to spend more time on the target gathering information or monitoring the state of the target, or the tester may want to use the target as a base for launching attacks against other targets. The occupation phase presents perhaps the greatest danger to the tester, because the tester will be exposed to detection for the duration of the time he or she is resident in the target environment. If the tester chooses to enter the occupation phase, steps should be taken to make the tester's presence undetectable to the greatest extent possible.

It is important to note that a typical penetration test may repeat the reconnaissance/attack/occupation cycle many times before the completion of the test. As each new attack is prepared and launched, the tester must react to the attack results and decide whether to move on to the next step of the test plan, or abandon the current attack and begin the reconnaissance for another type of attack. Through the repeated and methodical application of this cycle, the tester will eventually complete the test.

Each of the two basic test types—physical and electronic—has different tools and methodologies. Knowledge of the strengths and weaknesses of each type will be of tremendous help during the execution of the penetration test. For example, physical penetrations generally do not require an in-depth knowledge of technical information. While they may require some specialized technical experience (bypassing alarm systems, for example), physical penetrations require skills in the area of operations security, building and site operations, human nature, and social interaction.

The "tools" used during a physical penetration vary with each tester, but generally fall into two general areas: abuse of protection systems and abuse of social interaction. Examples of abuse of protection systems include walking past inattentive security guards, piggybacking (following someone through an access-controlled door), accessing a file room that is accidentally unlocked, falsifying an information request, or picking up and copying information left openly on desks. Protection systems are established to protect the target from typical and normal threats. Knowledge of the operational procedures of the target will enable the tester to develop possible test scenarios to test those operations in the face of both normal and abnormal threats.

Lack of security awareness on the part of the victim can play a large part in any successful physical penetration test. If people are unaware of the value of the information they possess, they are less likely to protect it properly. Lack of awareness of the policies and procedures for storing and handling sensitive information is abundant in many companies. The penetration tester can exploit this in order to gain access to information that should otherwise be unavailable.

Finally, social engineering is perhaps the ultimate tool for effective penetration testing. Social engineering exploits vulnerabilities in the physical and process controls, adds the element of "insider" assistance, and combines it with the lack of awareness on the part of the subject that they have actually contributed to the penetration. When done properly, social engineering can provide a formidable attack strategy.

Electronic penetrations, on the other hand, generally require more in-depth technical knowledge than do physical penetrations. In the case of many real-life attackers, this knowledge can be their own or "borrowed" from somebody else. In recent years, the technical abilities of many new attackers seem to have decreased, while the high availability of penetration and attack tools on the Internet, along with the sophistication of those tools, has increased. Thus, it has become relatively simple for someone without a great deal of technical knowledge to "borrow" the knowledge of the tool's developer and inflict considerable damage on a target. There are, however, still a large number of technically advanced attackers out there with the skill to launch a successful attack against a system.

The tools used in an electronic attack are generally those that provide automated analysis or attack features. For example, many freely available host and network security analysis tools provide the tester with an automated method for discovering a system's vulnerabilities. These are vulnerabilities that the skilled tester may be able to find manually, but the use of automated tools provides much greater efficiency. Likewise, tools like port scanners (that tell the tester what ports are in use on a target host), network "sniffers" (that record traffic on a network for later analysis), and "war dialers" (that systematically dial phone numbers to discover accessible modems) provide the tester with a wealth of knowledge about weaknesses in the target system and possible avenues the tester should take to exploit those weaknesses.

When conducting electronic tests there are three basic areas to exploit: the operating system, the system configuration, and the relationship the system has to other systems. Attacks against the operating system exploit bugs or holes in the platform that have not yet been patched by the administrator or the manufacturer of the platform. Attacks against the system configuration seek to exploit the natural tendency of overworked administrators not to keep up with the latest system releases and to overlook such routine tasks as checking system logs, eliminating unused accounts, or improper configuration of system elements. Finally, the tester can exploit the relationship a system has with respect other systems to which it connects. Does it have a trust relationship with a target system? Can the tester establish administrative rights on the target machine through another machine? In many cases, a successful penetration test will result not from directly attacking the target machine, but from first successfully attacking systems that have some sort of “relationship” to the target machine.

77.9 Reporting Results

The final step in a penetration test is to report the findings of the test to management. The overall purpose and tone of the report should actually be set at the beginning of the engagement with management’s statement of their expectation of the test process and outcome. In effect, what the tester is asked to look for will determine, in part, the report that is produced. If the tester is asked to examine a company’s overall physical security, the report will reflect a broad overview of the various security measures the company uses at its locations. If the tester is asked to evaluate the controls surrounding a particular computer system, the report will most likely contain a detailed analysis of that machine.

The report produced as a result of a penetration test contains extremely sensitive information about the vulnerabilities the subject has and the exact attacks that can be used to exploit those vulnerabilities. The penetration tester should take great care to ensure that the report is only distributed to those within the management of the target who have a need-to-know. The report should be marked with the company’s highest sensitivity label. In the case of particularly sensitive or classified information, there may be several versions of the report, with each version containing only information about a particular functional area.

The final report should provide management with a replay of the test engagement in documented form. Everything that happened during the test should be documented. This provides management with a list of the vulnerabilities of the target and allows them to assess the methods used to protect against future attacks.

First, the initial goals of the test should be documented. This will assist anyone who was not part of the original decision-making process in becoming familiar with the purpose and intent of the testing exercise. Next, the methodology used during the test should be described. This will include information about the types of attacks used, the success or failure of those attacks, and the level of difficulty and resistance the tester experienced during the test. While providing too much technical detail about the precise methods used may be overly revealing and (in some cases) dangerous, the general methods and procedures used by the testing team should be included in the report. This can be an important tool for management to get a sense of how easy or difficult it was for the testing team to penetrate the system. If countermeasures are to be put in place, they will need to be measured for cost-effectiveness against the value of the target and the vulnerabilities found by the tester. If the test revealed that a successful attack would cost the attacker U.S.$10 million, the company might not feel the need for additional security in that area. However, if the methodology and procedures show that an attack can be launched from the Internet for the price of a home computer and an Internet connection, the company might want to put more resources into securing the target.

The final report should also list the information found during the test. This should include information about what was found, where it was found, how it was found, and the difficulty the tester had in finding it. This information is important to give management a sense of the depth and breadth of the security problems uncovered by the test. If the list of items found is only one or two items long, it might not trigger a large response (unless, of course, the test was only looking for those one or two items). However, if the list is several pages long, it might spur management into making dramatic improvements in the company’s security policies and procedures.

The report should give an overall summary of the security of the target in comparison with some known quantity for analysis. For example, the test might find that 10 percent of the passwords on the subject’s computers were easily guessed. However, previous research or the tester’s own experience might show that the average computer on the Internet or other clients contains 30 percent easily guessed passwords. Thus, the company is actually doing better than the industry norm. However, if the report shows that 25 percent of the guards in the company's buildings did not check for employee badges during the test, that would most likely be considered high and be cause for further action.

The report should also compare the initial goals of the test to the final result. Did the test satisfy the requirements set forth by management? Were the results expected or unexpected, and to what degree? Did the test reveal problems in the targeted area, or were problems found in other unrelated areas? Was the cost or complexity of the tests in alignment with the original expectations of management?

Finally, the report should also contain recommendations for improvement of the subject's security. The recommendations should be based on the findings of the penetration test and include not only the areas covered by the test, but also ancillary areas that might help improve the security of the tested areas. For example, inconsistent system configuration might indicate a need for a more stringent change control process. A successful social engineering attempt that allowed the tester to obtain a password from the company's help desk might lead to better user authentication requirements.

77.10 Conclusion

Although it seems to parallel the activities of real attackers, penetration testing, in fact, serves to alert the owners of computers and networks to the real dangers present in their systems. Other risk analysis activities, such as automated port scanning, war dialing, and audit log reviews, tend to point out the theoretical vulnerabilities that might exist in a system. The owner of a computer will look at the output from one of these activities and see a list of holes and weak spots in a system without getting a good sense of the actual threat these holes represent. An effective penetration test, however, will show that same system owner the actual damage that can occur if those holes are not addressed. It brings to the forefront the techniques that can be used to gain access to a system or site and makes clear the areas that need further attention. By applying the proper penetration testing techniques (in addition to the standard risk analysis and mitigation strategies), the security professional can provide a complete security picture of the subject's enterprise.

Auditing Cryptography: Assessing System Security

Steve Stanek

After a start-up data security firm applied for a patent for its newly developed encryption algorithm, the company issued a public challenge: it promised to pay $5000 to anyone who could break the algorithm and another $5000 to the person's favorite charity.

William Russell, an Andersen technology risk manager, accepted the challenge. He is now $5000 richer, his charity is waiting for its money, and the data security firm has run out of business because Russell cracked the supposedly uncrackable code. It took him about 60 hours of work, during which time he developed a program to predict the correct encryption key. His program cracked the code after trying 6120 out of a possible 1,208,925,819,614,629,174,706,176 electronic keys. Clearly, it should not have been as easy as that!

78.1 Assessing Risk

In the course of performing a security risk assessment, auditors or security professionals may learn that cryptographic systems were used to address business risks. However, sometimes the cryptographic systems themselves are not reviewed or assessed—potentially overlooking an area of business risk to the organization.

Russell believes there is a lesson in this for information technology auditors: when it comes to encryption technology, rely on the tried and true. "You want the company to be using well-known, well-tested algorithms," Russell says. "Never use private encryption. That goes under the assumption that someone can create something that's as good as what's on the market. The reality is that there are only a few hundred people in the world who can do it well. Everyone else is hoping nobody knows their algorithm. That's a bad assumption."

Russell recently worked with a client who asked him to look at one of the company's data systems, which was secured with encryption technology developed in-house. Russell cracked that system's security application in 11 hours. "If it had been a well-known, well-tested algorithm, something like that would not have been at all likely," Russell says.

78.2 Encryption's Number-One Problem: Keeping Keys Secret

Security professionals who use cryptography rely on two factors for the security of the information protected by the cryptographic systems: (1) the rigor of the algorithm against attack and (2) the secrecy of the key that is used to encrypt the sensitive information. Because security professionals advocate well-documented and scrutinized algorithms, they assume that the algorithm used by the cryptographic system has been compromised by an attacker; thus the security professional ultimately relies on the protection of the keys used in the algorithm.

The more information encrypted with a key, the greater the harm if that key is compromised. So it stands to reason that keys must be changed from time to time to mitigate the risk of information compromise. The length of time a key is valid in a crypto-system is referred to as the cryptographic key period and is determined by factors such as the sensitivity of the information, the relative difficulty to "guess" the keys by a known crypto-analysis technique, and the environment in which the crypto-system functions and operates. While changing keys is important, it can be very costly, depending on the type of cryptography used, the storage media of the keying material, and the distribution mechanism of the keying material. It is a business decision on how to effectively balance security risk with cost, performance, and functionality within the business context.

Keys that can be accessed and used by attackers pose a serious security problem, and all aspects of the security program within an enterprise must be considered when addressing this issue. For example, ensure that the keys are not accessible by unauthorized individuals, that appropriate encryption is used to protect the keying material, that audit trails are maintained and protected, and that processes exist to prevent unauthorized modification of the keying material.

While cryptography is a technology subject, effective use of cryptography within a business is not just a technology issue.

78.3 Encryption's Number-One Rule

According to Mark Wilson, vice president of engineering at Embedics, a data security software and hardware design firm in Columbia, Maryland, "The No. 1 rule is that encryption needs to be based on standards." You want to follow well-known specifications for algorithms. For public key, you want to use an authenticated key agreement mechanism with associated digital signatures.

"A lot of people are trying new technologies for public key-based schemes. Most of the time they are not using published standards. They're not open to scrutiny. There are also often interoperability problems." Interoperability is important because it allows vendors to create cryptographic products that will seamlessly integrate with other applications. For example, vendors planning to develop cryptographic hardware should follow the RSA PKCS #11 standard for cryptographic hardware. If they do, then their product will work with several applications seamlessly, including Lotus Notes.

Russell and Wilson agree that even if a company is using widely tested and accepted encryption technologies, its data can be exposed to prying eyes. One Andersen client encrypted highly sensitive information using an encryption key, but the key was stored on a database that was not properly secured. Consequently, several individuals could have obtained the encryption key and accessed highly sensitive information without being noticed.

"Encryption is an important component of security, but it must be seen as a part of the whole. Encryption by itself doesn't solve anything, but as part of a system it can give security and confidence," says Russell.

Auditors also need to evaluate network, physical, and application security, and ask what algorithms the company is using and if they are commonly accepted. For example, Wilson says he often encounters companies that use good encryption technology but do not encrypt every dial-up port. Very important, too, is that while cryptography may be an important component of the technology component of security, process (including policies and procedures) and people (including organization, training) also are key factors in successful security within the enterprise. "A lot of times they have a secure encryptor, but the dial-up port is open," Wilson says. "They should look at secure modems for dial-in. The problem comes in the actual outside support for networks that have unsecured modems on them."

78.4 Remember to Encrypt E-Mail

Russell says that, in his view, the most common mistake is in e-mail. "Information is sent all the time internally that is sensitive and accessible," he says. "Ideas, contracts, product proposals, client lists, all kinds of stuff goes through e-mail, yet nobody considers it as an important area to secure. Nearly all organizations have underestimated the need to encrypt e-mail."

Most firms are using encryption somewhere within their organization, particularly for secure Web pages. While this protects information at the front end, it does not protect it at the back end, according to Russell. "On the back end, inside the company, somebody could get that information," he says. He suggests asking who should have access to it and how can it be kept out of everyone else's hands.

"Anything you consider sensitive information that you don't want to get into the wrong hands, you should consider encrypting," Russell says. "It must be sensitive and potentially accessible. If a computer is locked in a vault and nobody can get to it, it doesn't need encryption. If that computer is on a network, it becomes vulnerable."

Russell suggests internal auditors ask the following questions when evaluating security applications.

78.4.1 Does the Vendor Have Credibility in Security Circles?

As security awareness has increased, so has the number of security start-ups. Many of them are unqualified, according to Russell. Look for companies that frequent security conferences, such as RSA Security Inc.'s annual conference. Also look for vendors that are recognized in security journals. Although doing this is not foolproof, it will narrow the field of credible vendors. Depending on the criticality of the system and the intended investment, it may be best to solicit the help of a security consultant.

78.4.2 Does the Product Use Well-Known Cryptographic Algorithms?

The marketing of security applications tends to be an alphabet soup of acronyms. For this reason, it is helpful to know which ones really matter. There are essentially three categories of algorithms: asymmetric key, symmetric key, and hashing. Asymmetric key algorithms are normally used for negotiating a key between two parties. Symmetric key algorithms are normally used for traffic encryption. And hashing is used to create a message digest, which is a number computationally related to the message. It is generally used in relationship with an asymmetric key algorithm to create digital signatures. It also should be noted that although these three categories of algorithms are typical of new systems that are being built today, there exist many legacy applications at larger companies using crypto-systems from the 1970s. Because of the high associated costs, many of these companies have not been retrofitted with the "appropriate" form of cryptography.

The following list represents a few of the more popular algorithms that are tried and true:

- *RSA*. Named after Rivest, Shamir, and Adleman who created it, this asymmetric key algorithm is used for digital signatures and key exchanges.

- *Triple DES*. This algorithm uses the Data Encryption Standard three times in succession in order to provide 112-bit encryption. If it uses three keys, then sometimes it is referred to as having 168-bit encryption.
- *RC4*. This is a widely used variable-key-size symmetric key encryption algorithm that was created by RSA. The algorithm should be used with 128-bit encryption.
- *AES*. Advanced Encryption Standard is a new symmetric key algorithm also known as Rijndael. This new standard is intended to replace DES for protecting sensitive information.
- *SHA1*. The Secure Hash Algorithm was developed by the U.S. government. This algorithm is used for creating message digests and may be used to create a digital signature.
- *MD5*. Message Digest 5 was created by RSA, and is used to create message digests. It is frequently used with an asymmetric key algorithm to create a digital signature.

78.4.3 Does the Product Use SSL v3.0?

Secure Sockets Layer v3.0 is a transport-layer security protocol that is responsible for authenticating one or both parties, negotiating a key exchange, selecting an encryption algorithm, and transferring data securely. Although not every application needs to send information to another computer using this protocol, using it avoids some of the possible pitfalls that may go unnoticed in the development of a proprietary protocol.

78.4.4 Does the Company Report and Post Bug Fixes for Security Weaknesses?

No product is ever perfectly secure, but some vendors want you to think they are. When a company posts bug fixes and notices for security weaknesses, this should be considered a strength. This means they are committed to security, regardless of the impression it might give otherwise.

78.4.5 Does the Product Use an Accepted Random Number Generator to Create Keys?

Random number generators are notoriously difficult to implement. When they are implemented incorrectly, their output becomes predictable, negating the randomness required. Regardless of the encryption algorithm used, a sensitive message can be compromised if the key protecting it is predictable. RSA is currently developing a standard to address this issue. It will be called PKCS #14.

78.4.6 Does the Product Allow for Easy Integration of Hardware Tokens to Store Keys?

Whenever keys are stored as a file on a computer, they are accessible. Often the business case will determine the level of effort used to protect the keys, but the best protection for encryption keys is hardware. Smart cards and PCMCIA cards are often used for this purpose. An application should have the ability to utilize these hardware tokens seamlessly.

78.4.7 Has the Product Received a Federal Information Processing Standards (FIPS) 140-1 Verification?

The National Institute of Standards and Technology (NIST) has created a government-approved standard, referred to as FIPS 140-1, for cryptographic modules. NIST created four levels, which correspond to increasing levels of security. Depending on whether the crypto-module is a stand-alone component or one that is embedded in a larger component, and whether the crypto-model is a hardware device or a software implementation, the crypto-module is subjected to varying requirements to achieve specific validation levels. Issues such as tamper detection and response are addressed at Level 3 (that is, the ability for the cryptographic module to sense when it is being tampered with and to take appropriate action to zeroize the cryptographic keying material and sensitive unencrypted information within the module at the time of tamper). Level 4 considers the operating environment and requires that the module appropriately handle cryptographic security when the module is exposed to temperatures and voltages that are outside of the normal operating range of the module. Because FIPS 140-1 validation considered both the design and implementation of cryptographic modules, the following 11 components are scrutinized during the validation:

1. Basic design and documentation
2. Module interfaces
3. Roles and services
4. Finite state machine model
5. Physical security
6. Software security
7. Operating system security
8. Key management
9. Cryptographic algorithms
10. Electromagnetic compatibility (EMC/EMI)
11. Self-test

"Although no checklist will help you to avoid every security weakness, asking these questions could help you to avoid making a potentially bad decision," Russell says.

Cryptographic Transitions

Ralph Spencer Poore

Change is inevitable. As businesses adopted commercial cryptography as an important tool in protecting information, they transitioned from either reliance solely on physical security measures or, more often, reliance on no intentional protection to either a proprietary cryptographic process (e.g., PGP) or the, then newly established, federal cryptographic standard: Data Encryption Standard (DES). Cryptography, however, always includes a balancing of efficient use with effective security. This means that cryptographic techniques that provide computational efficiency sufficient to permit operational use in a commercial setting will degrade in security effectiveness as computational power increases (a corollary to Moore's Law). Cryptographic protocols and algorithms may also fall prey to advances in mathematics and cryptanalysis. Specific implementations believed secure when originally deployed may fail because of technological obsolesces of hardware or software components on which they depended. New technologies may permit previously infeasible attacks. Regardless of the specific reason, organizations will find it necessary to transition from one cryptographic security solution to another at some point in their existence.

Cryptographic transitions is the process by which an organization addresses the problems associated with updating (or initially implementing) cryptographic security measures in response to changes in the environment that require better information security. This chapter addresses a myriad of environmental changes that might motivate a cryptographic transition, including both technological and business events. It will then describe a process for such transitions.

79.1 Technological Obsolescence

Cryptographic implementations become technologically obsolete either when aspects of the cryptography itself cease to provide the appropriate levels of assurance or when the technology (e.g., hardware or software) on which it is based becomes obsolete.

Advanced cryptanalytic capabilities and faster computers have made the Data Encryption Algorithm (also known as the Data Encryption Standard—DES) obsolete. DES has long outlived its effectiveness except, perhaps, as Triple DES. Although cryptographic advances have produced the Advanced Encryption Standard (AES) that provides better security and higher efficiency than Triple DES when equivalent implementations (i.e., hardware versus hardware or software versus software) are compared, very little of the business infrastructure that previously depended on DES has successfully converted to AES. This occurs despite the many intervening years since published reports widely proclaimed the death of DES.[1]

What information security professionals can do to minimize the potential adverse impact to within their respective organizations will be further discussed throughout this chapter. The following are suggestions that may help information security professionals minimize these impacts:

1. Information security professionals should carefully research potential products. If a good body of experience for a given product cannot be found (vendor marketing material aside), then the business will be better served by letting someone else risk its assets. For example, businesses that jumped on wireless LANs discovered that they were providing free services to unintended parties and opening their LANs to attack outside of their physical control. Where cryptography was an option, they failed to implement it. But even when they learned to implement it, the available protocol was not secure. A transition from 802.11b to 802.11g, although apparently more secure and less subject to interference, was also more expensive and had a shorter range, requiring more units. Early adopters of the 802.11b wireless technology found themselves with equipment that needed years on their books for depreciation but that was, nonetheless, obsolete.

   The irony of bleeding edge technology that depends on security functionality for its business case can be seen. The advantages boasted in marketing material for adoption of the new technology (e.g., efficiency, cost savings) evaporate when the buyer must add to the equation fraud losses, down time, and premature forced replacement of the equipment. A further irony remains: the replacement technology may suffer the same fate as the technology it replaced.
2. Information security professionals should assess the business and legal risks. From the time the industry is officially on notice that an encryption method, protocol, or implementation no longer provides the necessary level of protection until the time an enterprise actually adopts an effective[2] alternative, the enterprise is increasingly at risk of litigation for negligence because it continued to rely on the faulty technology when it knew (or should have known) that it was unsafe. This aggravates the situation by increasing the pressure on the enterprise to buy a replacement product that may prematurely come to market without the benefit of rigorous vetting. To avoid this becoming a vicious circle, balance the risks of the exposures with the costs associated with a transition to the new product. Compensating controls in the existing environment (for example, the use of encryption at a higher level in the ISO stack) may be more cost effective.
3. A cryptographic lifecycle plan should be designed, and appropriate procedures in existing software development and acquisition processes should be integrated.

79.2 Cryptographic Lifecycle

The lifecycle for cryptographic security products is much like the lifecycle for humans. In cryptography, an end happens when an easily exploitable flaw is found in the algorithm, and the underlying cryptosystem is deemed beyond repair. For example, the Fast Data Encipherment Algorithm (FEAL), developed by the Nippon Telephone and Telegraph with the intent that it be an improvement to DES, was found susceptible to a variety of cryptanalytic attacks, some requiring as few as twelve chosen plaintexts, that prematurely ended its life.

[1] See, for example, Ben Rothke's article "DES is Dead! Long Live ????" published in the Spring 1998 edition of the Information Systems Security by which time, this was the general consensus.

[2] At least one currently perceived as effective.

Effectiveness is gradually lost, often a victim of Moore's Law or cumulative breakthroughs in cryptanalysis' drastically reducing the time necessary to ascertain the cryptographic key (or the message directly without the key). Some cryptosystems will have very short lives, and others may span centuries. Predicting the life of any given cryptographic security product, however, is probably about the same as reading a person's lifeline on his or her palm.

A cryptographic system contains many elements with all remaining secure if the overall system is to remain cryptographically effective. If a backdoor to the algorithm is discovered or a cryptanalytic attack efficiently reduces the key space against which a brute-force attack succeeds, the algorithm no longer provides adequate cryptographic strength. If the protocol associated with key management or registration fails to withstand an attack, then the cryptosystem is likely compromised. If the source of random values, e.g., a pseudo-random number generator (PRNG)—also more accurately called a deterministic random number generator (DRNG), is discovered to have a predictable pattern or to generate values within a space significantly smaller than the target key space, a cryptanalyst may exploit this weakness to the detriment of the cryptosystem. In recent years, researchers have found that timing, power consumption, error states, failure modes, and storage utilization all may act as covert channels, leaking information that may permit the solving of the implemented cryptosystem without benefit of the keys.

In addition to the potential for failures related to the cryptographic algorithm, cryptographic security implementations depend on other factors. These factors vary depending on the cryptographic services intended for use. For example, to use cryptography for user authentication, a means of binding an identity with a certificate is necessary. This requires a registration process where an identity is asserted, it is authenticated in some manner, and a cryptographically signed piece of data to represent that identity is created. Weaknesses in the registration process, the signing process, the revocation process, or the chain of trust on which the resulting certificate relies are all potentially exploitable. A National Institute of Standards and Technology (NIST) Special Publication addresses this complex area and its impact to the cryptographic key lifecycle. NIST Special Publication 800-57[3] provides guidance on over a dozen different kinds of cryptographic keys (e.g., Private Signature Key, Public Signature Key, Symmetric Authentication Key, Private Authentication Key, Public Authentication Key, Symmetric Data Encryption Key, Symmetric Key Wrapping Key, Symmetric and Asymmetric Random Number Generator Key, Symmetric Master Key, Private Key Transport Key, Public Key Transport Key, Symmetric Key Agreement Key, Private Static Key Agreement Key, Public Static Key Agreement Key, Private Ephemeral Key Agreement Key, Public Ephemeral Key Agreement Key, Symmetric Authorization Key, Private Authorization Key, and Public Authorization Key). With the many differences in the application of cryptography come differences in the overall cryptographic lifecycle of the products used. Products that encrypt a message, send it, receive it, and decrypt it serve their cryptographic purpose in almost real time. Products that encrypt for archival or sign contracts that must be capable of authentication a decade later will have much longer cryptographic lifecycles.

The services supported by encryption, e.g., confidentiality, authentication, and nonrepudiation, have nearly perpetual lives. Business functions that require such services almost never cease to require them. Nonetheless, a given implementation of these services will have a planned lifecycle associated with the business functions that rely on these services. Secrets rarely require perpetual protection. For most trade secrets, three years of confidentiality might provide sufficient protection for the business to profit from its advantage. Of course, robust cryptographic security measures may have a shelf life far in excess of three years. Selecting the cryptosystem and key length deemed safe for the length of time that management believes is appropriate for a given business function is more art than science. In many applications, however, little difference in acquisition and implementation costs for cryptosystems using are found (for example, 128 bits of active key and 512 bits of active key). But changing from a system based on 128 bits to one of 512 bits might be costly. Here is one place where planning and foresight gives

[3] For a copy of this special publication, refer to http://csrc.nist.gov/publications/nistpubs/

the information security professional an opportunity to control at least some of the cryptographic security product lifecycle parameters.

The speed at which new implementations of cryptographic protocols issue from RFC and proprietary development efforts leaves implementers in the dust. Vetting (i.e., formally testing and proving) an implementation requires time and great skill. The great commercial pressure to bring new products to market rarely admits to the necessity for such vetting. The wireless protocol 802.11b was a good example. Implementations were in the field before the protocol weaknesses were fully understood. The tools for freely exploiting its weaknesses were available well before a newer, more secure standard. The new standard, 802.11g, was not compatible with the equipment already in the field. Manufacturers had to productize this standard before companies could acquire the new devices. For the purchasers of the previous technology, nothing short of replacing the equipment would avail to correct the deficiency (a host of products to compensate for the protocol weakness not withstanding).

Cryptographic transitions pose special challenges with similarities to forced system or hardware conversions. The change is rarely limited to a single application or platform. Similar to data transmission or data storage strategies, cryptographic security is infrastructural. In current commerce applications, a company relies on cryptographic security measures whether it knows it or not. The default use of cryptography rarely reflects the needs of a specific business (other than, perhaps, the vendor's business).

79.3 Lifecycles for Encryption Products

Cryptographic security products may have features or specific implementation factors that may provide a better clue to its lifecycle. Just as certain life-style factors may increase or decrease a person's health and longevity, so too do aspects of product implementations. For example, a hardware implementation for a specific speed, latency, and physical layer protocol may fall victim to rapid changes in telecommunication technology. Here, obsolescence is unrelated to merits of the cryptosystem. The product ends its lifecycle just as tubes gave way to transistors that gave way to integrated circuits, etc. An additional source of obsolescence is the vendor's planning for its product. The vendor simply decides not to support the product. RSA Security's SecurPC, introduced in 1992, is an example of this for RSA ended support for it in 1996. Archived files or e-mail protected by this product would require a Windows 98 software platform for decryption because the product does not run on Windows 2000 or Windows XP. Clearly, factors beyond the efficacy of the algorithm will limit the life expectancy of a cryptographic security product.

Perhaps, just as strangely, it may be found that the birth of a new cryptographic security product is premature. Such a product might die if a market for it does not develop quickly. Or if the sponsoring company has sufficient staying power, the premature product may live long and prosper.

Because breakthroughs like RSA's public key technology may have come to market before the industry even understood what problems it might solve, businesses have struggled with public key infrastructure (PKI) projects and other attempts at implementing cryptographic products. Many organizations have dozens of cryptographic products—often where a single, well-chosen product would have sufficed. The efficacy of these products remains generally unknowable by the people who buy and implement them. Few information technology professionals (or information security administrators) follow the cryptographic research literature or have access to a cryptographic laboratory for testing.

Since the early works on public key cryptography, e.g., Whitfield Diffie's and Martin Hellman's work in 1975, cryptographers have devised many asymmetric key schemes based on an almost limitless array of algorithms. Current work includes advances in elliptic curves cryptography (ECC),[4] hyper-elliptic cryptosystems,[5] RSA variants and optimizations,[6] multivariate quadratic equations over a finite field

[4] For example, work by Katsuyuki Okeya and Tsuyoshi Takagi or work by Kristen Eisenträger, Kristen Lauter, and Peter L. Montgomery. V. Miller and N. Koblitz introduced ECC in mid-1980.

[5] Hyper-elliptic cryptosystems, a generalization of ECC, was introduced by N. Koblitz ca.1989.

[6] For example, work by Adi Shamir (the "S" in "RSA").

(the MQ problem),[7] and lattices.[8] Future advances in quantum cryptographic key management and biological computing (i.e., using genetic structures to form living computers) may drastically change cryptographic products. Unfortunately for most information security practitioners, a Ph.D. in mathematics seems to be only a good starting point for research in cryptosystems.

To a greater extent, professionals depend on the vendors of cryptographic products to educate them on the products' merits. Without casting aspersions on the sales forces for these products, few will have the motivation or objectivity or the academic background sufficient to evaluate their own product. Fewer will have sufficient access to fairly compare and contrast the technical merits of competitors' products. And few, if any, will have the ability to assess the current state of cryptanalysis versus their and their competitors' products. But if such salespeople existed, would information security professionals understand the assessments?

To protect from ignorance, information security professionals should rely on products evaluated through nationally accredited laboratories, e.g., the National Institute of Standards and Technology (NIST) National Voluntary Laboratory Accreditation Program (NVLAP).[9] However, this may lead to another potential end-of-life situation for a cryptographic product, i.e., the loss of accreditation. Once a previously approved product loses accreditation, any continued use of the product places an organization at risk. Having a transition plan for accredited products is the best defense.

Beyond technical reasons for cryptographic technology lifecycles' running out prematurely, political factors may also lead to the stillbirth of a cryptographic technology. NSA's Skipjack is a good example of this. It had two embodiments: Clipper Chip for voice communications and Capstone for data. Whatever the merits of the Skipjack algorithm, the concept of cryptographic key escrow by the federal government created such political backlash that few commercial implementations resulted.[10]

79.4 Business Implications of Lifecycle

Most business functions have a financial justification as does the basis for investments in the technologies that support them. To replace (or physically upgrade where feasible) a hundred billion dollars of automated teller machines (ATM) and point of sale (POS) equipment in order to support a replacement for DES, for example, cannot (and did not) happen quickly. The United States' financial services industry, however, expected a long life for its rollout of ATM. The need for the long life was partly based on the large investment it had to make in equipment and systems, but it also reflected the risk inherent in a change of business model. Very early adopters had the opportunity to upgrade or replace equipment several times before the forced migration from DES to Triple-DES. Exhibit 79.1 gives a timeline of Triple-DES in the financial services industry. (AES came out too late and would have required a more massive revolution instead of evolution of existing systems.) Weaknesses in PIN-block format, setup protocols, and nonstandard messages required changes as the networks became more interdependent and attacks against the systems became more sophisticated. The replacement of equipment well before its scheduled and booked depreciation date creates a financial hardship for the business as it may invalidate planning assumptions used to justify the original implementation. Far worse, however, is the potential harm if the resulting business model is made null and void. Privacy concerns, in large measure because of inadequate security and to public perception that this inadequacy was wide spread, probably hastened the demise of many already stressed dotcoms whose business models assumed privacy as a given.

[7] Examples of public key cryptosystems based on the MQ problem include Hidden Fields Default (HFE), Quartz, and Sflash. For more information, see www.nicolascourtois.net.

[9] The Directory of Accredited Laboratories maintained by NIST is available at http://ts.nist.gov/ts/htdocs/210/214/scopes/programs.htm.

[10] For more information, see http://www.epic.org/crypto/clipper/

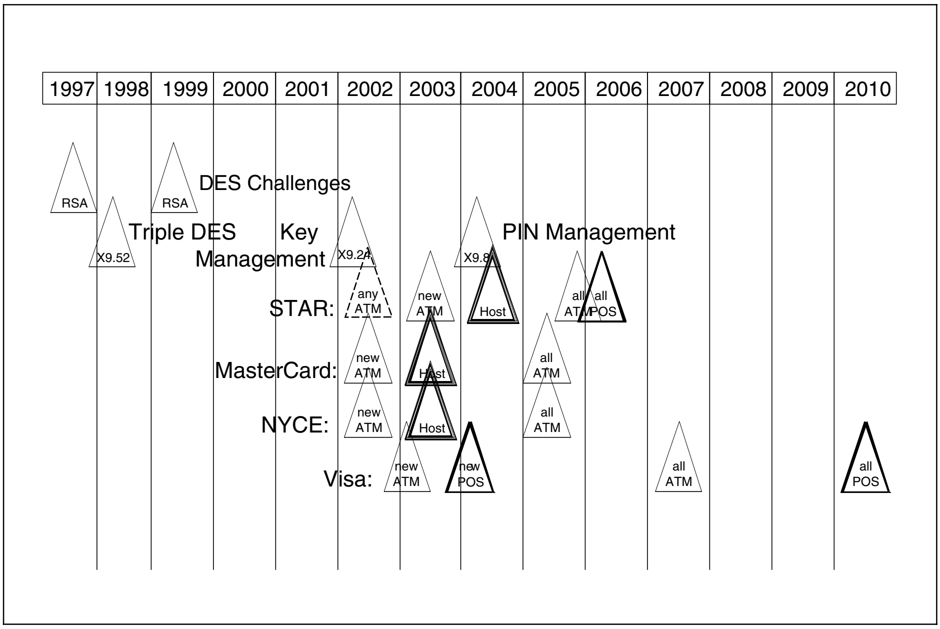

EXHIBIT 79.1 Triple DES time line.

Businesses already feel the pain of near constant desktop system upgrades. Here, vendors try to make the transition smooth with as much backward compatibility as possible. With advances in cryptography, entire classes of algorithms may become obsolete in a single breakthrough. Transitions from a newly broken cryptosystem to a cryptosystem believed to be safe, at least for the moment, are unlikely to be simple migrations.

Business planning for cryptographic security measures needs to include planning for cryptographic lifecycle contingencies. Just as businesses need business continuity planning against adverse events (e.g., natural disasters, fire, sabotage, and human error), businesses need to plan for the inevitable transition from one cryptographic technology to the next. This includes contingency funding and planning for catastrophic cryptographic failure where a rapid transition must occur and for more gradual evolution to more advanced technologies as existing ones approach obsolesce.

79.5 Principles for Cryptographic Transitions

The following four principles prescribe the process for a successful cryptographic transition: vulnerability assessment, impact analysis, implementation, and reconciliation.

79.5.1 Vulnerability Assessment

The principle of the vulnerability assessment addresses the need to understand the applications or infrastructural elements that cryptography will protect or support. With an understanding of the business issues and of the technical vulnerabilities to be addressed by cryptographic measures, a foundation is created on which cryptographic transitions must be based.

The first task is to ascertain legacy system requirements. The current security requirements must then be confirmed. Typically, this is accomplished by reviewing legacy documentation and current operating procedures. However, legacy systems may not be fully documented or specifications identify what was planned but not necessarily implemented. Further, operating procedures may be obsolete or simply not followed. It may be necessary to augment documentation with interviews to determine legacy system requirements.

The second task is to determine new system requirements. This can be accomplished by reviewing projects currently in progress and—even more importantly—by reviewing strategic business plans. Because many cryptographic systems can remain in use for 10 or more years, transitioning to a security architecture and an enterprise management system that can support short-term and long-term business strategies is an important aspect of determining new system requirements.

The third task is to determine the infrastructure requirements. Unless the business strategies have previously identified and documented such requirements, it will be necessary to conduct interviews. One important group that should be interviewed is the operations staff because it supports the production applications and relies on documented procedures. Another group that should be interviewed is the information technology staff because it addresses the gap between the production systems and the users. Other important groups include database administrators, security officers, and general counsel. The collective knowledge of these groups is critical in determining the infrastructure requirements.

The fourth task is to perform a formal vulnerability assessment of systems and infrastructures to ascertain the potential threats, realistic vulnerabilities, and business and technical risks and to derive the appropriate security requirements.

79.5.2 Impact Analysis

The principle of the impact analysis addresses the effect that cryptography has and will have on the business systems. The impact analysis also translates technical issues into financial or business terms important to internal communication.

The first task is to perform an inventory assessment to determine where cryptography is used, how it is used, and why it is used versus other controls. In this inventory, information should be gathered about the algorithms, protocols, and devices or products currently in use.

The second task is to perform a dependency analysis to determine where systems have interdependencies and whether applications, infrastructural elements, or devices are or can be algorithm independent. If specific functions can be identified that might be common, e.g., key generation, digital signature, message encryption, or file encryption, the potential for isolating these functions into an abstraction layer that would reduce the future impact of cryptographic transitions should be documented.

The third task is to address jurisdictional issues to determine current and future needs for cryptography in multi-national, national, and regional locations. Different nations have different rules and laws that may affect the overall security architecture.[11]

The fourth task is to address migration issues to determine availability of cryptographic products to buy solutions or cryptographic tools to build solutions where products are insufficient or unavailable. In some cases, further analysis is necessary to determine alternatives to cryptography solutions.

79.5.3 Implementation

The implementation principle is the basic project management lifecycle that has been summarized here into development, testing, quality assurance, and deployment planning tasks. Development planning is documenting the manpower, resources, time tables, reporting, and auditing for the modification or replacement of the application, infrastructure, or equipment. Test planning includes documenting test cases and test results approved by management for unit testing, integration testing, system testing, and parallel testing. Quality assurance planning includes documenting final acceptance with roll-back plans that have been reviewed, approved, and signed off by management. Careful planning avoids any

[11] For more information, see Poore, R.S. 2000. Jurisdictional issues in global transmissions. In *Information Security Management Handbook*, M. Krause and H.F. Tipton, eds., *4th Ed.*, *Vol. 1.* Boca Raton: CRC Press.

cold cut-over. Further, deployment planning must include documented roll-out schedules with incremental modifications and the ability to roll-back in the case of unforeseen problems.

79.5.4 Reconciliation

The fourth and final principle's, reconciliation, objective is to determine the cryptographic transition's successfulness. A post mortem should be conducted to review the project's successes and failures and to document these for future improvements. The team should learn from its mistakes and convey that wisdom to future project teams. In addition to the post mortem, a monitor program should be implemented to measure system results against expected results. Any unexpected events should be investigated, documented, and resolved. The initial monitoring should be frequent (e.g., hourly, daily, weekly) and eventually reduced to normal operational status reports (e.g., monthly, quarterly).

Because external factors, many that have been previously addressed, may force the organization to initiate a cryptographic transition sooner than planned, these principles should be formalized into its business planning and the organization should be informed of changes in cryptography.

79.6 Prudent Measures

In closing, here are eight considerations to incorporate in cryptographic transition planning for an organization:

1. Do not ask the company to invest in products that depend on "bleeding edge" cryptosystems. The best safeguard against a poor cryptosystem is time. Let researchers have the time to properly vet the new cryptosystem, and let competitors debug their own implementations.
2. Require independent certification or vetting of cryptosystems, where possible, utilizing recognized standards (e.g., Common Criteria—for additional information in the U.S.A., see NIST Special Publication 800-37, Guidelines for the Security Certification, and Accreditation of Federal Information Technology Systems).
3. Use cryptosystems based on recognized national or international standards. Beware of proprietary algorithms, protocols, or embodiments.
4. Understand the target environment for a vendor's product, including any explicit limitations; ensure the appropriateness of the product for the environment where the organization will run it. For example, some cryptographic security products assume the existence of a physically secure environment or they will run on a trusted workstation. If the plan is to roll one of these products out to remote users whose environments are unknown, the product should be expected to fail.
5. To the degree possible, negotiate assurances into the contract that share the risk of cryptographic failure with the vendor. Always believe a vendor's risk judgment when the vendor is unwilling to take any responsibility for its product. If the vendor does not trust its product, neither should a company.
6. Seek qualified experts' opinions and colleagues' experiences. Learning from the experience of others is almost always preferable to experiencing the learning. If no one in the organization has had an experience with this vendor or product, then refer back to the first measure listed here.
7. Incorporate cryptographic life-cycle considerations into business continuity planning. A cryptographic security failure can pose a serious threat to business operations both by potentially exceeding acceptable business risks for normal operations (a threshold that management may potentially waive to permit a period of operations while a transition to a new product occurs) and by exposing network or database operations to attacks that prevent operations.
8. Create (or follow) an architecture that isolates cryptographic services to an abstraction layer that is independently invoked. This permits replacement or upgrade with minimal impact to the overall application. As discussed in regards to lifecycles, they can be depended on for their uncertainty.

Use as a design assumption that the cryptographic security product will require changes or replacement sooner than the application depending on it will go away.

This last item is perhaps the most important. The field of cryptography is rapidly advancing with cryptanalysis' finding more rapid introduction to general use than more advanced cryptosystems. These advances increase the risk that a given cryptographic implementation will provide effective security for a shorter life than predicted at the time of implementation. Although issues such as Y2K could easily have been anticipated well in advance, programming languages and practices in the 1960–1980 decades generally failed to consider the pending obsolescence, believing instead that the applications they were creating would not live until then. Enough of these applications did survive to cost businesses billions of dollars to address the oversight. Waiting until a business is forced to change cryptographic implementations increases costs and places information assets at risk. Cryptographic transitions are inevitable. Companies should plan for it now.

Blind Detection of Steganographic Content in Digital Images Using Cellular Automata

Sasan Hamidi

80.1 Introduction

Steganography is the art of hiding messages or other forms of data and information within another medium. The goal of steganography is to hide the information so it can escape detection. On the other hand, steganalysis attempts to uncover such hidden messages through a variety of techniques. Many freeware and commercially available steganographic tools are currently available for hiding information in digital images (Johnson et al., 2001). Corresponding to these tools are methods devised specifically for each algorithm to detect the hidden contents. Almost all current steganalysis tools today require prior knowledge of the algorithm that was used during the steganography process; in other words, some statistical test must be performed to determine the signature associated with a particular steganographic tool or technique. Hence, by introducing new complexities and techniques, current steganalysis techniques become obsolete. The method proposed in this chapter represents a digital image in a cellular automata-based, two-dimensional array. Each cell within this two-dimensional plane is examined for anomalies presented by the process of steganography. The author believes that the technique used here is statistically more robust than other techniques presented thus far and is capable of handling complex and chaotic steganographic algorithms.

80.2 Motivation for Research

Current steganographic detection methods have several deficiencies:

- The detection method has to match the algorithm used in the steganography process. Tests must be performed to match the signature to a specific technique used to embed the data within the medium.
- Slight variations in steganographic methods can render the current techniques useless.
- Almost all steganalysis techniques suffer from a high rate of false positives (Berg et al., 2003).

To the best of the author's knowledge, to date no techniques utilize cellular automata (CA) for the detection of steganographic content in any medium. Additionally, only two methods today propose techniques to improve on the deficiencies mentioned above. The methods proposed by Berg et al. (2003) and Lyu and Farid (2002) utilize machine learning as their underlying concept.

Artificial neural networks (ANNs) are a particular method for empirical learning. ANNs have proven to be equal, or superior, to other empirical learning systems over a wide range of domains when evaluated in terms of their generalization ability (Cox et al., 1996; Schatten, 2005); however, although these methods have significantly improved on the areas mentioned earlier, they suffer from the following problems (Ahmad, 1988; Atlas et al., 1989; Shavlik et al., 1991; Towell and Shavlik, 1992):

- Training times are lengthy.
- The initial parameters of the network can greatly affect how well concepts are learned.
- No problem-independent way to choose a good network topology exists yet, although considerable research has been aimed in this direction.
- After training, neural networks are often very difficult to interpret.

The proposed method has the advantage of being able to be applied to both index- and compression-based images. Examples of index-based images are GIF and BMP file types, and compression-based examples are MPEG and JPEG.

80.3 Background on Cellular Automata

The basic element of a CA is the cell. A cell is a kind of a memory element that is capable of retaining its state. In the simplest case, each cell can have the binary states 1 or 0. In more complex simulation, the cells can have more different states. These cells are arranged in a spatial web, called a *lattice*. The simplest one is the one-dimensional lattice, where all cells are arranged in a line like a string. The most common CA is built in one or two dimensions. For the cells to grow, or transition from their static state to a

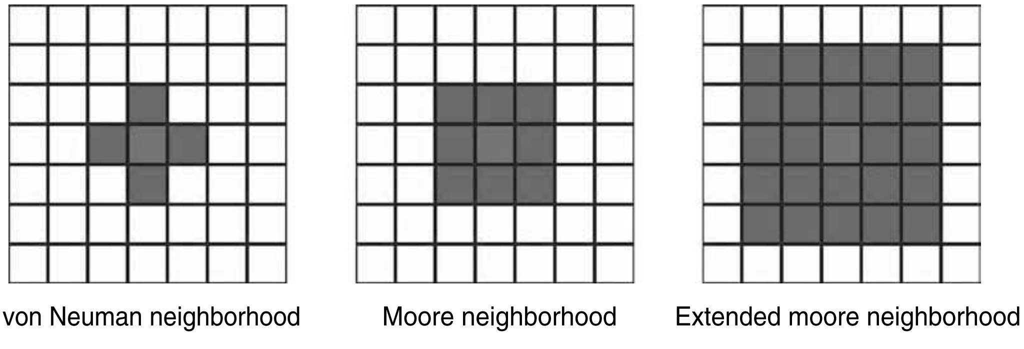

EXHIBIT 80.1 Three different neighborhoods.

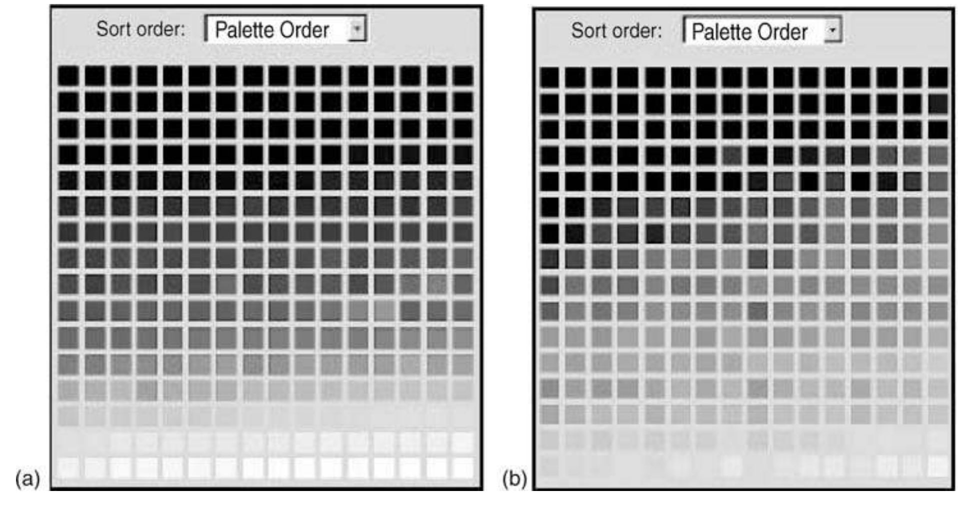
dynamic one, rules must be applied. Each rule defines the state of the next step in forming new cells. Additionally, in a cellular automata lattice, the state of the next cell depends on its neighbor. Thus, the concept of neighborhood is an important one. Exhibit 80.1 shows three different neighborhoods. The distinguishing characteristic is the rules that are applied to each cell to form the lattice (Schatten, 2005).

80.4 Background on Digital Images and Steganography

To a computer, an *image* is an array of numbers that represent light intensities at various points (pixels). These pixels make up the *raster data* of the image. A common image size is 640×480 pixels and 256 colors (or 8 bits per pixel). Such an image could contain about 300 kilobits of data. Digital images are typically stored in either 24-bit or 8-bit files. A 24-bit image provides the most space for hiding information; however, it can be quite large (with the exception of JPEG images). All color variations for the pixels are derived from three primary colors: red, green, and blue. Each primary color is represented by 1 byte; 24-bit images use 3 bytes per pixel to represent a color value. These 3 bytes can be represented as hexadecimal, decimal, and binary values. In many Web pages, the background color is represented by a six-digit hexadecimal number—actually three pairs representing red, green, and blue. A white background would have the value FFFFFF: 100 percent red (FF), 100 percent green (FF), and 100 percent blue (FF). Its decimal value is 255, 255, 255, and its binary value is 11111111, 11111111, 11111111, which are the 3 bytes making up white.

Most steganography software neither supports nor recommends using JPEG images but recommends instead the use of lossless 24-bit images such as BMP. The next-best alternative to 24-bit images is 256-color or grayscale images. The most common of these found on the Internet are GIF files (Cox et al. 1996). In 8-bit color images such as GIF files, each pixel is represented as a single byte, and each pixel merely points to a color index table (a palette) with 256 possible colors. The value of the pixel, then, is between 0 and 255. The software simply paints the indicated color on the screen at the selected pixel position. Exhibit 80.2a, a red palette, illustrates subtle changes in color variations: visually differentiating between many of these colors is difficult. Exhibit 80.2b shows subtle color changes as well as those that seem drastic. Many steganography experts recommend using images featuring 256 shades of gray (Aura, 1995). Grayscale images are preferred because the shades change very gradually from byte to byte, and the less the value changes between palette entries, the better they can hide information.



Sort order: Palette Order

Sort order: Palette Order

EXHIBIT 80.2 Color palettes: (a) red palette; (b) color palette.

Least significant bit (LSB) encoding is by far the most popular of the coding techniques used for digital images. By using the LSB of each byte (8 bits) in an image for a secret message, it is possible to store 3 bits of data in each pixel for 24-bit images and 1 bit in each pixel for 8-bit images. Obviously, much more information can be stored in a 24-bit image file. Depending on the color palette used for the cover image (e.g., all gray), it is possible to take 2 LSBs from one byte without the human visual system (HVS) being able to tell the difference. The only problem with this technique is that it is very vulnerable to attack such as image changes and formatting (e.g., changing from a GIF format to JPEG).

80.5 Methodology

The entire premise of the proposed method is that by introducing steganographic content the intensity of each pixel will change, and the condition of the neighboring cells can be determined by devising CA rules. Regardless of the steganographic technique, this phenomenon occurs in every instance. The detection of this change in intensity could help in the detection process. The image in this case is represented as a plane, with each pixel conceptualized as a cell in a cellular automation lattice. This method uses a technique similar to that of Adriana Popovici and Dan Popovici (Wolfram, 2002) to enhance the quality of digital images. Each cell representing each pixel in the target image is identified by its position within the plane (i, j); however, unlike the Popovici proposal, the next identifying value will be the cell's binary value of its corresponding color. Thus, each cell will have a binary value that consists of its position and the color its represents. In this proposal, each cell points to a color index table (a palette) with 256 possible colors and values between 0 and 255. As mentioned earlier, most steganographic techniques do not use JPEG images as their preferred medium because these image types are easily distorted and detection is therefore much simpler. Instead, other image types, such as BMP and GIF are used.

For example, cell A could be represented as A (0001, 0010, 1111), which means that cell A is in the first row of the second column pointing to the palette of color white in an $N \times N$ plane. The proposal calls for testing all of Wolfram's 256 rules (0 to 255) to devise a set of rules to explain a normal condition for an unaltered image (Wolfram, 2002). In the plane, a normal picture (one that has not been embedded with any data) would exhibit a certain behavior (transition of cells and the neighborhood rule). The method proposes a sample test of 100 pictures to determine the general CA rule that can be deduced for each image type. A similar test of 100 images that contain steganographic content is performed to come up with a similar rule for these images. Because compression and index-type images use different techniques for image creation, multiple CA rules must be developed to detect the presence of hidden data within each file type.

80.6 Test Results

Using the Jsteg Shell steganographic tool and OutGuess, commonly used tools to embed information in JPEG files, ten pictures (from a family album) were embedded with plaintext. The original images (before steganography) and embedded ones were subjected to Wolfram's 256 rules. Initial tests have shown that rules 4 and 123 exhibit similar behavior when processing the original pictures. In other words, the single most common kind of behavior exhibited by the experiment was one in which a pattern consisting of a single cell or a small group of cells persisted. In other cases, however, such as rules 2 and 103, it moved to the left or right. When processing the embedded images using the same method, an emerging common pattern could not initially be deduced. The significant finding is that, at the very least, there are observable distinguishable patterns between an original picture and one that has been embedded using Jsteg and OutGuess.

Exhibit 80.3a shows the original picture in JPEG format. Exhibit 80.3b shows the same picture embedded with a Word file 24 KB in size. A distinguishable distortion in size and image quality can be observed in Exhibit 80.3b. As stated earlier, JPEG is not favorite medium of steganographic tools

EXHIBIT 80.3 (a) Original *versus* (b) carrier picture.

and algorithms; however, this file type was chosen for this initial experiment to ensure that all distortions were captured when converting the images into CA rules. Future tests must be performed on all other image types to determine their distinguishable patterns (if any) through cellular automata representation. Refinements of CA rules are also necessary in order to produce better patterns for both original and carrier images. (Carrier images are those that contain steganographic content.)

80.7 Conclusion

Steganography has developed from its humble beginnings as the secret little hobby of a few bored security gurus to a hot topic of discussion at many technology conferences. In the past three years, the SANS and RSA conferences, two of the most important security conferences in the United States, have featured tracts on the area of information hiding and steganography. The war on terrorism seems to have had a profound effect on the growth of steganography. It has been argued that the terrorists involved with the September 11 tragedy communicated through many convert channels, mainly through the use of steganography. A great deal of research must be performed to determine the applicability of cellular automata to the detection of steganographic content in digital images. The results of this research must be compared with many steganalysis applications and algorithms along with other proposed detection methods (Berg et al. 2003; Lyu and Farid, 2002) to determine its efficiency. Proposed improvements could be the development of a hybrid system where the capability of cellular automata could be paired with machine learning techniques to develop a robust and adaptive detection method. Automated learning and data-mining techniques are other avenues that could be pursued. There is little doubt that development in the area of covert communications and steganography will continue. Research in building more robust methods that can survive image manipulation and attacks is ongoing. Steganalysis techniques will be useful to law enforcement authorities working in computer forensics and digital traffic analysis. The idea of a steganalysis algorithm that can learn the behavior exhibited by carrier mediums is tremendously appealing.

An Overview of Quantum Cryptography

Ben Rothke

Quantum cryptography:

- Potentially solves significant key distribution and management problems
- Offers a highly secure cryptography solution
- Is not meant to replace, nor will it replace, existing cryptography technologies
- Is a new hybrid model that combines quantum cryptography and traditional encryption to create a much more secure system
- Although not really ready for widespread commercial use, is developing very fast.

81.1 Introduction

Over the past few years, much attention has been paid to the domains of quantum computing and quantum cryptography. Both quantum computing and quantum cryptography have huge potential, and when they are ultimately deployed in totality will require massive changes in the state of information security. As of late 2005, quantum cryptography is still an early commercial opportunity; however, actual commercial quantum computing devices will not appear on the scene for another 15 to 25 years. This chapter provides a brief overview on the topic of quantum cryptography and the effects it will have on the information security industry.

81.2 Cryptography Overview

This section is not intended to be a comprehensive overview of cryptography; for that, the reader is advised to consult the references mentioned in Exhibit 81.1, Exhibit 81.2, and Exhibit 81.3. Nonetheless, before discussing the details of quantum cryptography, an initial overview of cryptography in general is necessary. Cryptography is the science of using mathematics to encrypt and decrypt data to be sure that communications between parties are indeed private. Specifically, it is the branch of cryptology dealing with the design of algorithms for encryption and decryption, which are used to ensure the secrecy and authenticity of data. Cryptography is derived from the Greek word *Kryptos*, meaning "hidden."

Cryptography is important in that it allows people to experience the same level of trust and confidence in the digital world as in the physical world. Today, cryptography allows millions of people to interact electronically via e-mail, E-commerce, ATMs, cell phones, etc. The continuous increase of data transmitted electronically has led to an increased need for and reliance on cryptography. Ironically, until 2000, the U.S. government considered strong cryptography to be an export-controlled munition, much like an M-16 or F-18. The four objectives of cryptography (see Exhibit 81.4) are:

- *Confidentiality*—Data cannot be read by anyone for whom it was not intended.
- *Integrity*—Data cannot be altered in storage of transit between sender and intended receiver without the alteration being detected.
- *Authentication*—Sender and receiver can confirm each other's identity.
- *Nonrepudiation*—It is not possible to deny at a later time one's involvement in a cryptographic process.

EXHIBIT 81.1 An Explanation of Photons

A photon is a finite unit of light, carrying a fixed amount of energy ($E=hf$), where f is the frequency of the light, and h is the value of planck's constant. No doubt you've heard that light may be *polarized*; polarization is a physical property that emerges when light is regarded as an electromagnetic wave. The direction of a photon's polarization can be fixed to any desired angle (using a polarizing filter) and can be measured using a calcite crystal.

A photon that is rectilinearly polarized has a polarization direction at 0° or 90° with respect to the horizontal. A diagonally polarized photon has a polarization direction at 45° or 135°. It is possible to use polarized photons to represent individual bits in a key or a message, with the following conventions:

	0	**1**
Rectilinear	0°	90°
Diagonal	45°	135°

That is, a polarization direction of 0° or 45° may be taken to stand for binary 0, while the directions of 90° and 135° may be taken to stand for binary 1. This is the convention used in the quantum key distribution scheme BB84, which will be described shortly. The process of mapping a sequence of bits to a sequence of rectilinearly and diagonally polarized photons is referred to as *conjugate coding*, and the rectilinear and diagonal polarization are known as *conjugative variables*. Quantum theory stipulates that it is impossible to measure the values of any pair of conjugate variables simultaneously.

The position and momentum of a particle are the most common examples of conjugate variables. When experimenters try to measure the position of a particle, they have to project light on it of a very short wavelength; however, short-wavelength light has a direct impact on the momentum of the particle, making it impossible for the experimenter to measure momentum to any degree of accuracy. Similarly, to measure the momentum of a particle, long-wavelength light is used, and this necessarily makes the position of the particle uncertain. In quantum mechanics, position and momentum are also referred to as *incompatible observables*, by virtue of the impossibility of measuring both at the same time. This same impossibility applies to rectilinear and diagonal polarization for photons. If you try to measure a rectilinearly polarized photon with respect to the diagonal, all information about the rectilinear polarization of the photon is lost —permanently.

EXHIBIT 81.2 The Two-Slit Experiment

Clinton Davisson of Bell Labs originally performed the two-slit experiment in 1927. Davisson observed that, when you place a barrier with a single slit in it between a source of electrons and a fluorescent screen, a single line is illuminated on the screen. When you place a barrier with two parallel slits in it between the source and the screen, the illumination takes on the form of a series of parallel lines fading in intensity the farther away they are from the center. This is not surprising and is entirely consistent with a wave interpretation of electrons, which was the commonly held view at the time. However, Davisson discovered that when you turn down the intensity of the electron beam to the point where individual electrons can be observed striking the fluorescent screen, something entirely unexpected happens: the positions at which the electrons strike are points distributed randomly with a probability matching the illumination pattern observed at higher intensity. It is as if each electron has physical extent so that it actually passed through both slits, but when it is observed striking the screen, it collapses to a point whose position is randomly distributed according to a wave function. Waves and particles are both familiar concepts at the everyday scale, but, at the subatomic level, objects appear to possess properties of both.

This observation was one of the first to suggest that our classical theories were inadequate to explain events on the subatomic scale and eventually gave rise to quantum theory. It has now been discovered that objects on an extremely small scale behave in a manner that is quite different from objects on an everyday scale, such as a tennis ball. Perhaps the most surprising observation is that objects on this very small scale, such as subatomic particles and photons, have properties that can be described by probability functions and that they adopt concrete values only when they are observed. While the probability functions are entirely amenable to analysis, the concrete values they adopt when observed appear to be random.

One of the most dramatic illustrations of the probabilistic wave function representation of objects on the quantum scale is a thought experienment described by Erwin Schrödinger that is universally referred to as “Schrödinger’s cat.”[a] We are asked to imagine a box containing a cat, a vial of cyanide, a radioactive source, and a Geiger counter. The apparatus is arranged such that, if the Geiger counter detects the emission of an electron, then the vial is broken, the cyanide is released, and the cat dies. According to quantum theory, the two states in which the electron has been emitted and the electron has not been emitted exist simultaneously. So, the two states of cat dies and cat lives exist simultaneously until the box is opened and the fate of the cat is determined. What Davisson showed is that quantum objects adopt multiple states simultaneously, in a process called *superposition*, and that they collapse to a single random state only when they are observed.

[a] For more on this, see John Gribbin’s *In Search of Schrödinger’s Cat: Quantum Physics and Reality*, Toronto, Bantam Books, 1994.

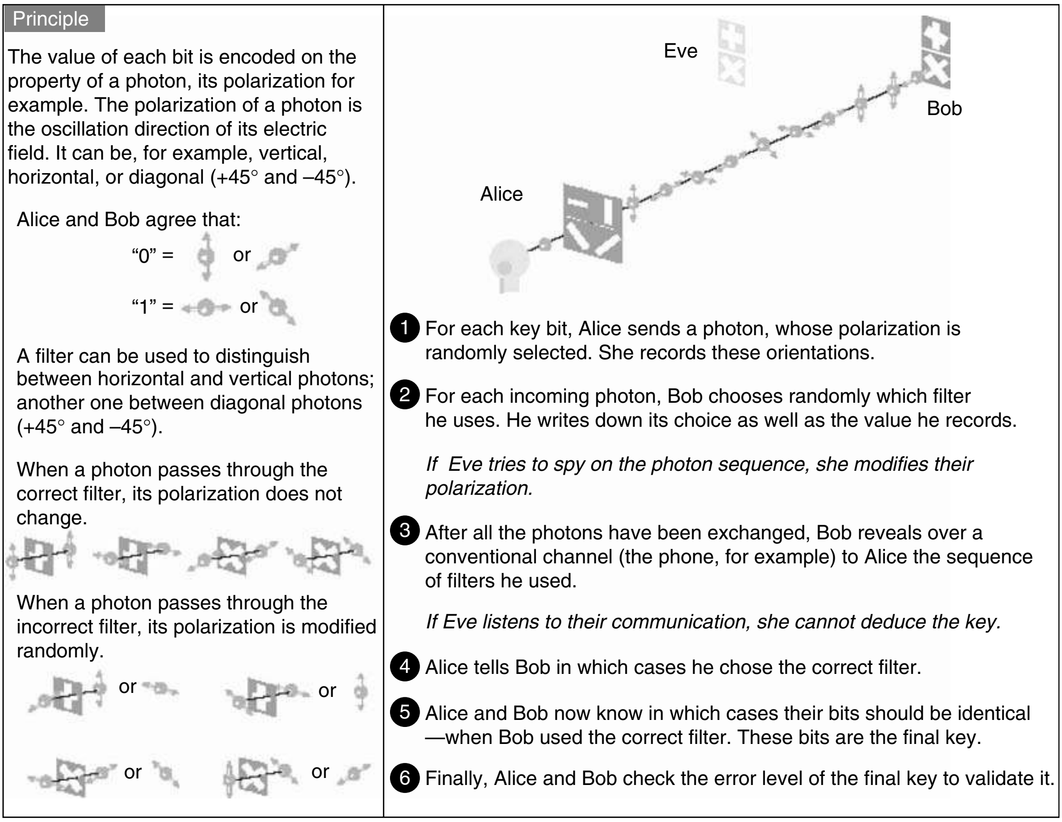
Source: From Addison, TX: Entrust (www.entrust.com/resources/whitepapers.cfm).

The origin of cryptography is usually considered to date back to about 2000 B.C. The earliest form of cryptography was the Egyptian hieroglyphics, which consisted of complex pictograms, the full meaning of which was known to only an elite few. The first known use of a modern cipher was by Julius Caesar (100–44 B.C). Caesar did not trust his messengers when communicating with his governors and officers. For this reason, he created a system in which each character in his messages was replaced by a character three positions ahead of it in the Roman alphabet. In addition to Caesar, myriad other historical figures have used cryptography, including Benedict Arnold, Mary Queen of Scotts, and Abraham Lincoln. Cryptography has long been a part of war, diplomacy, and politics.

The development and growth of cryptography in the last 20 years is directly tied to the development of the microprocessor. Cryptography is computationally intensive, and the PC revolution and the ubiquitous Intel x86 processor have allowed the economical and reasonable deployment of cryptography.

The concept of cryptography can be encapsulated in the following six terms:

- *Encryption*—Conversion of data into a pattern, called ciphertext, rendering it unreadable
- *Decryption*—Process of converting ciphertext data back into its original form so it can be read
- *Algorithm*—Formula used to transform the plaintext into ciphertext; also called a cipher
- *Key*—Complex sequence of alphanumeric characters produced by the algorithm that allows data encryption and decryption
- *Plaintext*—Decrypted or unencrypted data
- *Ciphertext*—Data that has been encrypted.



Principle

The value of each bit is encoded on the property of a photon, its polarization for example. The polarization of a photon is the oscillation direction of its electric field. It can be, for example, vertical, horizontal, or diagonal (+45° and –45°).

Alice and Bob agree that:

A filter can be used to distinguish between horizontal and vertical photons; another one between diagonal photons (+45° and –45°).

When a photon passes through the correct filter, its polarization does not change.

When a photon passes through the incorrect filter, its polarization is modified randomly.

1 For each key bit, Alice sends a photon, whose polarization is randomly selected. She records these orientations.

2 For each incoming photon, Bob chooses randomly which filter he uses. He writes down its choice as well as the value he records.

If Eve tries to spy on the photon sequence, she modifies their polarization.

3 After all the photons have been exchanged, Bob reveals over a conventional channel (the phone, for example) to Alice the sequence of filters he used.

If Eve listens to their communication, she cannot deduce the key.

4 Alice tells Bob in which cases he chose the correct filter.

5 Alice and Bob now know in which cases their bits should be identical —when Bob used the correct filter. These bits are the final key.

6 Finally, Alice and Bob check the error level of the final key to validate it.

EXHIBIT 81.3 Quantum cryptography. (From IdQuantique. *A Quantum Leap for Cryptograhy*, p. 4, IdQuantique, Geneva. [www.idquantique.com/products/files/clavis-white.pdf].)

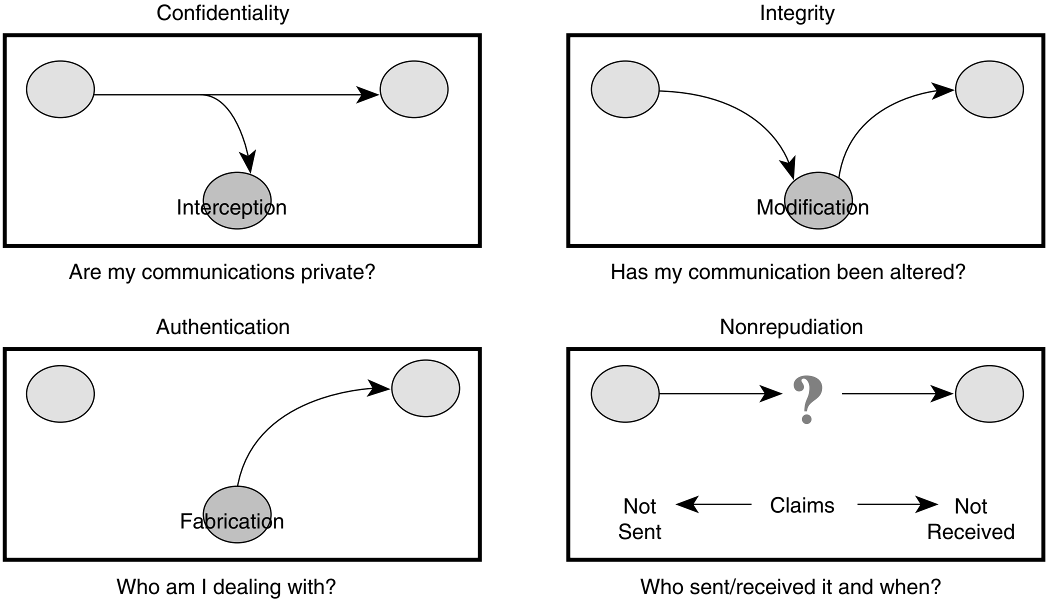


EXHIBIT 81.4 Four objectives of cryptography.

As stated earlier, one of the functions of digital cryptography is to allow people to experience the same level of trust and confidence in their information in the digital world as in the physical world. In a paper based society, we:

- Write a letter and sign it.
- Have a witness verify that the signature is authentic.
- Put the letter in an envelope and seal it.
- Send it by certified mail.

Correspondingly, this gives the recipient confidence that the:

- Contents have not been read by anyone else.
- Contents of the envelope are intact.
- Letter came from the person who claimed to have sent it.
- Person who sent it could not easily deny having sent it.

The two basic forms of cryptography are *symmetric* and *asymmetric*. Symmetric cryptography is the oldest form of cryptography, where a single key is used both for encryption and decryption. Exhibit 81.5 shows how a single key is used within symmetric cryptography to encrypt the plaintext. Both the party encrypting the data and decrypting the data share the key. While effective, the difficulty with symmetric cryptography is that of key management. With symmetric cryptography, as the number of users increases, the number of keys required to provide secure communications among those users increases rapidly For a group of n users, we must have a total of $1/2(n^2-n)$ keys to communicate. The number of parties (n) can increases to a point where the number of symmetric keys becomes unreasonably large for practical use. This is known as the n^2 problem. Exhibit 81.6 shows how many keys can be required. For 1,000 users (which is a very small number in today's distributed computing environments), an unmanageable 499,500 keys are required to share to share communications.

The key management problem created the need for a better solution, which has arrived in the form of symmetrical or public-key cryptography. Public-key cryptography is a form of encryption based on the use of two mathematically related keys (the *public key* and the *private key*) such that one key cannot be derived from the other. The public key is used to encrypt data and verify a digital signature, and the private key is used to decrypt data and digitally sign a document. The five main concepts of public-key cryptography are:

- Users publish their public keys to the world but keep their private keys secret.
- Anyone with a copy of a user's public key can encrypt information that only the user can read, even people the user has never met.

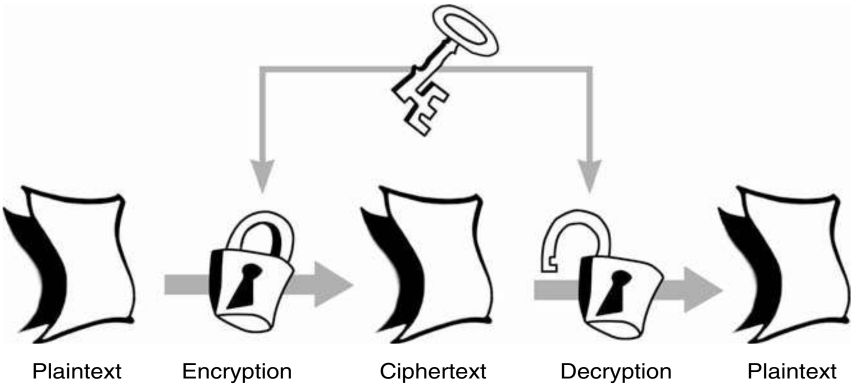

EXHIBIT 81.5 Single-key symmetric cryptography.

EXHIBIT 81.6 Keys Needed

Users	$1/2(n^2-n)$	Shared Key Pairs Required
2	1/2(4−2)	1
3	1/2(9−3)	3
10	1/2(100−10)	45
100	1/2(10,000−100)	4,950
1,000	1/2(1,000,000−1000)	499,500

- It is not possible to deduce the private key from the public key.
- Anyone with a public key can encrypt information but cannot decrypt it.
- Only the person who has the corresponding private key can decrypt the information.

Exhibit 81.7 shows how asymmetric cryptography is used to encrypt the plaintext. The parties encrypting the data and decrypting the data use different keys.

The primary benefit of public-key cryptography is that it allows people who have no preexisting security arrangement to exchange messages securely. The need for sender and receiver to share secret keys via a secure channel is eliminated; all communications involve only public keys, and no private key is ever transmitted or shared.

It should be noted that an intrinsic flaw with public-key cryptography is that it is vulnerable to a large-scale brute force attack. In addition, because it is based on hard mathematics, if a simple way to solve the mathematical problem is ever found, then the security of public-key cryptography would be immediately compromised. From a mathematical perspective, public-key cryptography is still not provably secure. This means that algorithms such as RSA (which obtains its security from the difficulty of factoring large numbers) have not been proven mathematically to be secure. The fact that it is not a proven system does not mean that it is not capable, but if and when mathematicians comes up with a fast procedure for factoring large integers, then RSA-based cryptosystems could vanish overnight.

From a security functionality perspective, symmetric cryptography is for the most part just as strong as asymmetric crytography, but symmetric is much quicker. Where asymmetric shines is in solving the key management issues. In the absence of key management issues, there is no compelling reason to use asymmetric cryptography.

81.3 Quantum Mechanics and Quantum Theory

Two observations about quantum mechanics are notable. Nobel prize-winning physicist Richard Feynman stated that, "Nobody understands quantum theory," and fellow physicist Niels Bohr noted decades earlier that, "If quantum mechanics hasn't profoundly shocked you, you haven't understood it yet." With that in mind, let us attempt to uncover the basic ideas about quantum theory and quantum cryptography.

For the most part, classical physics applies to systems that are larger than 1 micron (1 millionth of a meter) in size and was able to work quite handily when attempting to describe macroscopic objects.

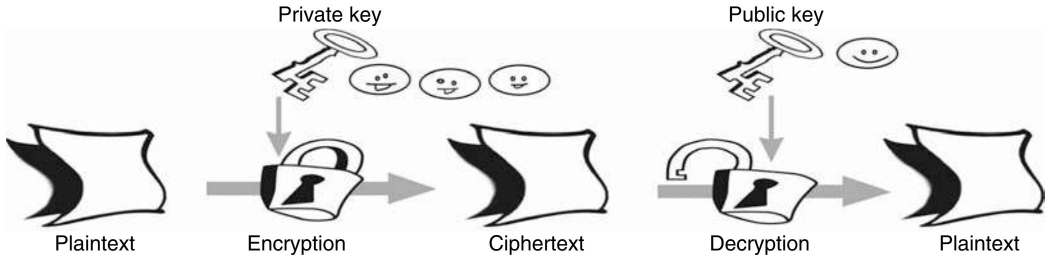

EXHIBIT 81.7 Asymmetric cryptography.

In the early 1900s, however, a radically new set of theories was created in the form of quantum physics. The quantum theory of matter developed at the turn of the century in response to a series of unexpected experimental results that did not conform to the previously accepted Newtonian model of the universe. The core of quantum theory is that elementary particles (e.g., electrons, protons, neutrons) have the ability to behave as waves. When Albert Einstein developed his general theory of relatively, he showed that space-time is curved by the presence of mass. This is true for large objects, as well as smaller objects encountered in everyday living (see Exhibit 81.2 for more details).

Quantum physics describes the microscopic world of subatomic particles such as molecules, atoms, quarks, and elementary particles, whereas classical physics describes the macroscopic world. Quantum physics also differs drastically from classical physics in that it is not a deterministic science; rather, it includes concepts such as randomness.

Quantum cryptography deals extensively with photons (see Exhibit 81.1), which are elementary quantum particles that lack mass and are the fundamental light particles. For the discussion at hand, quantum cryptography uses Heisenberg's uncertainty principle to allow two remote parties to exchange a cryptography key. One of the main laws of quantum mechanics manifest in Heisenberg's uncertainty principle is that every measurement perturbs the system; therefore, a lack of perturbation indicates that no measurement or eavesdropping has occurred. This is a potentially powerful tool within the realm of information security if it can be fully utilized.

One of the many applications of quantum mechanics is quantum computing. Standard computers use bits that are set to either one or zero. Quantum computers use electrons spinning either clockwise or counterclockwise to represent one and zeroes. These quantum bits are known as *qubits*. If these are in a superposition of states and have not been observed, all the possible states can be evaluated simultaneously and the solution obtained in a fraction of the time required by a standard computer, This generational leap in processing power is a huge threat to the security of all currently existing ciphers, as they are based on hard mathematical problems. The current security of the RSA algorithm would be eliminated.

The era of quantum cryptography began in the mid-1970s when researchers Charles Bennett at IBM and Gilles Brassard at the University of Montreal published a series of papers on its feasibility. They displayed the first prototype in 1989. In 1984, they created the first and, to date, best-known quantum cryptographic protocol which is known as BB84. Exhibit 81.8 demonstrates how BB84 carries out a quantum cryptographic key exchange.

81.4 Quantum Computing *versus* Quantum Cryptography

It should be noted that quantum computing and quantum cryptography are two discrete areas sharing a common term. Quantum computing is still in the theoretical state, but quantum cryptography is a functional, commercial solution. A quantum computer is a theoretical computer based on ideas from quantum theory; theoretically, it is capable of operating nondeterministically. According to the RSA Crypto FAQ,[1] quantum computing is a new field in computer science that has been developed in concert with the increased understanding of quantum mechanics. It holds the key to computers that are exponentially faster than conventional computers (for certain problems). A Quantum computer is based on the idea of a quantum bit or qubit. In classical computers, a bit has a discrete range and can represent either a zero state or a one state. A qubit can be in a linear superposition of the two states; hence, when a qubit is measured, the result will be zero with a certain probability and one with the complementary probability. A quantum register consists of *n* qubits. Because of superposition, a phenomenon known as quantum parallelism allows exponentially many computations to take place simultaneously, thus vastly increasing the speed of computation. It has been proven that a quantum computer will be able to factor and compute discrete logarithms in polynomial time. Unfortunately, the development of a practical quantum computer is still decades away.

81.5 Quantum Cryptography *versus* Traditional Cryptography

A fundamental difference between traditional cryptography and quantum cryptography is that traditional cryptography primarily uses difficult mathematical techniques (such as integer factorization in RSA) as its fundamental mechanism. Quantum cryptography, on the other hand, uses physics to secure data. Whereas traditional cryptography stands on a foundation of strong math, quantum cryptography has a radically different premise in that the security should be based on known physical laws rather than on mathematical problems (see Exhibit 81.9). Quantum cryptography, also known as quantum key distribution or (QKD), is built on quantum physics. Perhaps the most well-known aspect of quantum physic is the uncertainty principle of Werner Heisenberg, which states that we cannot know both the position and momentum of a particle with absolute accuracy at the same time.

Specifically, quantum cryptography is a set of protocols, systems, and procedures that make it possible to create and distribute secret keys. Quantum cryptography can be used to generate and distribute secret keys, which can then be used together with traditional cryptography algorithms and protocols to encrypt and transfer data. It is important to note that quantum cryptography is not used to encrypt data, transfer encrypted data, or store encrypted data.

As noted early, the need for asymmetric key systems arose from the issue of key distribution. The quandary is that it is necessary to have a secure channel to set up a secure channel. Quantum cryptography solves the key distribution problem by allowing the exchange of a cryptographic key between two remote parties with complete security as dictated by the laws of physics. When the key exchange takes place, conventional cryptographic algorithms are used. For that reason, many prefer the term *quantum key distribution* as opposed to *quantum cryptography*.

The following is a basic and overly simplistic explanation of how quantum cryptography can be used in a commercial setting:

- Two parties need to exchange data electronically in a highly secure manner.
- They choose standard cryptography algorithms, protocols, systems, and transport technologies to exchange the data in an encrypted form.
- They use a quantum cryptography channel to generate and exchange the secret keys required by the algorithms.

EXHIBIT 81.9 Comparison between QKD and Public/Private Key Protocols

Quantum Key Distribution	Pro/Con	Public/Private Key	Pro/Con
Requires dedicated hardware and communication lines	Con	Can be implemented in software; very portable	Pro
Mathematically proven secure based on basic physics laws	Pro	Mathematically undecided; based on mathematical problems for which an easy solution is not known (but could be discovered)	Con
Security is based on basic principles; does not require changes in future	Pro	Requires using longer private and public keys as computer power increases	Con
Will still be secure even when a quantum computer is built	Pro	Can be broken by a quantum computer, when and if one is built	Con
Very expensive	Con	Affordable by anyone	Pro
Still young and in development	Con	Extensively tested and deployed	Pro
Works only at limited distances and only with (direct) optical fibers	Con	Works at any distance and with any kind of network connection	Pro
Bit rate for key creation still low for some kinds of applications, but it will improve soon (when technical problems are solved)	?	Requires considerable amount of computing power, which is not a problem with data such as normal secret keys but not practical with larger data	?
Can be used with one-time pad, the only mathematically proven secure cryptographical algorithm	Pro	Cannot be used with one-time pad	Con

- They use the secret keys generated by quantum cryptography and the classical algorithms to encrypt the data.
- They exchange the encrypted data using the chosen classical protocols and transfer technologies.

Within quantum cryptography are two distinct channels. One channel is used for the transmission of the quantum key material via single photon light pulses; the other channel carries all message traffic, including the cryptographic protocols, encrypted user traffic, and more.

According to the laws of quantum physics, when a photon has been observed, its state changes. This makes quantum cryptography ideal for security purposes, because when someone tries to eavesdrop on a secure channel it will cause a disturbance in the flow of the photons that can be easily identified to provide extra security.

Quantum algorithms are orders of magnitude better than current systems. It is estimated that quantum factorization can factor a number a million times longer than any used for RSA in a millionth of the time. In addition, it can crack a Data Encryption Standard (DES) cipher in less than four minutes! The increased speed is due to the superposition of numbers. Quantum computers are able to perform calculations on various superpositions simultaneously, which creates the effect of a massive parallel computation.

81.6 Quantum Key Generation and Distribution

One current use of quantum cryptography is for key distribution. Because it is based on quantum mechanics, the keys generated and disseminated using quantum cryptography have been proven to be completely random and secure. The crypto keys are encoded on an individual photon basis, and the laws of quantum mechanics guarantee that an eavesdropper attempting to intercept even a single photon will permanently change the information encoded on that photon; therefore, the eavesdropper cannot copy or even read the photon and the data on it without modifying it. This enables quantum cryptography to detect this type of attack.

Before the advent of a public-key infrastructure, the only way to distribute keys securely was via trusted courier or some physical medium (keys on a floppy disk or CD-ROM). Much of the security of public-key cryptography is based on one-way functions. A mathematical one-way function is one that is easy to compute but difficult to reverse; however, reversing a one-way function can indeed be done if one has adequate time and computing resources. The resources necessary to crack an algorithm depend on the length of the key, but with the advent of distributed computing and increasing computer speeds this is becoming less of an issue.

In the late 1970s, the inventors of the RSA algorithm issued a challenge to crack a 129-bit RSA key. They predicted at the time that such a brute force attack would take roughly 40 quadrillion years, but it did not take quite that long. By 1994, a group of scientists working over the Internet solved RSA-129. In essence, the security of public keys would quickly be undermined if there was a way to quickly process the large numbers.

Quantum cryptography has the potential to solve this vexing aspect of the key distribution problem by allowing the exchange of a cryptographic key between two remote parties with absolute security guaranteed by the laws of physics (again, if the keys can be kept secret, then the underlying security is vastly improved). Quantum key distribution exploits the fact, as mentioned earlier, that according to quantum physics the mere fact of observing a system will perturb it in an irreparable way. The simple act of reading this article alters it in a way that cannot be observed by the reader. Although this alteration cannot be observed at the macroscopic level, it can be observed at the microscopic level. A crucial factor is that it is provably impossible to intercept the key without introducing perturbations.

This characteristic has vast value to cryptography. If a system encodes the value of a bit on a quantum system, any interception will automatically create a perturbation due to the effect of the observer. This perturbation then causes errors in the sequence of bits shared by the two endpoints. When the quantum cryptographic system finds such an error, it will assume that the key pair was intercepted and then create a new key pair. Because the perturbation can only be determined after the interception, this explains why to date quantum cryptography has been used to exchange keys only and not the data itself.

What does it mean in practice to encode the value of a digital bit on a quantum system?[2] In telecommunications, light is routinely used to exchange information. For each bit of information, a pulse is emitted and sent down an optical fiber to the receiver where it is registered and transformed back into an electronic form. These pulses typically contain millions of particles of light, called photons. In quantum cryptography, one can follow the same approach, with the only difference being that the pulses contain only a single photon. A single photon represents a very tiny amount of light (when reading this article, your eyes are registering billions of photons every second) and follows the laws of quantum physics. In particular, it cannot be split in half. This means that an eavesdropper cannot take half of a photon to measure the value of the bit it carries, while letting the other half continue on its course. To obtain the value of the bit, an eavesdropper must detect the photon which will affect the communication and reveal its being observed.

81.7 Quantum Cryptography *versus* Public-Key Cryptography

In many ways, quantum cryptography and public-key cryptography are similar. Both address the fundamental problem of creating and distributing keys to remote parties in a highly secure manner; they both solve the key distribution problem encountered by any two entities wishing to communicate using a cryptographically protected channel. But, quantum cryptography obtains its fundamental security from the fact that each qubit is carried by a single photon, and these photons are altered as soon as they are read, which makes it impossible to intercept messages without being detected.

[2] See IdQuantique, *A Quantum Leap for Cryptography.*, p. 4, Geneva, IdQuantique, (www.idquantique.com/products/files/clavis-white.pdf).

81.8 Quantum Cryptography and Heisenberg's Uncertainty Principle

The foundation of quantum cryptography lies in the Heisenberg uncertainty principle, which states that certain pairs of physical properties are related in such a way that measuring one property prevents the observer from simultaneously knowing the value of the other. This law, put forward in 1927 by German physicist Werner Heisenberg, suggests that the mere act of observing or measuring a particle will ultimately change its behavior. At the macroscopic levels, we do not notice this occurring.

Under the laws of quantum physics, a moving photon has one of four orientations; vertical, horizontal, or diagonal in opposing directions. Quantum cryptographic devices emit photons one at a time, and each photon has a particular orientation. Photon sniffers are able to record the orientation of each photon, but, according to Heisenberg's uncertainty principle, doing so will change the orientation of some of the particles which in turn will warn both the sender and the recipient that their channel is being monitored. Where Heisenberg's uncertainty principle is of huge benefit to information security is that, if quantum cryptography is used to send keys via photons then perfect encryption is assured. If it is found that the keys have been observed and are therefore at risk, then it is a simple matter to create a new set of keys. In traditional key exchange, it is not possible to know if a key has been tampered with to the same degree of certainty as with quantum cryptography.

Many of the quantum cryptography proponents and vendors publicly state that quantum cryptography provides absolute security; however, for those with a background in cryptography, the only provably secure cryptosystems are one-time pads.[3] Can quantum cryptography really create a scheme that provides absolute security? Traditional cryptographic schemes, such as RSA, are based on hard mathematical problems; quantum cryptography is based on the laws of physics and Heisenberg's uncertainty principle, which would seem to provide absolute security.

81.9 Disadvantages of Quantum Cryptography

Like everything else in the world of information security, quantum cryptography is no panacea. The main drawbacks of quantum cryptography are:

- It is slow.
- It is expensive.
- It works only over relatively short distances.
- It is new and unproven.
- It requires a dedicated connection.
- It lacks digital signatures.
- The speed of the actual key exchange is roughly 100 kbps.

Also, because it must transfer the actual physical properties of photons, it only works over relatively short distances. Current limitations now mean that the cryptographic devices can be a maximum of 75 miles apart. The reason for the short distance is that optical amplification destroys the qubit state. A repeater cannot be used to extend the distance because the repeater would change the state of the photon. In addition, attenuation of the fiber-optic links would degrade the quality of the signal and ultimately make the transmitted photon unreadable.

The photon emitters and detectors themselves are currently far from perfect and can cause errors that often require retransmission of the keys. The signals themselves are currently a significant problem for those implementing quantum cryptography, due to the presence of noise in all of the communications

[3] For more information on why, see http://world.std.com/~franl/crypto/one-time-pad.html.

channels, most prominently in the optical fibers themselves. As the systems evolve, however, noise is less likely to be a problem.

In order to transmit the photon, both parties must have a live, unbroken, and continuous communications channel between them. Although no quantum routers now exist, research is being conducted on how to build them. The value of a quantum router is that it would enable quantum cryptography to be used on a network. Finally, quantum cryptography today does not have a seamless method for obtaining a digital signature. Quantum digital signature schemes are in development but are still not ready for the commercial environment.

81.10 Effects of Quantum Computing and Cryptography on Information Security

It is clear that if a functioning quantum computer was to be constructed, it would immediately undermine the security provided by both symmetric-key algorithms and public-key algorithms. Quantum computing would be able to break public-key cryptosystems in inconsequential amounts of time. It is estimated that a 1024-bit RSA key could be broken with roughly 3,000 qubits. Given that current quantum computers have less than 10 qubits, public-key cryptography is safe for the foreseeable future, but this is not an absolute guarantee.

81.11 Conclusion

Quantum cryptography, while still in a nascent state, is certain to have a huge and revolutionary effect on the world of cryptography and secure communications. As of late 2005, quantum cryptography was not in heavy use in the Fortune 1000 community, but it will likely find much greater application in the coming years as it matures and the price drops.

81.12 Glossary of Quantum Physics Terms

Entanglement—The phenomenon that two quantum systems that have been prepared in a state such that they interacted in the past may still have some locally inaccessible information in common.

Interference—The outcome of a quantum process depends on all of the possible histories of that process.

Observable—Anything within a quantum mechanical system that can be observed, measured, and quantitatively defined (e.g., electron spin, polarization).

Quanta—Discrete packets or entities in quantum systems; observables in quantum systems tend to vary discretely, not continuously.

Superposition—The concept that a quantum system may be simultaneously in any number of possible states at once.

Elliptic Curve Cryptography: Delivering High-Performance Security for E-Commerce and Communications

Paul Lambert

Elliptic curve cryptography (ECC) provides the highest strength per key bit of any known public-key security technology. The relative strength advantage of ECC means that it can offer the same level of cryptographic security as other algorithms using a much smaller key. ECC's shorter key lengths result in smaller system parameters, smaller public-key certificates, and, when implemented properly, faster performance with lower power requirements and smaller hardware processors. As a result, ECC is able to meet the security and performance demands of virtually any application.

With the increased amount of sensitive information being transmitted wirelessly and over the Internet, information security has become a critical component to many applications. Cryptography in turn has become a fundamental part of the solution for secure applications and devices. Across a variety of platforms, cryptographic technology provides security to a wide range of applications such as electronic commerce, access control, and secure wireless communications. The ongoing challenge for manufacturers, systems integrators, and service providers is to incorporate efficient, cost-effective security into the mobile, high-performance devices and applications that the market demands. While other cryptographic algorithms cannot effectively meet this challenge, ECC's strength and performance advantages make it an ideal solution to secure Internet commerce, smart card, and wireless applications, as will be demonstrated further on in this chapter.

82.1 Understanding the Strong, Compact Security of ECC

All public-key cryptosystems are based on a hard one-way mathematical problem. ECC is able to deliver strong security at smaller key sizes than other public-key cryptographic systems because of the difficulty of the hard problem upon which it is based. ECC is one of three different types of cryptographic systems that are considered to provide adequate security, defined in standards and deployed in today's applications. Rather than explaining the complete mathematical operation of each of these three systems, this chapter will serve to introduce and compare each system.

First, what is meant by a hard or difficult mathematical problem? A mathematical problem is difficult if the fastest known algorithm to solve the problem takes a long time relative to the input size. To analyze how long an algorithm takes, computer scientists introduced the notion of *polynomial time* algorithms and *exponential time* algorithms. Roughly speaking, a polynomial time algorithm runs quickly relative to the size of its input, and an exponential time algorithm runs slowly relative to the size of its input. Therefore, easy problems have polynomial time algorithms, and difficult problems have exponential time algorithms.

The phrase *relative to the input size* is fundamental in the definition of polynomial and exponential time algorithms. All problems are straightforward to solve if the input size is very small, but cryptographers are interested in how much harder a problem gets as the size of the input grows. Thus, when looking for a mathematical problem on which to base a public-key cryptographic system, cryptographers seek one that cannot be solved in less than exponential time because the fastest known algorithm takes exponential time. Generally, the longer it takes to compute the best algorithm for a problem, the more secure is a public-key cryptosystem based on that problem.

What follows is a discussion of the three different types of cryptographic systems along with an explanation of the hard mathematical problems on which they are based.

82.1.1 RSA and the Integer Factorization Problem

The best-known cryptosystem based on the integer factorization problem, *RSA*, is named after its inventors, Ron Rivest, Adi Shamir, and Len Adleman. Another example is the Rabin–Williams system. The core concept of the integer factorization problem is that an integer p (a whole number) is a *prime number* if it is divisible only by 1 and p itself. When an integer n is the product of two large primes, to determine what these two factors are we need to find the prime numbers p and q such that: $p \times q = n$. The integer factorization problem, then, is to determine the prime factors of a large number.

82.1.2 DSA and the Discrete Logarithm Problem

The Diffie–Hellman key agreement scheme, the grandfather of all public-key cryptography schemes, is based on the discrete log problem. Taher Elgamal first proposed the first public-key cryptographic system that included digital signatures based on this problem. Elgamal proposed two distinct systems: one for encryption and one for digital signatures. In 1991, Claus Schnorr developed a more efficient variant of Elgamal's digital signature system. The U.S. Government's Digital Signature Algorithm (DSA), the best-known of a large number of systems with security based on the discrete logarithm problem, is based on Elgamal's work. The *discrete logarithm problem* modulo prime p is defined in terms of modular arithmetic. This problem starts with a prime number p. Then, given an integer g (between 0 and $p-1$) and a multiplicand y (the result of exponentiating g), the following relationship exists between g and y for some x: $y = g^x \pmod{p}$. The discrete logarithm problem is to determine the integer x for a given pair g and y: Find x so that $g^x = y \pmod{p}$. Like the integer factorization problem, no efficient algorithm is known to solve the discrete logarithm problem.

82.1.3 ECC and the Elliptic Curve Discrete Logarithm Problem

The Security of ECC rests on the difficulty of the elliptic curve discrete logarithm problem. As with the integer factorization problem and the discrete logarithm problem, no efficient algorithm is known to solve the elliptic curve discrete logarithm problem. In fact one of the advantages of ECC is that the elliptic curve discrete logarithm problem is believed to be more difficult than either the integer factorization problem or the generalized discrete logarithm problem. For this reason, ECC is the strongest public-key cryptographic system known today.

In 1985, mathematicians Neil Koblitz and Victor Miller independently proposed the *elliptic curve cryptosystem*, with security resting on the discrete logarithm problem *over the points on an elliptic curve*. Before explaining the hard problem, a brief introduction to elliptic curves is needed.

An *elliptic curve* defined modulo a prime p, is the set of solutions (x,y) to the equation: $y^2=x^3+ax+b \pmod p$ for the two numbers a and b. This means that y^2 has the remainder x^3+ax+b when divided by p. If (x,y) satisfies the above equation, then $p=(x,y)$ is a *point* on the elliptic curve.

An elliptic curve can also be defined over the finite field consisting of 2^m (even numbers) elements. This field, referred to as F_2^m, increases the efficiency of ECC operation in some environments. One can define the addition of two points on the elliptic curve. If P and Q are both points on the curve, then $P+Q$ is always another point on the curve. The elliptic curve discrete logarithm problem starts with selecting a field (a set of elements) and an elliptic curve. (Selecting an elliptic curve consists of selecting values for a and b in the equation $y^2=x^3+ax+b$.) Then xP represents the point P added to itself x times.

Suppose Q is a multiple of P, so that $Q=xP$ for some x. The elliptic curve discrete logarithm problem is to determine x with any given P and Q.

82.2 A Comparison of Cryptographic Systems

Of the three problems, the integer factorization problem and the discrete logarithm problem both can be solved by general algorithms that run in *subexponential time*, meaning that the problem is still considered hard but not as hard as those problems that admit only fully exponential time algorithms. On the other hand, the best general algorithm for the elliptic curve discrete logarithm problem is fully exponential time. This means that the elliptic curve discrete logarithm problem is currently considered more difficult than either the integer factorization problem or the discrete logarithm problem.

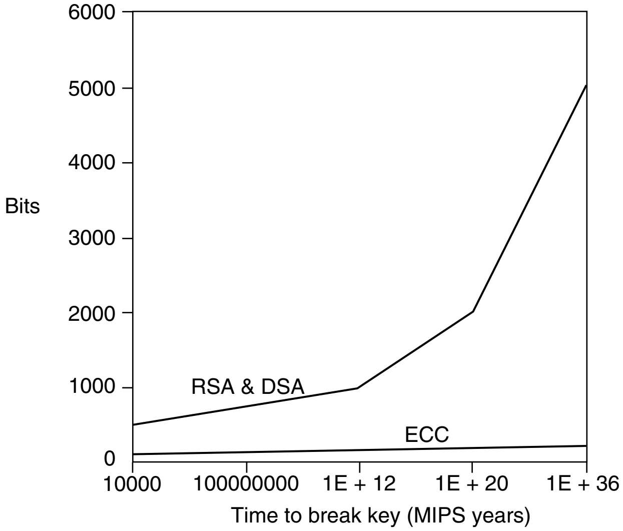

EXHIBIT 82.1 Comparison of security levels.

In Exhibit 82.1, the graph compares the time required to break ECC with the time required to break RSA or DSA for various key sizes using the best-known algorithm. The values are computed in *MIPS years*. A MIPS year represents the computing time of 1 year on a machine capable of performing 1 million instructions per second. As a benchmark, it is generally accepted that 10^{12} MIPS years represents reasonable security at this time, as this would require most of the computing power on the planet to work for a considerable amount of time. To achieve reasonable security, RSA and DSA need to use a 1024-bit key, while a 160-bit key is sufficient for ECC. The graph in Exhibit 82.1 shows that the gap between the systems grows as the key size increases. For example, note how the ratio increases with the 300-bit ECC key compared with the 2000-bit RSA and DSA keys. With this background in ECC's high security relative to small key size, we can explore how ECC benefits today's leading-edge applications.

82.3 Securing Electronic Transactions on the Internet

One prominent application that requires strong security is electronic payment on the Internet. When making Internet-based credit card purchases, users want to know that their credit card information is protected, while the merchant wants assurance that the person making the purchase cannot later refute the transaction. Combined with these authentication needs, a secure electronic payment system must operate fast enough to handle consumer's needs conveniently. It must be capable of handling a high volume of transactions reliably and, simultaneously, be accessible from multiple locations, and be easy to use. ECC can meet all these needs. For example, consider the role ECC plays in securing a recently launched experimental pilot for Internet commerce. The pilot is based on the Secure Electronics Transaction (SET) specification developed to address the requirements of the participants in these Internet transactions.

The SET specification is administered by an organization known as Secure Electronic Transaction LLC (SETCo) formed by Visa and MasterCard. The initial specification provided a complex security protocol using RSA for the public-key components. Because the release of the SET 1.0 specification, implementations of the protocol have been increasing worldwide along with the growing consumer confidence in electronic commerce. Vendors and financial institutions have proposed a number of enhancements to the protocol to further its appeal.

In an ongoing effort to explore ways to improve the SET specification, an experimental pilot program was launched in July 1998 that ran until September 1998. A consortium of players joined together to implemented some exciting leading-edge technologies for use with the SET protocol including ECC, chip cards, and PCI cryptographic hardware. During the pilot, up to 200 selected participants received a smart card, which was a Zions Bank MasterCard with an embedded microprocessor, along with a SET software wallet and a Litronics card reader. These participants shopped at the U.S. Department of Treasury's Bureau of Engraving and Printing Website and were assured that their transactions were protected.

82.3.1 Pilot Operation

1. Cardholder has certificate request and receipt.
2. Cardholder visits Web site at www.bep.treas.gov, selects goods, and initiates payment.
3. Certificates and digital certificates are exchanged.
4. Purchase order and digital signatures are sent via the Internet to the MasterCard payment gateway. Both parties are authenticated; data is decrypted and reformatted.
5. The data is sent via leased lines to Global Payment Systems (GPS) in Atlanta.
6. GPS sends reformed credit card information and purchase data over MasterCard's private BankNet leased line network to Zions Bank.
7. Zions debits cardholder account and issues payment to the Bureau's account via its acquiring bank, Mellon Bank.

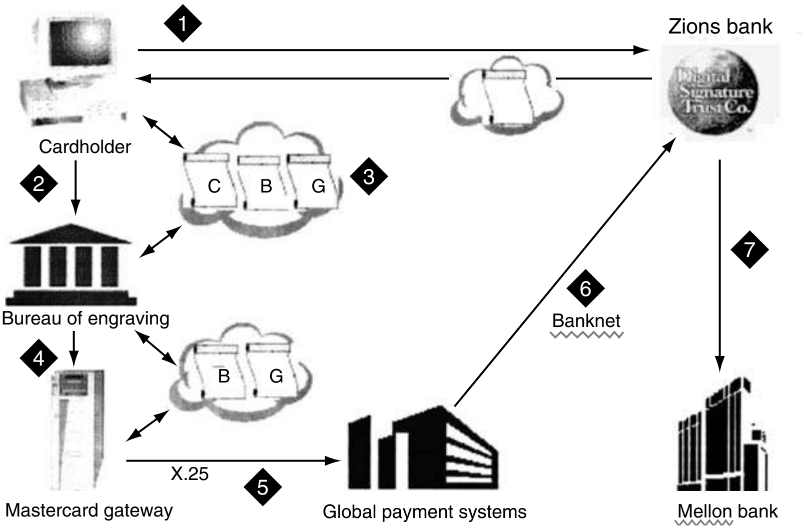

EXHIBIT 82.2 Experimental SET™ pilot.

As represented by Exhibit 82.2, upon receiving the card and reader, the cardholder applies online for a digital certificate with the ECC smart-card-enabled GlobeSet Wallet through Digital Signature Trust Company (DST). DST issues certificates on behalf of Zions Bank using GlobeSet's ECC-enabled CA. The public key is securely sent to DST where a certificate is created and sent back to the cardholder via the Internet. The certificate is stored on the smart card for future use.

82.3.1.1 Procedure

The shopper visits the Bureau's Website at www.bep.treas.gov and selects an item to purchase with his or her Zions Bank MasterCard. The ECC-enabled GlobeSet POS (point of sale) submits a SET wake-up message to the wallet, and the cardholder initiates a transaction by inserting his or her card in to the Litronics reader. All sensitive communication between the two parties is encrypted for privacy and the data is digitally signed for integrity and nonrepudiation according to the SET specification. The purchase order and accompanying information are sent via the Internet through the merchant to the ECC-enabled GlobeSet payment gateway at MasterCard, also employing certificates, signatures, and encryption. The gateway decrypts the data, authenticates both parties, and reformats the data. The data is sent over MasterCard's private BankNet leased-line network to receive payment authorization from Zions Bank, which debits the cardholder's MasterCard account and issues payment to the Bureau through its acquiring bank, Mellon Bank. Cardholders receive their merchandise via the U.S. Postal Service in the usual manner. Implemented end-to-end within an algorithm coexistent system, ECC is an enabling technology adding performance and cost advantages to SET as demonstrated in this pilot.

82.3.1.2 Improving Performance

A comprehensive benchmarking process comparing the performance of ECC and RSA was completed at GlobeSet and audited by a team from SETCo. Improved performance is especially desirable for banks and vendors because cryptographic processing is frequently a bottleneck that can be cleared only with increased hardware costs. In preliminary software-only benchmark tests, ECC demonstrated a positive and significant performance advantage, with overall cryptographic processing overhead reduced by 73 percent. ECC is around 40 times faster than RSA on the payment gateway, which is the SET component more prone to bottlenecks. Signing alone is more than 100 times faster with ECC on this component.

82.3.1.3 Increasing Cardholder Security

Smart cards offer a higher level of security than software-only-based digital wallets because a user's private key and certificate can be stored on the card. As a cryptographic hardware token, smart cards provide stronger user authentication and nonrepudiation than software. Their use translates into lower risk and less fraud for banks, merchants, and consumers.

82.3.1.4 Reducing the Cost of Smart Card Deployment

Smart cards (Exhibit 82.3) are small, portable, tamper-resistant devices providing users with convenient storage and processing capability. As a result, smart cards have been proposed for use in a wide variety of applications such as electronic commerce, identification, and healthcare. For many of these proposed applications, cryptographic security is essential. This requirement is complicated by the fact that smart cards need to be inexpensive in order to be practical for widespread use. The problem is not how to implement cryptography on a smart card but how to do so efficiently and cost-effectively. The smart card is amenable to cryptographic implementations for several reasons. The card contains many security features that enable the protection of sensitive cryptographic data, providing a secure environment for processing. The protection of the private key is critical; to provide cryptographic services, this key must never be revealed. The smart card protects the private key and many consider the smart card to be an ideal cryptographic token; however, implementing public-key cryptography in a smart card application poses numerous challenges. Smart cards present a combination of implementation constraints that other platforms do not: Constrained memory and limited computing power are two of them. The majority of the smart cards on the market today have between 128 and 1024 bytes of RAM, 1 and 16 kb of EEPROM, and 6 and 16 kb of ROM with the traditional 8-bit CPU typically clocked at a mere 3.57 MHz. Any addition to memory or processing capacity increases that cost of each card because both are extremely cost sensitive. Smart cards are also slow transmitters, so to achieve acceptable application speeds data elements must be small (to limit the amount of data passed between the card and the terminal). While cryptographic services that are efficient in memory usage and processing power are needed to contain costs, reductions in transmission times are also needed to enhance usability.

82.3.2 Use of EEC in Smart Cards

Elliptic curve cryptography is ideally suited for implementations in smart cards for a number of reasons:

- *Less memory and shorter transmission times*—The strength (difficulty) of the elliptic curve discrete logarithm problem algorithm means that strong security is achievable with proportionately smaller key and certificate sizes. The smaller key size in turn means that less memory is required to

EXHIBIT 82.3 The smart card.

store keys and certificates and that less data must be passed between the card and the application, so transmission times are shorter.

- *Scalability*—As smart card applications require stronger and stronger security (with longer keys), ECC can continue to provide the security with proportionately fewer additional system resources. This means that with ECC smart cards are capable of providing higher levels of security without increasing their costs.
- *No coprocessor*—The reduced processing times of ECC also make it ideal for the smart card platform. Other public-key systems involve so much computation that a dedicated hardware device, known as a *crypto coprocessor*, is required. The crypto coprocessors not only take up precious space on the card, but they also increase the cost of the chip by about 20 to 30 percent, which translates to an increase of about $3 to $5 on the cost of each card. With ECC, the algorithm can be implemented in available ROM, so no additional hardware is required to perform strong, fast security functions.
- *On-card key generation*—As mentioned earlier, the private key in a public key pair must be kept secret. To truly prevent a transaction from being refuted, the private key must be completely inaccessible to all parties except the entity to which it belongs. In applications using the other types of public key systems currently in use, cards are personalized (keys are either loaded or injected into the cards) in a secure environment to meet this requirement. Because of the complexity of the computation required, generating keys on the card is inefficient and typically impractical.

With ECC, the time needed to generate a key pair is so short that even a device with a very limited computing power of a smart card can generate the key pair, provided a good random number generator is available. This means that the card personalization process can be streamlined for applications in which nonrepudiation is important.

82.4 Extending the Desktop to Wireless Devices

Wireless consumers want access to many applications that previously have only been available from the desktop or wired world. In response to the growing demand for new wireless data services, Version 1.0 of the Wireless Application Protocol (WAP) provides secure Internet access and other advanced services to digital cellular phones and a variety of other digital wireless devices. The new specification enables manufactures, network operators, content providers, and applications developers to offer compatible products and secure services that work across different types of digital devices and networks. Wireless devices are not unlike smart cards in that they also introduce many security implementation challenges. The devices themselves must be small enough to have the portability that users demand. More importantly, the bandwidth must be substantially reduced. The WAP Forum, the organization that developed the WAP specification, has responded to these market and technology challenges by incorporating ECC into the WAP security layer (Wireless Transport Layer Security, or WTLS) specification. With ECC, the same type of sensitive Web-based electronic commerce applications (such as banking and stock trades) that are currently confined to the fixed, wired world can run securely on resource-constrained wireless devices. Strong and efficient security that requires minimal bandwidth, power consumption, and code space is uniquely achievable with ECC. ECC meets the stringent security requirements of the market by incorporating elliptic curve-based Diffie–Hellman key management and the elliptic curve digital signature algorithm (ECDSA) into a complete public-based security system.

Exhibit 82.4 and Exhibit 82.5 compare the signature size and encrypted message size for each of the three cryptosystems discussed earlier. The reduced digital signature and encrypted message sizes result in huge savings of bandwidth, a critical resource in the wireless environment.

EXHIBIT 82.4 Signature Size for a 2000-Bit Message

System Type	Signature Size (bits)	Key Size (bits)
RSA	1024	1024
DSA	320	1024
ECDSA	320	160

EXHIBIT 82.5 Size of Encrypted 100-Bit Message

System Type	Encrypted Message (bits)	Key Size (bits)
RSA	1024	1024
EIGamal	2048	1024
ECES	321	160

82.5 Conclusions

Three types of public-key cryptographic systems are available to developers and implementers today: integer factorization system, discrete logarithm systems, and elliptic curve discrete logarithm systems. Each of these systems can provide confidentially, authentication, data integrity, and nonrepudiation. Of the three public-key systems, ECC offers significant advantages that are all derived (directly or indirectly) from to its superior strength per bit. These efficiencies are especially advantageous in thin-client applications in which computational power, bandwidth, or storage space is limited. The advantages and resulting benefits of ECC for a wide range of applications are well recognized by many in the industry. ECC is being incorporated by a growing number of international standards organizations into general cryptographic standards such as IEEE and ANSI and is being considered for integration into vertical market standards for telecommunications, electronic commerce, and the Internet. Meanwhile, an increasing number of computing and communications manufacturers are building ECC technology into their products to secure a variety of applications for corporate enterprise, the financial community, government agencies, and end users alike. ECC technology has earned its reputation as a truly enabling technology by making many of these products and applications possible by providing viable security.

83

Cryptographic Key Management Concepts

Ralph Spencer Poore

83.1 Cryptographic Security

83.1.1 A Brief History

Cryptography, the art of "secret writing," has existed for almost as long as writing itself. Originally, the use of symbols to represent letters or words in phrases was a skill reserved for scribes or learned clerics. However, for a scribe's work to be truly useful, others needed the ability to read the scribe's work. As standardized writing and reading skills became more widespread, the risk of unauthorized reading increased. Primarily for purposes of political intrigue and military secrecy, practical applications of secret writing evolved. There are examples of simple alphabetic substitution ciphers dating back to the time of Julius Caesar. Julius Caesar is honored today by our naming an entire class of mono-alphabetic substitution ciphers after him. The following (translated into our modern alphabet) is an example of a cipher he is believed to have used:

A B C D E F G H I J K L M N O P Q R S T U V W X Y Z
D E F G H I J K L M N O P Q R S T U V W X Y Z A B C

The rotation of the alphabet by three places is enough to transform a simple plaintext message from "we attack to the north at dawn" into "ZH DWWDFN WR WKH QRUWK DW GDZQ." By finding each letter of plaintext in the first alphabet and substituting the letter underneath from the second alphabet, one can generate the ciphertext. By finding each letter of the ciphertext in the lower alphabet and substituting the letter directly above it, one can translate the ciphertext back to its plaintext. In general, one refers to any rotation of an alphabet as a Caesar alphabet.

An improvement on the Caesar alphabet is the keyed mono-alphabetic substitution cipher. It uses a key word or phrase as follows:

A B C D E F G H I J K L M N O P Q R S T U V W X Y Z
S H A Z M B C D E F G I J K L N O P Q R T U V W X Y

where "SHAZAM" is the key word from which any duplicate letters (in this case the second "A") are removed, giving "SHAZM." The key word is then used for the first letters of the cipher alphabet, with the unused letters following in order. The recipient of a coded message only needs to know the word "SHAZAM" in order to create the keyed cipher alphabet. A further improvement, but one that requires the entire cipher alphabet to act as the key, is the use of a randomly generated cipher alphabet. All such mono-alphabetic substitutions, however, are easily solved if enough ciphertext is available for frequency analysis and trial-and-error substitutions. Mono-alphabetic ciphers today are relegated to the entertainment section of the newspaper and no longer serve as protectors of secrecy.

Poly-alphabetic systems, however, still pose a challenge. In these systems, each letter comes from a cipher alphabet different from the previously enciphered letter. As shown in Exhibit 83.1, for example, a

EXHIBIT 83.1 Rotating Among Four Cipher Alphabets

	1	2	3	4
A	H	B	J	K
B	T	I	E	A
C	Z	D	V	T
D	X	M	O	G
E	L	X	N	O
F	P	Q	R	S
G	V	U	T	W
H	A	C	Z	Y
I	B	G	D	E
J	F	E	A	U
K	W	Y	B	C
L	D	F	G	H
M	J	K	L	R
N	S	V	Q	M
O	N	R	X	Z
P	R	P	M	F
Q	K	I	Y	X
R	C	A	W	D
S	Y	H	U	L
T	O	Q	S	I
U	E	L	C	B
V	T	N	F	J
W	M	O	I	N
X	I	S	H	P
Y	G	J	K	Q
Z	Q	T	P	V

system rotating among four cipher alphabets would mean that each possible plaintext letter could be represented by any of four different ciphertext letters.

The cipher alphabets are labeled 1, 2, 3, and 4, respectively. Notice that the plaintext letter “A” can be represented by “H,” “B,” “J,” or “K.” The use of multiple alphabets complicates frequency analysis. On short messages such as “LAUNCH MISSILE NOW,” the resulting ciphertext, “DBCMZC LEYHDHL VXN,” contains no matching letters that have the same plaintext meaning. The letter “D,” for example, is in the ciphertext twice, but the first time it decodes to the letter “L” and the second time it decodes to the letter “I.” Similarly, the letter “C” decodes first to the letter “U” and then to the letter “H.” Very difficult ciphers used in World War II (e.g., ENIGMA) relied on more complex variations of this class of ciphers. They used multiple wheels, where each wheel was a cipher alphabet. The wheels would advance some distance after each use. To decode, one needed the wheels, their respective order and starting positions, and the algorithm by which they were advanced.

83.1.2 Cryptography and Computers

With the advent of computers, cryptography really came of age. Computers could quickly execute complex algorithms and convert plaintext to ciphertext (encrypt) and ciphertext back to plaintext (decrypt) rapidly. Up until the 1960s, however, cryptography was almost exclusively the property of governments. A prototype for commercial applications, IBM’s Lucifer system was a hardware implementation of a 128-bit key system. This system became the basis for the Data Encryption Standard (DES), a 64-bit key system (8 bits of which were for parity, leaving an effective key length of 56 bits), the algorithm for which is known as the Data Encryption Algorithm (DEA) as codified in American National Standard X3.92.

83.1.3 An Encryption Standard

For dependable commercial use, secret or proprietary cryptographic algorithms are problematic. Secret/proprietary algorithms are, by definition, not interoperable. Each requires its own implementation, forcing companies into multiple, bilateral relationships and preventing vendors from obtaining economies of scale. As a practical matter, cryptographic security was cost prohibitive for business use until DEA. With a standard algorithm, interoperability became feasible. High-quality cryptographic security became commercially viable.

Auditors and security professionals should also understand two other important problems with secret algorithms. First, who vets the algorithm (i.e., proves that it has no weaknesses or “trapdoors” that permit solving of the encrypted text without the cryptographic key)? This is both an issue of trust and an issue of competence. If the cryptographic section of a foreign intelligence service certified to a U.S. firm that a secret algorithm was very strong and should be used to protect all of the firm’s trade secrets, would the U.S. firm be wise in trusting the algorithm? Such an agency might have the expertise, but can one trust any organization with a vested interest in intelligence gathering to tell you if a security weakness existed in the algorithm?

Vetting cryptographic algorithms is not an exact science. Cryptographers design and cryptanalysts (first coined by W. F. Friedman in 1920 in his book entitled *Elements of Cryptanalysis*) attempt to break new algorithms. When an algorithm is available to a large population of cryptographic experts (i.e., when it is made public), weaknesses, if any, are more likely to be found and published. With secret algorithms, weaknesses found are more likely to remain secret and secretly exploited. However, a secret algorithm is not without merit. If you know the algorithm, analysis of the algorithm and brute-force attacks using the algorithm are easier. Also, a standard algorithm in widespread use will attract cryptanalysis. This is one of the reasons why DES is now obsolete and a new standard (the Advanced Encryption Standard [AES]) was created. In issues of national security, secret algorithms remain appropriate.

A publicly available algorithm is not the same as an algorithm codified in a standard. One might find the source code or mathematical description of an algorithm in a published book or on the Internet. Some algorithms (e.g., IDEA$^{\mathrm{TM}}$' [International Data Encryption Algorithm] invented in 1991 by James Massey and Xuejia Lai of ETH Zurich in Switzerland) used in PGP (Pretty Good Privacy authored by Phil Zimmermann) to package a public key cryptographic algorithm, may prove to be quite strong, while others thought to be strong (e.g., FEAL [Fast Encryption Algorithm invented by Akihiro Shimizu and Shoji Miyaguchi of NTT Japan]) prove breakable.

When an algorithm is publicly available, security rests solely with the secrecy of the cryptographic keys. This is true both in symmetric and asymmetric algorithms. Algorithms using the same key to decrypt as was used to encrypt are known as *symmetric algorithms*. The DEA is a symmetric algorithm (as is the algorithm used for AES[1]). If the key used to decrypt is not the same as the key used to encrypt, the algorithm is *asymmetric*. Public key algorithms (e.g., the RSA Data Security algorithm) are asymmetric. Symmetric algorithms are sometimes called “secret key” algorithms because the one key used for both encryption and decryption must remain secret. Asymmetric algorithms may have one or more “public” keys,[2] but always have at least one “private” key. The “private” key must remain secret.

83.2 Key Management Myths

Cryptographic security using a standard, publicly available algorithm (e.g., the Federal Information Processing Standard (FIPS) 197, *Advanced Encryption Standard*) depends on the secrecy of the cryptographic key. Even with “secret” algorithms that use keys, the secrecy of at least one key (e.g., the private key used in public key cryptography) remains critical to the security of the cryptographic process. This author’s experience in evaluating implementations has revealed some common misunderstandings about managing cryptographic keys. This chapter identifies these misunderstandings (referred to as “myths”), explains why they are wrong, and describes correct procedures. The examples used are taken from experience with automated teller machine (ATM) and point-of-sale (POS) implementations that depended on DEA (and now depend on Triple DES,[3] a backward-compatible implementation that allows for longer effective key lengths through multiple applications of DEA) for personal identification number (PIN) privacy. The concepts, however, apply to most implementations of cryptography where the objective is either message privacy or integrity. Some implementations may rely on fully automated key management processes. Even these may not be immune to key management fallacies.

83.2.1 Myth 1: A Key Qualifies as “Randomly Generated” If One or More Persons Create the Key Components from Their Imagination

To meet the statistical test for randomly generated, each possible key in the key space must be equally likely. No matter how hard a person tries, he cannot make up numbers that will meet this requirement. Concatenating the non-random number choices of several persons does not result in a random number either. When people are asked to select a number at random, they automatically attempt to avoid a number containing a pattern they recognize. This is but one simple example of how people bias their selections.

If a person wants to create a random hexadecimal number, that person could number identical balls from 0 through 9 and A through F; place them in a large bowl; mix them; select and remove (without looking) a ball; record its value; place the ball back into the bowl; and repeat the process 16 times for each key component. Another alternative is to use 64 coins of equal size (e.g., all pennies); toss them on to a

[1] AES uses the Rijndael algorithm; refer to FIPS 157 for details.

[2] While not widely used, public key systems exist that require “n” of “m” keys to encrypt or decrypt. Depending on the purpose of the cryptography (e.g., confidentiality or authentication), the multiple keys might be the public ones or the private ones (or both).

[3] See ANS X9.52 (Triple Data Encryption Algorithm Modes of Operation) for more details on Triple DES.

flat surface; and using a large straightedge (e.g., a yardstick), sweep them into a straight line. Starting from the left, record a "1" for each head and a "0" for each tail. The 64 bits can them be translated in blocks of four to form a 16, hexadecimal-character key. Most organizations, however, will simply have their cryptographic device generate an ersatz random number. (You will see documentation refer to "pseudo random" numbers. These are numbers generated by a repeatable, algorithmic process but exhibit properties ascribed to randomly generated numbers. I refer to these as ersatz random numbers here because "pseudo" means "false" [so even a sequence that did not meet statistical requirements for randomness would meet this definition] where "ersatz" means "imitation or artificial" and more accurately describes the nature of these numbers. However, the term "pseudo random" is well established. A newer term—"deterministic random bit generators"—has also entered the literature, a term that better addresses this author's linguistic concerns.)[4]

83.2.2 Myth 2: An "Authorized" Person Can Create or Enter Cryptographic Keys without Compromising a Key

When a cryptographic key becomes known to anyone, it is compromised (by definition). This is why "split knowledge" controls are required. No human should ever know an active key.

Allowing a person to know an active key places the person at risk (e.g., extortion), places the organization at risk (e.g., potential misuse or disclosure by that person), and creates the potential for accidental disclosure of the key through human error.

83.2.3 Myth 3: Requiring a Second Person to Supervise or Observe the Key Entry Process Is Dual Control

To qualify as a "dual control" process, it must be infeasible for any one person to perform the entire process alone. If one person can cause all essential steps to happen without the need for at least one additional person, then dual control is not achieved. Because observation and supervision are passive activities, the absence of which would not prevent the process, a person acting in such capacities is not acting as part of a dual control process.

If party "A" has the combination to the vault within an ATM and party "B" has the key to the ATM's locked door such that both parties "A" and "B" must participate in order to gain access to the cryptographic device within the ATM, then dual control exists. However, if party "B" learns the combination or party "A" gains access to the ATM's door key, then dual control ceases to exist.

83.2.4 Myth 4: "Split Knowledge" and "Dual Control" Are the Same Thing

The concept of "split knowledge" as used in cryptography means that two or more parties are needed, each with independent knowledge of a cryptographic key component, such that together they can create a cryptographic key of which each has no knowledge. "Split knowledge" meets the requirements for "dual control," but not vice versa.

The usual way of doing this is to create two teams of key entry persons. Team "A" will generate a full-length key component and record it. Team "B" will do the same. No member of Team "A" can ever see the Team "B" key components, and vice versa. One member of each team is then needed to load a key.

Note that the use of key halves (once common in the ATM/POS industry) does not qualify as split knowledge, because each person has knowledge of at least half of the actual key. True split knowledge requires that no one have any knowledge of the resulting key.

[4] For a more in-depth discussion of a pseudo random number generator (PRNG), refer to ANS X9.82 (Random Number Generation) or NIST Special Publication 800-22 (A Statistical Test Suite for the Validation of Random Number Generators and Pseudo Random Number Generators for Cryptographic Applications).

83.2.5 Summary: "Sergeant Schultz" and "Cannot"

I call the split knowledge requirement the "Sergeant Schultz principle," from the *Hogan's Heroes* television program where Sergeant Schultz would say, "I know nothing, nothing!" Properly implemented, every key component holder should always be able to affirm that they know nothing about the resulting live key.

This author's equally short name for dual control is the "Cannot" principle. If one person **cannot** perform a function because the function can only be accomplished with the collective efforts of two or more persons, then dual control exists. If any one person can accomplish all of the steps without anyone else, then dual control does not exist.

These are two easily remembered principles that are essential to effective key management.

83.3 Key Management: An Overview

Whether or not an algorithm is kept secret, the cryptographic key or keys needed to decipher a message must remain secret if we want to keep the communication private. Knowing the keys and any plaintext encrypted under those keys makes discernment of even a secret algorithm likely. Knowing the keys and the algorithm makes decryption of messages encrypted under those keys straightforward. The objective of key management is to prevent unauthorized disclosure of keying materials. When key management fails, cryptographic security fails.

83.3.1 Three Rules of Key Management

Three rules of key management must be followed if cryptographic keys are to remain secret. First, no human being should ever have access to active, cleartext keys. Benjamin Franklin wrote that "three can keep a secret if two of them are dead."[5] In cryptography, one might recast this as "three can keep a secret if all of them are dead."

Second, whenever keys must be distributed and entered manually, one uses full-length key components to facilitate split knowledge. By requiring that two (or more) full-length key components be entered, each by a separate individual who never sees any other component, one can keep any one person from knowing the resulting key. This technique, known as "split knowledge," is actually a zero knowledge process for each individual. Each key component (C_nK, where $n=1, 2, \ldots$) conveys by itself no knowledge of the ultimate key. This is accomplished by implementing a function $\oplus$ such that $C_1K \oplus C_2K$ results in a key dependent on every bit in both components. Modulo 2 arithmetic without carry (or logical exclusive OR) is one example of such a function. Using DEA, TDES, or AES with C_1K as the data and C_2K as the key is another example.

Third, use keys only for a single purpose. If a key was intended to protect other keys, never use it to protect non-key data. If the key was intended to authenticate messages, do not use it to encrypt a message. Using the same key for more than one purpose may give a cryptanalyst a better opportunity to solve for the key. More significantly, it makes a key compromise more painful and less easily investigated when the key was used for multiple purposes.

83.3.2 Automated Key Management

Systems of key generation do exist that require no human intervention or initial manual key distribution. Because some of these systems use proprietary approaches to key management, the buyer should exercise great care. For example, a vendor might deliver each device with a fixed private key of a public key/private key-pair. Each device would transmit its public key, resulting in an exchange of public keys. Each device could then encrypt a random value under the other party's public key and transmit this cryptogram of

[5] *Poor Richard's Almanac*, July 1733.

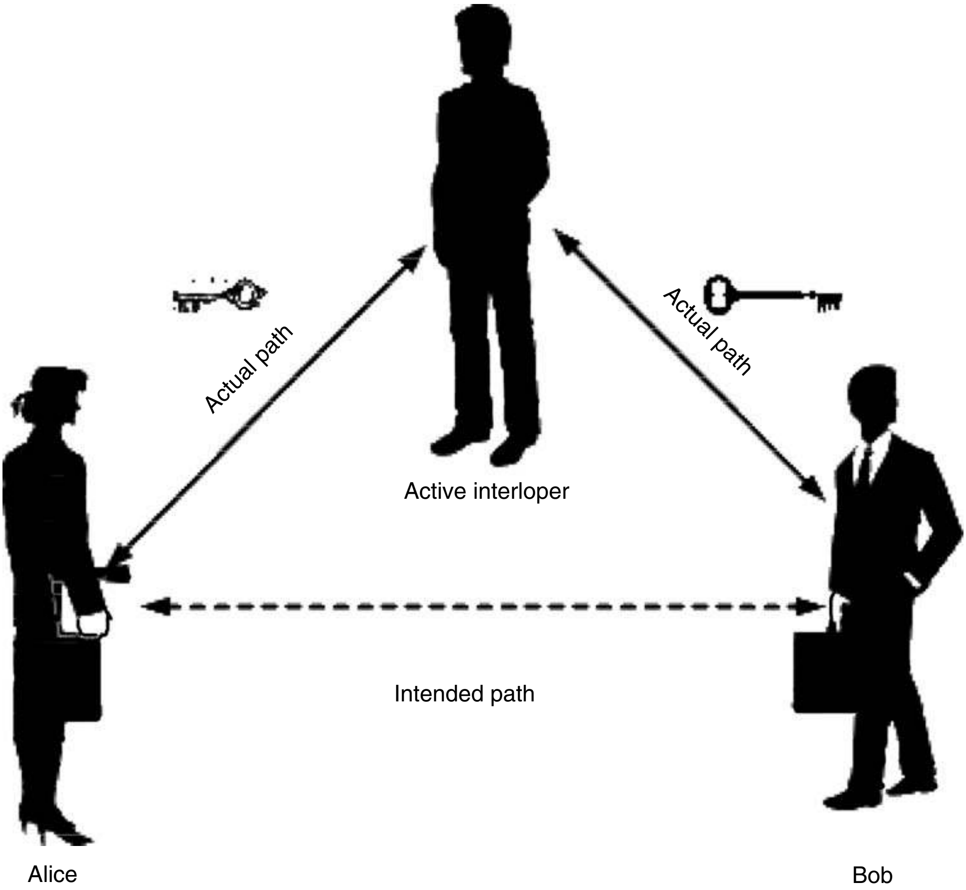

EXHIBIT 83.2 Intercepting both public keys and spoofing both sides.

the random value. The receiving device could then decrypt the cryptogram using its private key and add (modulo 2 addition without carry) the result to the cleartext, randomly chosen value it had encrypted and sent, thereby creating a unique session key between the two devices. However, an interloper could intercept both public keys and spoof both sides by substituting public keys for which the interloper knew the private keys. Exhibit 83.2 shows an example of how this might happen.

Many different automated schemes for key exchange exist—and some are known to be secure, some are probably secure, some are probably not secure, and some are not secure. Because many of the techniques are proprietary (i.e., "trade secrets"), evaluating them is difficult. Even when a vendor has patented a technique and is willing to fully disclose it to you, proving its security may require a cryptanalyst's expertise. So when a vendor describes what appears to be magic, remember that even David Copperfield relies on illusion. Best practice is to require compliance with a recognized standard for example, ANS X9.42-2003 (Public Key Cryptography for the Financial Services Industry: Agreement of Symmetric Keys Using Discrete Logarithm Cryptography) or ANS X9.63-2001 (Public Key Cryptography for the Financial Services Industry: Key Agreement and Key Management Using Elliptic Curve Cryptography).

83.4 Cryptographic Security Issues in Open Networks

The underlying assumption to open networks is the ability to establish arbitrary connections without previously having established a relationship. This poses a challenge for cryptographic key management because arbitrary parties will not have preexisting keying relationships. Two different approaches have evolved to answer the challenge: (1) the use of a hierarchy of trusted agents and (2) the use of key-exchange protocols. In one implementation of a hierarchy of trusted agents, we refer to an agent as a certificate authority (CA) because the agent issues a cryptographic certificate that binds a key representing one party to a chain of certificates from other CAs until a CA common to the parties who wish to securely communicate is reached. For example, Edward of Pan Omni Mega Corp. (POMC) wishes to send a secure message to Darwin of Central Middle Obaeratus Partners (CMOP); however, Edward and Darwin have never before communicated. POMC subscribes to AT&T's certificate authority (ATT CA). CMOP subscribes to General Services' certificate authority (GS CA) that, in turn, subscribes to MCI's certificate authority (MCI CA). AT&T and MCI have mutual keying relationships with the United States Postal Service certificate authority (USPS CA). POMC's CA chain becomes POMC/ATT/USPS and CMOP's becomes CMOP/GS/MCI/USPS. By exchanging authenticated certificates of authority, POMC can establish a trusted keying relationship with CMOP without worrying about key substitution. If the chains are long, if transmission speed is slow, or access to CA locations is limited, then Edward may have a long wait. But manual key distribution would usually force a longer wait.

If both Edward and Darwin have cryptographic facilities supporting a common key exchange protocol, they may be able to establish, directly and securely, a cryptographic session key. As described in the previous section, however, one may be unable to vet the vendor's techniques. (The term "vet" as used in cryptography means to investigate, examine, evaluate, or prove in a thorough or expert way. We trust properly vetted algorithms or protocols; otherwise, *caveat emptor*!) Best practice is to use standardized techniques whenever feasible, for example, ANS X9.24-2004 (Retail Financial Services, Symmetric Key Management, Part 1: Using Symmetric Techniques), ANS X9.42-2003 (Public Key Cryptography for the Financial Services Industry: Agreement of Symmetric Keys Using Discrete Logarithm Cryptography), ANS X9.44 (Key Agreement and Key Transport using Factoring Based Cryptography), and ANS X9.63 (Key Agreement and Key Transport using Elliptic Curve Cryptography [ECC]).

83.4.1 Issues beyond Key Exchange

Properly implemented, cryptographic security measures work. As a consequence of their effectiveness, governments have attempted to regulate their use and to control their availability. The United States historically took a two-pronged approach: restricted export and key escrow. Political pressure, however, led the United States to ease the export restrictions and, effectively, to abandon the key escrow approach. The U.S. Government treats cryptographic security implementations as if they were war munitions. However, not all nations have adopted this approach. Companies should have their legal counsels carefully examine the laws associated with encryption technology in each jurisdiction in which they plan its use.

Import controls reflect a nation's concern for its own exercise of sovereignty. Do secret messages contain government secrets? Do secret messages hide unlawful transactions? Are people evading taxes by electronic smuggling of software? Import controls will remain an issue for many nations.

For both import and export, governments generally base their restrictions on how effective the cryptography (including key management) is. Cryptographic effectiveness has at least three major components:

- The size of the cryptographic key space (i.e., how many possible keys there are)
- Whether the algorithm permits shortcuts in solving for the key
- Whether the key management functions introduce weaknesses (e.g., an early release of Netscape' relied on a key generation process that was weaker than the resulting key space, making it possible to attack the key generation process to gain the key much faster than by attacking the key space)

Exporting cryptographic systems based on keyspaces of 40 bits (i.e., having 2^{40} possible keys) or less is not a problem for the United States. Because of advances in computational power (i.e., Moore's law), even systems with much larger keyspaces (e.g., 60 bits) seem to pose no export problem. One of the selection criteria used in the development of an algorithm for the AES was that a 128-bit version would exist that would be exportable. Where very strong encryption is desired (e.g., >128 bits for a symmetric key), some authorities may permit it only if key escrow is used.

83.4.2 Key Escrow

Key escrow is a process through which you entrust your cryptographic keys to a third party who holds them securely until and unless forced to disclose them by legal process (e.g., a court order). This process is most controversial when that escrow agent is one or more elements of a national government. Key escrow has two serious types of errors: (1) Type I error, in which the key is disclosed without authorization; and (2) Type II error, in which the key becomes unavailable (corrupted, destroyed, inaccessible) and cannot be disclosed when lawfully demanded. A Type I compromise places the information assets at risk. A Type II compromise places law enforcement at risk (and may place the company in jeopardy of legal action). Because zeroization[6] of keys is a countermeasure used to prevent Type I failures (i.e., any attempt to tamper with the cryptographic equipment causes the keys to be set to zeroes) and because having backup copies of keying materials is a countermeasure for Type II failures, preventing both Type I and II failures is a difficult balancing act. One is not permitted to prevent a Type I failure by causing a Type II failure; nor is one permitted to protect against a Type II failure by increasing the risk of a Type I failure. In a project directed by Dr. Miles Smid, the National Institute of Standards and Technology (NIST) developed protocols for handling key escrow within the constraints of this delicate balance. For additional information, see FIPS 185 (Escrowed Encryption Standard).

In the United States, key escrow receives less attention today in the context of key management for export considerations than it does for business continuity planning where it remains an important technology.[7]

83.5 Advances in Cryptographic Key Management

The field of cryptography is experiencing rapid advancement. While many of the advances are more theoretical than currently useful, the auditor and security practitioner should have at least a rudimentary understanding of what is likely in the near future. Several key management techniques that are already technically available (or "bleeding edge"), but where standards may not have caught up, include:

- Diffie-Hellman key exchange using polynomials of base p (where $p \neq 2$)[8]
- Elliptic Curve Menezes-Qu-Vanstone (ECMQV)[9]
- Efficient Probabilistic Public-Key Encryption (EPOC) and a variant EPOC-3[10]

For use further into the future, one of the most promising advances is with quantum cryptography.

83.5.1 A Plethora of Key Management Techniques

With rapid advances in mathematics, almost every conceivable hard problem is potentially a cryptographic algorithm or basis for key agreement or transport. In general, if it is feasible (and preferably efficient and easy) to calculate a value from known values in one direction but extremely

[6] "Zeroization" is the technical term for destroying the keys by causing the storage medium to reset to all zeroes.

[7] See also Menezes, Alfred J., Paul C. van Oorschot, and Scott A. Vanstone. *Handbook of Applied Cryptography.* CRC Press, Boca Raton, FL, 1997. Chapter 13, especially §13.8.3. The Handbook (affectionately known as the "HAC") is an excellent—although much more technical and mathematical treatment—of cryptography.

[8] Rosing, Michael. 1999. *Implementing Elliptic Curve Cryptography.* p.299. Manning Publishing Co., Greenwich, CT.

[9] IEEE 1363–2000.

[10] Tatsuaki Okamoto and David Pointcheval. NTT Labs, Japan; paper submitted to IEEE P1363a Working Group, May 2000.

difficult (and preferably computationally infeasible) to work backward from the result without the benefit of secret values (i.e., cryptographic keys), there is the potential for a cryptosystem. One other promising area is the use of hyperelliptic curves. While these are no more hyperelliptic in the geometry sense than elliptic curves are ellipses, they form a class of mathematical curves, an example of which is described by the following formula:

$$y^2 = x^m + ax^{m-1} + \ldots + z$$

where m is assumed to be odd and greater than 3.[11]

However, the road from theory to practical implementation is a rough one. Some protocols have jumped prematurely to an implementation that was not secure. For example, the widely used Wired Equivalent Privacy (WEP)[12] protocol was found to contain exploitable flaws.[13] The ECMQV protocol may also have exploitable weaknesses under special circumstances. At the time of this writing, the practical implications of those weaknesses are unclear. Best practice will always be to follow well-vetted standards and to keep up with the literature as we practice a rapidly evolving field.

83.5.2 Quantum Cryptography

Quantum cryptography is a key agreement method for establishing a shared secret. It assumes that two users have a common communication channel over which they can send polarized photons. Photons can be polarized vertically or horizontally, circularly (clockwise or counterclockwise), or diagonally. Each of these can be viewed as having two states and assigned a binary representation (i.e., 0 or 1). By randomly choosing which measurement will be made for each pulse, two independent observers can compare observations and, following an interactive protocol, can agree on a resulting bit string without ever transmitting that string. Quantum cryptography has an advantage over traditional key exchange methods because it is based on the laws of physics instead of assumptions about the intractability of certain mathematical problems. The laws of physics guarantee (probabilistically) that the secret key exchange will be secure, even when assuming hypothetical eavesdroppers with unlimited computing power. However, a clear, practical disadvantage is the necessity of a communication channel over which the parties can send polarized photons.

Stephen Weisner is credited with the initial proposal[14] (*circa* 1970) on which quantum cryptography is based. He called it "Conjugate Coding," and eventually published it in 1983 in *Sigact News*. Charles H. Bennett and Gilles Brassard,[15] who were familiar with Weisner's ideas, published their own ideas shortly thereafter. They produced the first quantum cryptography protocol in 1984, which they named BB84.[16] It was not until 1991, however, that the first experimental prototype based on this protocol was made operable (over a distance of 32 centimeters). An online demonstration of this protocol is available at http://monet.mercersburg.edu/henle/bb84/. More recently, systems have been tested successfully on fiber optic cable over distances in the kilometers range.[17]

[12] IEEE 802.11 (including 802.11b).

[13] For more information on this weakness, refer to work performed jointly by Nikita Borisov, Ian Goldberg, and David Wagner described at the following Berkeley Web site: http://www.isaac.cs.berkeley.edu/isaac/wep-faq.html.

[14] Weisner, Stephen. 1983. "Conjugate Coding," *Sigact News*, Vol. 15. No. 1, pp. 78–88, manuscript written *circa* 1970, but remained unpublished until it appeared in *Sigact News*.

[15] Bennett, Charles H. and Brassard, G. 1984. "Quantum Cryptography: Public Key Distribution and Coin Tossing," *International Conference on Computers, Systems & Signal Processing*, December 10–12, pp. 175–179. Bangalore, India.

[16] Bennett, Charles H., Bessette, F., Brassard, G., Salvail, L., and Smolin, J. 1992. Experimental quantum cryptography. *Journal of Cryptology*, Vol. 5, 3–28.

[17] Stucky, Damien, Gisin, N., Guinnard, O., Ribordy, G., and Zbinden, H. 2002. Quantum key distribution over 67 km with a plug & play system. *New Journal of Physics*, Vol. 4, 41.1–41.8.

While this scheme may eventually replace more traditional methods (e.g., Diffie-Hellman) and has excellent potential in outer space where point-to-point laser might be feasible for long distances, current implementations impose both speed and distance limits (under 100 kilometers as of this writing) and expense that will make commercial implementations an issue for the future generation of information security professionals.[18]

83.6 Summary

Cryptology, which embraces both the creation of cipher systems (cryptography) and the breaking of those systems (cryptanalysis), has a long history. While this history is one of secrecy and intrigue and one of centuries of evolution, it was a history of little practical interest to business until only the past three decades. With the explosive proliferation of computers and networks, both cryptography and cryptanalysis have come to center stage. Our open network environments present security problems only cryptography can solve. As cryptography becomes universal, so will cryptanalysis. John Herbert Dillinger is alleged to have answered when asked why he robbed banks: "Because that's where the money is." The information security professional who knows little of cryptography will know little of security, for user authentication and access control, privacy protection and message integrity, audit trail assurance and non-repudiation, and automatic records retention will all depend on elements of cryptography. Understanding cryptographic key management and cryptographic implementations will permit us to manage securely the information assets of our enterprises.

84

Message Authentication

James S. Tiller

For centuries, various forms of encryption have provided confidentiality of information and have become integral components of computer communication technology. Early encryption techniques were based on shared knowledge between the communication participants. Confidentiality and basic authentication were established by the fact that each participant must know a common secret to encrypt or decrypt the communication, or as with very early encryption technology, the diameter of a stick.

The complexity of communication technology has increased the sophistication of attacks and has intensified the vulnerabilities confronting data. The enhancement of communication technology inherently provides tools for attacking other communications. Therefore, mechanisms are employed to reduce the new vulnerabilities that are introduced by new communication technology. The mechanisms utilized to ensure confidentiality, authentication, and integrity are built on the understanding that encryption alone, or simply applied to the data, will not suffice any longer. The need to ensure that the information is from the purported sender, that it was not changed or viewed in transit, and to provide a process to validate these concerns is, in part, the responsibility of message authentication.

This chapter describes the technology of message authentication, its application in various communication environments, and the security considerations of those types of implementations.

84.1 History of Message Authentication

An encrypted message could typically be trusted for several reasons. First and foremost, the validity of the message content was established by the knowledge that the sender had the appropriate shared information to produce the encrypted message. An extension of this type of assumed assurance was also recognized by the possession of the encrypting device. An example is the World War II German Enigma, a diabolically complex encryption machine that used three or four wheels to produce ciphertext as an operator typed in a message. The Enigma was closely guarded; if it fell into the enemy's possession, the process of deciphering any captured encrypted messages would become much less complex. The example of the Enigma demonstrates that possession of a device in combination with the secret code for a specific message provided insurance that the message contents received were genuine and authenticated.

As the growth of communication technology embraced computers, the process of encryption moved away from complex and rare mechanical devices to programs that provided algorithms for encryption. The mechanical algorithm of wheels and electrical conduits was replaced by software that could be loaded onto computers, which are readily available, to provide encryption. As algorithms were developed, many became open to the public for inspection and verification for use as a standard. Once the algorithm was exposed, the power of protection was in the key that was combined with the clear message and fed into the algorithm to produce ciphertext.

84.2 Why Authenticate a Message?

The ability of a recipient to trust the content of a message is placed squarely on the trust of the communication medium and the expectation that it came from the correct source. As one would imagine, this example of open communication is not suitable for information exchange and is unacceptable for confidential or any form of valuable data.

There are several types of attacks on communications that range from imposters posing as valid participants replaying or redelivering outdated information, to data modification in transit.

Communication technology has eliminated the basic level of interaction between individuals. For two people talking in a room, it can be assured—to a degree—that the information from one individual has not been altered prior to meeting the listener's ears. It can be also assumed that the person that is seen talking is the originator of the voice that is being heard. This example is basic, assumed, and never questioned—it is trusted. However, the same type of communication over an alternate medium must be closely scrutinized due to the massive numbers of vulnerabilities to which the session is exposed.

Computers have added several layers of complexity to the trusting process and the Internet has introduced some very interesting vulnerabilities. With a theoretically unlimited number of people on a single network, the options of attacks are similarly unlimited. As soon as a message takes advantage of the Internet as a communication medium, all bets are off without layers of protection.

How are senders sure that what they send will be the same when it reaches the intended recipient? How can senders be sure that the recipients are who they claim to be? The same questions hold true for the recipients and the question of initiator identity.

84.3 Technology Overview

It is virtually impossible to describe message authentication without discussing encryption. Message authentication is nothing more than a form of cryptography and, in certain implementations, takes advantage of encryption algorithms.

84.3.1 Hash Function

Hash functions are computational functions that take a variable-length input of data and produce a fixed-length result that can be used as a fingerprint to represent the original data. Therefore, if the hashes of two messages are identical, it can be reasonably assumed that the messages are identical as well. However, there are caveats to this assumption, which are discussed later.

Hashing information to produce a fingerprint will allow the integrity of the transmitted data to be verified. To illustrate the process, Alice creates the message "Mary loves basketball," and hashes it to produce a smaller, fixed-length message digest, "a012f7." Alice transmits the original message and the hash to Bob. Bob hashes the message from Alice and compares his result with the hash received with the original message from Alice. If the two hashes match, it can be assumed that the message was not altered in transit. If the message was changed after Alice sent it and before Bob received it, Bob's hash will not match, resulting in discovering the loss of message integrity. This example is further detailed in Exhibit 84.1.

In the example, a message from Alice in cleartext is used as input for a hash function. The result is a message digest that is a much smaller, fixed-length value unique to the original cleartext message. The message digest is attached to the original cleartext message and sent to the recipient, Bob. At this point, the message and the hash value are in the clear and vulnerable to attack. When Bob receives the message, he separates the message from the digest and hashes the message using the same hash function Alice used. Once the hash process is complete, Bob compares his message digest result with the one included with the original message from Alice. If the two match, the message was not modified in transit.

The caveat to the example illustrated is that an attacker using the same hashing algorithm could simply intercept the message and digest, create a new message and corresponding message digest, and forward it on to the original recipient. The type of attack, known as the "man in the middle," described here is the driving reason why message authentication is used as a component in overall message protection techniques.

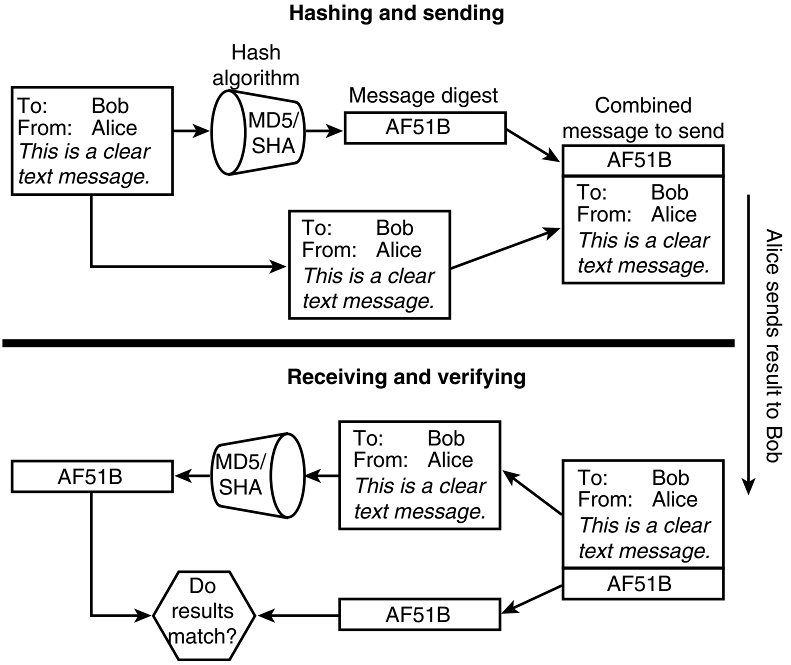

EXHIBIT 84.1 Hash function.

84.3.2 Encryption

Encryption, simply stated, is the conversion of plaintext into unintelligible ciphertext. Typically, this is achieved with the use of a key and an algorithm. The key is combined with the plaintext and computed with a specific algorithm.

There are two primary types of encryption keys: symmetrical and asymmetrical.

84.3.2.1 Symmetrical

Symmetrical keys, as shown in Exhibit 84.2, are used for both encryption and decryption of the same data. It is necessary for all the communication participants to have the same key to perform the encryption and decryption. This is also referred to as a shared secret.

In the example, Alice creates a message that is input into an encryption algorithm that uses a unique key to convert the clear message into unintelligible ciphertext. The encrypted result is sent to Bob, who has obtained the same key through a mechanism called "out-of-band" messaging. Bob can now decrypt the ciphertext by providing the key and the encrypted data as input for the encryption algorithm. The result is the original plaintext message from Alice.

84.3.2.2 Asymmetrical

To further accentuate authentication by means of encryption, the technology of public key cryptography, or asymmetrical keys, can be leveraged to provide message authentication and confidentiality.

Alice and Bob each maintain a private and public key pair that is mathematically related. The private key is well protected and is typically passphrase protected. The public key of the pair is provided to anyone who wants it and wishes to send an encrypted message to the owner of the key pair.

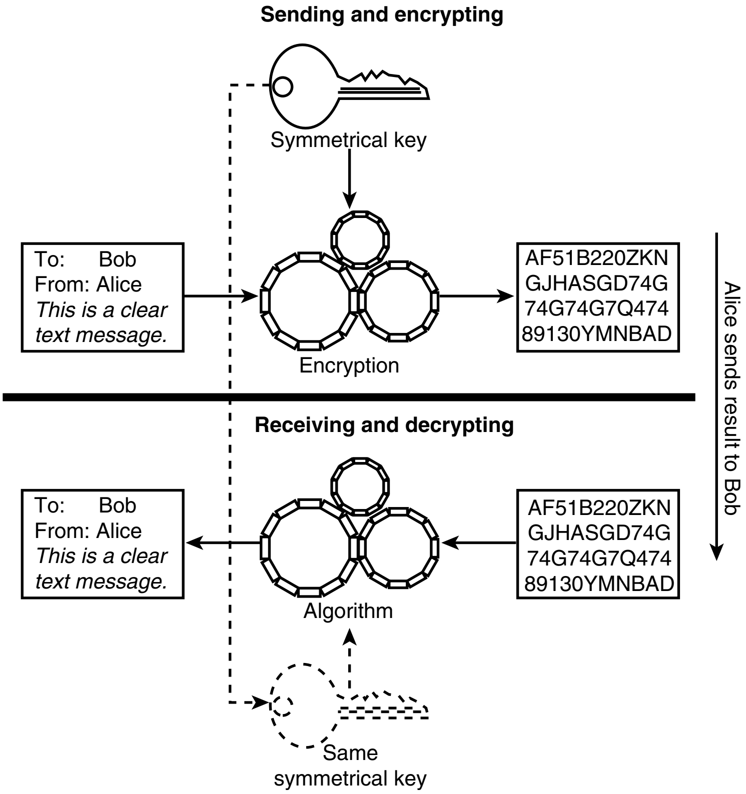

EXHIBIT 84.2 Symmetrical key encryption.

An example of public key cryptography, as shown in Exhibit 84.3, is that Alice could encrypt a message with Bob's public key and send the ciphertext to Bob. Because Bob is the only one with the matching private key, he would be the only recipient who could decrypt the message. However, this interaction only provides confidentiality and not authentication because anyone could use Bob's public key to encrypt a message and claim to be Alice.

As illustrated in Exhibit 84.3, the encryption process is very similar to normal symmetrical encryption. A message is combined with a key and processed by an algorithm to construct ciphertext. However, the key being used in the encryption cannot be used for decryption. As detailed in the example, Alice encrypts the data with the public key and sends the result to Bob. Bob uses the corresponding private key to decrypt the information.

To provide authentication, Alice can use her private key to encrypt a message digest generated from the original message, then use Bob's public key to encrypt the original cleartext message, and send it with the encrypted message digest. When Bob receives the message, he can use his private key to decrypt the message. The output can then be verified using Alice's public key to decrypt the message authentication that Alice encrypted with her private key. The process of encrypting information with a private key to allow the recipient to authenticate the sender is called digital signature. An example of this process is detailed in Exhibit 84.4.

The illustration conveys a typical application of digital signature. There are several techniques of creating digital signatures; however, the method detailed in the exhibit represents the use of a hash algorithm. Alice generates a message for Bob and creates a message digest with a hash function. Alice then encrypts the message digest with her private key. By encrypting the digest with her private key, Alice reduces the system load created by the processor-intensive encryption algorithm and provides an authenticator. The encrypted message digest is attached to the original cleartext message and encrypted

EXHIBIT 84.4 Digital signature with the use of hash functions.

using Bob's public key. The example includes the encrypted digest with the original message for the final encryption, but this is not necessary. The final result is sent to Bob. The entire package is decrypted with Bob's private key—ensuring recipient authentication. The result is the cleartext message and an encrypted digest. Bob decrypts the digest with Alice's public key, which authenticates the sender. The result is the original hash created by Alice that is compared to the hash Bob created using the cleartext message. If the two match, the message content has been authenticated along with the communication participants.

Digital signatures are based on the management of public and private keys and their use in the communication. The process of key management and digital signatures has evolved into certificates. Certificates, simply stated, are public keys digitally signed by a trusted Certificate Authority. This provides comfort in the knowledge that the public key being used to establish encrypted communications is owned by the proper person or organization.

84.3.3 Message Authentication Code

Message authentication code (MAC) with DES is the combination of encryption and hashing. As illustrated in Exhibit 84.5, as data is fed into a hashing algorithm, a key is introduced into the process.

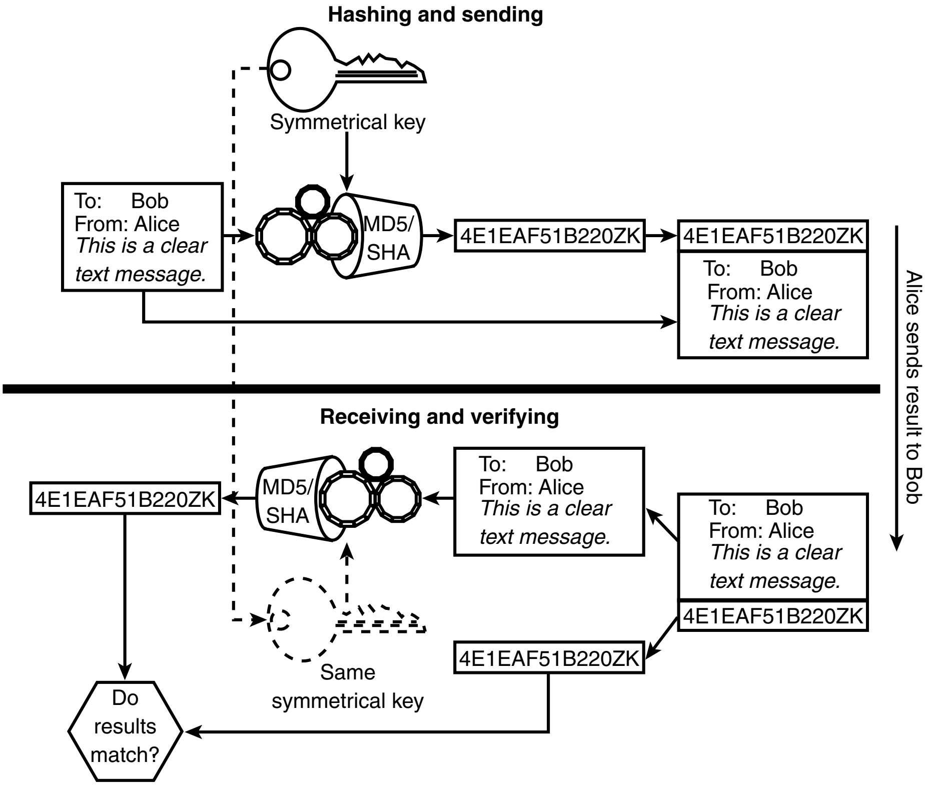

EXHIBIT 84.5 Message authentication code.

MAC is very similar to encryption but the MAC is designed to be irreversible, like a standard hash function. Because of the computational properties of the MAC process, and the inability to reverse the encryption designed into the process, MACs are much less vulnerable to attacks than encryption with the same key length. However, this does not prevent an attacker from forging a new message and MAC.

MAC ensures data integrity like a message digest but adds limited layers of authentication because the recipient would have to have the shared secret to produce the same MAC to validate the message.

The illustration of a message authentication code function appears very similar to symmetrical encryption; however, the process is based on compressing the data into a smaller fixed length that is not designed for decryption. A message is passed into the algorithm, such as DES–CBC (Cipher Block Chaining), and a symmetrical key is introduced. The result is much like that of a standard message digest, but the key is required to reproduce the digest for verification.

84.4 The Need for Authentication

As data is shared across networks—networks that are trusted or not—the opportunities for undesirables to interact with the session are numerous. Of the attacks that communications are vulnerable to, message authentication, in general application, addresses only a portion of the attacks. Message authentication is used as a tool to combine various communication-specific data that can be verified by the valid parties for each message received. Message authentication alone is not an appropriate countermeasure; but when combined with unique session values, it can protect against four basic categories of attacks:

1. Masquerading
2. Content modification

3. Sequence manipulation
4. Submission modification

To thwart these vulnerabilities inherent in communications, hash functions can be used to create message digests that contain information for origination authentication and timing of the communications. Typically, time-sensitive random information, or a nonce, is provided during the initialization of the session. The nonce can be input with the data in the hashing process or used as key material to further identify the peer during communications. Also, sequence numbers and time stamps can be generated and hashed for communications that require consistent session interaction—not like that of nontime-sensitive data such as e-mail. The process of authentication, verification through the use of a nonce, and the creation of a key for MAC computations provides an authenticated constant throughout the communication.

84.4.1 Masquerading

The process of masquerading as a valid participant in a network communication is a type of attack. This attack includes the creation of messages from a fraudulent source that appears to come from an authorized origin. Masquerading can also represent the acknowledgment of a message by an attacker in place of the original recipient. False acknowledgment or denial of receipt could complicate nonrepudiation issues. The nonce that may have been used in the hash or the creation of a symmetrical key assists in the identification of the remote system or user during the communication. However, to accommodate origin authentication, there must be an agreement on a key prior to communication. This is commonly achieved by a preshared secret or certificate that can be used to authenticate the initial messages and create specific data for protecting the remainder of the communication.

84.4.2 Content Modification

Content modification is when the attacker intercepts a message, changes the content, and then forwards it to the original recipient. This type of attack is quite severe in that it can manifest itself in many ways, depending on the environment.

84.4.3 Sequence Manipulation

Sequence manipulation is the process of inserting, deleting, or reordering datagrams. This type of attack can have several types of effects on the communication process, depending on the type of data and communication standard. The primary result is denial of service. Destruction of data or confusion of the communication can also result.

84.4.4 Submission Modification

Timing modification appears in the form of delay or replay. Both of these attacks can be quite damaging. An example is session establishment. In the event that the protocol is vulnerable to replay, an attacker could use the existence of a valid session establishment to gain unauthorized access.

Message authentication is a procedure to verify that the message received is from the intended source and has not been modified or made susceptible to the previously outlined attacks.

84.5 Authentication Foundation

To authenticate a message, an authenticator must be produced that can be used later by the recipient to authenticate the message. An authenticator is a primitive reduction or representation of the primary message to be authenticated. There are three general concepts in producing an authenticator.

84.5.1 Encryption

With encryption, the ciphertext becomes the authenticator. This is related to the trust relationship discussed earlier by assuming the partner has the appropriate secret and has protected it accordingly.

Consider typical encrypted communications: a message sent from Alice to Bob encrypted with a shared secret. If the secret's integrity is maintained, confidentiality is assured by the fact that no unauthorized entities have the shared secret.

Bob can be assured that the message is valid because the key is secret and an attacker without the key would be unable to modify the ciphertext in a manner to make the desired modifications to the original plaintext message.

84.5.2 Message Digest

As briefly described above, hashing is a function that produces a unique fixed-length value that serves as the authenticator for the communication. Hash functions are one-way, in that the creation of the hash is quite simple, but the reverse is infeasible. A well-constructed hash function should be collision resistant. A collision is when two different messages produce the same result or digest. For a function to take a variable length of data and produce a much smaller fixed-length result, it is mathematically feasible to experience collisions. However, a well-defined algorithm with a large result should have a high resistance to collisions.

Hash functions are used to provide message integrity. It can be argued that encryption can provide much of the same integrity. An example is an attacker could not change an encrypted message to modify the resulting cleartext. However, hash functions are much faster than encryption processes and can be utilized to enhance performance while maintaining integrity. Additionally, the message digest can be made public without revealing the original message.

84.5.3 Message Authentication Code

Message authentication code with DES is a function that uses a secret key to produce a unique fixed-length value that serves as the authenticator. This is much like a hash algorithm but provides the added protection by use of a key. The resulting MAC is appended to the original message prior to sending the data. MAC is similar to encryption but cannot be reversed and does not directly provide any authentication process because both parties share the same secret key.

84.6 Hash Process

As mentioned, a hash function is a one-way computation that accepts a variable-length input and produces a fixed-length result. The hash function calculates each bit in a message; therefore, if any portion of the original message changes, the resulting hash will be completely different.

84.6.1 Function Overview

A hash function must meet several requirements to be used for message authentication. The function must:

- Be able to accept any size data input
- Produce a fixed-length output
- Be relatively easy to execute, using limited resources
- Make it computationally impractical to derive a message from the digest (one-way property)
- Make it computationally impractical to create a message digest that is equal to a message digest created from different information (collision resistance)

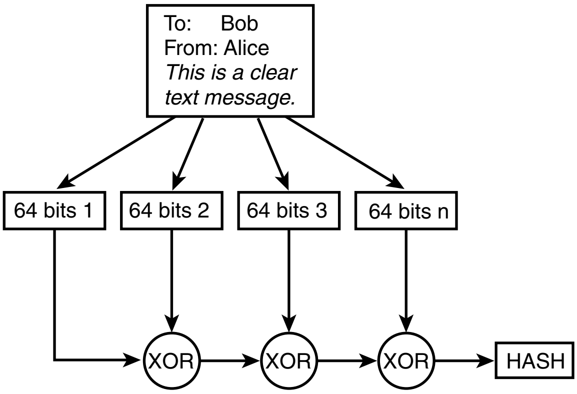

EXHIBIT 84.6 Simple hash function example.

Hash functions accommodate these requirements by a set of basic principles. A message is processed in a sequence of blocks, as shown in Exhibit 84.6. The size of the blocks is determined by the hash function. The function addresses each block one at a time and produces parity for each bit. Addressing each bit provides the message digest with the unique property that dramatic changes will occur if a single bit is modified in the original message.

As detailed in Exhibit 84.6, the message is separated into specific portions. Each portion is XOR with the next portion, resulting in a value the same size of the original portions, not their combined value. As each result is processed, it is combined with the next portion until the entire message has been sent through the function. The final result is a value the size of the original portions that were created and a fixed-length value is obtained.

84.7 Message Authentication Codes and Processes

Message authentication code with DES is applying an authentication process with a key. MACs are created using a symmetrical key so the intended recipient or the bearer of the key can only verify the MAC. A plain hash function can be intercepted and replaced or brute-force attacked to determine collisions that can be of use to the attacker. With MACs, the addition of a key complicates the attack due to the secret key used in its computation.

There are four modes of DES that can be utilized:

1. Block cipher-based
2. Hash function-based
3. Stream cipher-based
4. Unconditionally secure

84.7.1 Block Cipher-Based Mode

Block cipher-based message authentication can be derived from block cipher algorithms. A commonly used version is DES–CBC–MAC, which, simply put, is DES encryption based on the CBC mode of block cipher to create a MAC. A very common form of MAC is Data Authentication Algorithm (DAA), which is based on DES. The process uses the CBC mode of operation of DES with a zero initialization vector. As illustrated in Exhibit 84.7, the message is grouped into contiguous blocks of 64 bits; the last group is padded on the right with zeros to attain the 64-bit requirement. Each block is fed into the DES algorithm with a key to produce a 64-bit Data Authentication Code (DAC). The resulting DAC is XOR and the next

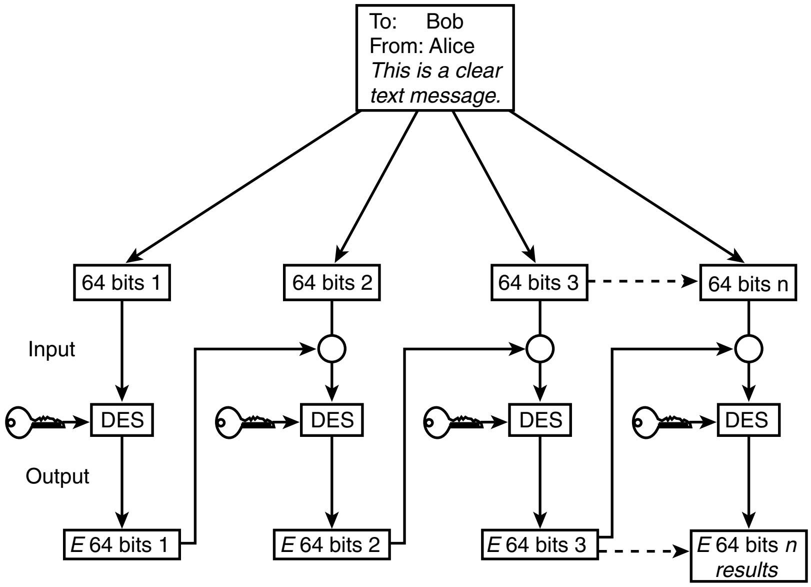

EXHIBIT 84.7 MAC based on DES–CBC.

64-bits of data is then fed again into the DES algorithm. This process continues until the last block, and returns the final MAC.

A block cipher is a type of symmetric key encryption algorithm that accepts a fixed block of plaintext to produce ciphertext of the same length—a linear relationship. There are four primary modes of operation on which the block ciphers can be based:

1. *Electronic Code Book (ECB)*. Electronic Code Book mode accepts each block of plaintext and encrypts it independently of previous block cipher results. The weakness in ECB is that identical input blocks will produce identical cipher results of the same length. Interestingly, this is a fundamental encryption flaw that affected the Enigma. For each input, there was a corresponding output of the same length. The "step" of the last wheel in an Enigma could be derived from determinations in ciphertext patterns.
2. *Cipher Block Chaining (CBC)*. With CBC mode, each block result of ciphertext is exclusively OR'ed (XOR) with the previous calculated block, and then encrypted. Any patterns in plaintext will not be transferred to the cipher due to the XOR process with the previous block.
3. *Cipher Feedback (CFB)*. Similar to CBC, CFB executes an XOR between the plaintext and the previous calculated block of data. However, prior to being XORed with the plaintext, the previous block is encrypted. The amount of the previous block to be used (the feedback) can be reduced and not utilized as the entire feedback value. If the full feedback value is used and two cipher blocks are identical, the output of the following operation will be identical. Therefore, any patterns in the message will be revealed.
4. *Output Feedback (OFB)*. Output Feedback is similar to CFB in that the result is encrypted and XORed with the plaintext. However, the creation of the feedback is generated independently of the ciphertext and plaintext processes. A sequence of blocks is encrypted with the previous block, the result is then XORed with the plaintext.

84.7.2 Hash Function-Based Mode

Hash function-based message authentication code (HMAC) uses a key in combination with hash functions to produce a checksum of the message. RFC 2104 defines that HMAC can be used with any iterative cryptographic hash function (e.g., MD5, SHA-1) in combination with a secret shared key. The cryptographic strength of HMAC depends on the properties of the underlying hash function.

The definition of HMAC requires a cryptographic hash function and a secret key. The hash function is where data is hashed by iterating a basic compression function on blocks of data, typically 64 bytes in each block. The symmetrical key to be used can be any length up to the block size of the hash function. If the key is longer than the hash block size, the key is hashed and the result is used as the key for the HMAC function.

This process is very similar to the DES–CBC–MAC discussed above; however, the use of the DES algorithm is significantly slower than most hashing functions, such as MD5 and SHA-1.

HMAC is a process of combining existing cryptographic functions and a keyed process. The modularity of the standard toward the type of cryptographic function that can be used in the process has become the point of acceptance and popularity. The standards treat the hash function as a variable that can consist of any hash algorithm. The benefits are that legacy or existing hash implementations can be used in the process and the hash function can be easily replaced without affecting the process. The latter example represents an enormous security advantage. In the event the hash algorithm is compromised, a new one can be immediately implemented.

There are several steps to the production of an HMAC; these are graphically represented in Exhibit 84.8. The first step is to determine the key length requested and compare it to the block size of the hash being implemented. As described above, if the key is longer than the block size it is hashed, the result will match the block size defined by the hash. In the event the key is smaller, it is padded with zeros to accommodate the required block size.

Once the key is defined, it is XOR'ed with a string of predefined bits "A" to create a new key that is combined with the message. The new message is hashed according to the function defined (see Exhibit 84.6). The hash function result is combined with the result of XOR the key with another defined set of bits "B." The new combination of the second key instance and the hash results are hashed again to create the final result.

84.7.3 Stream Cipher-Based Mode

A stream cipher is a symmetric key algorithm that operates on small units of plaintext, typically bits. When data is encrypted with a stream cipher, the transformation of the plaintext into ciphertext is

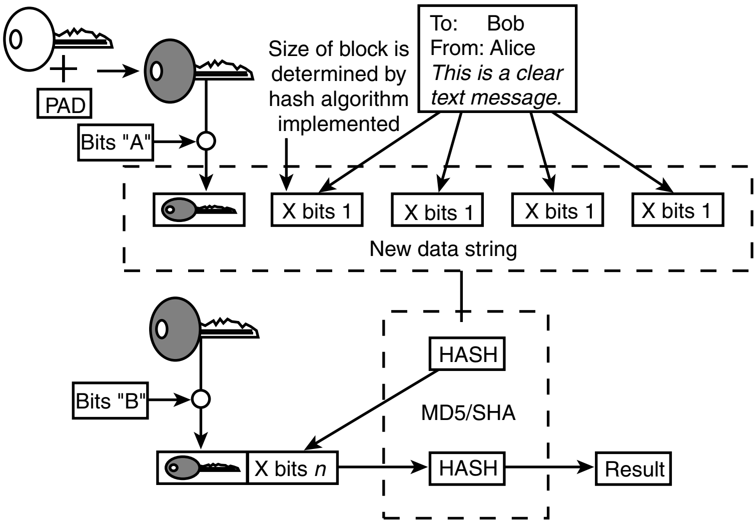

EXHIBIT 84.8 Simple HMAC example.

dependent on when the bits were merged during the encryption. The algorithm creates a keystream that is combined with the plaintext. The keystream can be independent of the plaintext and ciphertext (typically referred to as a synchronous cipher), or it can depend on the data and the encryption (typically referred to as self-synchronizing cipher).

84.7.4 Unconditionally Secure Mode

Unconditional stream cipher is based on the theoretical aspects of the properties of a one-time pad. A one-time pad uses a string of random bits to create the keystream that is the same length as the plaintext message. The keystream is combined with the plaintext to produce the ciphertext. This method of employing a random key is very desirable for communication security because it is considered unbreakable by brute force. Security at this level comes with an equally high price: key management. Each key is the same size and length as the message it was used to encrypt, and each message is encrypted with a new key.

84.8 Message Authentication over Encryption

Why use message authentication (e.g., hash functions and message authentication codes) when encryption seems to meet all the requirements provided by message authentication techniques? Following are brief examples and reasoning to support the use of message authentication over encryption.

84.8.1 Speed

Cryptographic hash functions, such as MD5 and SHA-1, execute much faster and use less system resources than typical encryption algorithms. In the event that a message only needs to be authenticated, the process of encrypting the entire message, such as a document or large file, is not entirely logical and consumes valuable system resources.

The reasoning of reducing load on a system holds true for digital signatures. If Alice needs to send a document to Bob that is not necessarily confidential but may contain important instructions, authentication is paramount. However, encrypting the entire document with Alice's private key is simply overkill. Hashing the document will produce a very small rendition of the original message, which then can be encrypted with her private key. The much smaller object encrypts quickly and provides ample authentication and abundant message integrity.

84.8.2 Limited Restrictions

No export restrictions on cryptographic functions are defined. Currently, the laws enforcing import and export restrictions in the international community are complicated and constantly changing. Basically, these laws are to control the level of technology and intellectual property of one country from another. Message authentication releases the communication participants from these restrictions.

84.8.3 Application Issues

There are applications where the same message is broadcast to several destinations. One system is elected as the communication monitor and verifies the message authentication on behalf of the other systems. If there is a violation, the monitoring system alerts the other systems.

Simple Network Management Protocol (SNMP) is an example where command messages can be forged or modified in transit. With the application of MAC, or HMAC, a password can be implemented to act as a key to allow a degree of authentication and message authentication. Each system in the community is configured with a password that can be combined with the data during the hash process and verified upon receipt. Because all the members are configured with the same password, the data can be hashed with the locally configured password and verified. It can also be forged at the destination.

84.8.4 System Operation

In the event that one of a communication pair is overburdened, the process of decryption would be overwhelming. Authentication can be executed in random intervals to ensure authentication with limited resources. Given the hashing process is much less intensive than encryption, periodical hashing and comparisons will consume fewer system cycles.

84.8.5 Code Checksum

Application authentication is achieved by adding the checksum to the program. While the program itself may be open to modification, the checksum can be verified at runtime to ensure that the code is in the original format and should produce the expected results. Otherwise, an attacker could have constructed a malicious activity to surreptitiously operate while the original application was running. It can be argued that if an attacker can modify the code, the checksum should pose little resistance because it can also be simply regenerated. Given the typically small size of checksums, it is typically published on several Web pages or included in an e-mail. In other words, an attacker would have to modify every existence of the checksum to ensure that the recipient would inadvertently verify the modified application. If encryption was utilized, the program would have to decrypt at each runtime, consuming time and resources. This is very important for systems that provide security functions, such as firewalls, routers, and VPN access gateways.

An example of the need for code protection can be illustrated by the heavy reliance on the Internet for obtaining software, updates, or patches. In early computing, systems patches and software were mailed to the recipient as the result of a direct request, or as a registered system user. As communication technology advanced, Bulletin Board Systems (BBS) could be directly accessed with modems to obtain the necessary data. In both of these examples, a fair amount of trust in the validity of the downloaded code is assumed.

In comparison, the complexity of the Internet is hidden from the user by a simple browser that is used to access the required files. The data presented in a Web page can come from dozens of different sources residing on many different servers throughout the Internet. There are few methods to absolutely guarantee that the file being downloaded is from a trusted source. To add to the complexity, mirrors can be established to provide a wider range of data sources to the Internet community. However, the security of a mirrored site must be questioned. The primary site may have extensive security precautions, but a mirror site may not. An attacker could modify the code on an alternate download location. When the code is finally obtained, a checksum can be validated to ensure that the code obtained is the code the creator intended for receipt.

84.8.6 Utilization of Existing Resources

There is available installed technology designed for DES encryption processes. The use of DEC–CBC–MAC can take advantage of existing technology to increase performance and support the requirements of the communication. The DES encryption standard has been available for quite some time. There are many legacy systems that have hardware designed specifically for DES encryption. As more advanced encryption becomes available and new standards evolve, the older hardware solutions can be utilized to enhance the message authentication process.

84.9 Security Considerations

The strength of any message authentication function, such as a MAC or hash, is determined by two primary factors:

1. One-way property
2. Collision resistance

One-way property is the ability of the hash to produce a message digest that cannot be used to determine the original message. This is one of the most significant aspects of message authentication algorithms. If a message authentication algorithm is compromised and a weakness is discovered, the result could have a detrimental effect on various forms of communication.

MD4 is an example of a function's poor one-way property. Within MD4, the data is padded to obtain a length divisible by 512, plus 448. A 64-bit value that defines the original message's length is appended to the padded message. The result is separated into 512-bit blocks and hashed using three distinct rounds of computation. Weaknesses were quickly discovered if the first or last rounds were not processed. However, it was later discovered that without the last round, the original message could be derived. MD4 had several computation flaws that proved the function had limited one-way capabilities.

Collision resistance is the most considered security aspect of message authentication functions. A collision is typically defined as when two different messages have the same hash result. In the event that a hash function has a collision vulnerability, such as MD2, a new message can be generated and used to replace the original in a communication, and the hash will remain valid. The combination of the original hash and the known vulnerability will provide the attacker with enough information to produce an alternative message that will produce the same checksum. An example is the hash algorithm MD2. It was created for 8-bit computers in the late 1980s and uses 16-bit blocks of the message against which to execute the hash. MD2 produces a 16-bit checksum prior to passing through the hash function. If this checksum is omitted, the production of a collision would be trivial. MD4 was subject to weak collision resistance as well, and it was proven that collisions could be produced in less than a minute on a simple personal computer.

The concept of a collision is a fundamental issue concerning probabilities. Take, for example, a hash function that produces an n-bit digest. If one is looking for a result of x, it can be assumed that one would have to try 2^n input possibilities. This type of brute-force attack is based on a surprising outcome referred to as the "birthday paradox": What is the least number of people in a group that can provide the probability, greater than half, that at least two people will have the same birthday?

If there are 365 days per year, and if the number of people exceeds 365, there will be a successful collision. If the number of people in the group is less than 365, then the number of possibilities is 365^n, where n is the number of people in a group. For those still wondering, the number of people, assuming there is a collision, is 23. This is a very small number; but when calculated against the number of possibilities that any two people's birthdays match, one sees that there are 253 possibilities. This is simply calculated as $n(n-1)/2$, which results in the probability of $P(365, 23) = .5073$, or greater than one half.

The birthday paradox states that given a random integer with a constant value between 1 and n, what is the selection of the number of permutations (the number of people required to meet 0.5 probability) that will result in a collision?

Given a fixed-length output that can represent an infinite amount of variation, it is necessary to understand the importance of a robust algorithm. It is also necessary for the algorithm to produce a relatively large result that remains manageable.

However, as certificates and other public key cryptography is utilized, message authentication processes will not be exposed to direct attack. The use of a hash to accommodate a digital signature process is based on the ownership and trust of a private key; the hash, while important, is only a step in a much more complicated process.

84.10 Conclusion

Communication technology has provided several avenues for unauthorized interaction with communications requiring the need to address security in ways previously unanalyzed. Message authentication provides a means to thwart various forms of attack and can enhance other aspects of communication security. A message "fingerprint" can be created in several ways, ranging from simple bit parity functions (hash) to utilization of encryption algorithms (DES–CBC–MAC) to complicated hybrids (HMAC). This fingerprint cannot only be used to ensure message integrity, but also given the inherent process of message reduction, it lends itself to authentication and signature processes.

Message authentication is a broad activity that employs several types of technology in various applications to achieve timely, secure communications. The combinations of the application of these technologies are virtually limitless and, as advancements in cryptography, cryptanalysis, and overall communication technology are realized, message authentication will most certainly remain an interesting process.

Fundamentals of Cryptography and Encryption

Ronald A. Gove

This chapter presents an overview of some basic ideas underlying encryption technology. The chapter begins by defining some basic terms and follows with a few historical notes so the reader can appreciate the long tradition that encryption, or secret writing, has had. The chapter then moves into modern cryptography and presents some of the underlying mathematical and technological concepts behind private and public key encryption systems such as DES and RSA. We will provide an extensive discussion of conventional private key encryption prior to introducing the concept of public key cryptography. We do this for both historical reasons (private key did come first) and technical reasons (public key can be considered a partial solution to the key management problem).

85.1 Some Basic Definitions

We begin our discussion by defining some terms that will be used throughout the chapter. The first term is *encryption*. In simplest terms, encryption is the process of making information unreadable by unauthorized persons. The process may be manual, mechanical, or electronic, and the core of this chapter is to describe the many ways that the encryption process takes place. Encryption is to be distinguished from message-hiding. Invisible inks, microdots, and the like are the stuff of spy novels and are used in the trade; however, we will not spend any time discussing these techniques for hiding information. Exhibit 85.1 shows a conceptual version of an encryption system. It consists of a sender and a receiver, a message (called the “plain text”), the encrypted message (called the “cipher text”), and an item called a “key.” The encryption process, which transforms the plain text into the cipher text, may be thought of as a “black box.” It takes inputs (the plain text and key) and produces output (the cipher text).

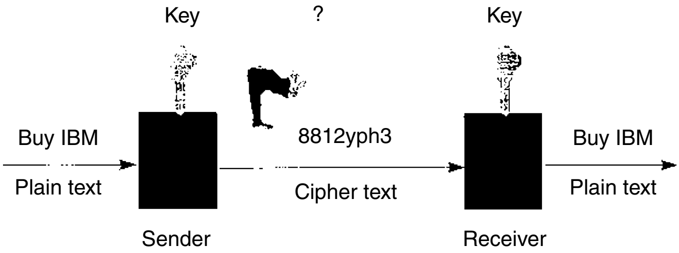

EXHIBIT 85.1 Conceptual version of an encryption system.

The messages may be handwritten characters, electromechanical representations as in a Teletype, strings of 1s and 0s as in a computer or computer network, or even analog speech. The black box will be provided with whatever input/output devices it needs to operate; the insides, or cryptographic algorithm will, generally, operate independently of the external representation of the information.

The *key* is used to select a specific instance of the encryption process embodied in the machine. It is more properly called the "*cryptovariable*." The use of the term "key" is a holdover from earlier times. We will discuss cryptovariables (keys) in more detail in later sections. It is enough at this point to recognize that the cipher text depends on both the plain text and the cryptovariable. Changing either of the inputs will produce a different cipher text. In typical operation, a cryptovariable is inserted prior to encrypting a message and the same key is used for some period of time. This period of time is known as a "cryptoperiod." For reasons having to do with cryptanalysis, the key should be changed on a regular basis. The most important fact about the key is that it embodies the security of the encryption system. By this we mean the system is designed so that complete knowledge of all system details, including specific plain and cipher text messages, is not sufficient to derive the cryptovariable.

It is important that the system be designed in this fashion because the encryption process itself is seldom secret. The details of the data encryption standard (DES), for example, are widely published so that anyone may implement a DES-compliant system. In order to provide the intended secrecy in the cipher text, there has to be some piece of information that is not available to those who are not authorized to receive the message; this piece of information is the cryptovariable, or key.

Inside the black box is an implementation of an algorithm that performs the encryption. Exactly how the algorithm works is the main topic of this chapter, and the details depend on the technology used for the message.

Cryptography is the study of the means to do encryption. Thus cryptographers design encryption systems. Cryptanalysis is the process of figuring out the message without knowledge of the cryptovariable (key), or more generally, figuring out which key was used to encrypt a whole series of messages.

85.2 Some Historical Notes

The reader is referred to Kahn[1] for a well-written history of this subject. We note that the first evidence of cryptography occurred over 4000 years ago in Egypt. Almost as soon as writing was invented, we had secret writing. In India, the ancients' version of Dr. Ruth's Guide to Good Sex, the *Kama-Sutra*, places secret writing as 45th in a list of arts women should know. The Arabs in the 7th century AD were the first to write down methods of cryptanalysis. Historians have discovered a text dated about 855 AD that describes cipher alphabets for use in magic.

One of the better known of the ancient methods of encryption is the Caesar Cipher, so called because Julius Caesar used it. The Caesar Cipher is a simple alphabetic substitution. In a Caesar Cipher, each plain

EXHIBIT 85.2. The caesar cipher.

text letter is replaced by the letter 3 letters away to the right. For example, the letter A is replaced by D, B by E, and so forth. (See Exhibit 85.2, where the plain-text alphabet is in lower case and the cipher text is in upper case.)

Caesar's Cipher is a form of a more general algorithm known as monoalphabetic substitution. While Julius Caesar always used an offset of 3, in principal one can use any offset, from one to 25. (An offset of 26 is the original alphabet.) The value of the offset is in fact the cryptovariable for this simplest of all monoalphabetic substitutions. All such ciphers with any offset are now called Caesar Ciphers.

There are many ways to produce alphabetic substitution ciphers. In fact, there are 26! (26 factorial or 26X25X24 … X2X1) ways to arrange the 26 letters of the alphabet. All but one of these yields a nonstandard alphabet. Using a different alphabet for each letter according to some well-defined rule can make a more complicated substitution. Such ciphers are called polyalphabetic substitutions.

Cryptography underwent many changes through the centuries often following closely with advances in technology. When we wrote by hand, encryption was purely manual. After the invention of the printing press various mechanical devices appeared such as Leon Batista Alberti's cipher disk in Italy. In the 18th century, Thomas Jefferson invented a ciphering device consisting of a stack of 26 disks each containing the alphabet around the face of the edge. Each disk had the letters arranged in a different order. A positioning bar was attached that allowed the user to align the letters along a row. To use the device, one spelled out the message by moving each disk so that the proper letter lay along the alignment bar. The bar was then rotated a fixed amount (the cryptovariable for that message) and the letters appearing along the new position of the bar were copied off as the cipher text. The receiver could then position the cipher text letters on his "wheel" and rotate the cylinder until the plain text message appeared.

By World War II very complex electromechanical devices were in use by the Allied and Axis forces. The stories of these devices can be found in many books such as Hodges.[2] The need for a full-time, professional cryptographic force was recognized during and after WWII and led to the formation of the National Security Agency by Presidential memorandum signed by Truman. See Bamford[3] for a history of the NSA.

Except for a few hobbyists, cryptography was virtually unknown outside of diplomatic and military circles until the mid-seventies. During this period, as the use of computers, particularly by financial institutions, became more widespread, the need arose for a "public," (non-military or diplomatic) cryptographic system. In 1973 the National Bureau of Standards (now the National Institute of Standards and Technology) issued a request for proposals for a standard cryptographic algorithm. They received no suitable response at that time and reissued the request in 1974. IBM responded to the second request with their Lucifer system, which they had been developing for their own use. This algorithm was evaluated with the help of the NSA and eventually was adopted as the Data Encryption Standard (DES) in 1976. See Federal Information Processing Standard NBS FIPS PUB 46.

The controversy surrounding the selection of DES[4] stimulated academic interest in cryptography and cryptanalysis. This interest led to the discovery of many cryptanalytic techniques and eventually to the concept of public key cryptography. Public key cryptography is a technique that uses distinct keys for encryption and decryption, only one of which need be secret. We will discuss this technique later in this chapter, as public key cryptography is more understandable once one has a firm understanding of conventional cryptography.

The 20 years since the announcement of DES and the discovery of public key cryptography have seen advances in computer technology and networking that were not even dreamed of in 1975. The Internet has created a demand for instantaneous information exchange in the military, government, and most importantly, private sectors that is without precedent. Our economic base, the functioning of our government, and our military effectiveness are more dependent on automated information systems than any country in the world. However, the very technology that created this dependence is its greatest weakness: the infrastructure is fundamentally vulnerable to attacks from individuals, groups, or nation-states that can easily deny service or compromise the integrity of information. The users of the Internet, especially those with economic interests, have come to realize that effective cryptography is a necessity.

85.3 The Basics of Modern Cryptography

Since virtually all of modern cryptography is based on the use of digital computers and digital algorithms, we begin with a brief introduction to digital technology and binary arithmetic. All information in a computer is reduced to a representation as 1s and 0s. (Or the "on" and "off" state of an electronic switch.) All of the operations within the computer can be reduced to logical OR, EXCLUSIVE OR, and AND. Arithmetic in the computer (called binary arithmetic) obeys the rules shown in Exhibit 85.3 (represented by "addition" and "multiplication" tables):

The symbol ⊕ is called modulo 2 addition and ⊗ is called modulo 2 multiplication. If we consider the symbol '1' as representing a logical value of TRUE and '0' as the logical value FALSE then ⊕ is equivalent to exclusive OR in logic (XOR) while ⊗ is equivalent to AND. For example, A XOR B is true only if A or B is TRUE but not both. Likewise, A AND B is true only when both A and B are TRUE.

All messages, both plain text and cipher text, may be represented by strings of 1s and 0s. The actual method used to digitize the message is not relevant to an understanding of cryptography so we will not discuss the details here.

We will consider two main classes of cryptographic algorithms:

- Stream Ciphers—which operate on essentially continuous streams of plain text, represented as 1s and 0s
- Block Ciphers—which operate on blocks of plain text of fixed size.

These two divisions overlap in that a block cipher may be operated as a stream cipher. Generally speaking, stream ciphers tend be implemented more in hardware devices, while block ciphers are more

[4] Many thought that NSA had implanted a "trap door" that would allow the government to recover encrypted messages at will. Others argued that the cryptovariable length (56 bits) was too short.

suited to implementation in software to execute on a general-purpose computer. Again, these guidelines are not absolute, and there are a variety of operational reasons for choosing one method over another.

85.4 Stream Ciphers

We illustrate a simple stream cipher in the table below and in Exhibit 85.4. Here the plain text is represented by a sequence of 1s and 0s. (The binary streams are to be read from right to left. That is, the right-most bit is the first bit in the sequence.) A keystream[5] generator produces a "random" stream of 1s and 0s that are added modulo 2, bit by bit, to the plaintext stream to produce the cipher-text stream.

The cryptovariable (key) is shown as entering the keystream generator. We will explain the nature of these cryptovariables later. There are many different mechanisms to implement the keystream generator, and the reader is referred to Schneier[6] for many more examples. In general, we may represent the internal operation as consisting of a finite state machine and a complex function. The finite state machine consists of a system state and a function (called the "next state" function) that cause the system to change state based on certain input.

The complex function operates on the system state to produce the keystream. Exhibit 85.5 shows the encryption operation. The decryption operation is equivalent; just exchange the roles of plain text and cipher text. This works because of the following relationships in modulo two addition: Letting p represent a plain-text bit, k a keystream bit, and c the cipher text bit

$$c = p \oplus k,$$

Plain text:	1	0	1	1	0	1	1	0	0
	⊖	⊕	⊕	⊕	⊕	⊖	⊕	⊕	⊕
Keystream	1	1	0	1	0	0	0	1	1
Cipher text	0	1	1	0	0	1	1	1	1

EXHIBIT 85.4 Stream cipher.

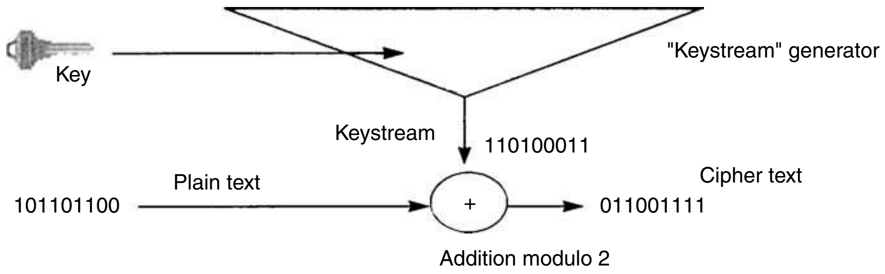

EXHIBIT 85.5 Stream ciphers.

[5] The reader is cautioned not to confuse "keystream" with key. The term is used for historical reasons and is not the "key" for the algorithm. It is for this reason that we prefer the term "cryptovariable."

EXHIBIT 85.6 Simple LFSR.

$$\text{so, } c \oplus k = (p \oplus k) \oplus k = p \oplus (k \oplus k) = p \oplus 0 = p,$$

since in binary arithmetic $x \oplus x$ is always 0. ($1 \oplus 1 = 0 \oplus 0 = 0$).

These concepts are best understood with examples. Exhibit 85.6 shows a simple linear feedback shift register (LFSR). A LFSR is one of the simplest finite state machines and is used as a building block for many stream ciphers (see Schneier's text). In Exhibit 85.6, the four-stage register (shown here filled with 1s) represents the state. During operation, at each tick of the internal clock, the 4 bits shift to the right (the right-most bit is dropped), and the last 2 bits (before the shift) are added (mod 2) and placed in the left-most stage. In general, an LFSR may be of any length, n, and any of the individual stages may be selected for summing and insertion into the left-most stage. The only constraint is that the right-most bit should always be one of the bits selected for the feedback sum. Otherwise, the length is really $n-1$, not n. Exhibit 85.6 shows the sequence of system states obtained from the initial value of 1111. In some systems, the initial value of the register is part of the cryptovariable.

Note that if we started the sequence with 0000, then all subsequent states would be 0000. This would not be good for cryptographic applications since the output would be constant. Thus the all-0 state is avoided. Note also that this four-stage register steps through $15 = 2^4 - 1$ distinct states before repeating. Not all configurations of feedback will produce such a maximal sequence. If we number the stages in Exhibit 85.6 from left to right as 1, 2, 3, 4, and instead of feeding back the sum of stages 3 and 4 we selected 2 and 4, then we would see a very different sequence. This example would produce 2 sequences (we call them cycles) of length 6, one cycle of length 3, and 1 of length 0. For example, starting with 1111 as before will yield:

$$1111 \rightarrow 0111 \rightarrow 0011 \rightarrow 1001 \rightarrow 1100 \rightarrow 1110 \rightarrow 1111$$

It is important to have as many states as possible produced by the internal state machine of the keystream generator. The reason is to avoid repeating the keystream. Once the keystream begins to repeat, the same plain text will produce the same cipher text. This is a cryptographic weakness and should be avoided. While one could select any single stage of the LFSR and use it as the keystream, this is not a good idea. The reason is that the linearity of the sequence of stages allows a simple cryptanalysis. We can avoid the linearity by introducing some more complexity into the system. The objective is to produce a keystream that looks completely random.[7] That is, the keystream will

[7] The output cannot be truly random since the receiving system has to be able to produce the identical sequence.

pass as many tests of statistical randomness as one cares to apply. The most important test is that knowledge of the algorithm and knowledge of a sequence of successive keystream bits does not allow a cryptanalyst to predict the next bit in the sequence. The complexity can often be introduced by using some nonlinear polynomial f(a_1, a_2, …, a_m) of a selection of the individual stages of the LFSR. Nonlinear means that some of the terms are multiplied together such as $a_1a_2 + a_3a_4 + \ldots a_{m-1}a_m$. The selection of which register stages are associated with which inputs to the polynomial can be part of the cryptovariable (key). The reader is encouraged to refer to texts such as Schneier[6] for examples of specific stream-cipher implementations. Another technique for introducing complexity is to use multiple LFSRs and to select output alternately from each based on some pseudorandom process. For example, one might have three LFSRs and create the keystream by selecting bits from one of the two, based on the output of a third.

Some of the features that a cryptographer will design into the algorithm for a stream cipher include:

1. Long periods without a repetition.
2. Functional complexity—each keystream bit should depend on most or all of the cryptovariable bits.
3. Statistically unpredictable—given n successive bits from the keystream it is not possible to predict the $n+1$st bit with a probability different from ½.
4. The keystream should be statistically unbiased—there should be as many 0s as 1s, as many 00s as 10s, 01s, and 11s, etc.
5. The keystream should not be linearly related to the cryptovariable.

We also note that in order to send and receive messages encrypted with a stream cipher the sending and receiving systems must satisfy several conditions. First, the sending and receiving equipment must be using identical algorithms for producing the keystream. Second, they must have the same cryptovariable. Third, they must start in the same state; and fourth, they must know where the message begins.

The first condition is trivial to satisfy. The second condition, ensuring that the two machines have the same cryptovariable, is an administrative problem (called key management) that we will discuss in a later section. We can ensure that the two devices start in the same state by several means. One way is to include the initial state as part of the cryptovariable. Another way is to send the initial state to the receiver at the beginning of each message. (This is sometimes called a message indicator, or initial vector.) A third possibility is to design the machines to always default to a specific state. Knowing where the beginning of the message is can be a more difficult problem, and various messaging protocols use different techniques.

85.5 Block Ciphers

A block cipher operates on blocks of text of fixed size. The specific size is often selected to correspond to the word size in the implementing computer, or to some other convenient reference (e.g., 8-bit ASCII text is conveniently processed by block ciphers with lengths that are multiples of 8 bits). Because the block cipher forms a one-to-one correspondence between input and output blocks it is nothing more or less than a permutation. If the blocks are n bits long, then there are 2^n possible input blocks and 2^n possible output blocks. The relationship between the input and output defines a permutation. There are $(2^n)!$ possible permutations, so theoretically there are $(2^n)!$ possible block cipher systems on n bit blocks.[8]

A simple block cipher on 4-bit blocks is shown in Exhibit 85.7.

With such a prodigious number of possible block ciphers, one would think it a trivial matter to create one. It is not so easy. First of all, the algorithm has to be easy to describe and implement. Most of the $(2^n)!$ permutations can only be described by listing the entries in a table such as the one in Exhibit 85.8. For a 32-bit block cipher this table would have on the order of $10^{9.6}$ entries, which is quite impractical. Another consideration is that there needs to be a relation between the cryptovariable and the permutation.

[8] For $n=7$, $2^n!$ is about 10^{215}. The case $n=8$ is more than I can calculate. Clearly, there is no lack of possible block ciphers.

EXHIBIT 85.8 Simple Block cipher.

In most implementations, the cryptovariable selects a specific permutation from a wide class of permutations. Thus one would need as many tables as cryptovariables. We conclude from this that it is not easy to design good block ciphers.

The most well-known block cipher is the Data Encryption Standard, DES. The cryptovariable for DES is 64 bits, 8 of which are parity check bits. Consequently the cryptovariable is effectively 56 bits long. DES operates as follows: a 64-bit plain text block, after going through an initial permutation (which has no cryptographic significance) is split onto left and right halves, L_0 and R_0. These two halves are then processed as follows for $i=0, 1, \ldots, 15$

$$L_i = R_{i-1}$$

$$R_i = L_{i-1} + f(R_{i-1}, K_i).$$

The blocks K_i are derived from the cryptovariable. The function *f* is a very complex function involving several expansions, compressions, and permutations by means of several fixed tables called the S-boxes and P-boxes. The reader is referred to FIPS PUB 46 for a detailed description of the S-boxes and P-boxes.

As was the case with the DES cryptovariable, there has been much discussion about the significance of the S-boxes. Some people have argued that the NSA designed the S-Boxes so as to include a “trap door” that would allow them to decrypt DES-encrypted messages at will. No one has been able to discover such a trap door. More recently it has been stated that the S-boxes were selected to minimize the danger from an attack called differential cryptanalysis.

Because of the widespread belief that the DES cryptovariable is too small, many have suggested that one encrypt a message twice with DES using two different cryptovariables. This “Double DES” is carried out in the following way. Represent the operation of DES encryption on message *P* and cryptovariable *K* as $C=E(P; K)$; and the corresponding decryption as $P=D(C; K) =D(E(P; K); K)$. The “Double DES” with cryptovariables K and K' is

$$C = E(E(P;K);K')$$

Since each cryptovariable is 56 bits long, we have created an effective cryptovariable length of $56+56=112$ bits. However, we shall see in the section on cryptanalysis that there is an attack on double-DES that requires about the same amount of computation as that required to attack a single DES. Thus double DES is really no more secure than single DES.

A third variant is triple DES, which applies the DES algorithm three times with two distinct cryptovariables. Let K and K' be DES cryptovariables. Then triple DES is

$$C = E(D(E(P;K);K');K).$$

That is, apply the encrypt function to P using the first cryptovariable, K. Then apply the decrypt function to the result using the second cryptovariable, K' Since the decrypt function is using a different cryptovariable, the message is not decrypted; it is transformed by a permutation as in any block cipher. The final step is to encrypt once again with the encrypt function using the first key, K. By using the D in the middle, a triple DES implementation can be used to encrypt a single DES message when $K=K'$:

$$C = E(D(E(P;K);K);K) = E(P;K).$$

Thus, someone using triple DES is still able to communicate securely with persons using single DES. No successful attacks have been reported on triple DES that are any easier than trying all possible pairs of cryptovariables. In the next section we deal with cryptanalysis in more detail.

85.6 Cryptanalysis

As we stated in the introduction, cryptography is the science of designing algorithms for encrypting messages. Cryptanalysis is the science (some would say art) of "breaking" the cryptographic systems. In the following we will try to explain just what "breaking" a cryptosystem means, as there are many misconceptions in the press.

There is an obvious analogy between cryptanalysis and cryptography and burglars and locks. As the locksmiths design better locks the burglars develop better ways to pick them. Likewise, as the cryptographer designs better algorithms the cryptanalyst develops new attacks. A typical design methodology would be to have independent design teams and attack teams. The design team proposes algorithms, and the attack teams tries to find weaknesses. In practice, this methodology is used in the academic world. Researchers publish their new algorithms, and the rest of the academic world searches for attacks to be published in subsequent papers. Each cycle provides new papers toward tenure.

Breaking or attacking a cryptosystem means recovering the plain-text message without possession of the particular cryptovariable (or key) used to encrypt that message. More generally, breaking the system means determining the particular cryptovariable (key) that was used. Although it is the message (or the information in the message) that the analyst really wants, possession of the cryptovariable allows the analyst to recover all of the messages that were encrypted in that cryptovariable. Since the cryptoperiod may be days or weeks, the analyst who recovers a cryptovariable will be able to recover many more messages than if he attacks a single message at a time.

Determining the specific details of the algorithm that was used to encrypt the message is generally not considered part of breaking an encryption system. In most cases, e.g., DES, the algorithm is widely known. Even many of the proprietary systems such as RC4 and RC5 have been published. Because it is very difficult to maintain the secrecy of an algorithm it is better to design the algorithm so that knowledge of the algorithm's details is still not sufficient to determine the cryptovariable used for a specific message without trying all possible cryptovariables.

Trying all cryptovariables is called a “brute force” or “exhaustion” attack. It is an attack that will always work as long as one is able to recognize the plain-text message after decryption. That is, in any attack you need to be able to decide when you have succeeded. One also has to be able to find the cryptovariable (and hence the message) in time for it to be of use. For example, in a tactical military environment, to spend one week to recover a message about an attack that will occur before the week is over will not be useful. Last, one has to be able to afford to execute the attack. One may often trade off time and computer power; an attack that may take one year on a PC might take only one day on 365 PCs. If one must have the message within a day for it to be valuable, but one does not have the funds to acquire or run 365 PCs, then one really doesn’t have a viable attack.

Often a cryptanalyst might assume that she possesses matched plain and cipher text. This is sometimes possible in real systems because military and diplomatic messages often have stereotyped beginnings. In any case it is not a very restrictive condition and can help the cryptanalyst evaluate the cryptographic strength of an algorithm.

Let us look at a brute force attack on some system. We suppose that the cryptovariable has n binary bits (e.g., DES has $n=56$). We suppose that we have a stream cipher and that we have matched plain and cipher text pairs P_i and C_i for $I=1, 2, \ldots$. For each possible cryptovariable there is some fixed amount of computation (“work”) needed to encrypt a P_i and see if it results in the corresponding C_i. We can convert this work into the total number, W, of basic bit operations in the algorithm such as shifts, mod 2 additions, compares, etc. Suppose for definiteness that $W=1000$ or 10^3.

There is a total of 2^n n-bit cryptovariables. For $n=56$, 2^{56} is about $10^{16.8}$ or 72,000,000,000,000,000. If we select one of the possible cryptovariables and encrypt P_1 we have a 50:50 chance of getting C_1 since the only choices are 1 and 0. If we do not obtain C_1 we reject the selected cryptovariable as incorrect and test the next cryptovariable. If we do get C_1 then we must test the selected cryptovariable on P_2 and C_2. How many tests do we need to make in order to be sure that we have the correct cryptovariable? The answer is: at least 56. The rationale is that the probability of the wrong cryptovariable successfully matching 56 or more bits is 2^{-56}. Since we potentially have to try 2^{56} cryptovariables the expected number of cryptovariables passing all the tests is $(2^{56})(2^{-56})=1$. With one “survivor” we may correctly assume it is the cryptovariable we want. If we tested only 2^{55} cryptovariables, then we would expect two survivors. (Cryptanalysts call a cryptovariable that passes all of the tests by chance a “non-causal survivor.”) If we test a few more than 56, the expected number of non-causal survivors is much less than 1. Thus we can be sure that the cryptovariable that does successfully match the 56 P_i and C_i is the one actually used. In a block cipher, such as DES, testing one block is usually sufficient since a correct block has 64 correct bits.

A natural question is how long does it take to execute a brute force attack (or any other kind of attack for that matter). The answer depends on how much computational power is available to the analyst. And since we want cryptographic systems to be useful for many years we also need to know how much computational power will be available in years hence. Gordan Moore, one of the founders of Intel, once noted that processing speeds seem to double (or costs halved) every 18 months. This is equivalent to a factor of 10 increase in speed per dollar spent about every 5 years. This trend has continued quite accurately for many years and has come to be known as “Moore’s law.”

Using Moore’s law we can make some predictions. We first introduce the idea of a MIPS year (*M.Y.*). This is the number of instructions a million-instruction-per-second computer can execute in one year. One *M.Y.* is approximately $10^{13.5}$ instructions. At today’s prices, one can get a 50 MIPS PC for about $750. We can then estimate the cost of a MIPS year at about $750/50 or $15, assuming we can run the computer for one year.

Let’s look at what this means in two examples. We consider two cryptographic systems. One with a 56-bit cryptovariable (e.g., DES) and the other a 40-bit cryptovariable. Note that 40 bits is the maximum cryptovariable length allowed for export by the U.S. government. We assume that each algorithm requires about 1000 basic instructions to test each cryptovariable. Statistics tells us that, on average, we may expect to locate the correct cryptovariable after testing about ½ of the cryptovariable space.

There are two perspectives: how much does it cost? And how long does it take? The cost may be estimated from:

$$(\tfrac{1}{2})(1000N(15))/M.Y.,$$

where N equals the number of cryptovariables (in the examples, either 2^{56} or 2^{40}), and $M.Y. = 10^{13.5}$. The elapsed time requires that we make some assumptions as to the speed of processing. If we set K equal to the number of seconds in one year, and R the number of cryptovariables tested per second, we obtain the formula:

$$\text{Time(in years)} = (\tfrac{1}{2})(N/KR).$$

The results are displayed in Exhibit 85.9.

One of the first public demonstrations of the accuracy of these estimates occurred during the summer of 1995. At that time a student at Ecole Polytechnique reported that he had "broken" an encrypted challenge message posted on the Web by Netscape. The message, an electronic transaction, was encrypted using an algorithm with a 40-bit cryptovariable. What the student did was to partition the cryptovariable space across a number of computers to which he had access and set them searching for the correct one. In other words he executed a brute force attack and he successfully recovered the cryptovariable used in the message. His attack ran for about 6 days and processed about 800,000 keys per second. While most analysts did not believe that a 40-bit cryptovariable was immune to a brute force attack, the student's success did cause quite a stir in the press. Additionally the student posted his program on a Web site so that anyone could copy the program and run the attack. At the RSA Data Security Conference, January 1997, it was announced that a Berkeley student using the idle time on a network of 250 computers was able to break the RSA challenge message, encrypted using a 40-bit key, in three and one-half hours.

More recently a brute force attack was completed against a DES message on the RSA Web page. We quote from the press release of the DES Challenge team (found on www.frii.com/~rtv/despr4.htm):

> LOVELAND, COLORADO (June 18, 1997). Tens of thousands of computers, all across the U.S. and Canada, linked together via the Internet in an unprecedented cooperative supercomputing effort to decrypt a message encoded with the government-endorsed Data Encryption Standard (DES).
>
> Responding to a challenge, including a prize of $10,000, offered by RSA Data Security, Inc., the DESCHALL effort successfully decoded RSA's secret message.
>
> According to Rocke Verser, a contract programmer and consultant who developed the specialized software in his spare time, "Tens of thousands of computers worked cooperatively on the challenge

Year	M.Y. cost	On 56 bit cryptovariable	On 40 bit cryptovariable
1998	$15	$17 million	$260
2003	$1.50	$1.7 million	$26
2008	$0.15	$170 thousand	$2.60

Number of cryptovariables tested per second	On 56 bit cryptovariable	On 40 bit cryptovariable
1,000	300 million years	17.5 years
1,000,000	300,000 years	6.2 days
1,000,000,000	300 years	9 minutes
1,000,000,000,000	109 days	0.5 seconds

EXHIBIT 85.9 Cost and time for brute force attack.

> in what is believed to be one of the largest supercomputing efforts ever undertaken outside of government."
>
> Using a technique called "brute-force," computers participating in the challenge simply began trying every possible decryption key. There are over 72 quadrillion keys (72,057,594,037,927,936). At the time the winning key was reported to RSADSI, the DESCHALL effort had searched almost 25% of the total. At its peak over the recent weekend, the DESCHALL effort was testing 7 billion keys per second.
>
> … And this was done with "spare" CPU time, mostly from ordinary PCs, by thousands of users who have never even met each other.

In other words, the DESCHALL worked as follows. Mr. Verser developed a client-server program that would try all possible keys. The clients were available to any and all who wished to participate. Each participant downloaded the client software and set it executing on their PC (or other machine). The client would execute at the lowest priority in the client PC and so did not interfere with the participant's normal activities. Periodically the client would connect to the server over the Internet and would receive another block of cryptovariables to test. With tens of thousands of clients it only took 4 months to hit the correct cryptovariable.

Another RSA Data Security Inc.'s crypto-cracking contest, launched in March 1997, was completed in October 1997. A team of some 4000 programmers from across the globe, calling themselves the "Bovine RC5 Effort," has claimed the $10,000 prize for decoding a message encrypted in 56-bit -RC5 code. The RC5 effort searched through 47 percent of the possible keys before finding the one used to encrypt the message.

RSA Data Security Inc. sponsored the contest to prove its point that 128-bit encryption must become the standard. Under current U.S. policy, software makers can sell only 40-bit key encryption overseas, with some exceptions available for 56-bit algorithms.

A second DES challenge was solved in February 1998 and took 39 days (see Exhibit 85.10). In this challenge, the participants had to test about 90 percent of the keyspace.

This chapter has focused mostly on brute force attacks. There may be, however, other ways to attack an encryption system. These other methods may be loosely grouped as analytic attacks, statistical attacks, and implementation attacks.

Analytic attacks make use of some weakness in the algorithm that enables the attacker to effectively reduce the complexity of the algorithm through some algebraic manipulation. We will see in the section on public key systems, that the RSA public key algorithm can be attacked by factoring with much less work than brute force. Another example of an analytic attack is the attack on double DES.

Approximate keys tested: 63,686,000,000,000,000

Peak keys Per second: 34,430,460,000

EXHIBIT 85.10 RSA project statistics.

Double DES, you recall, may be represented by:

$$C = E(E(P;\ K);\ L),$$

where K and L are 56-bit DES keys. We assume that we have matched plain and cipher text pairs C_i, P_i. Begin by noting that if $X = E(P;\ K)$. Then $D(C;\ L)\ = X$. Fix a pair C_1, P_1, and make a table of all 2^{56} values of $D(C_1;\ L)$ as L ranges through all 2^{56} possible DES keys. Then try each K in succession, computing $E(P_1;\ K)$ and looking for matches with the values of $D(C_1;\ L)$ in the table. Each pair K, L for which $E(P_1;\ K)$ matches $D(C_1;\ L)$ in the table is a possible choice of the sought-for cryptovariable. Each pair passing the test is then tested against the next plain-cipher pair P_2, C_2.

The chance of a non-causal match (a match given that the pair K, L is not the correct cryptovariable) is about 2^{-64}. Thus of the 2^{112} pairs K, L, about $2^{(112-64)} = 2^{48}$ will match on the first pair P_1, C_1. Trying these on the second block P_2, C_2 and only $2^{(48-64)} = 2^{-16}$ of the non-causal pairs will match. Thus, the probability of the incorrect cryptovariable passing both tests is about $2^{-16} \sim 0$. And the probability of the correct cryptovariable passing both tests is 1.

The total work to complete this attack (called the "meet in the middle" attack) is proportional to $2^{56} + 2^{48} = 2^{56}(1 + 2^{-8}) \sim 2^{56}$. In other words an attack on double DES has about the same work as trying all possible single DES keys. So there is no real gain in security with double DES.

Statistical attacks make use of some statistical weakness in the design. For example, if there is a slight bias toward 1 or 0 in the keystream, one can sometimes develop an attack with less work than brute force. These attacks are too complex to describe in this short chapter.

The third class of attacks is implementation attacks. Here one attacks the specific implementation of the encryption protocol, not simply the cryptographic engine. A good example of this kind of attack was in the news in late summer 1995. The target was Netscape; and this time the attack was against the 128-bit cryptovariable. Several Berkeley students were able to obtain source code for the Netscape encryption package and were able to determine how the system generated cryptovariables. The random generator was given a seed value that was a function of certain system clock values.

The students discovered that the uncertainty in the time variable that was used to seed the random-number generator was far less than the uncertainty possible in the whole cryptovariable space. By trying all possible seed values they were able to guess the cryptovariable with a few minutes of processing time. In other words, the implementation did not use a randomization process that could, in principle, produce any one of the 2^{128} possible keys. Rather it was selecting from a space more on the order of 2^{20}. The lesson here is that even though one has a very strong encryption algorithm and a large key space, a weak implementation could still lead to a compromise of the system.

85.7 Key (Cryptovariable) Management

We have noted in the previous sections that each encryption system requires a key (or cryptovariable) to function and that all of the secrecy in the encryption process is maintained in the key. Moreover, we noted that the sending and receiving party must have the same cryptovariable if they are to be able to communicate. This need translates to a significant logistical problem.

The longer a cryptovariable is used the more likely it is to be compromised. The compromise may occur through a successful attack or, more likely, the cryptovariable may be stolen by or sold to an adversary. Consequently, it is advisable to change the variable frequently. The frequency of change is a management decision based on the perceived strength of the algorithm and the sensitivity of the information being protected.

All communicating parties must have the same cryptovariable. Thus you need to know in advance with whom you plan to exchange messages. If a person needs to maintain privacy among a large number of different persons, then one would need distinct cryptovariables for each possible communicating pair. In a 1000-person organization, this would amount to almost one million keys.

Next, the keys must be maintained in secrecy. They must be produced in secret, and distributed in secret, and held by the users in a protected area (e.g., a safe) until they are to be used. Finally they must be destroyed after being used.

For centuries, the traditional means of distributing keys was through a trusted courier. A government organization would produce the cryptovariables. And couriers, who have been properly vetted and approved, would distribute the cryptovariables. A rigorous audit trail would be maintained of manufacture, distribution, receipt, and destruction. Careful plans and schedules for using the keys would be developed and distributed.

This is clearly a cumbersome, expensive, and time-consuming process. Moreover the process was and is subject to compromise. Many of history's spies were also guilty of passing cryptovariables (as well as other state secrets) to the enemy.

As our communications systems became more and more dependent on computers and communication networks, the concept of a key distribution center was developed. The key distribution center concept is illustrated in Exhibit 85.11. The operation is as follows: Initially each user, A, B, …, is given (via traditional distribution) a user-unique key that we denote by K_A, K_B, etc. These cryptovariables will change only infrequently, which reduces the key distribution problem to a minimum. The KDC maintains a copy of each user-unique key. When A calls B, the calling protocol first contacts the KDC and tells it that user A is sending a message to user B. The KDC then generates a random "session key," K, i.e., a cryptovariable that will be used only for this communicating session between A and B. The KDC encrypts K in user A's unique cryptovariable, $E(K; K_A)$ and sends this to A. User A decrypts this message obtaining K. The KDC likewise encrypts K in user B's unique cryptovariable, $E(K; K_B)$ and sends this result to B. Now A and B (and no other party) have K, which they use as the cryptovariable for this session.

A session here may be a telephone call or passing a message through a packet switch network; the principles are the same. In practice the complete exchange is done in seconds and is completely transparent to the user.

The KDC certainly simplifies the distribution of cryptovariables. Only the user-unique keys need to be distributed in advance, and only infrequently. The session key only exists for the duration of the message so there is no danger that the key might be stolen and sold to an unauthorized person at some later date. But the KDC must be protected, and one still has to know with whom they will be communicating. The KDC will not help if one needs to send an electronic mail message to some new party (i.e., a party unknown to the KDC) for example.

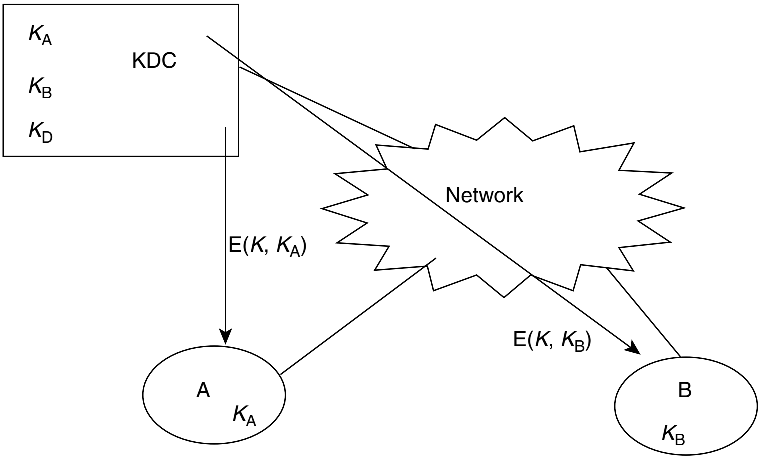

EXHIBIT 85.11 Key distribution center.

It is clear that cryptovariable (or key) management is difficult and does not provide much in the way of flexibility. Many people have wondered if it would be possible to develop an encryption system that did not require secret keys; a system where one could have a directory of public keys. When you wanted to send an encrypted message to someone, you would look up that person's cryptovariable in a "telephone book," encrypt the message, and send it. And no one intercepting the message would be able to decrypt it except the intended recipient. Can such a system be designed? The answer is yes. It is called public key cryptography.

85.8 Public Key Cryptography

The concept of public key cryptography was first discovered and publicly announced by Whitfield Diffie and Martin Hellman (and independently by Ralph Merkle) in 1976. Adm. Bobby Inmann, a former director of the National Security Agency once stated publicly that NSA knew of the idea for many years prior to the publication by Diffie and Hellman.

The public key concept is rather simple (as are most great ideas, once they are explained). We assume that we have two special functions, E and D, that can operate on messages M. (In actual applications large integers will represent the messages, and E and D will be integer functions.) We assume that E and D satisfy the following conditions:

1. $D(E(M))=M$
2. $E(D(M))=M$
3. Given E it is not possible to determine D
4. Given D it is not possible to determine E.

The use of the function E in encryption is straightforward. We assume that each person, A, B, C, has pairs of functions E_A, D_A, E_B, D_B, … that satisfy the conditions 1., 2., and 3. given above. Each user X makes their E_X publicly available but keeps their D_X secret and known only to themselves. When A wants to send a message, M, to B, A looks up E_B in the published list and computes $E_B(M)$. By property 2, $D_B(E_B(M)) = M$ so B can decrypt the message. From property 3, no person can determine D_B from knowledge of E_B so no one but B can decipher the message.

The functions can also be used to sign messages. Perhaps A wants to send a message M to B and she does not care if anyone else sees the message, but she does want B to know that it really came from her. In this case A computes $D_A(M)$, called a signature, and sends it along with M. When B gets these two messages, he looks up A's function E_A and computes $E_A(D_A(M))$ and obtains M from property 2. If this computed M agrees with the message sent as M, then B is sure that it came from A. Why? Because no one else has or can compute D_A except A and the likelihood of someone producing a fictitious X such that $E_A(X)=M$ is infinitesimally small.

Now suppose A wants to send B a secret message and sign it. Let M be the message. A first computes a "signature" $S=D_A(M)$ and concatenates this to the message M, forming M, S. A then encrypts both the message and the signature, $E_B(M, S)$ and sends it to B. B applies D_B to $\mathrm{E}_B(M, \mathrm{S})$ obtaining $D_B(E_B(M, S))=M$, S. B then computes $E_A(S)=E_A(D_A(M))=M$ and compares it to the message he decrypted. If both versions of M are the same, he can be assured that A sent the message.

The question the reader should be asking is "Do such functions exist?" The answer is yes, if we relax what we mean by conditions 3 and 4 above. If we only require that it be computationally infeasible to recover D from E (and vice versa) then the functions can be shown to exist. The most well-known example is the RSA algorithm, named for its discoverers, Rivest, Shamir, and Adleman.

A description of RSA requires a small amount of mathematics that we will explain as we proceed. We start with two large prime numbers, p and q. By large we mean they contain hundreds of digits. This is needed in order to meet conditions 3 and 4. A prime number, you recall, is a number that has no divisors except the number itself and 1. (In dealing with integers when we say a divides b we mean that there is no remainder; i.e., $b=ac$ for some integer c.) The numbers 2, 3, 7, 11, 13, 17 are all prime. The number 2 is the only even prime. All other primes must be odd numbers.

We then define a number n as the product of p and q:

$$n = pq$$

We also define a number t as:

$$t = (p-1)(q-1)$$

As an example, take $p=3$ and $q=7$. (These are not large primes, but the mathematics is the same.) Then $n=21$ and $t=12$. The next step in the construction of RSA is to select a number e that has no common divisors with t. (In this case e and t are said to be relatively prime.) In our numerical example we may take $e=5$ since 5 and 12 have no common divisors. Next we must find an integer d such that $ed-1$ is divisible by t. (This is denoted by ed $=1$ mod t.) Since 5*5 − 1 = 25 − 1 = 24 = 2*12 = 2*t, we may take $d=5$. (In most examples e and d will not be the same.)

The numbers d, p, and q are kept secret. They are used to create the D function. The numbers e and n are used to create the E function. The number e is usually called the public key and d the secret key. The number n is called the modulus. Once p and q are used to produce n and t, they are no longer needed and may be destroyed, but should never be made public.

To encrypt a message, one first converts the message into a string of integers, m_1, m_2, … all smaller than n. We then compute:

$$c_i = E(m_i) = m_i^e \text{mod } n$$

This means that we raise m_i to the e^th power and then divide by n. The remainder is $c_\text{i}=E(m_\text{i})$. In our example, we suppose that the message is $m_1=9$. We compute:

$$\begin{aligned} c_1 &= 9^5 \text{mod } 21 \\ &= 59049 \text{ mod } 21 \end{aligned}$$

Because 59049 = 89979*21 + 18, we conclude that $c_1 = 18$ mod 21.

The decryption, or D function, is defined by:

$$D(c_i) = c_i^d \text{mod } n$$

In our example,

$$\begin{aligned} &18^d \text{mod } n \\ &= 18^5 \text{mod } 21 \\ &= 1889668 \text{mod } 21 \end{aligned}$$

As 1889568 = 889979*21 + 9, we conclude that $D(18)=9$, the message we started with.

To demonstrate mathematically that the decryption function always works to decrypt the message (i.e., that properties 1 and 2 above hold) requires a result from number theory called Euler's generalization of Fermat's little theorem. The reader is referred to any book on number theory for a discussion of this result.

The security of RSA depends on the resistance of n to being factored. Since e is made public, anyone who knows the corresponding d can decrypt any message. If one can factor n into its two prime factors, p and q, then one can compute t and then easily find d. Thus it is important to select integers p and q such that it is not likely that someone can factor the product n. In 1983, the best factoring algorithm and the best computers could factor a number of about 71 decimal (235 binary) digits. By 1994, 129 digit (428 bits) numbers were being factored. Current implementations of RSA generate p and q on the order 256 to 1024 bits so that n is about 512 to 2048 bits.

The reader should note that attacking RSA by factoring the modulus n is a form of algebraic attack. The algebraic weakness is that the factors of n lead to a discovery of the "secret key." A brute force attack, by definition, would try all possible values for d. Since d is hundreds of digits long, the work is on the order of 10^{100}, which is a prodigiously large number. Factoring a number, n, takes at most on the order of square root of n operations or about 10^{50} for a 100-digit number. While still a very large number it is a vast improvement over brute force. There are, as we mentioned, factoring algorithms that are much smaller, but still are not feasible to apply to numbers of greater than 500 bits with today's technology, or with the technology of the near future.

As you can see from our examples, using RSA requires a lot of computation. As a result, even with special purpose hardware, RSA is slow; too slow for many applications. The best application for RSA and other public key systems is as key distribution systems.

Suppose A wants to send a message to B using a conventional private key system such as DES. Assuming that B has a DES device, A has to find some way to get a DES cryptovariable to B. She generates such a key, K, through some random process. She then encrypts K using B's public algorithm, $E_B(K)$ and sends it to B along with the encrypted message $E_{DES}(M; \mathrm{K})$. B applies his secret function D_B to $E_B(K)$ and recovers K, which he then uses to decrypt $\mathrm{E}_{DES}(M; K)$.

This technique greatly simplifies the whole key management problem. We no longer have to distribute secret keys to everyone. Instead, each person has a public key system that generates the appropriate E and D functions. Each person makes the E public, keeps D secret and we're done. Or are we?

85.8.1 The Man-in-the-Middle

Unfortunately there are no free lunches. If a third party can control the public listing of keys, or E functions, that party can masquerade as both ends of the communication.

We suppose that A and B have posted their E_A and E_B, respectively, on a public bulletin board. Unknown to them, C has replaced E_A and E_B with E_C, his own encryption function. Now when A sends a message to B, A will encrypt it as $E_C(M)$ although he believes he has computed $E_B(M)$. C intercepts the message and computes $D_C(E_C(M)) = M$. He then encrypts it with the real E_B and forwards the result to B. B will be able to decrypt the message and is none the wiser. Thus this man in the middle will appear as B to A and as A to B.

The way around this is to provide each public key with an electronically signed signature (a certificate) attesting to the validity of the public key and the claimed owner. The certificates are prepared by an independent third party known as a certificate authority (e.g., VeriSign). The user will provide a public key (E function) and identification to the certificate authority (CA). The CA will then issue a digitally signed token binding the customer's identity to the public key. That is, the CA will produce $D_{CA}(ID_A, E_A)$. A person, B, wishing to send a message to A will obtain A's public key, E_A and the token $D_{CA}(ID_A, E_A)$. Since the CA's public key will be publicized, B computes $E_{CA}(D_{CA}(ID_A, E_A)) = ID_A, E_A$. Thus B, to the extent that he can trust the certification authority, can be assured that he really has the public key belonging to A and not an impostor.

There are several other public key algorithms, but all depend in one way or another on difficult problems in number theory. The exact formulations are not of general interest since an implementation will be quite transparent to the user. The important user issue is the size of the cryptovariable, the speed of the computation, and the robustness of the implementation. However, there is a new implementation that is becoming popular and deserves some explanation.

85.9 Elliptic Curve Cryptography

A new public key technique based on elliptic curves has recently become popular. To explain this new process requires a brief digression. Recall from the previous section, that the effectiveness of public key algorithms depend on the existence of very difficult problems in mathematics. The security of RSA depends, for example, on the difficulty of factoring large numbers. While factoring small numbers is a simple operation, there are only a few (good) known algorithms or procedures for factoring large integers, and these still take prodigiously long times when factoring numbers that are hundreds of digits long. Another difficult mathematical problem is called the discrete logarithm problem. Given a number b, the base, and x, the logarithm, one can easily compute b^x or b^x mod N for any N. It turns out to be very difficult to solve the reverse problem for large integers. That is, given a large integer y and a base b, find x so that $b^x = y$ Mod N. The known procedures (algorithms) require about the same level of computation as finding the factors of a large integer. Diffie and Hellman[9] exploited this difficulty to define their public key distribution algorithm.

85.9.1 Diffie and Hellman Key Distribution

Suppose that Sarah and Tanya want to exchange a secret cryptovariable for use in a conventional symmetric encryption system, say a DES encryption device. Sarah and Tanya together select a large prime p and a base b. The numbers p and b are assumed to be public knowledge. Next Sarah chooses a number s and keeps it secret. Tanya chooses a number t and keeps it secret. The numbers s and t must be between 1 and $p-1$. Sarah and Tanya then compute (respectively):

$$x = b^s \text{Mod } p (\text{Sarah})$$

$$y = b^t \text{Mod } p \text{ (Tanya)}$$

In the next step of the process Sarah and Tanya exchange the numbers x and y; Tanya sends y to Sarah, and Sarah sends x to Tanya. Now Sarah can compute

$$y^s = b^{ts} \text{Mod } p$$

And Tanya can compute

$$x^t = b^{st} \text{Mod } p$$

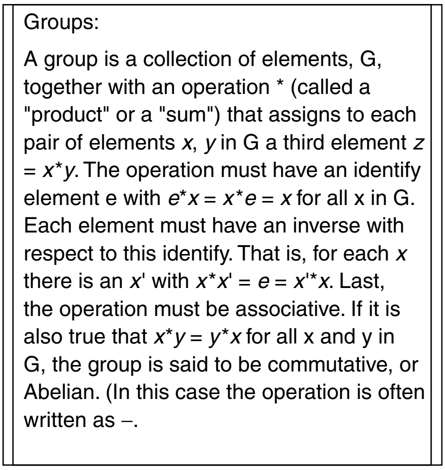
But,

$$b^{ts} \text{Mod } p = b^{st} \text{Mod } p = \text{K}$$

which becomes their common key. In order for a third party to recover K, that party must solve the discrete logarithm problem to recover s and t. (To be more precise, solving the discrete logarithm problem is sufficient to recover the key, but it might not be necessary. It is not known if there is another way to find b^{st} given b^s and b^t. It is conjectured that the latter problem is at least as difficult as the discrete logarithm problem.) The important fact regarding the Diffie-Hellman key exchange is that it applies to any mathematical object known as an Abelian group. (See Exhibit 85.12.)

Now we can get into the idea of elliptic curve cryptography, at least at a high level. An elliptic curve is a collection of points in the $x-y$ plane that satisfy an equation of the form

[9] Hellman, M.E. and Diffie, W. 1976. New directions in cryptography. *IEEE Transactions on Information Theory* IT-22, 644–654.



Groups:

A group is a collection of elements, G, together with an operation * (called a "product" or a "sum") that assigns to each pair of elements *x*, *y* in G a third element *z* = *x***y*. The operation must have an identify element e with *e***x* = *x***e* = *x* for all x in G. Each element must have an inverse with respect to this identify. That is, for each *x* there is an *x*' with *x***x*' = *e* = *x*'**x*. Last, the operation must be associative. If it is also true that *x***y* = *y***x* for all x and y in G, the group is said to be commutative, or Abelian. (In this case the operation is often written as –.

EXHIBIT 85.12 Definition of Abelian groups.

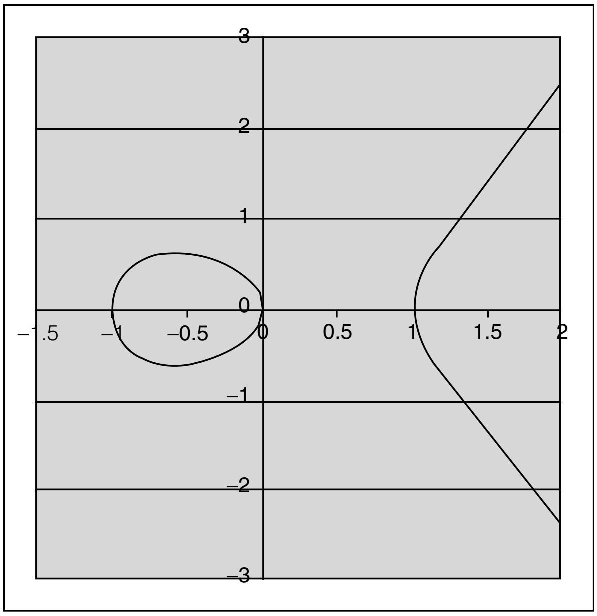


EXHIBIT 85.13 Graph of elliptic curve.

$$y^2 = x^3 + ax + b. \qquad (85.1)$$

The elements a and b can be real numbers, imaginary numbers, or elements from a more general mathematical object known as a field. As an example, if we take $a = -1$ and $b = 0$. The equation is:

$$y^2 = x^3 - x. \qquad (85.2)$$

A graph of this curve is shown in Exhibit 85.13. It turns out that the points of this curve (those pairs (x, y) that satisfy the equation 2) can form a group under a certain operation. Given two points $P = (x, y)$ and $Q = (x', y')$ on the curve we can define a third point $R =$ (x'', y$''$) on the curve called the "sum" of P and Q.

Furthermore this operation satisfies all of the requirements for a group. Now that we have a group we may define a Diffie-Hellman key exchange on this group. Indeed, any cryptographic algorithm that may be defined in a general group can be instantiated in the group defined on an elliptic curve. For a given size key, implementing an elliptic curve system seems to be computationally faster than the equivalent RSA. Other than the speed of the implementation there does not appear to be any advantage for using elliptic curves over RSA. RSA Data Security Inc. includes an elliptic curve implementation in their developer's kit (BSAFE) but they strongly recommend that the technique not be used except in special circumstances. Elliptic curve cryptographic algorithms have been subjected to significantly less analysis than the RSA algorithm so it is difficult to state with any confidence that elliptic curves are as secure or more secure than RSA. See Koblitz[10] for a complete discussion.

85.10 Conclusions

This short chapter presented a quick survey of some basic concepts in cryptography. No attempt was made to be comprehensive; the object was to help the reader better understand some of the reports about encryption and "breaking encryption systems" that often appear in the trade press and newspapers. The reader is referred to any of the many fine books that are available for more detail on any of the topics presented.

Steganography: The Art of Hiding Messages

Mark Edmead

Recently, there has been an increased interest in steganography (also called stego). We have seen this technology mentioned during the investigation of the September 11 attacks, where the media reported that the terrorists used it to hide their attack plans, maps, and activities in chat rooms, bulletin boards, and Web sites. Steganography had been widely used long before these attacks and, as with many other technologies, its use has increased due to the popularity of the Internet.

The word *steganography* comes from the Greek, and it means covered or secret writing. As defined today, it is the technique of embedding information into something else for the sole purpose of hiding that information from the casual observer. Many people know a distant cousin of steganography called watermarking—a method of hiding trademark information in images, music, and software. Watermarking is not considered a true form of steganography. In stego, the information is hidden in the image; watermarking actually adds something to the image (such as the word *Confidential*), and therefore it becomes part of the image. Some people might consider stego to be related to encryption, but they are not the same thing. We use encryption—the technology to translate something from readable form to something unreadable—to protect sensitive or confidential data. In stego, the information is not necessarily encrypted, only hidden from plain view.

One of the main drawbacks of using encryption is that with an encrypted message—although it cannot be read without decrypting it—it is recognized as an encrypted message. If someone captures a network data stream or an e-mail that is encrypted, the mere fact that the data is encrypted might raise suspicion. The person monitoring the traffic may investigate why, and use various tools to try to figure out the message's contents. In other words, encryption provides confidentiality but not secrecy. With steganography, however, the information is hidden; and someone looking at a JPEG image, for instance, would not be able to determine if there was any information within it. So, hidden information could be right in front of our eyes and we would not see it.

In many cases, it might be advantageous to use encryption and stego at the same time. This is because, although we can hide information within another file and it is not visible to the naked eye, someone can still (with a lot of work) determine a method of extracting this information. Once this happens, the hidden or secret information is visible for him to see. One way to circumvent this situation is to combine the two—by first encrypting the data and then using steganography to hide it. This two-step process adds additional security. If someone manages to figure out the steganographic system used, he would not be able to read the data he extracted because it is encrypted.

86.1 Hiding the Data

There are several ways to hide data, including data injection and data substitution. In data injection, the secret message is directly embedded in the host medium. The problem with embedding is that it usuallymakes the host file larger; therefore, the alteration is easier to detect. In substitution, however, the normal data is replaced or substituted with the secret data. This usually results in very little size change for the host file. However, depending on the type of host file and the amount of hidden data, the substitution method can degrade the quality of the original host file.

In the article "Techniques for Data Hiding," Walter Bender outlines several restrictions to using stego:

- The data that is hidden in the file should not significantly degrade the host file. The hidden data should be as imperceptible as possible.
- The hidden data should be encoded directly into the media and not placed only in the header or in some form of file wrapper. The data should remain consistent across file formats.
- The hidden (embedded) data should be immune to modifications from data manipulations such as filtering or resampling.
- Because the hidden data can degrade or distort the host file, error-correction techniques should be used to minimize this condition.
- The embedded data should still be recoverable even if only portions of the host image are available.

86.2 Steganography in Image Files

As outlined earlier, information can be hidden in various formats, including text, images, and sound files. In this chapter, we limit our discussion to hidden information in graphic images. To better understand how information can be stored in images, we need to do a quick review of the image file format. A computer image is an array of points called pixels (which are represented as light intensity). Digital images are stored in either 24- or 8-bit pixel files. In a 24-bit image, there is more room to hide information, but these files are usually very large in size and not the ideal choice for posting them on Web sites or transmitting over the Internet. For example, a 24-bit image that is 1024×768 in size would have a size of about 2 MB. A possible solution to the large file size is image compression. The two forms of image compression to be discussed are lossy and lossless compression. Each one of these methods has a different effect on the hidden information contained within the host file. Lossy compression provides high compression rates, but at the expense of data image integrity loss. This means the image might lose some of its image quality. An example of a lossy compression format is JPEG (Joint Photographic Experts Group). Lossless, as the name implies, does not lose image integrity, and is the favored compression used for steganography. GIF and BMP files are examples of lossless compression formats.

A pixel's makeup is the image's raster data. A common image, for instance, might be 640×480 pixels and use 256 colors (eight bits per pixel).

In an eight-bit image, each pixel is represented by eight bits, as shown in Exhibit 86.1. The four bits to the left are the most-significant bits (MSB), and the four bits to the right are the least-significant bits (LSB). Changes to the MSB will result in a drastic change in the color and the image quality, while changes in the LSB will have minimal impact. The human eye cannot usually detect changes to only one

EXHIBIT 86.1 Eight-Bit Pixel

1	1	0	0	1	1	0	1

or two bits of the LSB. So if we hide data in any two bits in the LSB, the human eye will not detect it. For instance, if we have a bit pattern of 11001101 and change it to 11001100, they will look the same. This is why the art of steganography uses these LSBs to store the hidden data.

86.3 A Practical Example of Steganography at Work

To best demonstrate the power of steganography, Exhibit 86.2 shows the host file before a hidden file has been introduced. Exhibit 86.3 shows the image file we wish to hide. Using a program called Invisible Secrets 3, by NeoByte Solution, Exhibit 86.3 is inserted into Exhibit 86.2. The resulting image file is shown in Exhibit 86.4. Notice that there are no visual differences to the human eye. One significant difference is in the size of the resulting image. The size of the original Exhibit 86.2 is 18 kb. The size of Exhibit 86.3 is 19 kb. The size of the resulting stego-file is 37 kb. If the size of the original file were known, the size of the new file would be a clear indication that something made the file size larger. In reality, unless we know what the sizes of the files should be, the size of the file would not be the best way to determine if an image is a stego carrier. A practical way to determine if files have been tampered with is to use available software products that can take a snapshot of the images and calculate a hash value. This baseline value can then be periodically checked for changes. If the hash value of the file changes, it means that tampering has occurred.

86.4 Practical (and Not So Legal) Uses for Steganography

There are very practical uses for this technology. One use is to store password information on an image file on a hard drive or Web page. In applications where encryption is not appropriate (or legal), stego can be used for covert data transmissions. Although this technology has been used mainly for military operations, it is now gaining popularity in the commercial marketplace. As with every technology, there are illegal uses for stego as well. As we discussed earlier, it was reported that terrorists use this technology

EXHIBIT 86.2 Unmodified image.

EXHIBIT 86.3 Image to be hidden in Exhibit 86.2.

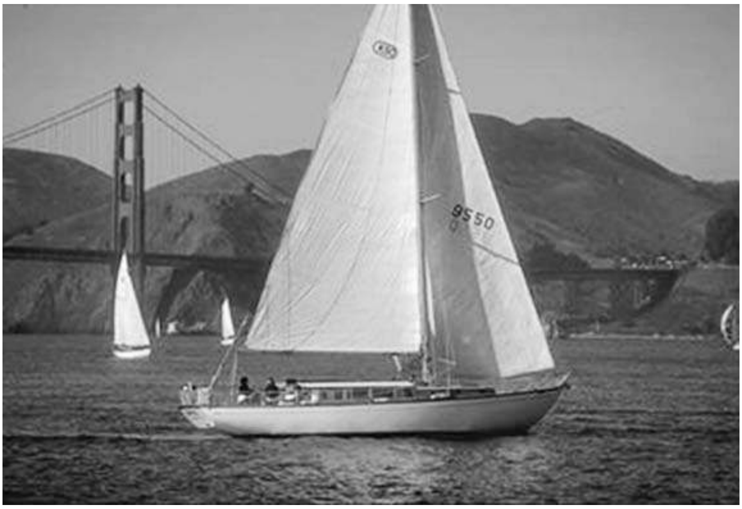

EXHIBIT 86.4 Image with Exhibit 86.3 inserted into Exhibit 86.2.

to hide their attacks plans. Child pornographers have also been known to use stego to illegally hide pictures inside other images.

86.5 Defeating Steganography

Steganalysis is the technique of discovering and recovering the hidden message. There are terms in steganography that are closely associated with the same terms in cryptography. For instance, a steganalyst, like his counterpart a cryptanalyst, applies steganalysis in an attempt to detect the existence of hidden information in messages. One important—and crucial—difference between the two is that in cryptography, the goal is not to detect if something has been encrypted. The fact that we can see the encrypted information already tells us that it is. The goal in cryptanalysis is to decode the message.

In steganography, the main goal is first to determine if the image has a hidden message and to determine the specific steganography algorithm used to hide the information. There are several known attacks available to the steganalyst: stego-only, known cover, known message, chosen stego, and chosen message. In a stego-only attack, the stego host file is analyzed. A known cover attack is used if both the original (unaltered) media and the stego-infected file are available. A known message attack is used when the hidden message is revealed. A chosen stego attack is performed when the algorithm used is known and the stego host is available. A chosen message attack is performed when a stego-media is generated using a predefined algorithm. The resulting media is then analyzed to determine the patterns generated, and this information is used to compare it to the patterns used in other files. This technique will not extract the hidden message, but it will alert the steganalyst that the image in question does have embedded (and hidden) information.

Another attack method is using dictionary attacks against steganographic systems. This will test to determine if there is a hidden image in the file. All of the stenographic systems used to create stego images use some form of password validation. An attack could be perpetrated on this file to try to guess the password and determine what information had been hidden. Much like cryptographic dictionary attacks, stego dictionary attacks can be performed as well. In most steganographic systems, information is embedded in the header of the image file that contains, among other things, the length of the hidden message. If the size of the image header embedded by the various stego tools is known, this information could be used to verify the correctness of the guessed password.

Protecting yourself against steganography is not easy. If the hidden text is embedded in an image, and you have the original (unaltered) image, a file comparison could be made to see if they are different. This comparison would not be to determine if the size of the image has changed—remember, in many cases the image size does not change. However, the data (and the pixel level) does change. The human eye usually cannot easily detect subtle changes—detection beyond visual observation requires extensive analysis. Several techniques are used to do this. One is the use of stego signatures. This method involves analysis of many different types of untouched images, which are then compared to the stego images. Much like the analysis of viruses using signatures, comparing the stego-free images to the stego-images may make it possible to determine a pattern (signature) of a particular tool used in the creation of the stego-image.

86.6 Summary

Steganography can be used to hide information in text, video, sound, and graphic files. There are tools available to detect steganographic content in some image files, but the technology is far from perfect. A dictionary attack against steganographic systems is one way to determine if content is, in fact, hidden in an image.

Variations of steganography have been in use for quite some time. As more and more content is placed on Internet Web sites, the more corporations—as well as individuals—are looking for ways to protect their intellectual properties. Watermarking is a method used to mark documents, and new technologies for the detection of unauthorized use and illegal copying of material are continuously being improved.

An Introduction to Cryptography

Javek Ikbal

This chapter presents some basic ideas behind cryptography. This is intended for an audience evaluators, recommenders, and end users of cryptographic algorithms and products rather than implementers. Hence, the mathematical background will be kept to a minimum. Only widely adopted algorithms are described with some mathematical detail. We also present promising technologies and algorithms that information security practitioners might encounter and may have to choose or discard.

87.1 The Basics

87.1.1 What Is Cryptography?

Cryptography is the art and science of securing messages so unintended audiences cannot read, understand, or alter that message.

87.1.2 Related Terms and Definitions

A message in its original form is called the plaintext or cleartext. The process of securing that message by hiding its contents is encryption or enciphering. An encrypted message is called ciphertext, and the process of turning the ciphertext back to cleartext is called decryption or deciphering. Cryptography is often shortened to crypto.

Practitioners of cryptography are known as cryptographers. The art and science of breaking encryptions is known as cryptanalysis, which is practiced by cryptanalysts. Cryptography and cryptanalysis are covered in the theoretical and applied branch of mathematics known as cryptology, and practiced by cryptologists.

A cipher or cryptographic algorithm is the mathematical function or formula used to convert cleartext to ciphertext and back. Typically, a pair of algorithms is used to encrypt and decrypt.

An algorithm that depends on keeping the algorithm secret to keep the ciphertext safe is known as a restricted algorithm. Security practitioners should be aware that restricted algorithms are inadequate in the current world. Unfortunately, restricted algorithms are quite popular in some settings. Exhibit 87.1 shows the schematic flow of restricted algorithms. This can be mathematically expressed as $E(M)=C$ and $D(C)=M$, where M is the cleartext message, E is the encryption function, C is the ciphertext, and D is the decryption function.

A major problem with restricted algorithms is that a changing group cannot use it; every time someone leaves, the algorithm has to change. Because of the need to keep it a secret, each group has to build its own algorithms and software to use it.

These shortcomings are overcome by using a variable known as the key or cryptovariable. The range of possible values for the key is called the keyspace. With each group using its own key, a common and well-known algorithm may be shared by any number of groups.

The mathematical representation now becomes: $E_k(M)=C$ and $D_k(C)=M$, where the subscript k refers to the encryption and decryption key. Some algorithms will utilize different keys for encryption and decryption. Exhibit 87.2 illustrates that the key is an input to the algorithm.

Note that the security of all such algorithms depends on the key and not the algorithm itself. We submit to the information security practitioner that any algorithm that has not been publicly discussed, analyzed, and withstood attacks (i.e., zero restriction) should be presumed insecure and rejected.

EXHIBIT 87.1 Encryption and decryption with restricted algorithms.

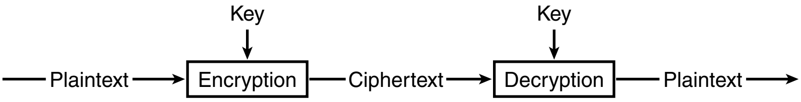

EXHIBIT 87.2 Encryption and decryption with keys.

87.1.3 A Brief History

Secret writing probably came right after writing was invented. The earliest known instance of cryptography occurred in ancient Egypt 4000 years ago, with the use of hieroglyphics. These were purposefully cryptic; hiding the text was probably not the main purpose—it was intended to impress. In ancient India, government spies communicated using secret codes. Greek literature has examples of cryptography going back to the time of Homer. Julius Caesar used a system of cryptography that shifted each letter three places further through the alphabet (e.g., A shifts to D, Z shifts to C, etc.). Regardless of the amount of shift, all such monoalphabetic substitution ciphers (MSCs) are also known as Caesar ciphers. While extremely easy to decipher if you know how, a Caesar cipher called ROT-13 (N = A, etc.) is still in use today as a trivial method of encryption. Why ROT-13 and not any other ROT-N? By shifting down the middle of the English alphabet, ROT-13 is self-reversing—the same code can be used to encrypt and decrypt. How this works is left as an exercise for the reader. Exhibit 87.3 shows the alphabet and corresponding Caesar cipher and ROT-13.

During the seventh century A.D., the first treatise on cryptanalysis appeared. The technique involves counting the frequency of each ciphertext letter. We know that the letter E occurs the most in English. So if we are trying to decrypt a document written in English where the letter H occurs the most, we can assume that H stands for E. Provided we have a large enough sample of the ciphertext for the frequency count to be statistically significant, this technique is powerful enough to cryptanalyze any MSC and is still in use.

Leon Battista Alberti invented a mechanical device during the 15th century that could perform a polyalphabetic substitution cipher (PSC). A PSC can be considered an improvement of the Caesar cipher because each letter is shifted by a different amount according to a predetermined rule.

The device consisted of two concentric copper disks with the alphabet around the edges. To start enciphering, a letter on the inner disk is lined up with any letter on the outer disk, which is written as the first character of the ciphertext. After a certain number of letters, the disks are rotated and the encryption continues. Because the cipher is changed often, frequency analysis becomes less effective.

The concept of rotating disks and changing ciphers within a message was a major milestone in cryptography.

The public interest in cryptography dramatically increased with the invention of the telegraph. People wanted the speed and convenience of the telegraph without disclosing the message to the operator, and cryptography provided the answer.

After World War I, U.S. military organizations poured resources into cryptography. Because of the classified nature of this research, there were no general publications that covered cryptography until the late 1960s; and the public interest went down again.

During this time, computers were also gaining ground in nongovernment areas, especially the financial sector; and the need for a nonmilitary crypto-system was becoming apparent. The organization currently known as the National Institute of Standards and Technology (NIST), then called the National Bureau of Standards (NBS), requested proposals for a standard cryptographic algorithm. IBM responded with Lucifer, a system developed by Horst Feistel and colleagues. After adopting two modifications from the National Security Agency (NSA), this was adopted as the federal Data Encryption Standard (DES) in 1976.[1] NSA's changes caused major controversy, specifically because it suggested DES use 56-bit keys instead of 112-bit keys as originally submitted by IBM.

During the 1970s and 1980s, the NSA also attempted to regulate cryptographic publications but was unsuccessful. However, general interest in cryptography increased as a result. Academic and business

interest in cryptography was high, and extensive research led to significant new algorithms and techniques.

Advances in computing power have made 56-bit keys breakable. In 1998, a custom-built machine from the Electronic Frontier Foundation costing $210,000 cracked DES in four and a half days.[2] In January 1999, a distributed network of 100,000 machines cracked DES in 22 hours and 15 minutes.

As a direct result of these DES cracking examples, NIST issued a Request for Proposals to replace DES with a new standard called the Advanced Encryption Standard (AES).[3] On November 26, 2001, NIST selected Rijndael as the AES.

87.1.4 The Alphabet-Soup Players: Alice, Bob, Eve, and Mike

In our discussions of cryptographic protocols, we will use an alphabet soup of names that are participating in (or are trying to break into) a secure message exchange:

- *Alice*, first participant
- *Bob*, second participant
- *Eve*, eavesdropper
- *Mike*, masquerader

87.1.5 Ties to Confidentiality, Integrity, and Authentication

Cryptography is not limited to confidentiality only—it can perform other useful functions.

- *Authentication*. If Alice is buying something from Bob's online store, Bob has to assure Alice that it is indeed Bob's Web site and not Mike's, the masquerader pretending to be Bob. Thus, Alice should be able to authenticate Bob's Web site, or know that a message originated from Bob.
- *Integrity*. If Bob is sending Alice, the personnel manager, a message informing her of a $5000 severance pay for Mike, Mike should not be able to intercept the message in transit and change the amount to $50,000. Cryptography enables the receiver to verify that a message has not been modified in transit.
- *Non-repudiation*. Alice places an order to sell some stocks at $10 per share. Her stockbroker, Bob, executes the order, but then the stock goes up to $18. Now Alice claims she never placed that order. Cryptography (through digital signatures) will enable Bob to prove that Alice did send that message.

87.1.6 Section Summary

- Any message or data in its original form is called plaintext or cleartext.
- The process of hiding or securing the plaintext is called encryption (verb: to encrypt or to encipher).
- When encryption is applied on plaintext, the result is called ciphertext.
- Retrieving the plaintext from the ciphertext is called decryption (verb: to decrypt or to decipher).
- The art and science of encryption and decryption is called cryptography, and its practitioners are cryptographers.
- The art and science of breaking encryption is called cryptanalysis, and its practitioners are cryptanalysts.
- The process and rules (mathematical or otherwise) to encrypt and decrypt are called ciphers or cryptographic algorithms.
- The history of cryptography is over 4000 years old.

- Frequency analysis is an important technique in cryptanalysis.
- Secret cryptographic algorithms should not be trusted by an information security professional.
- Only publicly available and discussed algorithms that have withstood analysis and attacks may be used in a business setting.
- Bottom line: do not use a cryptographic algorithm developed in-house (unless you have internationally renowned experts in that field).

87.2 Symmetric Cryptographic Algorithms

Algorithms or ciphers that use the same key to encrypt and decrypt are called symmetric cryptographic algorithms. There are two basic types: stream and block.

87.2.1 Stream Ciphers

This type of cipher takes messages in a stream and operates on individual data elements (characters, bits, or bytes).

Typically, a random-number generator is used to produce a sequence of characters called a key stream. The key stream is then combined with the plaintext via exclusive-OR (XOR) to produce the ciphertext. Exhibit 87.4 illustrates this operation of encrypting the letter Z, the ASCII value of which is represented in binary as 01011010. Note that in an XOR operation involving binary digits, only XORing 0 and 1 yields 1; all other XORs result in 0. Exhibit 87.4 shows how a stream cipher operates.

Before describing the actual workings of a stream cipher, we will examine how shift registers work because they have been the mainstay of electronic cryptography for a long time.

A linear feedback shift register (LFSR) is very simple in principle. For readers not versed in electronics, we present a layman's representation. Imagine a tube that can hold four bits with a window at the right end. Because the tube holds four bits, we will call it a four-bit shift register. We shift all bits in the tube and, as a result, the bit showing through the window changes. Here, shifting involves pushing from the left so the right-most bit falls off; and to keep the number of bits in the tube constant, we place the output of some addition operation as the new left-most bit. In the following example, we will continue with our four-bit LFSR, and the new left-most bit will be the result of adding bits three and four (the feedback) and keeping the right-most bit (note that in binary mathematics, $1+1=10$, with 0 being the right-most bit, and $1+0=1$). For every shift that occurs, we look through the window and note the right-most bit. As a result, we will see the sequence shown in Exhibit 87.5.

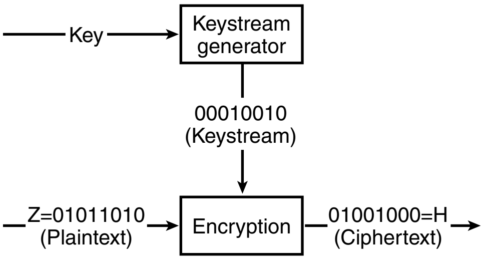

EXHIBIT 87.4 Stream cipher operation.

1111.-> 0111 -> 0011 -> 0001 -> 1000 -> 0100 -> 0010 -> 1001 -> 1100 -> 0110 -> 1011 -> 0101 -> 1010 -> 1101 -
1101 -> 1110 -> 1111
Keystream: 111100010011010 (Right-most bit through the window before repetition).

EXHIBIT 87.5 4-bit LFSR output.

Note that after $2^{(N=4)}-1=15$ iterations, we will get a repetition. This is the maximum number of unique sequences (also called period) when dealing with a four-bit LFSR (because we have to exclude 0000, which will always produce a sequence of 0000s). Choosing a different feedback function may have reduced the period, and the longest unique sequence is called the maximal length. The maximal length is important because repeating key streams mean the same plaintext will produce the same ciphertext, and this will be vulnerable to frequency analysis and other attacks.

To construct a simple stream cipher, take an LFSR (or take many different sizes and different feedback functions). To encrypt each bit of the plaintext, take a bit from the plaintext, XOR it with a bit from the key stream to generate the ciphertext (refer to Exhibit 87.4), and so on.

Of course, other stream ciphers are more complex and involve multiple LFSRs and other techniques.[4] We will discuss RC4 as an example of a stream cipher. First, we will define the term S-box.

An S-box is also known as a substitution box or table and, as the name implies, it is a table or system that provides a substitution scheme. Shift registers are S-boxes; they provide a substitution mechanism.

RC4 uses an output feedback mechanism combined with 256 S-boxes (numbered S0…S255) and two counters, i and j.

A random byte K is generated through the following steps:

```
i = (i + 1) mod 256
j = (j + $S_i$) mod 256
swap ($S_i$, $S_j$)
t = ($S_i$ + $S_j$) mod 256
K = $S_t$
```

Now, K XOR Plaintext = Ciphertext, and K XOR Ciphertext = Plaintext

87.2.2 Block Ciphers

A block cipher requires the accumulation of some amount of data or multiple data elements before ciphering can begin. Encryption and decryption happen on chunks of data, unlike stream ciphers, which operate on each character or bit independently.

87.2.3 DES

The Data Encryption Standard (DES) is over 25 years old; because of its widespread implementation and use, it will probably coexist with the new Advanced Encryption Standard (AES) for a few years.

Despite initial concern about NSA's role in crafting the standard, DES generated huge interest in cryptography; vendors and users alike were eager to adopt the first government-approved encryption standard that was released for public use.

The DES calls for reevaluations of DES every five years. Starting in 1987, the NSA warned that it would not recertify DES because it was likely that it soon would be broken; they proposed secret algorithms available on tamper-proof chips only. Users of DES, including major financial institutions, protested; DES got a new lease on life until 1992. Because no new standards became available in 1992, it lived on to 1998 and then until the end of 2001, when AES became the standard.

DES is a symmetric block cipher that operates in blocks of 64 bits of data at a time, with 64-bit plaintext resulting in 64-bit ciphertext. If the data is not a multiple of 64 bits, then it is padded at the end. The effective key-length is 56 bits with 8 bits of parity. All security rests with the key.

A simple description of DES is as follows:[1]

Take the 64-bit block of message (M).
Rearrange the bits of M (initial permutation, IP).
Break IP down the middle into two 32-bit blocks (L & R).
Shift the key bits, and take a 48-bit portion from the key.
Save the value of R into R_{old}.

Expand R via a permutation to 48 bits.
XOR R with the 48-bit key and transform via eight S-boxes into a new 32-bit chunk.
Now, R takes on the value of the new R XOR-ed with L.
And L takes on the value of R_{old}.
Repeat this process 15 more times (total 16 rounds).
Join L and R.
Reverse the permutation IP (final permutation, FP).

There are some implementations without IP and FP; because they do not match the published standard, they should not be called DES or DES-compliant, although they offer the same degree of security.

Certain DES keys are considered weak, semiweak, or possibly weak: a key is considered weak if it consists of all 1s or all 0s, or if half the keys are 1s and the other half are 0s.[5]

Conspiracy theories involving NSA backdoors and EFFs DES-cracking machine notwithstanding, DES lives on in its original form or a multiple-iteration form popularly known as Triple-DES.

Triple-DES is DES done thrice, typically with two 56-bit keys. In the most popular form, the first key is used to DES-encrypt the message. The second key is used to DES-decrypt the encrypted message. Because this is not the right key, the attempted decryption only scrambles the data even more. The resultant ciphertext is then encrypted again with the first key to yield the final ciphertext. This three-step procedure is called Triple-DES. Sometimes, three keys are used.

Because this follows an Encryption > Decryption > Encryption scheme, it is often known as DES-EDE.

ANSI standard X9.52 describes Triple-DES encryption with keys k_1, k_2, k_3 as:

$$C = E_{k3}(D_{k2}(E_{k1}(M)))$$

where E_k and D_k denote DES encryption and DES decryption, respectively, with the key k. Another variant is DES-EEE, which consists of three consecutive encryptions. There are three keying options defined in ANSI X9.52 for DES-EDE:

The three keys k_1, k_2, and k_3 are different (three keys).
k_1 and k_2 are different, but $k_1 = k_3$ (two keys).
$k_1 = k_2 = k_3$ (one key).
The third option makes Triple-DES backward-compatible with DES and offers no additional security.

87.2.4 AES (Rijndael)

In 1997, NIST issued a Request for Proposals to select a symmetric-key encryption algorithm to be used to protect sensitive (unclassified) federal information. This was to become the Advanced Encryption Standard (AES), the DES replacement. In 1998, NIST announced the acceptance of 15 candidate algorithms and requested the assistance of the cryptographic research community in analyzing the candidates. This analysis included an initial examination of the security and efficiency characteristics for each algorithm.

NIST reviewed the results of this preliminary research and selected MARS, RC6™, Rijndael, Serpent, and Twofish as finalists. After additional review, in October 2000, NIST proposed Rijndael as AES. For research results and rationale for selection, see Reference 5.

Before discussing AES, we will quote the most important answer from the Rijndael FAQ:

> If you're Dutch, Flemish, Indonesian, Surinamer or South African, it's pronounced like you think it should be. Otherwise, you could pronounce it like reign dahl, rain doll, or rhine dahl. We're not picky. As long as you make it sound different from region deal.[6]

Rijndael is a block cipher that can process blocks of 128-, 192-, and 256-bit length using keys 128-, 192-, and 256-bits long. All nine combinations of block and key lengths are possible.[7] The AES standard specifies only 128-bit data blocks and 128-, 192-, and 256-bit key lengths. Our discussions will be confined to AES and not the full scope of Rijndael. Based on the key length, AES may be referred to as AES-128, AES-192, or AES-256. We will present a simple description of Rijndael. For a mathematical treatment, see References 8 and 9.

Rijndael involves an initial XOR of the state and a round key, nine rounds of transformations (or rounds), and a round performed at the end with one step omitted. The input to each round is called the state. Each round consists of four transformations: SubBytes, ShiftRow, MixColumn (omitted from the tenth round), and AddRoundKey.

In the SubBytes transformation, each of the state bytes is independently transformed using a nonlinear S-box.

In the ShiftRow transformation, the state is processed by cyclically shifting the last three rows of the state by different offsets.

In the MixColumn transformation, data from all of the columns of the state are mixed (independently of one another) to produce new columns.

In the AddRoundKey step in the cipher and inverse cipher transformations, a round key is added to the state using an XOR operation. The length of a round key equals the size of the state.

87.2.5 Weaknesses and Attacks

A well-known and frequently used encryption is the stream cipher available with PKZIP. Unfortunately, there is also a well-known attack involving known plaintext against this—if you know part of the plaintext, it is possible to decipher the file.[10] For any serious work, information security professionals should not use PKZIP's encryption.

In 1975, it was theorized that a customized DES cracker would cost $20 million. In 1998, EFF built one for $220,000.[2] With the advances in computing power, the time and money required to crack DES has significantly gone down even more. Although it is still being used, if possible, use AES or Triple-DES.

87.2.6 Section Summary

- Symmetric cryptographic algorithms or ciphers are those that use the same key to encrypt and decrypt.
- Stream ciphers operate one bit at a time.
- Stream ciphers use a key stream generator to continuously produce a key stream that is used to encrypt the message.
- A repeating key stream weakens the encryption and makes it vulnerable to cryptanalysis.
- Shift registers are often used in stream ciphers.
- Block ciphers operate on a block of data at a time.
- DES is the most popular block cipher.
- DES keys are sometimes referred to as 64-bit, but the effective length is 56 bits with 8 parity bits; hence, the actual key length is 56 bits.
- There are known weak DES keys; ensure that those are not used.
- DES itself has been broken and it should be assumed that it is not secure against attack.
- Make plans to migrate away from DES; use Triple-DES or Rijndael instead of DES, if possible.
- Do not use the encryption offered by PKZIP for nontrivial work.

87.3 Asymmetric (Public Key) Cryptography

Asymmetric is the term applied in a cryptographic system where one key is used to encrypt and another is used to decrypt.

87.3.1 Background

This concept was invented in 1976 by Whitfield Diffie and Martin Hellman[11] and independently by Ralph Merkle. The basic theory is quite simple: is there a pair of keys so that if one is used to encrypt, the other can be used to decrypt—and given one key, finding the other would be extremely hard?

Luckily for us, the answer is yes, and this is the basis of asymmetric (often called public key) cryptography.

There are many algorithms available, but most of them are either insecure or produce ciphertext that is larger than the plaintext. Of the algorithms that are both secure and efficient, only three can be used for both encryption and digital signatures.[4] Unfortunately, these algorithms are often slower by a factor of 1000 compared to symmetric key encryption.

As a result, hybrid cryptographic systems are popular: Suppose Alice and Bob want to exchange a large message. Alice generates a random session key, encrypts it using asymmetric encryption, and sends it over to Bob, who has the other half of the asymmetric key to decode the session key. Because the session key is small, the overhead to asymmetrically encipher/decipher it is not too large. Now Alice encrypts the message with the session key and sends it over to Bob. Bob already has the session key and deciphers the message with it. As the large message is enciphered/deciphered using much faster symmetric encryption, the performance is acceptable.

87.3.2 RSA

We will present a discussion of the most popular of the asymmetric algorithms—RSA, named after its inventors, Ron Rivest, Adi Shamir, and Leonard Adleman. Readers are directed to Reference[12] for an extensive treatment. RSA's patent expired in September 2000; and RSA has put the algorithm in the public domain, enabling anyone to implement it at zero cost.

First, a mathematics refresher:

- If an integer P cannot be divided (without remainders) by any number other than itself and 1, then P is called a prime number. Other prime numbers are 2, 3, 5, and 7.
- Two integers are relatively prime if there is no integer greater than one that divides them both (their greatest common divisor is 1). For example, 15 and 16 are relatively prime, but 12 and 14 are not.
- The mod is defined as the remainder. For example, $5 \bmod 3 = 2$ means divide 5 by 3 and the result is the remainder, 2.

Note that RSA depends on the difficulty of factoring large prime numbers. If there is a sudden leap in computer technology or mathematics that changes that, security of such encryption schemes will be broken. Quantum and DNA computing are two fields to watch in this arena.

Here is a step-by-step description of RSA:

1. Find P and Q, two large (e.g., 1024-bit or larger) prime numbers. For our example, we will use $P = 11$ and $Q = 19$, which are adequate for this example (and more manageable).
2. Calculate the product PQ, and also the product $(P-1)(Q-1)$. So $PQ = 209$, and $(P-1)(Q-1) = 180$.
3. Choose an odd integer E such that E is less than PQ, and such that E and $(P-1)(Q-1)$ are relatively prime. We will pick $E = 7$.
4. Find the integer D so that $(DE-1)$ is evenly divisible by $(P-1)(Q-1)$. D is called the multiplicative inverse of E. This is easy to do: let us assume that the result of evenly dividing

(DE−1) by (P−1)(Q−1) is X, where X is also an integer. So we have X=(DE−1)/(P−1)(Q−1); and solving for D, we get D=(X(P−1)(Q−1)+1)/E. Start with X=1 and keep increasing its value until D is an integer. For our example, D works out to be 103.

5. The public key is (E and PQ), the private key is D. Destroy P and Q (note that given P and Q, it would be easy to work out E and D; but given only PQ and E, it would be hard to determine D). Give out your public key (E, PQ) and keep D secure and private.
6. To encrypt a message M, we raise M to the Eth power, divide it by PQ, and the remainder (the mod) is the ciphertext. Note that M must be less than PQ. A mathematical representation will be ciphertext=ME mod PQ. So if we are encrypting 13 (M=13), our ciphertext=13^7 mod 209=29.
7. To decrypt, we take the ciphertext, raise it to the Dth power, and take the mod with PQ. So plaintext=29^{103} mod 209=13.

Compared to DES, RSA is about 100 times slower in software and 1000 times slower in hardware. Because AES is even faster than DES in software, the performance gap will widen in software-only applications.

87.3.3 Elliptic Curve Cryptosystems (ECC)

As we saw, solving RSA depends on a hard math problem: factoring very large numbers. There is another hard math problem: reversing exponentiation (logarithms). For example, it is possible to easily raise 7 to the 4th power and get 2401; but given only 2401, reversing the process and obtaining 7^4 is more difficult (at least as hard as performing large factorizations).

The difficulty in performing discrete logarithms over elliptic curves (not to be confused with an ellipse) is even greater;[13] and for the same key size, it presents a more difficult challenge than RSA (or presents the same difficulty/security with a smaller key size). There is an implementation of ECC that uses the factorization problem, but it offers no practical advantage over RSA.

An elliptic curve has an interesting property: it is possible to define a point on the curve as the sum of two other points on the curve. Following is a high-level discussion of ECC. For details, see Reference 13.

Example: Alice and Bob agree on a nonsecret elliptic curve and a nonsecret fixed curve point F. Alice picks a secret random integer A_k as her secret key and publishes the point $A_P=A_k$*F as her public key. Bob picks a secret random integer B_k as his secret key and publishes the point $B_P=B_k$*F as his public key. If Alice wants to send a message to Bob, she can compute A_k*B_P and use the result as the secret key for a symmetric block cipher like AES. To decrypt, Bob can compute the same key by finding B_k*A_P, because B_k*A_P=B_k*(A_k*F)=A_k*(B_k*F)=A_k*Bp.

ECC has not been subject to the extensive analysis that RSA has and is comparatively new.

87.3.4 Attacks

It is possible to attack RSA by factoring large numbers, or guessing all possible values of (P−1)(Q−1) or D. These are computationally infeasible, and users should not worry about them. But there are chosen ciphertext attacks against RSA that involve duping a person to sign a message (provided by the attacker). This can be prevented by signing a hash of the message, or by making minor cosmetic changes to the document by signing it. For a description of attacks against RSA, see Reference[14]. Hash functions are described later in this chapter.

87.3.5 Real-World Applications

Cryptography is often a business enabler. Financial institutions encrypt the connection between the user's browser and Web pages that show confidential information such as account balances. Online merchants similarly encrypt the link so customer credit card data cannot be sniffed in transit. Some even use this as a selling point: "Our Web site is protected with the highest encryption available." What they are really saying is that this Web site uses 128-bit Secure Sockets Layer (SSL).

As an aside, there are no known instances of theft of credit card data in transit; but many high-profile stories of customer information theft, including theft of credit card information, are available. The theft was possible because enough safeguards were not in place, and the data was usable because it was in cleartext, that is, not encrypted. Data worth protecting should be protected in all stages, not just in transit.

87.3.6 SSL and TLS

Normal Web traffic is cleartext—your ISP can intercept it easily. SSL provides encryption between the browser and a Web server to provide security and identification. SSL was invented by Netscape[15] and submitted to the Internet Engineering Task Force (IETF). In 1996, IETF began with SSL v3.0 and, in 1999, published TLS v1.0 as a proposed standard.[16] TLS is a term not commonly used, but we will use TLS and SSL interchangeably.

Suppose Alice, running a popular browser, wants to buy a book from Bob's online book store at bobsbooks.com, and is worried about entering her credit card information online. (For the record, SSL/TLS can encrypt connections between any two network applications and not Web browsers and servers only.) Bob is aware of this reluctance and wants to allay Alice's fears—he wants to encrypt the connection between Alice's browser and bobsbooks.com. The first thing he has to do is install a digital certificate on his Web server.

A certificate contains information about the owner of the certificate: e-mail address, owner's name, certificate usage, duration of validity, and resource location or distinguished name (DN), which includes the common name (CN, Web site address or e-mail address, depending on the usage), and the certificate ID of the person who certifies (signs) this information. It also contains the public key, and finally a hash to ensure that the certificate has not been tampered with.

Anyone can create a digital certificate with freely available software, but just like a person cannot issue his own passport and expect it to be accepted at a border, browsers will not recognize self-issued certificates. Digital certificate vendors have spent millions to preinstall their certificates into browsers, so Bob has to buy a certificate from a well-known certificate vendor, also known as root certificate authority (CA). There are certificates available with 40- and 128-bit encryptions. Because it usually costs the same amount, Bob should buy a 128-bit certificate and install it on his Web server. As of this writing, there are only two vendors with wide acceptance of certificates: VeriSign and Thawte. Interestingly, VeriSign owns Thawte, but Thawte certificate prices are significantly lower.

So now Alice comes back to the site and is directed toward a URL that begins with https instead of http. That is the browser telling the server that an SSL session should be initiated. In this negotiation phase, the browser also tells the server what encryption schemes it can support. The server will pick the strongest of the supported ciphers and reply back with its own public key and certificate information. The browser will check if it has been issued by a root CA. If not, it will display a warning to Alice and ask if she still wants to proceed. If the server name does not match the name contained in the certificate, it will also issue a warning.

If the certificate is legitimate, the browser will:

- Generate a random symmetric encryption key
- Encrypt this symmetric key with the server's public key
- Encrypt the URL it wants with the symmetric key
- Send the encrypted key and encrypted URL to the server

The server will:

- Decrypt the symmetric key with its private key
- Decrypt the URL with the symmetric key
- Process the URL

- Encrypt the reply with the symmetric key
- Send the encrypted reply back to the browser

In this case, although encryption is two-way, authentication is one-way only: the server's identity is proven to the client but not vice versa. Mutual authentication is also possible and performed in some cases. In a high-security scenario, a bank could issue certificates to individuals, and no browser would be allowed to connect without those individual certificates identifying the users to the bank's server.

What happens when a browser capable of only 40-bit encryption (older U.S. laws prohibited export of 128-bit browsers) hits a site capable of 128 bits? Typically, the site will step down to 40-bit encryption. But CAs also sell super or step-up certificates that, when encountered with a 40-bit browser, will temporarily enable 128-bit encryption in those browsers. Step-up certificates cost more than regular certificates.

Note that the root certificates embedded in browsers sometimes expire; the last big one was VeriSign's in 1999. At that time, primarily financial institutions urged their users to upgrade their browsers. Finally, there is another protocol called Secure HTTP that provides similar functionality but is very rarely used.

87.4 Choosing an Algorithm

What encryption algorithm, with what key size, would an information security professional choose? The correct answer is: it depends; what is being encrypted, who do we need to protect against, and for how long?

If it is stock market data, any encryption scheme that will hold up for 20 minutes is enough; in 20 minutes, the same information will be on a number of free quote services. Your password to the *New York Times* Web site? Assuming you do not use the same password for your e-mail account, SSL is overkill for that server. Credit card transactions, bank accounts, and medical records need the highest possible encryption, both in transit and in storage.

87.4.1 Export and International Use Issues

Until recently, exporting 128-bit Web browsers from the United States was a crime, according to U.S. law. Exporting software or hardware capable of strong encryption is still a crime. Some countries have outlawed the use of encryption, and some other countries require a key escrow if you want to use encryption. Some countries have outlawed use of all but certain approved secret encryption algorithms. We strongly recommend that information security professionals become familiar with the cryptography laws of the land, especially if working in an international setting.[17]

87.4.2 Section Summary

- In asymmetric cryptography, one key is used to encrypt and another is used to decrypt.
- Asymmetric cryptography is often also known as public key cryptography.
- Asymmetric cryptography is up to 1000 times slower than symmetric cryptography.
- RSA is the most popular and well-understood asymmetric cryptographic algorithm.
- RSA's security depends on the difficulty of factoring very large ($>$1024-bit) numbers.
- Elliptic curve cryptography depends on the difficulty of finding discrete logarithms over elliptic curves.
- Smaller elliptic curve keys offer similar security as comparatively larger RSA keys.
- It is possible to attack RSA through chosen plaintext attacks.
- SSL is commonly used to encrypt information between a browser and a Web server.

- Choosing a cipher and key length depends on what needs to be encrypted, for how long, and against whom.
- There are significant legal implications of using encryption in a multinational setting.

87.5 Key Management and Exchange

In symmetric encryption, what happens when one person who knows the keys goes to another company (or to a competitor)? Even with public key algorithms, keeping the private key secret is paramount: without it, all is lost. For attackers, the reverse is true; it is often easier to attack the key storage instead of trying to crack the algorithm. A person who knows the keys can be bribed or kidnapped and tortured to give up the keys, at which time the encryption becomes worthless. Key management describes the problems and solutions to securely generating, exchanging, installing and storing, verifying, and destroying keys.

87.5.1 Generation

Encryption software typically generates its own keys (it is possible to generate keys in one program and use them in another); but because of the implementation, this can introduce weaknesses. For example, DES software that picks a known weak or semiweak key will create a major security issue. It is important to use the largest possible keyspace: a 56-bit DES key can be picked from the 256 ASCII character set, the first 128 of ASCII, or the 26 letters of the alphabet. Guessing the 56-bit DES key (an exhaustive search) involves trying out all 56-bit combinations from the keyspace. Common sense tells us that the exhaustive search of 256 bytes will take much longer than that for 26 bytes. With a large keyspace, the keys must be random enough so as to be not guessable.

87.5.2 Exchange

Alice and Bob are sitting on two separate islands. Alice has a bottle of fine wine, a lock, its key, and an empty chest. Bob has another lock and its key. An islander is willing to transfer items between the islands but will keep anything that he thinks is not secured, so you cannot send a key, an unlocked lock, or a bottle of wine on its own.

How does Alice send the wine to Bob? See the answer at the end of this section.

This is actually a key exchange problem in disguise: how does Alice get a key to Bob without its being compromised by the messenger? For asymmetric encryption, it is easy—the public key can be given out to the whole world. For symmetric encryption, a public key algorithm (like SSL) can be used; or the key may be broken up and each part sent over different channels and combined at the destination.

Answer to our key/wine exchange problem: Alice puts the bottle into the chest and locks it with her lock, keeps her key, and sends the chest to the other island. Bob locks the chest with his lock, and sends it back to Alice. Alice takes her lock off the chest and sends it back to Bob. Bob unlocks the chest with his key and enjoys the wine.

87.5.3 Installation and Storage

How a key is installed and stored is important. If the application does no initial validation before installing a key, an attacker might be able to insert a bad key into the application. After the key is installed, can it be retrieved without any access control? If so, anyone with access to the computer would be able to steal that key.

87.5.4 Change Control

How often a key is changed determines its efficiency. If a key is used for a long time, an attacker might have sufficient samples of ciphertext to be able to cryptanalyze the information. At the same time, each change brings up the exchange problem.

87.5.5 Destruction

A key no longer in use has to be disposed of securely and permanently. In the wrong hands, recorded ciphertext may be decrypted and give an enemy insights into current ciphertext.

87.5.6 Examples and Implementations

87.5.6.1 PKI

A public key infrastructure (PKI) is the set of systems and software required to use, manage, and control public key cryptography. It has three primary purposes: publish public keys, certify that a public key is tied to an individual or entity, and provide verification as to the continued validity of a public key. As discussed before, a digital certificate is a public key with identifying information for its owner. The certificate authority (CA) "signs" the certificate and verifies that the information provided is correct. Now all entities that trust the CA can trust that the identity provided by a certificate is correct. The CA can revoke the certificate and put it in the certificate revocation list (CRL), at which time it will not be trusted anymore. An extensive set of PKI standards and documentation is available.[18] Large companies run their own CA for intranet/extranet use. In Canada and Hong Kong, large public CAs are operational. But despite the promises of the "year of the PKI," market acceptance and implementation of PKIs are still in the future.

87.5.6.2 Kerberos

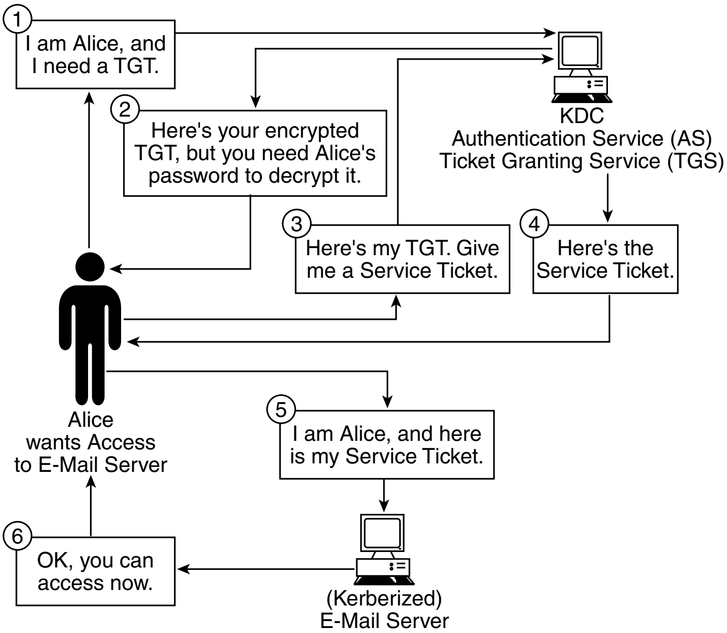
From the comp.protocol.kerberos FAQ:

> Kerberos; also spelled Cerberus. *n.* The watchdog of Hades, whose duty it was to guard the entrance—against whom or what does not clearly appear; it is known to have had three heads.
>
> **—Ambrose Bierce**
> *The Enlarged Devil's Dictionary*

Kerberos was developed at MIT in the 1980s and publicly released in 1989. The primary purposes were to prevent cleartext passwords from traversing the network and to ease the log-in process to multiple machines.[19] The current version is 5—there are known security issues with version 4. The three heads of Kerberos comprise the key distribution center (KDC), the client, and the server that the client wants to access. Kerberos 5 is built into Windows 2000 and later, and will probably result in wider adoption of Kerberos (notwithstanding some compatibility issues of the Microsoft implementation of the protocol[20]).

The KDC runs two services: authentication service (AS) and ticket granting service (TGS). A typical Kerberos session (shown in Exhibit 87.6) proceeds as follows when Alice wants to log on to her e-mail and retrieve it.

1. She will request a ticket granting ticket (TGT) from the KDC, where she already has an account. The KDC has a hash of her password, and she will not have to provide it. (The KDC must be extremely secure to protect all these passwords.)
2. The TGS on the KDC will send Alice a TGT encrypted with her password hash. Without knowing the password, she cannot decrypt the TGT.
3. Alice decrypts the TGT; then, using the TGT, she sends another request to the KDC for a service ticket to access her e-mail server. The service ticket will not be issued without the TGT and will only work for the e-mail server.
4. The KDC grants Alice the service ticket.
5. Alice can access the e-mail server.



1
I am Alice, and I need a TGT.
2
Here's your encrypted TGT, but you need Alice's password to decrypt it.
KDC
Authentication Service (AS)
Ticket Granting Service (TGS)
3
Here's my TGT. Give me a Service Ticket.
4
Here's the Service Ticket.
Alice
wants Access
to E-Mail Server
5
I am Alice, and here is my Service Ticket.
6
OK, you can access now.
(Kerberized)
E-Mail Server

EXHIBIT 87.6 Kerberos in operation.

Note that both the TGT and the ST have expiration times (default is ten hours); so even if one or both tickets are captured, the exposure is only until the ticket expiration time. All computer system clocks participating in a Kerberos system must be within five minutes of each other and all services that grant access. Finally, the e-mail server must be kerberized (support Kerberos).

87.5.7 Section Summary

- Key management (generating/exchanging/storing/installing/destroying keys) can compromise security.
- Public key cryptography is often the best solution to key distribution issues.
- A public key infrastructure (PKI) is a system that can manage public keys.
- A certificate authority (CA) is a PKI that can validate public keys.
- Digital certificates are essentially public keys that also include key owner information. The key and information are verified by a CA.
- If an entity trusts a CA, it can also trust digital certificates that the CA signs (authenticates).
- Kerberos is a protocol for eliminating cleartext passwords across networks.
- A ticket granting ticket (TGT) is issued to the user, who will use that to request a service ticket. All tickets expire after a certain time.
- Under Kerberos, tickets are encrypted and cleartext passwords never cross the network.

87.6 Hash Functions

A hash function is defined as a process that can take an arbitrary-length message and return a fixed-length value from that message. For practical use, we require further qualities:

- Given a message, it should be easy to find the hash.
- Given the hash, it should be hard to find the message.
- Given the message, it should be hard to find another (specific or random) message that produces the same hash.

87.6.1 Message Digests

A message digest is the product of a one-way hash function applied on a message: it is a fingerprint or a unique summary that can uniquely identify the message.

87.6.2 MD2, MD4, and MD5

Ron Rivest (the R in RSA) designed all of these. All three produce 128-bit hashes. MD4 has been successfully attacked. MD5 has been found weak in certain cases; it is possible to find another random message that will produce the same hash. MD2 is slower, although no known weaknesses exist.

87.6.3 SHA

The secure hash algorithm (SHA) was designed by NIST and NSA, and is used in the digital signature standard, officially known as the Secure Hash Standard (SHS) and is available as FIPS-180-1.[21]

The current SHA produces a 160-bit hash and is also known as SHA-1. There are additional standards undergoing public comments and reviews that will offer 256-, 384-, and 512-bit hashes. The draft standard is available.[16] The proposed standards will offer security matching the level of AES. The draft is available as FIPS-180-2.[22]

87.6.4 Applications of Message Digests

Message digests are useful and should be used to provide message integrity. Suppose Alice wants to pay $2000 to Eve, a contract network administrator. She types an e-mail to Bob, her accountant, to that effect. Before sending the message, Alice computes the message digest (SHA-1 or MD5) of the message and then sends the message followed by the message digest. Eve intercepts the e-mail and changes $2000 to $20,000; but when Bob computes the message digest of the e-mail, it does not match the one from Alice, and he knows that the e-mail has been tampered with.

But how do we ensure that the e-mail to Bob indeed came from Alice, when faking an e-mail source address is notoriously easy? This is where digital signatures come in.

87.6.5 Digital Signatures

Digital signatures were designed to provide the same features of a conventional ("wet") signature. The signature must be non-repudiatable, and it must be nontransferable (cannot be lifted and reused on another document). It must also be irrevocably tied back to the person who owns it.

It is possible to use symmetric encryption to digitally sign documents using an intermediary who shares keys with both parties, but both parties do not have a common key. This is cumbersome and not practical.

Using public key cryptography solves this problem neatly. Alice will encrypt a document with her private key, and Bob will decrypt it with Alice's public key. Because it could have been encrypted with only Alice's private key, Bob can be sure it came from Alice. But there are two issues to watch out for: (1) the rest of the world may also have Alice's public key, so there will be no privacy in the message; and (2) Bob will need a trusted third party (a certificate authority) to vouch for Alice's public key.

In practice, signing a long document may be computationally costly. Typically, first a one-way hash of the document is generated, the hash is signed, and then both the signed hash and the original document are sent. The recipient also creates a hash and compares the decrypted signed hash to the generated one. If both match, then the signature is valid.

87.6.6 Digital Signature Algorithm (DSA)

NIST proposed DSA in 1991 to be used in the Digital Signature Standard and the standard issued in May 1994. In January 2000, it announced the latest version as FIPS PUB 186-2.[23] As the name implies, this is purely a signature standard and cannot be used for encryption or key distribution.

The operation is pretty simple. Alice creates a message digest using SHA-1, uses her private key to sign it, and sends the message and the digest to Bob. Bob also uses SHA-1 to generate the message digest from the message and uses Alice's public key on the received message digest to decrypt it. Then the two message digests are compared. If they match, the signature is valid.

Finally, digital signatures should not be confused with the horribly weakened "electronic signature" law passed in the United States, where a touch-tone phone press could be considered an electronic signature and enjoy legal standing equivalent to an ink signature.

87.6.7 Message Authentication Codes (MACs)

MACs are one-way hash functions that include the key. People with the identical key will be able to verify the hash. MACs provide authentication of files between users and may also provide file integrity to a single user to ensure files have not been altered in a Web site defacement. On a Web server, the MAC of all files could be computed and stored in a table. With only a one-way hash, new values could have been inserted in the table and the user will not notice. But in a MAC, because the attacker will not know the key, the table values will not match; and an automated process could alert the owner (or automatically replace files from backup).

A one-way hash function can be turned into a MAC by encrypting the hash using a symmetric algorithm and keeping the key secret. A MAC can be turned into a one-way hash function by disclosing the key.

87.6.8 Section Summary

- Hash functions can create a fixed-length digest of arbitrary-length messages.
- One-way hashes are useful: given a hash, finding the message should be very hard.
- Two messages should not generate the same hash.
- MD2, MD4, and MD5 all produce 128-bit hashes.
- SHA-1 produces a 160-bit hash.
- Encrypting a message digest with a private key produces a digital signature.
- Message authentication codes are one-way hashes with the key included.

87.7 Other Cryptographic Notes

87.7.1 Steganography

Steganography is a Greek word that means sheltered writing. This is a method that attempts to hide the existence of a message or communication. In February 2001, *USA Today* and various other news organizations reported that terrorists are using steganography to hide their communication in images on the Internet.[24] A University of Michigan study[25] examined this by analyzing two million images downloaded from the Internet and failed to find a single instance.

In its basic form, steganography is simple. For example, every third letter of a memo could hide a message. And it has the added advantage over encryption that it does not arouse suspicion: often, the presence of encryption could set off an investigation; but a message hidden in plain sight would be ignored.

The medium that hides the message is called the cover medium, and it must have parts that can be altered or used without damaging or noticeably changing the cover media. In case of digital cover media, these alterable parts are called redundant bits. These redundant bits or a subset can be replaced with the message we want to hide.

Interestingly, steganography in digital media is very similar to digital watermarking, where a song or an image can be uniquely identified to prevent theft or unauthorized use.

87.7.2 Digital Notary Public

Digital notary service is a logical extension of digital signatures. Without this service, Alice could send a digitally signed offer to Bob to buy a property; but after property values drop the next day, she could claim she lost her private key and call the message a forgery. Digital notaries could be trusted third parties that will also time-stamp Alice's signature and give Bob legal recourse if Alice tries to back out of the deal. There are commercial providers of this type of service.

With time-sensitive offers, this becomes even more important. Time forgery is a difficult if not impossible task with paper documents, and it is easy for an expert to detect. With electronic documents, time forgeries are easy and detection is almost impossible (a system administrator can change the time stamp of an e-mail on the server). One do-it-yourself time-stamping method suggests publishing the one-way hash of the message in a newspaper (as a commercial notice or advertisement). From then on, the date of the message will be time-stamped and available for everyone to verify.

87.7.3 Backdoors and Digital Snake Oil

We will reiterate our warnings about not using in-house cryptographic algorithms or a brand-new encryption technology that has not been publicly reviewed and analyzed. It may promise speed and security or low cost, but remember that only algorithms that withstood documented attacks are worthy of serious use—others should be treated as unproven technology, not ready for prime time.

Also, be careful before using specific software that a government recommends. For example, Russia mandates use of certain approved software for strong encryption. It has been mentioned that the government certifies all such software after behind-the-scenes key escrow. To operate in Russia, a business may not have any choice in this matter, but knowing that the government could compromise the encryption may allow the business to adopt other safeguards.

Hash Algorithms: From Message Digests to Signatures

Keith Pasley

There are many information-sharing applications that are in use on modern networks today. Concurrently, there are a growing number of users sharing data of increasing value to both sender and recipient. As the value of data increases among users of information-sharing systems, the risks of unauthorized data modification, user identity theft, fraud, unauthorized access to data, data corruption, and a host of other business-related problems mainly dealing with data integrity and user authentication, are introduced. The issues of integrity and authentication play an important part in the economic systems of human society. Few would do business with companies and organizations that do not prove trustworthy or competent.

For example, the sentence "I owe Alice US$500" has a hash result of "gCWXVcL3fPV8VrJNajm8J-KA= =," while the sentence "I owe Alice US$5000" has a hash of "DSAyXRTza2bHLH46IPMrSq= =." As can be seen, there is a big difference in hash results between the two sentences. If an attacker were trying to misappropriate the $4500 difference, hashing would allow detection.

88.1 Why Hash Algorithms Are Needed and the Problems They Solve

- Is the e-mail you received really from who it says it is?
- Can you ensure the credit card details you submit are going to the site you expected?

- Can you be sure the latest anti-virus, firewall, or operating system software upgrade you install is really from the vendor?
- Do you know if the Web link you click on is genuine?
- Does the program hash the password when performing authentication or just passing it in the clear?
- Is there a way to know who you are really dealing with when disclosing your personal details over the Internet?
- Are you really you?
- Has someone modified a Web page or file without authorization?
- Can you verify that your routers are forwarding data only to authorized peer routers?
- Has any of the data been modified in route to its destination?
- Can hash algorithms help answer these questions?

88.2 What Are Hash Algorithms?

A hash algorithm is a one-way mathematical function that is used to compress a large block of data into a smaller, fixed-size representation of that data.

To understand the concept of hash functions, it is helpful to review some underlying mathematical structures. One such structure is called a function. When hash functions were first introduced in the 1950s, the goal was to map a message into a smaller message called a message digest. This smaller message was used as a sort of shorthand of the original message. The digest was used originally for detection of random and unintended errors in processing and transmission by data processing equipment

88.2.1 Functions

A function is a mathematical structure that takes one or more variables and outputs a variable. To illustrate how scientists think about functions, one can think of a function in terms of a machine (see Exhibit 88.1). The machine in this illustration has two openings. In this case the input opening is labeled x and the output opening is labeled y. These are considered traditional names for input and output. The following are the basic processing steps of mathematical functions:

1. A number goes in.
2. Something is done to it.
3. The resulting number is the output.

The same thing is done to every number input into the function machine. Step 2 above describes the actual mathematical transformation done to the input value, or hashed value, which yields the

EXHIBIT 88.1 The Hash Function

4×3	12

Drop the first digit (4) leaves	2
2×next number (3)	6
6×next number (8)	48
Drop the first digit (4)	8

resulting output, or hash result. In this illustration, Step 2 can be described as a mathematical rule as follows: $x+3=y$. In the language of mathematics, if x is equal to 1, then y equals 4. Similarly, if x is equal to 2, then y equals 5. In this illustration the function, or mathematical structure, called an algorithm, is: for every number x, add 3 to the number. The result, y, is dependent on what is input, x.

As another example, suppose that, to indicate an internal company product shipment, the number 43738 is exchanged. The hash function, or algorithm, is described as: multiply each number from left to right, and the first digit of any multiplied product above 9 is dropped. The hash function could be illustrated in mathematical notation as: $x\times$the number to the right $=y$ (see Exhibit 88.1).

The input into a hash algorithm can be of variable length, but the output is usually of fixed length and somewhat shorter in length than the original message. The output of a hash function is called a message digest. In the case of the above, the hash input was of arbitrary (and variable) length; but the hash result, or message digest, was of a fixed length of 1 digit, 8. As can be seen, a hash function provides a shorthand representation of the original message. This is also the concept behind error checking (checksums) done on data transmitted across communications links. Checksums provide a nonsecure method to check for message accuracy or message integrity. It is easy to see how the relatively weak mathematical functions described above could be manipulated by an intruder to change the hash output. Such weak algorithms could result in the successful alteration of message content leading to inaccurate messages. If you can understand the concept of what a function is and does, you are on your way to understanding the basic concepts embodied in hash functions. Providing data integrity and authentication for such applications requires reliable, secure hash algorithms.

88.2.2 Secure Hash Algorithms

A hash algorithm was defined earlier as a one-way mathematical function that is used to compress a large block of data into a smaller, fixed size representation of that data. An early application for hashing was in detecting unintentional errors in data processing. However, due to the critical nature of their use in the high-security environments of today, hash algorithms must now also be resilient to deliberate and malicious attempts to break secure applications by highly motivated human attackers—more so than by erroneous data processing. The one-way nature of hash algorithms is one of the reasons they are used in public key cryptography. A one-way hash function processes a bit stream in a manner that makes it highly unlikely that the original message can be deduced by the output value. This property of a secure hash algorithm has significance in situations where there is zero tolerance for unauthorized data modification or if the identity of an object needs to be validated with a high assurance of accuracy. Applications such as user authentication and financial transactions are made more trustworthy by the use of hash algorithms.

Hash algorithms are called secure if they have the following properties:

- The hash result should not be predictable. It should be computationally impractical to recover the original message from the message digest (one-way property).
- No two different messages, over which a hash algorithm is applied, will result in the same digest (collision-free property).

Secure hash algorithms are designed so that any change to a message will have a high probability of resulting in a different message digest. As such, the message alteration can be detected by comparing hash results before and after hashing. The receiver can tell that a message has suspect validity by the fact that the message digest computed by the sender does not match the message digest computed by the receiver, assuming both parties are using the same hash algorithm. The most common hash algorithms as of this writing are based on Secure Hash Algorithm-1 (SHA-1) and Message Digest 5 (MD5).

EXHIBIT 88.2 Output Bit Lengths

Hash Algorithm	Output Bit Length
SHA-1	160
SHA-256	256
SHA-384	384
SHA-512	512

88.2.3 Secure Hash Algorithm

SHA-1, part of the Secure Hash Standard (SHS), was one of the earliest hash algorithms specified for use by the U.S. federal government (see Exhibit 88.2). SHA-1 was developed by NIST and the NSA. SHA-1 was published as a federal government standard in 1995. SHA-1 was an update to the SHA, which was published in 1993.

88.2.4 How SHA-1 Works

Think of SHA-1 as a hash machine that has two openings, input and output. The input value is called the hashed value, and the output is called the hash result. The hashed values are the bit streams that represent an electronic message or other data object. The SHA-1 hash function, or algorithm, transforms the hashed value by performing a mathematical operation on the input data. The length of the message is the same as the number of bits in the message. The SHA-1 algorithm processes blocks of 512 bits in sequence when computing the message digest. SHA-1 produces a 160-bit message digest. SHA-1 has a limitation on input message size of less than 18 quintillion (that is, 2^{64} or 18,446,744,073,709,551,616) bits in length.

SHA-1 has five steps to produce a message digest:

1. Append padding to make message length 64 bits less than a multiple of 512.
2. Append a 64-bit block representing the length of the message before padding out.
3. Initialize message digest buffer with five hexadecimal numbers. These numbers are specified in the FIPS 180-1 publication.
4. The message is processed in 512-bit blocks. This process consists of 80 steps of processing (four rounds of 20 operations), reusing four different hexadecimal constants, and some shifting and adding functions.
5. Output blocks are processed into a 160-bit message digest.

88.2.5 MD5

SHA was derived from the secure hash algorithms MD4 and MD5, developed by Professor Ronald L. Rivest of MIT in the early 1990s. As can be expected, SHA and MD5 work in a similar fashion. While SHA-1 yields a 160-bit message digest, MD5 yields a 128-bit message digest. SHA-1, with its longer message digest, is considered more secure than MD5 by modern cryptography experts, due in part to the longer output bit length and resulting increased collision resistance. However, MD5 is still in common use as of this writing.

88.2.6 Keyed Hash (HMAC)

Modern cryptographers have found the hash algorithms discussed above to be insufficient for extensive use in commercial cryptographic systems or in private electronic communications, digital signatures, electronic mail, electronic funds transfer, software distribution, data storage, and other applications that require data integrity assurance, data origin authentication, and the like. The use of asymmetric cryptography and, in some cases, symmetric cryptography, has extended the usefulness of hashing by associating identity with a hash result. The structure used to convey the property of identity (data origin) with a data object's integrity is hashed message authentication code (HMAC), or keyed hash.

For example, how does one know if the message and the message digest have not been tampered with? One way to provide a higher degree of assurance of identity and integrity is by incorporating a cryptographic key into the hash operation. This is the basis of the keyed hash or hashed message authentication code (HMAC). The purpose of a message authentication code (MAC) is to provide verification of the source of a message and integrity of the message without using additional mechanisms. Other goals of HMAC are as follows:

- To use available cryptographic hash functions without modification
- To preserve the original performance of the selected hash without significant degradation
- To use and handle keys in a simple way
- To have a well-understood cryptographic analysis of the strength of the mechanism based on reasonable assumptions about the underlying hash function
- To enable easy replacement of the hash function in case a faster or stronger hash is found or required

To create an HMAC, an asymmetric (public/private) or a symmetric cryptographic key can be appended to a message and then processed through a hash function to derive the HMAC. In mathematical terms, if $x = (\text{key} + \text{message})$ and $f = \text{SHA-1}$, then $f(x) = \text{HMAC}$. Any hash function can be used, depending on the protocol defined, to compute the type of message digest called an HMAC. The two most common hash functions are based on MD5 and SHA. The message data and HMAC (message digest of a secret key and message) are sent to the receiver. The receiver processes the message and the HMAC using the shared key and the same hash function as that used by the originator. The receiver compares the results with the HMAC included with the message. If the two results match, then the receiver is assured that the message is authentic and came from a member of the community that shares the key.

Other examples of HMAC usage include challenge-response authentication protocols such as Challenge Handshake Authentication Protocol (CHAP, RFC 1994). CHAP is defined as a peer entity authentication method for Point-to-Point Protocol (PPP), using a randomly generated challenge and requiring a matching response that depends on a cryptographic hash of the challenge and a secret key. Challenge-Response Authentication Mechanism (CRAM, RFC 2195), which specifies an HMAC using MD5, is a mechanism for authenticating Internet Mail Access Protocol (IMAP4) users. Digital signatures, used to authenticate data origin and integrity, employ HMAC functions as part of the "signing" process. A digital signature is created as follows:

1. A message (or some other data object) is input into a hash function (i.e., SHA-1, MD5, etc.).
2. The hash result is encrypted by the private key of the sender.

The result of these two steps yields what is called a *digital signature* of the message or data object. The properties of a cryptographic hash ensure that, if the data object is changed, the digital signature will no longer match it. There is a difference between a digital signature and an HMAC. An HMAC uses a shared secret key (symmetric cryptography) to "sign" the data object, whereas a digital signature is created by

EXHIBIT 88.3 Other Hash Algorithms

Hash Algorithm	Output Bit Length	Country
RIPEMD (160,256,320)	160, 256, 320	Germany, Belgium
HAS-160	160	Korea
Tiger	128,160,192	United Kingdom

using a private key from a private/public key pair (asymmetric cryptography) to sign the data object. The strengths of digital signatures lend themselves to use in high-value applications that require protection against forgery and fraud.

See Exhibit 88.3 for other hash algorithms.

88.3 How Hash Algorithms Are Used in Modern Cryptographic Systems

In the past, hash algorithms were used for rudimentary data integrity and user authentication; today hash algorithms are incorporated into other protocols—digital signatures, virtual private network (VPN) protocols, software distribution and license control, Web page file modification detection, database file system integrity, and software update integrity verification are just a few. Hash algorithms used in hybrid cryptosystems discussed next.

88.3.1 Transport Layer Security (TLS)

TLS is a network security protocol that is designed to provide data privacy and data integrity between two communicating applications. TLS was derived from the earlier Secure Sockets Layer (SSL) protocol developed by Netscape in the early 1990s. TLS is defined in IETF RFC 2246. TLS and SSL do not interoperate due to differences between the protocols. However, TLS 1.0 does have the ability to drop down to the SSL protocol during initial session negotiations with an SSL client. Deference is given to TLS by developers of most modern security applications. The security features designed into the TLS protocol include hashing.

The TLS protocol is composed of two layers:

1. The Record Protocol provides in-transit data privacy by specifying that symmetric cryptography be used in TLS connections. Connection reliability is accomplished by the Record Protocol through the use of HMACs.
2. TLS Handshake Protocol (really a suite of three subprotocols). The Handshake Protocol is encapsulated within the Record Protocol. The TLS Handshake Protocol handles connection parameter establishment. The Handshake Protocol also provides for peer identity verification in TLS through the use of asymmetric (public/private) cryptography.

There are several uses of keyed hash algorithms (HMAC) within the TLS protocol.

TLS uses HMAC in a conservative fashion. The TLS specification calls for the use of both HMAC MD5 and HMAC SHA-1 during the Handshake Protocol negotiation. Throughout the protocol, two hash algorithms are used to increase the security of various parameters:

- Pseudorandom number function
- Protect record payload data
- Protect symmetric cryptographic keys (used for bulk data encrypt/decrypt)
- Part of the mandatory cipher suite of TLS

If any of the above parameters were not protected by security mechanisms such as HMACs, an attacker could thwart the electronic transaction between two or more parties. The TLS protocol is the basis for most Web-based in-transit security schemes. As can be seen by this example, hash algorithms provide an intrinsic security value to applications that require secure in-transit communication using the TLS protocol.

88.3.2 IPSec

The Internet Protocol Security (IPSec) Protocol was designed as the packet-level security layer included in IPv6. IPv6 is a replacement TCP/IP protocol suite for IPv4. IPSec itself is flexible and modular in design, which allows the protocol to be used in current IPv4 implementations. Unlike the session-level security of TLS, IPSec provides packet-level security. VPN applications such as intranet and remote access use IPSec for communications security.

Two protocols are used in IPSec operations, Authentication Header (AH) and Encapsulating Security Payload (ESP). Among other things, ESP is used to provide data origin authentication and connectionless integrity. Data origin authentication and connectionless integrity are joint services and are offered as an option in the implementation of the ESP. RFC 2406, which defines the ESP used in IPSec, states that either HMAC or one-way hash algorithms may be used in implementations. The authentication algorithms are used to create the integrity check value (ICV) used to authenticate an ESP packet of data. HMACs ensure the rapid detection and rejection of bogus or replayed packets. Also, because the authentication value is passed in the clear, HMACs are mandatory if the data authentication feature of ESP is used. If data authentication is used, the sender computes the integrity check value (ICV) over the ESP packet contents minus the authentication data. After receiving an IPSec data packet, the receiver computes and compares the ICV of the received datagrams. If they are the same, then the datagram is authentic; if not, then the data is not valid, it is discarded, and the event can be logged. MD5 and SHA-1 are the currently supported authentication algorithms.

The AH protocol provides data authentication for as much of the IP header as possible. Portions of the IP header are not authenticated due to changes to the fields that are made as a matter of routing the packet to its destination. The use of HMAC by the ESP has, according to IPSec VPN vendors, negated the need for AH.

88.3.3 Digital Signatures

Digital signatures serve a similar purpose as those of written signatures on paper—to prove the authenticity of a document. Unlike a pen-and-paper signature, a digital signature can also prove that a message has not been modified. HMACs play an important role in providing the property of integrity to electronic documents and transactions. Briefly, the process for creating a digital signature is very much like creating an HMAC. A message is created, and the message and the sender’s private key (asymmetric cryptography) serve as inputs to a hash algorithm. The hash result is attached to the message. The sender creates a symmetric session encryption key to optionally encrypt the document. The sender then encrypts the session key with the sender’s private key, reencrypts it with the receiver’s public key to ensure that only the receiver can decrypt the session key, and attaches the signed session key to the document. The sender then sends the digital envelope (keyed hash value, encrypted session key, and the encrypted message) to the intended receiver. The receiver performs the entire process in reverse order. If the results match when the receiver decrypts the document and combines the sender’s public key with the document through the specified hash algorithm, the receiver is assured that (1) the message came from the original sender and (2) the message has not been altered. The first case is due to use of the sender’s private key as part of the hashed value. In asymmetric cryptography, a mathematical relationship exists between the public and private keys such that either can encrypt and decrypt; but the same key cannot both encrypt and decrypt the same item. The private key is known only to its owner. As such, only the owner of the private key could have used it to develop the HMAC.

88.3.4 Other Applications

HMACs are useful when there is a need to validate software that is downloaded from download sites. HMACs are used in logging onto various operating systems, including UNIX. When the user enters a password, the password is usually run through a hash algorithm; and the hashed result is compared to a user database or password file.

An interesting use of hash algorithms to prevent software piracy is in the Windows XP registration process. SHA-1 is used to develop the installation ID used to register the software with Microsoft.

During installation of Windows XP, the computer hardware is identified, reduced to binary representation, and hashed using MD5. The hardware hash is an eight-byte value that is created by running ten different pieces of information from the PC's hardware components through the MD5 algorithm. This means that the resultant hash value cannot be backward-calculated to determine the original values. Further, only a portion of the resulting hash value is used in the hardware hash to ensure complete anonymity.

Unauthorized file modification such as Web page defacement, system file modification, virus signature update, signing XML documents, and signing database keys are all applications for which various forms of hashing can increase security levels.

88.4 Problems with Hash Algorithms

Flaws have been discovered in various hash algorithms. One such basic flaw is called the birthday attack.

88.4.1 Birthday Attack

This attack's name comes from the world of probability theory out of any random group of 23 people, it is probable that at least two share a birthday. Finding two numbers that have the same hash result is known as the birthday attack. If hash function f maps into message digests of length 60 bits, then an attacker can find a collision using only 230 inputs ($2^{f/2}$). Differential cryptanalysis has proven to be effective against one round of MD5. (There are four rounds of transformation defined in the MD5 algorithm.) When choosing a hash algorithm, speed of operation is often a priority. For example, in asymmetric (public/private) cryptography, a message may be hashed into a message digest as a data integrity enhancement. However, if the message is large, it can take some time to compute a hash result. In consideration of this, a review of speed benchmarks would give a basis for choosing one algorithm over another. Of course, implementation in hardware is usually faster than in a software-based algorithm.

88.5 Looking to the Future

88.5.1 SHA-256, -384, and -512

In the summer of 2001, NIST published for public comment a proposed update to the Secure Hash Standard (SHS) used by the U.S. government. Although SHA-1 appears to be still part of SHS, the update includes the recommendation to use hash algorithms with longer hash results. Longer hash results increase the work factor needed to break cryptographic hashing. This update of the Secure Hash Standard coincides with another NIST update—selection of the Rijndael symmetric cryptography algorithm for U.S. government use for encrypting data. According to NIST, it is thought that the cryptographic strength of Rijndael requires the higher strength of the new SHS algorithms. The new SHS algorithms feature similar functions but different structures. Newer and more secure algorithms, such as SHA-256, -384, and -512, may be integrated into the IPSec specification in the future to complement the Advanced Encryption Standard (AES), Rijndael. In May 2002, NIST announced that the Rijndael algorithm had been selected as the AES standard, FIPS 197.

88.6 Summary

Hash algorithms have existed in many forms at least since the 1950s. As a result of the increased value of data interactions and the increased motivation of attackers seeking to exploit electronic communications, the requirements for hash algorithms have changed. At one time, hashing was used to detect inadvertent errors generated by data processing equipment and poor communication lines. Now, secure hash algorithms are used to associate source of origin with data integrity, thus tightening the bonds of data and originator of data. So-called HMACs facilitate this bonding through the use of public/private cryptography. Protocols such as TLS and IPSec use HMACs extensively. Over time, weaknesses in algorithms have been discovered and hash algorithms have improved in reliability and speed. The present digital economy finds that hash algorithms are useful for creating message digests and digital signatures.

A Look at the Advanced Encryption Standard (AES)

Ben Rothke

In the early 1970s, the Data Encryption Standard (DES) became a Federal Information Processing Standard[1,2] (FIPS). This happened with little fanfare and even less public notice. In fact, in the late 1960s and early 1970s, the notion of the general public having an influence on U.S. cryptographic policy was utterly absurd. It should be noted that in the days before personal computers were ubiquitous, the force of a FIPS was immense, given the purchasing power of the U.S. government. Nowadays, the power of a FIPS has a much lesser effect on the profitability of computer companies given the strength of the consumer market.

Jump to the late 1990s and the situation is poles apart. The proposed successor to DES, the AES, was publicized not only in the *Federal Register* and academic journals, but also in consumer computing magazines and the mainstream media.[3]

The entire AES selection process was, in essence, a global town hall event. This was evident from submissions from cryptographers from around the world. The AES process was completely open to public scrutiny and comment. This is important because, when it comes to the design of effective encryption algorithms, history has shown time and time again that secure encryption algorithms cannot

[1] FIPS 46-3, see http://csrc.nist.gov/publications/fips/fips46-3/fips46-3.pdf. Reaffirmed for the final time on October 25, 1999.

[2] Under the Information Technology Management Reform Act (Public Law 104–106), the Secretary of Commerce approves standards and guidelines that are developed by the National Institute of Standards and Technology (NIST) for federal computer systems. These standards and guidelines are issued by NIST as Federal Information Processing Standards (FIPS) for use government wide. NIST develops FIPS when there are compelling federal government requirements, such as for security and interoperability, and there are no acceptable industry standards or solutions.

[3] While IBM and the U.S. government essentially designed DES between them in what was billed as a public process, it attracted very little public interest at the time.

be designed, tested, and verified in a vacuum. In fact, if a software vendor decides to use a proprietary encryption algorithm, that immediately makes the security and efficacy of the algorithm suspect[4] Prudent consumers of cryptography will *never* use a proprietary algorithm.

This notion is based on what is known as Kerckhoff's assumption[5]. This assumption states the security of a cryptosystem should rest entirely in the secrecy of the key and not in the secrecy of the algorithm. History has shown, and unfortunately, that some software vendors still choose to ignore the fact that completely open-source encryption algorithms are the only way to design a truly world-class encryption algorithm.

89.1 The AES Process

In January 1997, the National Institute of Standards and Technology (NIST, a branch within the Commerce Department) commenced the AES process[6] A replacement for DES was needed due to the ever-growing frailty of DES. Not that any significant architectural breaches were found in DES; rather, Moore's law had caught up with it. By 1998, it was possible to build a DES-cracking device for a reasonable sum of money.

The significance of the availability of a DES-cracking device to an adversary cannot be understated because DES is the world's most widely used, general-purpose cryptosystem. For the details of this cracking of DES,[7] see *Cracking DES: Secrets of Encryption Research, Wiretap Politics and Chip Design* by the Electronic Frontier Foundation (1998, O'Reilly & Assoc.).

DES was reengineered and put back into working order via the use of Triple-DES. Triple-DES takes the input data and encrypts it three times. Triple-DES (an official standard in use as ANSI X9.52-1998[8]) is resilient against brute-force attacks, and from a security perspective, it is adequate. So why not simply use Triple-DES as the new AES? This is not feasible because DES was designed to be implemented in hardware and is therefore not efficient in software implementations. Triple-DES is three times slower than DES; and although DES is fast enough, Triple-DES is far too slow. One of the criteria for AES is that it must be efficient when implemented in software, and the underlying architecture of Triple-DES makes it unsuitable as an AES candidate.

The AES specification called for a symmetric algorithm (same key for encryption and decryption) using block encryption of 128 bits in size, with supporting key sizes of 128, 192, and 256 bits. The algorithm was required to be royalty-free for use worldwide and offer security of a sufficient level to

[4] See B. Schneier, Security in the Real World: How to Evaluate Security Technology, *Computer Security Journal*, 15(4), 1999; and B. Rothke, Free Lunch, *Information Security Magazine*, Feb. 1999, www.infosecuritymag.com.

[5] There are actually six assumptions. Dutch cryptographer Auguste Kerckhoff wrote *La Cryptographie Militare* (Military Cryptography) in 1883. His work set forth six highly desirable elements for encryption systems:

a. A cipher should be unbreakable. If it cannot be theoretically proven to be unbreakable, it should at least be unbreakable in practice.

b. If one's adversary knows the method of encipherment, this should not prevent one from continuing to use the cipher.

c. It should be possible to memorize the key without having to write it down, and it should be easy to change to a different key.

d. Messages, after being enciphered, should be in a form that can be sent by telegraph.

e. If a cipher machine, code book, or the like is involved, any such items required should be portable and usable by one person without assistance.

f. Enciphering or deciphering messages in the system should not cause mental strain, and should not require following a long and complicated procedure.

[6] http://csrc.nist.gov/encryption/aes/pre-round1/aes_9701.txt.

[7] Details are also available at www.eff.org/descracker.html.

[8] The X9.52 standard defines triple-DES encryption with keys k_1, k_2 and k_3; k_3 as: $C = Ek_3 (D_{k2} (E_{k1} (M)))$ where E_k and D_k denote DES encryption and DES decryption, respectively, with the key k.

protect data for 30 years. Additionally, it must be easy to implement in hardware as well as software, and in restricted environments (i.e., smart cards, DSP, cell phones, FPGA, custom ASIC, satellites, etc.).

AES will be used for securing sensitive but unclassified material by U.S. government agencies.[9] As a likely outcome, all indications make it likely that it will, in due course, become the de facto encryption standard for commercial transactions in the private sector as well.

In August 1998, NIST selected 15 preliminary AES candidates at the first AES Candidate Conference in California. At that point, the 15 AES candidates were given much stronger scrutiny and analysis within the global cryptography community. Also involved with the process was the National Security Agency (NSA).

This is not the place to detail the input of the NSA into the AES selection process, but it is obvious that NIST learned its lesson from the development of DES. An initial complaint against DES was that IBM kept its design principles secret at the request of the U.S. government. This, in turn, led to speculation that there was some sort of trapdoor within DES that would provide the U.S. intelligence community with complete access to all encrypted data. Nonetheless, when the DES design principles were finally made public in 1992,[10] such speculation was refuted.

89.2 The AES Candidates

The 15 AES candidates chosen at the first AES conference are listed in Exhibit 89.1.

A second AES Candidate Conference was held in Rome in March 1999 to present analyses of the first-round candidate algorithms. After this period of public scrutiny, in August 1999, NIST selected five algorithms for more extensive analysis (see Exhibit 89.2).

In October 2000, after more than 18 months of testing and analysis, NIST announced that the Rijndael algorithm had been selected as the AES candidate. It is interesting to note that only days after NIST's announcement selecting Rijndael, advertisements were already springing up stating support for the new standard.

In February 2001, NIST made available a Draft AES FIPS[11] for public review and comment, which concluded on May 29, 2001.

This was followed by a 90-day comment period from June through August 2001. In August 2002, NIST announced the approval of Federal Information Processing Standards (FIPS) 180-2, Secure Hash Standard, which contains the specifications for the Secure Hash Algorithm (SHA-1, SHA-256, SHA-384, and SHA-512).

89.2.1 DES Is Dead

It is clear that not only is 56-bit DES ineffective, it is dead. From 1998 on, it is hoped that no organization has implemented 56-bit DES in any type of high-security or mission-critical system. If such is the case, it should be immediately retrofitted with Triple-DES or another secure public algorithm.

Although DES was accepted as an ANSI standard in 1981 (ANSI X3.92) and later incorporated into several American Banking Association Financial Services (X9) standards, it has since been replaced by Triple-DES.

Replacing a cryptographic algorithm is a relatively straightforward endeavor because encryption algorithms are, in general, completely interchangeable. Most hardware implementations allow plug-ins and replacements of different algorithms. The greatest difficulty is in the logistics of replacing the software for companies with tens or hundreds of thousands of disparate devices. Also, for those organizations that have remote sites, satellites, etc., this point is ever more germane.

[9] It should be noted that AES (like DES) will only be used to protect sensitive but unclassified data. Classified data is protected by separate, confidential algorithms.

Algorithm	Submitted By	Overview[a]
CAST-256	Entrust Technologies, Canada	A 48-round unbalanced Feistel cipher using the same round functions as CAST-128, which use +—XOR rotates and 4 fixed 6-bit S-boxes; with a key schedule.
Crypton	Future Systems, Inc., Korea	A 12-round iterative cipher with a round function using & | XOR rotates and 2 fixed 8-bit S-boxes; with various key lengths supported, derived from the previous SQUARE cipher.
DEAL	Richard Outerbridge (UK) and Lars Knudsen (Norway)	A rather different proposal, a 6- to 8-round Feistel cipher which uses the existing DES as the round function. Thus a lot of existing analysis can be leveraged, but at a cost in speed.
DFC	Centre National pour la Recherche Scientifique, France	An 8-round Feistel cipher design based on a decorrelation technique and using +x and a permutation in the round function; with a 4-round key schedule.
E2	Nippon Telegraph and Telephone Corporation, Japan	A 12-round Feistel cipher, using a nonlinear function comprised of substitution using a single fixed 8-bit S-box, a permutation, XOR mixing operations, and a byte rotation.
FROG	TecApro International, South Africa	An 8-round cipher, with each round performing four basic operations (with XOR, substitution using a single fixed 8-bit S-box, and table value replacement) on each byte of its input.
HPC	Rich Schroeppel, United States	An 8-round Feistel cipher, which modifies 8 internal 64-bit variables as well as the data using +—x & | XOR rotates and a lookup table.
LOKI97	Lawrie Brown, Josef Pieprzyk, and Jennifer Seberry, Australia	A 16-round Feistel cipher using a complex round function f with two S–P layers with fixed 11-bit and 13-bit S-boxes, a permutation, and + XOR combinations; and with a 256-bit key schedule using 48 rounds of an unbalanced Feistel network using the same complex round function f.
Magenta	Deutsche Telekom, Germany	A 6- to 8-round Feistel cipher, with a round function that uses a large number of substitutions using a single fixed S-box (based on exponentiation on $GF(2^8)$), that is combined together with key bits using XOR.
MARS	IBM, United States	An 8+16+8-round unbalanced Feistel cipher with four distinct phases: key addition and 8 rounds of unkeyed forward mixing, 8 rounds of keyed forwards transformation, 8 rounds of keyed backwards transformation, and 8 rounds of unkeyed backwards mixing and keyed subtraction. The rounds use +—x rotates XOR and two fixed 8-bit S-boxes.
RC6	RSA Laboratories, United States	A 20-round iterative cipher, developed from RC5 (and fully parameterized), which uses a number of 32-bit operations (+—x XOR rotates) to mix data in each round.
Rijndael	Joan Daemen and Vincent Rijmen, Belgium	A 10- to 14-round iterative cipher, using byte substitution, row shifting, column mixing, and key addition, as well as an initial and final round of key addition, derived from the previous SQUARE cipher.
SAFER+	Cylink Corp., United States	An 8- to 16-round iterative cipher, derived from the earlier SAFER cipher. SAFER+ uses +x XOR and two fixed 8-bit S-boxes.
SERPENT	Ross Anderson (U.K.), Eli Biham (Israel), and Lars Knudsen (Norway)	A 32-round Feistel cipher, with key mixing using XOR and rotates, substitutions using 8 key-dependent 4-bit S-boxes, and a linear transformation in each round.
Twofish	Bruce Schneier et al., United States	A 16-round Feistel cipher using four key-dependent 8-bit S-boxes, matrix transforms, rotations, and based in part on the Blowfish cipher.

EXHIBIT 89.2 Five Algorithms Selected by NIST

Algorithm	Main Strength	Main Weaknesses
MARS	High security margin	Complex implementation
RC6	Very simple	Lower security margin as it used operations specific to 32-bit processors
Rijndael	Simple elegant design	Insufficient rounds
Serpent	High security margin	Complex design and analysis, poor performance
Twofish	Reasonable performance, high security margin	Complex design

AES implementations have already emerged in many commercial software security products as an optional algorithm (in addition to Triple-DES and others). Software implementations have always come before hardware products due to the inherent time it takes to design and update hardware. It is generally easier to upgrade software than to perform a hardware replacement or upgrade, and many vendors have already incorporated AES into their latest designs.

For those organizations already running Triple-DES, there are not many compelling reasons (except for compatibility) to immediately use AES. It is likely that the speed at which companies upgrade to AES will increase as more products ship in AES-enabled mode.

89.3 Rijndael

Rijndael, the AES candidate, was developed by Dr. Joan Daemen of Proton World International and Dr. Vincent Rijmen, a postdoctoral researcher in the electrical engineering department of Katholieke Universiteit of the Netherlands.[12] Drs. Daemen and Rijmen are well-known and respected in the cryptography community. Rijndael has its roots in the SQUARE cipher,[13] also designed by Daemen and Rijmen.

The details on Rijndael are specified in its original AES proposal.[14] From a technical perspective,[15] Rijndael is a substitution-linear transformation network (i.e., non-Feistel[16,17]) with multiple rounds, depending on the key size. Rijndael's key length and block size is either 128, 192, or 256 bits. It does not support arbitrary sizes, and its key and block size must be one of the three lengths.

Rijndael uses a single S-box that acts on a byte input in order to give a byte output. For implementation purposes, it can be regarded as a lookup table of 256 bytes. Rijndael is defined by the equation

$$S(x) = M(1/x) + b$$

over the field $GF(2^8)$, where M is a matrix and b is a constant.

A data block to be processed under Rijndael is partitioned into an array of bytes and each of the cipher operations is byte oriented. Rijndael's ten rounds each perform four operations. In the first layer, an 8×8 S-box (S-boxes used as nonlinear components) is applied to each byte. The second and third layers are

[15] http://csrc.nist.gov/encryption/aes/round2/r2report.pdf.

[16] Feistel ciphers are block ciphers in which the input is split in half. Feistel ciphers are provably invertible. Decryption is the algorithm in reverse, with subkeys used in the opposite order.

[17] Of the four other AES finalists, MARS uses an extended Feistel network; RC6 and Twofish use a standard Feistel network; and Serpent uses a single substitution-permutation network.

linear mixing layers, in which the rows of the array are shifted and the columns are mixed. In the fourth layer, subkey bytes are XORed into each byte of the array. In the last round, the column mixing is omitted.[18]

89.4 Why Did NIST Select the Rijndael Algorithm?

According to the NIST,[19] Rijndael was selected due to its combination of security, performance, efficiency, ease of implementation, and flexibility.[20] Specifically, NIST felt that Rijndael was appropriate for the following reasons:

- Good performance in both hardware and software across a wide range of computing environments
- Good performance in both feedback and nonfeedback modes
- Key setup time is excellent
- Key agility is good
- Very low memory requirements
- Easy to defend against power and timing attacks (this defense can be provided without significantly impacting performance).

89.5 Problems with Rijndael

Although the general consensus is that Rijndael is a fundamentally first-rate algorithm, it is not without opposing views.[21] One issue was with its underlying architecture; some opined that its internal mathematics were simple, almost to the point of being rudimentary. If Rijndael were written down as a mathematical formula, it would look much simpler than any other AES candidate. Another critique was that Rijndael avoids any kind of obfuscation technique to hide its encryption mechanism from adversaries.[22] Finally, it was pointed out that encryption and decryption use different S-boxes, as opposed to DES which uses the same S-boxes for both operations. This means that an implementation of Rijndael that both encrypts and decrypts is twice as large as an implementation that only does one operation, which may be inconvenient on constrained devices.

The Rijndael team defended its design by pointing out that the simpler mathematics made Rijndael easier to implement in embedded hardware. The team also argued that obfuscation was not needed. This, in turn, led to speculation that the Rijndael team avoided obfuscation to evade scrutiny from Hitachi, which had expressed its intentions to seek legal action against anyone threatening its U.S.-held patents. Hitachi claimed to hold exclusive patents on several encryption obfuscation techniques, and had not been

[18] Known as the key schedule, the Rijndael key (which is from 128 to 256 bits) is fed into the key schedule. This key schedule is used to generate the sub-keys, which are the keys used for each round. Each sub-key is as long as the block being enciphered, and thus, if 128 bits long, is made up of 16 bytes. A good explanation of the Rijndael key schedule can be found at http://home.ecn.ab.ca/∼jsavard/crypto/co040801.htm.

[19] http://csrc.nist.gov/encryption/aes.

20As clarified in the report by NIST (*Report on the Development of the Advanced Encryption Standard*), the fact that NIST rejected MARS, RC6, Serpent, and Twofish does not mean that they were inadequate for independent use. Rather, the sum of all benefits dictated that Rijndael was the best candidate for the AES. The report concludes that “all five algorithms appear to have adequate security for the AES.”

[21] Improved Cryptanalysis of Rijndael, N. Ferguson, J. Kelsey, et al., www.counterpane.com/rijndael.html.

[22] Contrast this with Twofish; see *The Twofish Team’s Final Comments on AES Selection*, www.counterpane.com/twofish-final.html.

forthcoming about whether it would consider licensing those techniques to any outside party.[23] In fact, in early 2000, Hitachi issued patent claims against four of the AES candidates (MARS, RC6, Serpent, and Twofish).

89.6 Can AES Be Cracked?

Although a public-DES cracker has been built[24] as detailed in Cracking *DES: Secrets of Encryption Research, Wiretap Politics and Chip Design*, there still exists the question of whether an AES-cracking device can be built?

It should be noted that after nearly 30 years of research, no easy attack against DES has been discovered. The only feasible attack against DES is a brute-force exhaustive search of the entire keyspace. Had the original keyspace of DES been increased, it is unlikely that the AES process would have been undertaken.

DES-cracking machines were built that could recover a DES key after a number of hours by trying all possible key values. Although an AES cracking machine could also be built, the time that would be required to extricate a single key would be overwhelming.

As an example, although the entire DES keyspace can feasibly be cracked in less than 48 hours, this is not the case with AES. If a special-purpose chip, such as a field-programmable gate array[25] (FPGA), could perform a billion AES decryptions per second, and the cracking host had a billion chips running in parallel, it would still require an infeasible amount of time to recover the key. Even if it was assumed that one could build a machine that could recover a DES key in a second (i.e., try 2^{55} keys per second), it would take that machine over 140 trillion years to crack a 128-bit AES key.

Given the impenetrability of AES (at least with current computing and mathematical capabilities), it appears that AES will fulfill its requirement of being secure until 2030. But then again, a similar thought was assumed for DES when it was first designed.

Finally, should quantum computing transform itself from the laboratory to the realm of practical application, it could potentially undermine the security afforded by AES and other cryptosystems.

89.7 The Impact of AES

The two main bodies to put AES into production will be the U.S. government and financial services companies. For both entities, the rollout of AES will likely be quite different.

For the U.S. government sector, after AES is confirmed as a FIPS, all government agencies will be required to use AES for secure (but unclassified) systems. Because the government has implemented DES and Triple-DES in tens of thousands of systems, the time and cost constraints for the upgrade to AES will be huge.

AES will require a tremendous investment of time and resources to replace DES, Triple-DES, and other encryption schemes in the current government infrastructure. A compounding factor that can potentially slow down the acceptance of AES is the fact that because Triple-DES is fundamentally secure (its main caveat is its speed), there is no compelling security urgency to replace it. Although AES may be required, it may be easier for government agencies to apply for a waiver for AES as opposed to actually implementing it.[26] With the budget and time constraints of interchanging AES, its transition will occur over time, with economics having a large part in it.

[23] www.planetit.com/techcenters/docs/security/qa/PIT20001106S0015.

[24] It is an acceptable assumption to believe that the NSA has had this capability for a long time.

[25] An FPGA is an integrated circuit that can be programmed in the field after manufacture. They are heavily used by engineers in the design of specialized integrated circuits that can later be produced in large quantities for distribution to computer manufacturers and end users.

[26] Similar to those government agencies that applied for waivers to get out of the requirement for C2 (*Orange Book*) certification.

The financial services community also has a huge investment in Triple-DES. Because there is currently no specific mandate for AES use in the financial services community, and given the preponderance of Triple-DES, it is doubtful that any of the banking standards bodies will require AES use.

While the use of single DES (also standardized as X9.23-1995, Encryption of Wholesale Financial Messages) is being withdrawn by the X9 committee (see X9 TG-25-1999); this nonetheless allows continued use of DES until another algorithm is implemented.

But although the main advantages of AES are its efficiency and performance for both hardware and software implementations, it may find a difficult time being implemented in large-scale nongovernmental sites, given the economic constraints of upgrading it, combined with the usefulness of Triple-DES. Either way, it will likely be a number of years before there is widespread use of the algorithm.

Principles and Applications of Cryptographic Key Management

William Hugh Murray

90.1 Introduction

The least appreciated of the (five) inventions that characterize modern cryptography is automated key management. This powerful mechanism enables us to overcome the lack of rigor and discipline that leads to the inevitable compromise of crypto systems. By permitting us to change keys frequently and safely, it overcomes the fundamental limitations of the algorithms that we use. It enables us to compensate for such human limitations as the inability to remember or transcribe long random numbers.

This chapter attempts to tell the information security professional the minimum that he needs to know about key management. It must presume that the professional already understands modern cryptography. This chapter defines key management, enumerates its fundamental principles, and describes its use. It will make recommendations on the key choices that confront the user and manager.

90.2 Context

First a little context. Cryptography is the use of secret codes to hide data and to authenticate its origin and content. Although public codes could be used to authenticate content, secret codes are necessary to authenticate origin. This use of cryptography emerged only in the latter half of the 20th century and has been surprising to all but a few.

Of all security mechanisms, cryptography is the one most suited to open and hostile environments, environments where control is otherwise limited, environments like the modern, open, flat, broadcast, packet-switched, heterogeneous networks.

It is broadly applicable. In the presence of cheap computing power, its uses are limited only by our imaginations. Given that most of the power of our computers goes unused, we could, if we wished, use secret codes by default, converting into public codes only for use. Indeed, modern distributed computing systems and applications would be impossible without it.

It is portable; the necessary software to encode or decode the information can be distributed at or near the time of use in the same package and channel. Within minor limits, it is composable; we can put together different functions and algorithms without losing any strength. One can put together mechanisms in such a way as to emulate any environmental or media-based control that we have ever had.

Not only is cryptography effective, it is efficient. That is to say, it is usually the cheapest way to achieve a specified degree of protection. The cost of cryptography is low. Not only is it low in absolute terms, it is low in terms of the security value it delivers. It is low compared to the value of the data it protects. It is low compared to the alternative ways of achieving the same degree of security by such alternative means as custody, supervision, or automated access control.

Its low cost is the result in part of the low cost of the modern computer, and it is falling with the cost of that computing. The cost of a single cryptographic operation today is one ten thousandth of what it was as recently as 20 years ago and can be expected to continue to fall.

Another way of looking at it is that its relative strength is rising when cost is held constant; the cost to the user is falling relative to the cost to the attacker. As we will see, automated key management is one mechanism that permits us to trade the increasing power of computing for increased security.

Modern cryptography is arbitrarily strong; that is, it is as strong as we need it to be. If one knows what data he wishes to protect, for how long, and from whom, then it is possible to use modern cryptography to achieve the desired protection. There are limitations; if one wanted to encrypt tens of gigabytes of data for centuries, it is hard to know how to achieve that. However, this is a theoretical rather than a practical problem. In practice, there are no such applications or problems.

Cryptography is significantly stronger than other security mechanisms. Almost never will cryptography be the weak link in the security chain. However, in practice its strength is limited by the other links in the chain, for example, key management. As it is not efficient to make one link in a chain significantly stronger than another, so it is not necessary for cryptography to be more than a few hundred times stronger than the other mechanisms on which the safety of the data depends.

The cryptography component of a security solution is robust and resilient, not likely to break. While history suggests that advances in technology may lower the cost of attack against a particular cryptographic mechanism, it also suggests that the cost does not drop suddenly or precipitously. It is very unlikely to collapse. Given the relative effectiveness and efficiency of cryptography relative to other security measures, changes in the cost of attack against cryptography are unlikely to put security at risk. The impact is obvious, and there is sufficient opportunity to compensate.

Changes in technology reduce the cost to both the user of cryptography and the attacker. Because the attacker enjoys economies of scale, historically, advances such as the computer have favored him first and the user second. However, that probably changed forever when both the scale and the cost of the computer fell to within the discretion of an individual. Further advances in technology are likely to favor the cryptographer.

As we will see, as the cost of attack falls, the user will spend a little money to compensate. However, it is in the nature of cryptography that as his costs rise linearly, the costs to the attacker rise exponentially. For example, the cost of attack against the Data Encryption Standard (DES) has fallen to roughly a million MIPS years. Although this is still adequate for most applications, some users have begun to use Triple DES-112. This may quadruple their cost but double the cost of a brute-force attack.

One way of looking at cryptography is that it changes the problem of maintaining the secrecy of the message to one of maintaining the secrecy of the keys. How we do that is called *key management*.

90.3 Key Management Defined

Key management can be defined as the generation, recording, transcription, distribution, installation, storage, change, disposition, and control of cryptographic keys. History suggests that key management is very important. It suggests that each of these steps is an opportunity to compromise the cryptographic system. Further, it suggests that attacks against keys and key management are far more likely and efficient than attacks against algorithms.

Key management is not obvious or intuitive. It is very easy to get it wrong. For example, students found that a recent release of Netscape's SSL (Secure Sockets Layer) implementation chose the key from a recognizable subspace of the total keyspace. Although the total space would have been prohibitively expensive to exhaust, the subspace was quite easy. Key management provides all kinds of opportunities for these kinds of errors.

As a consequence, key management must be rigorous and disciplined. History tells us that this is extremely difficult to accomplish. The most productive cryptanalytic attacks in history, such as ULTRA, have exploited poor key management. Modern automated key management attempts to use the computer to provide the necessary rigor and discipline. Moreover, it can be used to compensate for the inherent limitations in the algorithms we use.

90.4 Key Management Functions

This section addresses the functions that define key management in more detail. It identifies the issues around each of these functions that the manager needs to be aware of.

90.4.1 Key Generation

Key generation is the selection of the number that is going to be used to tailor an encryption mechanism to a particular use. The use may be a sender and receiver pair, a domain, an application, a device, or a data object. The key must be chosen in such a way that it is not predictable and that knowledge of it is not leaked in the process.

It is necessary but not sufficient that the key be randomly chosen. In an early implementation of the SSL protocol, Netscape chose the key in such a manner that it would, perforce, be chosen from a small subset of the total set of possible keys. Thus, an otherwise secure algorithm and secure protocol was weakened to the strength of a toy. Students, having examined how the keys were chosen, found that they could find the keys chosen by examining a very small set of possible keys.

In addition to choosing keys randomly, it is also important that the chosen key not be disclosed at the time of the selection. Although a key may be stored securely after its generation, it may be vulnerable to disclosure at the time of its generation when it may appear in the clear. Alternatively, information that is used in the generation of the key may be recorded at the time it is collected, thus making the key more predictable than might otherwise be concluded by the size of the keyspace. For example, some key-generation routines, requiring random numbers, ask the user for noisy data. They may ask the user to run his hands over the keyboard. While knowledge of the result of this action might not enable an attacker to predict the key, it might dramatically reduce the set of keys that the attacker must search.

90.4.2 Distribution

Key distribution is the process of getting a key from the point of its generation to the point of its intended use. This problem is more difficult in symmetric key algorithms, where it is necessary to protect the key from disclosure in the process. This step must be performed in a channel separate from the one that the traffic moves in.

During the World War II, the Germans used a different key each day in their Enigma Machine but distributed the keys in advance. In at least one instance, the table of future keys, recorded on water-soluble paper, was captured from a sinking submarine.

90.4.3 Installation

Key installation is the process of getting the key into the storage of the device or process that is going to use it. Traditionally this step has involved some manual operations. Such operations might result in leakage of information about the key, error in its transcription, or it might be so cumbersome as to discourage its use.

The German Enigma Machine had two mechanisms for installing keys. One was a set of three (later four) rotors. The other was a set of plug wires. In one instance, the British succeeded in inserting a listening device in a code room in Vichy, France. The clicking of the rotors leaked information about the delta between key n and key $n+1$.

The plugging of the wires was so cumbersome and error prone as to discourage its routine use. The British found that the assumption that today's plug setting was the same as yesterday's was usually valid.

90.4.4 Storage

Keys may be protected by the integrity of the storage mechanism itself. For example, the mechanism may be designed so that once the key is installed, it cannot be observed from outside the encryption machine itself. Indeed, some key-storage devices are designed to self-destruct when subjected to forces that might disclose the key or that are evidence that the key device is being tampered with.

Alternatively, the key may be stored in an encrypted form so that knowledge of the stored form does not disclose information about the behavior of the device under the key.

Visual observation of the Enigma Machine was sufficient to disclose the rotor setting and might disclose some information about the plug-board setting.

90.4.5 Change

Key change is ending the use of one key and beginning that of another. This is determined by convention or protocol. Traditionally, the time at which information about the key was most likely to leak was at key-change time. Thus, there was value to key stability. On the other hand, the longer the key is in use, the more traffic that is encrypted under it, the higher the probability that it will be discovered and the more traffic that will be compromised. Thus, there is value to changing the key.

The Germans changed the key every day but used it for all of the traffic in an entire theatre of operations for that day. Thus, the compromise of the key resulted in the compromise of a large quantity of traffic and a large amount of information or intelligence.

90.4.6 Control

Control of the key is the ability to exercise a directing or restraining influence over its content or use. For example, selecting which key from a set of keys is to be used for a particular application or party is part of key control. Ensuring that a key that is intended for encrypting keys cannot be used for data is part of key control. This is such a subtle concept that its existence is often overlooked. On the other hand, it is usually essential to the proper functioning of a system.

The inventors of modern key management believe that this concept of key control and the mechanism that they invented for it, which they call the *control vector*, is one of their biggest contributions.

90.4.7 Disposal

Keys must be disposed of in such a way as to resist disclosure. This was more of a problem when keys were used for a long time and when they were distributed in persistent storage media than it is now. For example, Enigma keys for submarines were distributed in books with the keys for the future. In at least one instance, such a book was captured.

90.5 Modern Key Management

Modern key management was invented by an IBM team in the 1970s[1]. It was described in the IBM *Systems Journal*[2] at the same time as the publication of the Data Encryption Standard (DES). However, although the DES has inspired great notice, comment, and research, key management has not gotten the recognition it deserves. While commentators were complaining about the length of the DES key, IBM was treating it as a solved problem; they always knew how they would compensate for fixed key length and believed that they had told the world.

Modern key management is fully automated; manual steps are neither required nor permitted. Users do not select, communicate, or transcribe keys. Not only would such steps require the user to know the key and permit him to disclose it, accidentally or deliberately, they would also be very prone to error.

Modern key management permits and facilitates frequent key changes. For example, most modern systems provide that a different key will be used for each object, e.g., file, session, message, or transaction, to be encrypted. These keys are generated at the time of the application of encryption to the object and specifically for that object. Its life is no longer than the life of the object itself. The most obvious example is a session key. It is created at the time of the session, exchanged under a key-encrypting key, and automatically discarded at the end of the session. (Because of the persistence of TCP sessions, even this may result in too much traffic under a single key. The IBM proposal for secure-IP is to run two channels [TCP sessions], one for data and one for keys. The data key might change many times per session.)

One can compare the idea of changing the key for each object or method with the practices used during World War II. The Germans used the same key across all traffic for a service or theater for an entire day. Since the British were recording all traffic, the discovery of one key resulted in the recovery of a large amount of traffic.

Manual systems of key management were always in a difficult bind; the more frequently one changed the key, the greater the opportunity for error and compromise. On the other hand, the more data encrypted under a single key, the easier the attack against that key and the more data that might be compromised with that key. To change or not to change? How to decide?

Automating the system changes the balance. It permits frequent secure key changes that raise the cost of attack to the cryptanalyst. The more keys that are used for a given amount of data, the higher the cost of attack (the more keys to be found), and the lower the value of success (the less data for each key). As the number of keys increases, the cost of attack approaches infinity and the value of success approaches zero. The cost of changing keys increases the cost of encryption linearly, but it increases the cost of attack

[1] Dr. Dorothy Denning has told me privately that she believes that automated key management was invented by the National Security Agency prior to IBM. Whether or not that is true is classified. In the absence of contemporaneous publication, it is unknowable. However, even if it is true, their invention did not ever make a difference; as far as we know, it never appeared in a system or an implementation. The IBM team actually implemented theirs, and it has made a huge difference. I remember being told by a member of the IBM team about the reaction of NSA to IBM's discussion of key management. He indicated that the reaction was as to a novel concept.

[2] Elander, R. et al., *Systems Journal*, 1977; IBM pub G321-5066, A *Cryptographic Key Management Scheme*.

exponentially. All other things being equal, changing keys increases the effective key length of an algorithm.

Because many algorithms employ a fixed-length key, and one can almost always find the key in use by exhausting the finite set of keys, and because the falling cost and increasing speed of computers is always lowering the cost and elapsed time for such an attack, the finite length of the key might be a serious limitation on the effectiveness of the algorithm. In the world of the Internet, in which thousands of computers have been used simultaneously to find one key, it is at least conceivable that one might find the key within its useful life. Automatic key change compensates for this limit.

A recent challenge key[3] was found using more than 10,000 computers for months at the rate of billions of keys per second. The value of success was only $10,000. By definition, the life of a challenge key is equal to the duration of the attack. Automated key management enables us to keep the life of most keys to minutes to days rather than days to months.

However, modern key management has other advantages in addition to greater effective key length and shorter life. It can be used to ensure the involvement of multiple people in sensitive duties. For example, the Visa master key is stored in San Francisco inside a box called the BBN SafeKeyper. It was created inside that box and no one knows what it is. Beneficial use of the key requires possession of the box and its three physical keys. Because it is at least conceivable that the box could be destroyed, it has exported information about the key. Five trustees share that information in such a way that any three of them, using another SafeKeyper box, could reconstruct the key.

Key management can also be used to reduce the risk associated with a lost or damaged key. Although in a communication application there is no need to worry about lost keys, in a file encryption application, a lost key might be the equivalent of loss of the data. Key management can protect against that. For example, one of my colleagues has information about one of my keys that would enable him to recover it if anything should happen to me. In this case he can recover the key all by himself. Because a copy of a key halves its security, the implementation that we are using permits me to compensate by specifying how many people must participate in recovering the key.

Key management may be a stand-alone computer application or it can be integrated into another application. IBM markets a product that banks can use to manage keys across banks and applications. The Netscape Navigator and Lotus Notes have key management built in.

Key management must provide for the protection of keys in storage and during exchange. Smart cards may be used to accomplish this. For example, if one wishes to exchange a key with another, one can put it in a smart card and mail it. It would be useless to anyone who took it from the mail.

90.6 Principles of Key Management

A number of principles guide the use and implementation of key management. These are necessary, but may not be sufficient, for safe implementation. That is, even implementations that adhere to these principles may be weak, but all implementations that do not adhere to these principles are weak.

First, *Key* management must be fully automated. There may not be any manual operations. This principle is necessary both for discipline and for the secrecy of the keys.

Second, *No* key may ever appear in the clear outside a cryptographic device. This principle is necessary for the secrecy of the keys. It also resists known plain-text attacks against keys.

Keys must be randomly chosen from the entire keyspace. If there is any pattern to the manner in which keys are chosen, this pattern can be exploited by an attacker to reduce his work. If the keys are drawn in such a way that all possible keys do not have an equal opportunity to be drawn, then the work of the attacker is reduced. For example, if keys are chosen so as to correspond to natural language words, then only keys that have such a correspondence, rather than the whole space, must be searched.

[3] RSA $10,000 Challenge, http://www.frii.com/~rcv/deschall.htm

Key-encrypting keys must be separate from data keys. Keys that are used to encrypt other keys must not be used to encrypt data, and vice versa. Nothing that has ever appeared in the clear may be encrypted under a key-encrypting key. If keys are truly randomly chosen and are never used to encrypt anything that has appeared in the clear, then they are not vulnerable to an exhaustive or brute-force attack. In order to understand this, it is necessary to understand how a brute-force attack works.

In a brute-force attack, one tries keys one after another until one finds the key in use. The problem that the attacker has is that he must be able to recognize the correct key when he tries it. There are two ways to do this, corresponding clear- and cipher-text attacks, and cipher-text-only attacks. In the former, the attacker keeps trying keys on the cipher text until he finds the one that produces the expected clear text.

At a minimum, the attacker must have a copy of the algorithm and a copy of the cryptogram. In modern cryptography, the algorithm is assumed to be public. Encrypted keys will sometimes appear in the environment, and encrypted data, cipher text, is expected to appear there.

For the first attack, the attacker must have corresponding clear and cipher text. In historical cryptography, when keys were used widely or for an extended period of time, the attacker could get corresponding clear and cipher text by duping the cryptographer into encrypting a message that he already knew. In modern cryptography, where a key is used only once and then discarded, this is much more difficult to do.

In the cipher-text-only attack, the attacker tries a key on the cipher text until it produces recognizable clear text. Clear text may be recognized because it is not random. In the recent RSA DES Key Challenge, the correct clear-text message could be recognized because the message was known to begin with the words, "The correct message is…" However, even if this had not been the case, the message would have been recognizable because it was encoded in ASCII.

To resist cipher-text-only attacks, good practice requires that all such patterns as format, e.g., file or e-mail message, language (e.g., English), alphabet (e.g., Roman), and public code (e.g., ASCII or EBCDIC) in the clear text object must be disguised before the object is encrypted.

Note that neither of these attacks will work on a key-encrypting key if the principles of key management are adhered to. The first one cannot be made to work because the crypto engine cannot be duped into encrypting a known value under a key-encrypting key. The only thing that it will encrypt under a key-encrypting key is a random value which it produced inside itself. The cipher-text-only attack cannot be made to work because there is no information in the clear text key that will allow the attacker to recognize it. That is, the clear text key is, by definition, totally random, without recognizable pattern, information, or entropy.

Keys with a long life must be sparsely used. There are keys, such as the Visa master key mentioned earlier, whose application is such that a very long life is desirable. As we have already noted, the more a key is used, the more likely is a successful attack and the greater the consequences of its compromise. Therefore, we compensate by using this key very sparsely and only for a few other keys. There is so little data encrypted under this key and that data is so narrowly held that a successful attack is unlikely. Because only this limited number of keys is encrypted under this key, changing it is not prohibitively expensive.

90.7 Asymmetric Key Cryptography

In traditional and conventional cryptography, the key used for encrypting and the one used for decrypting have the same value; that is to say that the relationship between them is one of symmetry or equality. In 1976, Whitfield Diffie and Martin Hellman pointed out that although the relationship between these two numbers must be fixed, it need not be equality. Other relationships could serve. Thus was born the idea of asymmetric key cryptography.

In this kind of cryptography the key has two parts; the parts are mathematically related to each other in such a way that what is encrypted with one part can only be decrypted by the other. The value of one of the keys does not necessarily imply the other; one cannot easily calculate one from the other. However,

EXHIBIT 90.1 DES versus RSA

Characteristic	DES	RSA
Relative speed	Fast	Slow
Functions used	Transportation, substitution	Multiplication
Key length	56 bits	400–800 bits
Least-cost attack	Exhaustion	Factoring
Cost of attack	Centuries	Centuries
Time to generate a key	Microseconds	Tens of seconds
Key type	Symmetric	Asymmetric

one of the keys, plus a message encrypted under it, does imply the other key. From a message and one part of the key, it is mathematically possible to calculate the other but it is not computationally feasible to do so.

Only one part, called the *private key*, need be kept secret. The other part, the *public key*, is published to the world. Anyone can use the public key to encrypt a message that can only be decrypted and read by the owner of the private key. Conversely, anyone can read a message encrypted with the private key, but only the person with beneficial use of that key could have encrypted it.

Note that if A and B share a symmetric key, then either knows that a message encrypted under that key originated with the other. Because a change in as little as one bit of the message will cause it to decode to garbage, the receiver of a good message knows that the message has not been tampered with. However, because each party has beneficial use of the key and could have created the cryptogram, they cannot demonstrate that it originated with the other. In asymmetric key cryptography only the possessor of the private key can have created the cryptogram. Any message that will decrypt with the public key is therefore known to all to have originated with the person who published it. This mechanism provides us with a digital signature capability that is independent of medium and far more resistant to forgery than marks on paper.

Although key management can be accomplished using only symmetric key cryptography, it requires secret key exchange, a closed population, some prearrangement, and it benefits greatly from trusted hardware. Asymmetric key cryptography enables us to do key management without secret key exchange, in an open population, with a minimum of prearrangement. It reduces the need for trusted hardware for key distribution though it is still desirable for key storage and transcription.

However, when otherwise compared to symmetric key cryptography, asymmetric key cryptography comes up short. Exhibit 90.1 compares a symmetric key algorithm, DES, to an asymmetric key algorithm, RSA. Exhibit 90.1 shows that the asymmetric key algorithm requires much longer keys to achieve the same computational resistance to attack (i.e., to achieve the same security). It takes much longer to generate a key. It is much slower in operation, and its cost goes up faster than the size of the object to be encrypted.

However, for keys that are to be used for a long period of time, the time required to generate a key is not an issue. For short objects to be encrypted, performance is not an issue. Therefore, asymmetric key cryptography is well suited to key management applications, and in practice its use is limited to that role. Most products use symmetric key cryptography to encrypt files, messages, sessions, and other objects, but use asymmetric key cryptography to exchange and protect keys.

90.8 Hybrid Cryptography

If one reads the popular literature, he is likely to be gulled into believing that he has to make a choice between symmetric and asymmetric key cryptography. In fact and in practice, this is not the case. In practice we use a hybrid of the two that enables us to enjoy the benefits of each. In this style of use, a symmetric key algorithm is used to hide the object, while an asymmetric key mechanism is used to manage the keys of this symmetric algorithm.

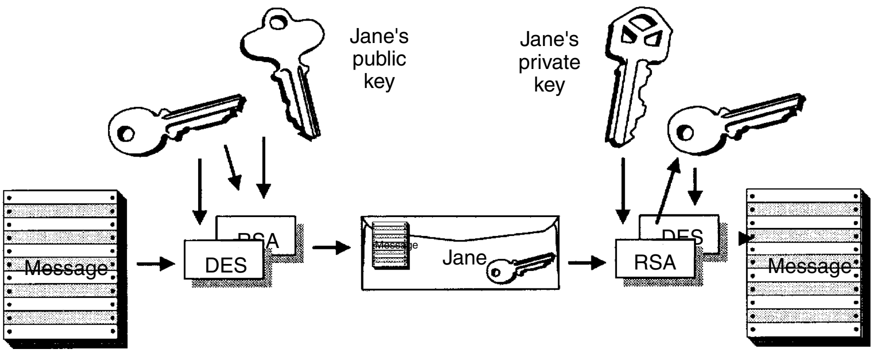

EXHIBIT 90.2 Hybrid cryptography.

The symmetric key algorithm is well suited for hiding the data object. It is fast and secure, even with a short key. Because keys are easily chosen, they can be changed for each object. The asymmetric key algorithm would not be suitable for this purpose because it is slow and requires a long key that is expensive to choose.

On the other hand, the asymmetric algorithm is well suited to managing keys. Because symmetric keys are short, one need not worry about the speed of encrypting them. Because key management keys are relatively stable, one need not worry about the cost of finding them.

Exhibit 90.2 illustrates a simple implementation of hybrid cryptography. A randomly selected 56-bit key is used to encrypt a message using the DES algorithm. This key is then encrypted using Jane's public key. The encrypted message along with its encrypted key are now broadcast. Everyone can see these; however, their meaning is hidden from all but Jane. Jane uses her private key to recover the message key and the message key to recover the message.

90.9 Public Key Certificates

As we have noted, by definition, there is no need to keep public keys secret. However, it is necessary to ensure that one is using the correct public key. One must obtain the key in such a way as to preserve confidence that it is the right key. Also, as already noted, the best way to do that is to obtain the key directly from the party. However, in practice we will get public keys at the time of use and in the most expeditious manner.

As we do with traditional signatures, we may rely on a trusted third party to vouch for the association between a particular key and a particular person or institution. For example, the state issues credentials that vouch for the bind between a photo, name and address, and a signature. This may be a driver's license or a passport. Similar credentials, called *public key certificates*, will be issued for public keys by the same kinds of institutions that issue credentials today: employers, banks, credit card companies, telephone companies, state departments of motor vehicles, health insurers, and nation-states.

A public key certificate is a credential that vouches for the bind or join between a key pair and the identity of the owner of the key. Most certificates will vouch for the bind between the key pair and a legal person. It contains the identifiers of the key pair owner and the public half of the key pair. It is signed by the private key of the issuing authority and can be checked using the authority's public key. In addition to the identifiers of the owner and the key, it may also contain the start and end dates of its validity, and its intended purpose, use, and limitations. Like other credentials, it is revocable at the discretion of the issuer and used or not at the discretion of the key owner. Like other credentials, it is likely to be one of several and, for some purposes, may be used in combination with others.

Credential issuers or certification authorities (CAs) are legal persons trusted by others to vouch for the bind, join, or association between a public key and another person or entity. The CA may be a principal, such as the management of a company, a bank, or a credit card company. It may be the secretary of a "club" or other voluntary association, such as a bank clearing house association. It may be a government agency or designee, such as the post office or a notary public. It may be an independent third party operating as a fiduciary and for a profit.

The principal requirement for a certification authority is that it must be trusted by those who will use the certificate and for the purpose for which the certificate is intended. The necessary trust may come from its role, independence, affinity, reputation, contract, or other legal obligation.

90.10 Use of Certificates for Managing Keys

In one-to-one relationships, one knows that one is using the correct public key because one obtains it directly and personally from one's correspondent. However, for large populations and most applications, this is not feasible. In most such cases, it is desirable to obtain the key automatically and late, that is, at or near the time of use.

In a typical messaging application, one might look up one's correspondent in a public directory, using his name as a search argument. As a function, one would get an e-mail address, a public key, and a certificate that bound the key to the name and address.

Exhibit 90.3 illustrates looking up the address whmurray@sprynet.com in the public directory operated by VeriSign, Inc. In addition to the address, the directory returns a public key that goes with that name and address. It also returns a certificate for that key. As a rule, the user will never see nor care about the key or the certificate. They will be handled automatically by the application. However, if one clicked on the <properties> button, one would see the certificate shown in Exhibit 90.4.

If one now clicks <Encrypt> on the message options, the message will now be encrypted using this key. If one signs a message using a private key, the corresponding public key and its certificate will

automatically be attached to the message. Other applications work in a similar manner. Tool kits can be purchased to incorporate these functions into enterprise-developed applications.

90.11 Implementations

To illustrate the power, use, and limitations of modern key management, this section discusses a number of implementations or products. Because the purpose of this discussion is to make points about key management, it will not provide a complete discussion of any of the products. The products are used only for their value as examples of key management. The order of presentation is chosen for illustrative purposes rather than to imply importance.

90.11.1 Kerberos Key Distribution Center

The Kerberos key distribution center (KDC) is a trusted server to permit any two processes that it knows about to obtain trusted copies of a key-session key. Kerberos shares a secret with every process or principal in the population. When A wants to talk to B, it requests a key from the KDC. The KDC takes a random number and encrypts it under the secret it shares with B, appends a second copy of the key, and encrypts the result under the secret that it shares with A. It broadcasts the result into the network addressed to A.

A uses the secret it shares with the KDC to recover its copy of the key and B's copy (encrypted under the secret that B shares with the KDC). It broadcasts B's copy into the network addressed to B. Although everyone in the network can see the messages, only A and B can use them. B uses its secret to recover its copy of the key. Now A and B share a key that they can use to talk securely to each other.

This process requires that the KDC be fully trusted to vouch for the identity of A and B, but not to divulge the secrets or the key to other processes or even to use it itself. If the KDC is compromised, all of the secrets will have to be changed, i.e., the principals must all be reenrolled. These limitations could be reduced if, instead of keeping a copy of the secret shared with the principals, the KDC kept only its public key. Then whatever other remedies might be necessary if the KDC were compromised, there would be no secrets to change.

90.11.2 PGP

PGP stands for Phil's "Pretty Good Privacy." Phil Zimmerman, its author, has received honors and awards for this product, not so much because of its elegant design and implementation, as for the fact that it brought the power of encryption to the masses. It is the encryption mechanism of choice for confidential communication among individuals.

PGP is implemented exclusively in software. It is available in source code, and implementations are available for all popular personal computers. It is available for download from servers all over the world and is free for private use. It is used to encrypt files for protection on the storage of the local system and to encrypt messages to be sent across a distance.

It uses a block cipher, IDEA, with a 128-bit key to encrypt files or messages. It automatically generates a new block-cipher key for each file or message to be encrypted. It uses an asymmetric key algorithm, Rivest–Shamir–Adelman (RSA), to safely exchange this key with the intended recipient by encrypting it using the recipient's public key. Only the intended recipient, by definition the person who has beneficial use of the mathematically corresponding private key, can recover the symmetric key and read the message.

Because the principles of key management require that this key not be stored in the clear, it is stored encrypted under the block cipher. The key for this step is not stored but is generated every time it is needed by compressing to 128 bits an arbitrarily long passphrase chosen by the owner of the private key. Thus, beneficial use of the private key requires both a copy of the encrypted key and knowledge of the passphrase.

Of course, while PGP does not require secret exchange of a key in advance, it does require that the public key be securely acquired. That is, it must be obtained in a manner that preserves confidence that it is the key of the intended recipient. The easiest way to do this is to obtain it directly, hand-to-hand, from that recipient. However, PGP has features to preserve confidence while passing the public key via e-mail, public servers, or third parties.

Note that if the passphrase is forgotten, the legitimate owner will have lost beneficial use of the private key and all message or file keys that were hidden using the public key. For communication encryption the remedy is simply to generate a new key-pair, publish the new public key, and have the originator resend the message using the new key. However, for file encryption, access to the file is lost. As we will see, commercial products use key management to provide a remedy for this contingency.

PGP stores keys in files called *key rings*. These files associate user identifiers with their keys. It provides a number of mechanisms for ensuring that one is using the correct and intended public key for a correspondent. One of these is called the *key fingerprint*. This is a relatively short hash of the key that can be exchanged out of channel and used to check the identity of a key. Alice sends a key to Bob. On receiving the key, Bob computes the fingerprint and checks it with Alice. Note that although fingerprints are information about the public key, they contain even less information about the private key than does the public key itself. Therefore, the fingerprint need not be kept secret.

PGP also provides a record of the level of trust that was attributed to the source of the key when it was obtained. This information is available whenever the key is used. Of course, the existence of this mechanism suggests that all sources are not trusted equally nor equally trustworthy. In practice, entire key rings are often exchanged and then passed on to others. In the process, the provenance of and confidence in a key may be obscured; indeed, the confidence in a key is often no better than hearsay.

The documentation of PGP suggests that the potential for duping someone into using the wrong key is one of the greatest limitations to the security of PGP.

90.11.3 ViaCrypt PGP, Business Edition

ViaCrypt PGP, Business Edition, is licensed for business or commercial use and includes emergency key recovery features to address some of the limitations of PGP noted above. Instead of encrypting the private key under a key generated on-the-fly from the passphrase, it introduces another level of key. This key will be used to encrypt the private key and will itself be hidden using the passphrases of the "owners" of the private key. This may be the sole user or it may be an employee and manager representing his employer. In the latter case, the employee is protected from management abuse of the private key by the fact that he has possession of it, and management only has possession of a copy of the key used to hide it. However, both the employee and management are protected from the consequences of loss of a single passphrase.

90.11.4 RSA SecurePC

RSA SecurePC is an add-in to the Windows file manager that is used for file encryption. It has features that extend the ideas in PGP BE and illustrate some other uses of key management. It encrypts specified files, directories, or folders, on command, that is, by marking and clicking; or by default, by marking a file or directory and indicating that everything in it is always to be encrypted. Marking the root of a drive would result in all files on the drive, except executables, always being stored in encrypted form.

The object of encryption is always the individual file rather than the drive or the directory. When a file is initially encrypted, the system generates a 64-bit block-cipher key to be used to encrypt the file. This file key is then encrypted using the public key of the system and is stored with the file.

The private key for the system is stored encrypted using a two-level key system and passphrase as in PGP BE. In order for a user to read an encrypted file, he must have the file key in the clear. To get that, he must have the private key in the clear. Therefore, when he opens a file, the system looks to see if the private key is in the clear in its memory. If not, then the user is prompted for his passphrase so that the private key can be recovered. At the time of this prompt, the user is asked to confirm or set the length of time that the private key is to be kept in the clear in system memory. The default is five minutes. Setting it to zero means that the user will be prompted for a second use. The maximum is 8 hours. The lower the user sets the time that the key may remain in memory, the more secure it is; the higher he sets it, the less often he will be prompted for the passphrase.

RSA SecurePC also implements emergency key-recovery features. These features go beyond those described above in that management may specify that multiple parties must be involved in recovering the private key. These features not only permit management to specify the minimum number of parties that must be involved but also permits them to specify a larger set from which the minimum may be chosen. Multiparty emergency key recovery provides both the user and management with greater protection against abuse.

90.11.5 BBN SafeKeyper

BBN SafeKeyper is a book-size hardware box for generating and protecting private keys. It generates a private-key/public-key pair. The private key cannot be removed from the box. Beneficial use of the key requires possession of the box and its three physical keys. SafeKeyper is intended for the root key for institutions.

The box has a unique identity and a public key belonging to BBN. After it generates its key pair, it encrypts its public key and its identity under the public key of BBN and broadcasts it into the network addressed to BBN. When BBN recovers the key, it uses its own private key to create a "certificate" for the

SafeKeyper that vouches for the bind between the public key and the identity of the person or institution to whom BBN sold the box.

Although the SafeKeyper box is very robust, it is still conceivable that it could be destroyed and its key lost. Therefore, it implements emergency key recovery. Although it is not possible to make an arbitrary copy of its key, it will publish information about its key sufficient to enable another SafeKeyper box to recreate it. For example, information about the Visa master key is held by five people. Any three of them acting in concert can reproduce this key.

90.11.6 Secure Sockets Layer (SSL)

SSL is both an API and a protocol intended for end-to-end encryption in client-server applications across an arbitrary network. The protocol was developed by Netscape, and the Navigator browser is its reference implementation. It uses public key certificates to authenticate the server to the client and, optionally, the client to the server.

When the browser connects to the secure server, the server sends its public key along with a certificate issued by a public certification authority. The browser automatically uses the issuer's public key to check the certificate, and manifests this by setting the URL to that of the server. It then uses the server's public key to negotiate a session key to be used for the session. It manifests this by setting a solid key icon in the lower left-hand corner of the screen.

Optionally, the client can send its public key and a certificate for that key issued by the management of the server or a certification authority trusted by the management of the server.

90.12 Recommendations for Key Management

To ensure rigor and discipline, automate all encryption, particularly including key management; hide all encryption from users.

To resist disclosure or arbitrary copies of a key, prefer trusted hardware for key storage. Prefer evaluated (FIPS-140)[4] hardware, dedicated single-application-only machines (such as those from Atalla, BBN, Cylink, and Zergo), smart cards, PCMCIA cards, laptops, diskettes, and trusted desktops, in that order. As a general rule, one should discourage the use of multi-user systems for key storage except for keys that are the property of the system owner or manager (e.g., payroll manager key).

Prefer one copy of a key; avoid strategies that require multiple copies of a key. Every copy of a key increases the potential for disclosure. For example, rather than replicating a single key across multiple servers, use different keys on each server with a certificate from a common source.

Change keys for each file, message, session, or other object.

Prefer one key per use or application rather than sharing a key across multiple uses. The more data that is encrypted under a single key, the greater the potential for successful cryptanalysis and the more damaging the consequences. With modern key management, keys are cheap.

To reduce the consequences of forgotten passphrases, use emergency key recovery for file encryption applications. Do not use emergency key recovery for communication encryption; change the key and resend the message.

Employ multiparty control for emergency key recovery; this reduces the potential for abuse, improves accountability, and increases trust all around. Consider requiring that the parties come from different levels of management and from different business or staff functions.

To ensure that keys are randomly selected from the entire keyspace, prefer closed and trusted processes for key generation. Avoid any manual operations in key selection.

[4] Federal Information Processing Standard 140, http://csrc.ncsl.nist.gov/fips/fips1401.htm

Prefer encryption and key management that are integrated into the application. The easiest way to hide encryption from the user and to avoid errors is to integrate the encryption into the application.

Similarly, prefer applications with integrated encryption and key management. No serious business applications can be done in the modern network environment without encryption. Integrated encryption is a mark of good application design.

Finally, buy key management code from competent laboratories; do not attempt to write your own.

91

Preserving Public Key Hierarchy

Geoffrey C. Grabow

Public key infrastructures (PKIs) have always been designed with a top-level key called a root key. This single key is responsible for providing the starting point of trust for all entities below it in the hierarchy. If this root key is ever compromised, the entire trust hierarchy is immediately questionable.

The root key is primarily responsible for digitally signing subordinate Certificate Authorities (CAs). A compromise of the root means that an unauthorized CA will appear perfectly valid to users. Users will then engage in a transaction completely unaware that the security upon which they are relying is worse than worthless.

This single root key introduces a single point of failure.

It is a standard practice in security to design and build systems with a series of checks and balances to prevent any one part of the system from causing a catastrophic failure. However, this practice, for all practical purposes, has been ignored when it comes to a hierarchical PKI.

It is the intention of this chapter to propose a system in which this single point of failure is removed.

Cryptographically secure digital timestamps (CSDTs) have been used for a wide variety of purposes, including document archiving, digital notary services, etc. By adding a CSDT to every digital certificate issued within a PKI, one now has a method for ensuring not only that the certificate is valid, but also at what point in time that validity was declared.

When properly configured, certificates within a PKI, which are protected using CSDTs, can survive the compromise of the root key. If the root key is exposed, certificates still have their original value, and all that is lost is the ability to create new certificates. This allows transactions to continue, and the recovery process only requires the replacement of the root key.

A significant advantage of the system proposed herein is that it works within the parameters set forth in existing PKI standards.

91.1 Public Key Infrastructure (PKI)

Public key (or asymmetric) cryptography uses two different keys, usually referred to as a public key and a private key. Any information encrypted by K_{PUB}(Recipient) can only be decrypted by K_{PRI}(Recipient), and vice versa. The two keys are mathematically linked and it is computationally infeasible[1] to determine the private key from the public key. This allows the recipient to create a key pair and to publish K_{PUB}(Recipient) in a location that anyone can find it. Once the sender has a copy of K_{PUB}(Recipient), encrypted information can be sent to the recipient without the problem of transporting a secret key.

Sender:

$$\text{DATA} + K_{PUB}(\text{Recipient}) + \text{Encryption algorithm} = EK_{PUB}(\text{Recipient})[\text{Data}]$$

Recipient:

$$EK_{PUB}(\text{Recipient})[\text{Data}] + K_{PRI}(\text{Recipient}) + \text{Decryption algorithm} = \text{Data}$$

The reverse of this process is also true. If the recipient encrypts data with K_{PRI}(Recipient), it can be decrypted with K_{PUB}(Recipient). This means that anyone can decrypt the information and confidentiality has not been achieved; but if it can be decrypted using K_{PUB}(Recipient), then only K_{PRI}(Recipient) could have encrypted it, thereby identifying the individual[2] who sent the data. This is the principle behind a digital signature. However, in a true digital signature scheme, only a hash of the data is encrypted/decrypted to save processing time.

91.1.1 Standard PKI Hierarchical Construction

While asymmetric key systems have solved the key management problem in traditional symmetric key systems, they have introduced a new problem called "trust management." This problem raises the question of "How can I be sure the public key I am using really belongs to the intended recipient?" This problem, typically referred to as a man-in-the-middle attack, happens when a third party (attacker) introduces its public key to the sender, who is fooled into believing that it is the public key of recipient, and vice versa. Obviously, this would allow the attacker to read and potentially modify all communication between the sender and the recipient without either of them being aware of the attacker whatsoever.

This problem is solved through the use of a Certificate Authority. The CA digitally signs a certificate that belongs to the sender and another certificate that belongs to the recipient. The certificate includes the name and public key of its owners, the integrity of which can be checked through the use of the CA's public key. Unfortunately, that means that the sender and the recipient must belong to the same CA. If they are not members of the same CA, a hierarchy of CAs must be established (see Exhibit 91.1).

Each entity in Exhibit 91.1 has its own certificate that is signed by an entity higher up in the hierarchy. This is the method used to transfer trust from a known entity to one that is unknown. The exception to this is the Root, which creates a self-signed certificate. The Root must establish trust through direct contact and business relationships with the CAs.

[1] "Computationally infeasible" indicates that the time or resources required to determine the private key, given only the public key, are well beyond what is available.

[2] This assumes that the private keys are generated, used, stored, and destroyed in a secure and proper manner.

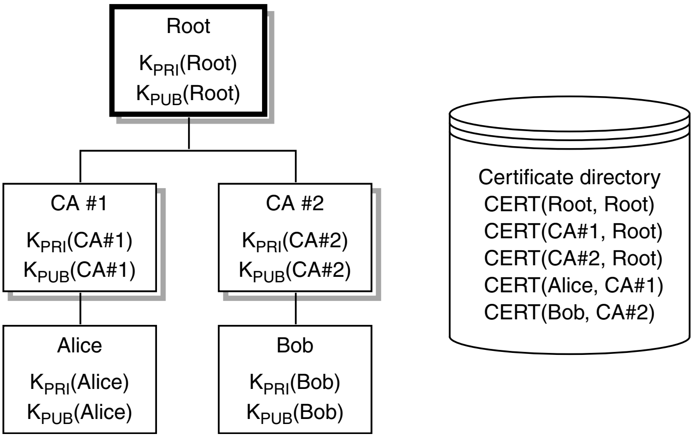

EXHIBIT 91.1 Basic PKI hierarchy.

In this environment, Alice can digitally sign a document and send it to Bob, along with a copy of her certificate as well as the certificate of CA#1. Because Bob already has a trust relationship with CA#2, and CA#2 has a trust relationship with the Root, Bob can validate the certificate of CA#2 and then validate Alice's certificate. Once Bob trusts Alice's certificate, he believes that anything that he can verify with Alice's public key must have been signed by Alice's private key, and therefore must have come from Alice.

91.1.2 The Impact of a Root Key Compromise

The problem with this hierarchical construction is the total reliance on the security of the Root private key. If the K_{PRI}(Root) is compromised by an attacker, that attacker can create a fraudulent CA#3, and then fraudulent users under that CA. Because CA#3 can be positively validated using the public key of the Root, Alice, Bob, and everyone who trusts the Root will accept any users under CA#3. This puts Alice, Bob, and everyone else in this hierarchy in a situation in which they are trusting fraudulent users and are unaware that there is a problem.

If this occurs, the entire system falls apart. No transactions can take place because there is no basis for trust. An even more significant impact of this situation is that as soon as Alice and Bob are informed about the problem, they will not only stop trusting users under CA#3, but also not be able to trust anyone in the entire hierarchy. Because a CA#3 was created fraudulently, any number of fraudulent CAs can be created and there is no way to determine the CAs not to be trusted from those that should be.

If one cannot determine which CAs are to be trusted, then there is no way to determine which users' certificates are to be trusted. This causes the complete collapse of the entire hierarchy, from the top down.

91.2 Constructing Cryptographically Secure Digital Timestamps

Cryptographically secure digital timestamps (CSDTs) are nothing new. A wide variety of applications have been making use of secure timestamps for many years. It is not the intention of this chapter to delve into the details of the actual creation of a CSDT, but rather to indicate the minimum required data for inclusion within digital certificates.

91.2.1 Timestamp

Of course, because one of the primary components of a CSDT is the timestamp itself, a "trusted" time source is required. This can be achieved in several accepted methods and, for the purposes of this construct, it will be assumed that the actual timestamp within the CSDT is the correct one.

To allow for high-volume transaction environments, a 16-bit sequence number is appended to the timestamp to ensure that there can be no two CSDTs with the identical time. This tie-breaker value should be reset with each new timestamp. Therefore, if the time resolution is 0.0001 seconds, it is possible to issue 65,536 CSDTs that all happen within that same 0.0001 second, but the exact sequence of CSDT creation can be determined at any future time.

91.2.2 Hash of the Certificate

For a CSDT to be bound to a particular certificate, some data must be included to tie it to the certificate in question. A hash generated by a known and trusted algorithm, such as SHA-1 or MD5, is used to provide this connection. This is the same hash that is calculated and encrypted during the Certificate Authority signing process.

More importantly, it is critical to know that the time in the CSDT is the time when the CA signs the certificate. Therefore, not just the hash of the certificate should be included, but rather the entire digital signature added to the certificate by the CA. Using the CA's signature will also provide for future changes in CA signing standards.

However, because one of the goals of this chapter is to provide a new feature to existing certificate standards without changing the standards, one cannot append information to the certificate after the signature. Rather, the CSDT must be added to the certificate prior to it being signed by the CA and inserted into an x.509v3 extension field.

91.2.3 Certificate Authority Certificate Hash

As an additional measure, the hash of the CA's certificate is embedded in the CSDT to provide a record of which CA made the request to the Time Authority (TA).

91.2.4 Digital Signature of the Time Authority

To prevent tampering, the CSDT must be cryptographically sealed using a standard digital signature. Because the total amount of data in a CSDT is small, this can be accomplished by simply encrypting the data fields with the private key of the TA. However, to allow for growth and additional fields to be added in the future, it is better to encrypt a hash of all of the data to be secured.

91.3 Separation of Hierarchies

Of course, the x.509 standard already includes a timestamp so it can be determined at what date and time a certificate was signed by its CA. However, if the root private key was compromised and a fraudulent CA is created, that CA could simply set the time to any value desired prior to signing the certificate.

What is proposed is the inclusion of a timestamp signed by an authority that exists outside the hierarchy of which the CA is part (see Exhibit 91.2).

When a CA creates a certificate, it would follow its normal process for acquiring the public key and other data to be included in the certificate. However, prior to signing the certificate, it would request a CSDT from the Time Authority (TA). This CSDT would then be generated by the TA and returned to the CA. The CA would add the CSDT to the certificate, then sign it in the usual manner.

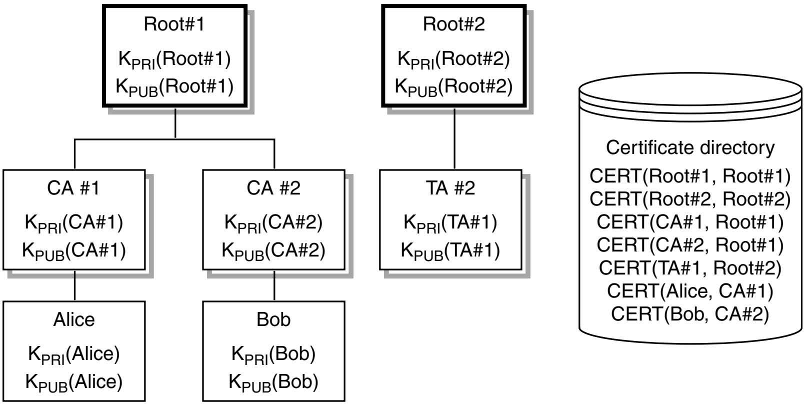

EXHIBIT 91.2 PKI with time authority.

Should Root#1 be compromised at some point thereafter, all of the CAs created prior to the compromise can still be trusted because access to Root#1 does not give the ability to create the CSDTs. Users can then be informed that anything signed by the Root after a specific date is not to be trusted, but anything signed before that date is still trustworthy.

91.4 Walk-Through of Issuance of a Certificate Containing a CSDT

The sequence of events to add a CSDT to a public key certificate is as follows:

1. User generates the public/private key pair.
2. User sends public key and user-specific information to the Registration Authority (RA).
3. RA validates user's request and forwards the certificate request to the CA.
4. CA forms the certificate and calculates the User Certificate Hash (UCH).
5. CA sends a digitally signed request to the Time Authority (TA) containing the UCH.
6. TA receives the request and validates the CA's signature on the request using the CA's public key certificate.
7. TA gets the current time from its secure time source.
8. TA calculates the sequential tie-breaker counter value.
9. TA forms the contents of the CSDT:
   a. UCH (Step 4)
   b. Timestamp (Step 7)
   c. Tie-breaker counter (Step 8)
   d. Hash of CA's certificate (same value used in Step 6)
10. TA calculates the hash of the contents of the CSDT.
11. TA encrypts hash with its private key.
12. TA returns CSDT to the CA.
13. CA validates the TA's signature on the CSDT using the TA's public key certificate.
14. CA verifies UCH in the CSDT against the UCH sent to the TA.
15. CA adds CSDT to the user certificate.
16. CA performs a standard signing process on the completed certificate.
17. CA sends digital certificate to the user.

91.5 Recovery Walk-Through

With any system providing assurance, it is necessary to have a plan of action in the event of some problem. The following outlines the minimum necessary steps if a CA is compromised.

Given:

- A CA signed by a CA Root
- A TA signed by a TA Root
- 10,000 users, each of which has generated a public/private key pair
- Each user has gone through the process of getting a public key certificate
- The CA root key is compromised by some form of attack

In infrastructures where CSDTs are not used, all 10,000 user certificates are immediately questionable and cannot be trusted for further transactions. A typical scenario requires the CA to have already created a second replacement root, and to have distributed the second root's self-signed public key certificate when the first was distributed. Users then are told to stop trusting the first root or to delete it from their applications. All users must then generate new key pairs and go through the enrollment process under the new root before business can return to normal.

This is obviously a scenario that requires considerable time and effort, and causes considerable inconvenience for users attempting to execute E-business transactions. Additionally, as the number of users increases, the recovery time increases linearly.

When CSDTs are employed and CSDT-aware applications are used, much of that effort is not required. Immediately upon determining that a compromise has occurred, the CA must:

- Inform the TA not to accept any further requests under the compromised key
- Inform its users
- Generate a new set of keys
- Issue no further certificates under the compromised key

Users need take no action other than to inform their applications of the date/time of the compromise of the CA. All future certificate validation is tested with the CA's certificate as well as the CSDT. If the CA's signature on a certificate is valid, but the CSDT is not present or indicates a date after the compromise, the certificate is rejected and the users are informed that they were presented with an invalid certificate.

91.6 Known Issues

Because events such as generating a hash, encryption, and decryption are processes of nonzero duration, it must be acknowledged that the actual time of certificate issuance is not the time within the CSDT. This is not a problem because the time within the CSDT, and within the certificate itself, are not to be used as an absolute time, but rather as a starting point from which the certificate is to be considered valid.

As with any cryptographic system, timely knowledge of any compromise of the system is a critical factor in limiting any "window of opportunity" for an attacker. In this case, it is up to the CA to inform its users that it has had a compromise. Information regarding a compromise of the TA must also be disseminated to users, but users need not take any direct action as a result.

One of the primary responsibilities of a CA is to ensure that everyone who wished to rely on its signature has access to its public key certificate. This is also true for the TA, which must use similar methods to establish trust in its public keys. This may cause some extra effort on the part the CA and its users.

91.7 Summary

What has been proposed and discussed in this chapter is a method of providing redundancy in a PKI where none has previously existed. Previous methods of breaking the Root private key into multiple parts created dual control over a single point of failure, but did nothing to provide any systemic redundancy.

It is worthwhile noting that this system is being prototyped by beTRUSTed, the trusted third-party service established by PricewaterhouseCoopers. Their testing, in cooperation with several PKI software vendors, may prove the usefulness and security of this system in a real-world environment.

As with any cryptographic system or protocol, the system of using CSDTs described herein must be analyzed and checked by numerous third parties for possible weaknesses or areas where an attacker may compromise the system.

PKI Registration

Alex Golod

PKI is comprised of many components: technical infrastructure, policies, procedures, and people. Initial registration of subscribers (users, organizations, hardware, or software) for a PKI service has many facets, pertaining to almost every one of the PKI components. There are many steps between the moment when subscribers apply for PKI certificates and the final state, when keys have been generated and certificates have been signed and placed in the appropriate locations in the system. These steps are described either explicitly or implicitly in the PKI Certificate Practices Statement (CPS).

Some of the companies in the PKI business provide all services: hosting Certificate and Registration Authorities (CAs and RAs); registering subscribers; issuing, publishing, and maintaining the current status of all types of certificates; and supporting a network of trust. Other companies sell their extraordinarily powerful software, which includes CAs, RAs, gateways, connectors, toolkits, etc. These components allow buyers (clients) to build their own PKIs to meet their business needs. In all the scenarios, the processes for registration of PKI subscribers may be very different.

This chapter does not claim to be a comprehensive survey of PKI registration. We will simply follow a logical flow. For example, when issuing a new document, we first define the type of document, the purpose it will serve, and by which policy the document will abide. Second, we define policies by which all participants will abide in the process of issuing that document. Third, we define procedures that the parties will follow and which standards, practices, and technologies will be employed. Having this plan in mind, we will try to cover most of the aspects and phases of PKI registration.

92.1 CP, CPS, and the Registration Process

The process of the registration of subjects, as well as a majority of the aspects of PKI, are regulated by its Certificate Policies (CP) and Certification Practices Statement (CPS). The definition of CP and CPS is given in RFC 2527, which provides a conduit for implementation of PKIs:

Certificate Policy: A named set of rules indicating the applicability of a certificate to a particular community or class of application with common security requirements. For example, a particular certificate policy might indicate applicability of a type of certificate to the authentication of electronic data interchange transactions for the trading of goods within a given price range.

Certification Practice Statement (CPS): A statement of the practices that a certification authority employs in issuing certificates.

In other words, CP says where and how a relying party will be able to use the certificates. CPS says which practice the PKI (and in many cases its supporting services) will follow to guarantee to all the parties, primarily relying parties and subscribers, that the issued certificates may be used as is declared in CP. The relying parties and subscribers are guided by the paradigm that a certificate "… binds a public key value to a set of information that identifies the entity (such as person, organization, account, or site) associated with use of the corresponding private key (this entity is known as the "subject" of the certificate)."[1] The entity or subject in this quote is also called an *end entity* (EE) or *subscriber.*

A CPS is expressed in a set of provisions. In this chapter we focus only on those provisions that pertain to the process of registration, which generally include:

- Identification and authentication
- Certificate issuance
- Procedural controls
- Key-pairs generation and installation
- Private key protection
- Network security in the process of registration
- Publishing

Reference to CP and CPS associated with a certificate may be presented in the X509.V3 certificates extension called "Certificate Policies." This extension may give to a relying party a great deal of information, identified by attributes *Policy Identifier* in the form of Abstract Syntax Notation One Object IDs (ASN.1 OID) and Policy Qualifier. One type of *Policy Qualifier* is a reference to CPS, which describes the practice employed by the issuer to register the subscriber (the subject of the certificate; see Exhibit 92.1).

92.2 Registration, Identification, and Authentication

For initial registration with PKI, a subscriber usually has to go through the processes of identification and authentication. Among the rules and elements that may comprise these processes in a CPS are:

1. Types of names assigned to the subject
2. Whether names have to be meaningful
3. Rules for interpreting various name forms
4. Whether names have to be unique
5. How name claim disputes are resolved
6. Recognition, authentication, and role of trademarks
7. If and how the subject must prove possession of the companion private key for the public key being registered
8. Authentication requirements for organizational identity of subject (CA, RA, or EE)
9. Authentication requirements for a person acting on behalf of a subject (CA, RA, or EE), including:
   - Number of pieces of identification required
   - How a CA or RA validates the pieces of identification provided
   - If the individual must present personally to the authenticating CA or RA
   - How an individual as an organizational person is authenticated

EXHIBIT 92.1 Certificate policies.

The first six items of the list are more a concern of the legal and naming conventions. They are beyond the scope of this chapter.

Other items basically focus on three issues:

1. How the subject proves its organizational entity (above)
2. How the person, acting on behalf of the subject, authenticates himself in the process of requesting a certificate (above)
3. How the certificate issuer can be sure that the subject, whose name is in the certificate request, is really in the possession of the private key, and which public key is presented in the certificate request along with the subject name (above)

Another important component is the integrity of the process. Infrastructure components and subscribers should be able to authenticate themselves and support data integrity in all the transactions during the process of registration.

92.2.1 How the Subject Proves Its Organizational Entity

Authentication requirements in the process of registration with PKI depend on the nature of applying EE and CP, stating the purpose of the certificate. Among end entities, there can be individuals, organizations, applications, elements of infrastructure, etc.

Organizational certificates are usually issued to the subscribing organization's devices, services, or individuals representing the organization. These certificates support authentication, encryption, data integrity, and other PKI-enabled functionality when relying parties communicate to the organization. Among organizational devices and services may be:

- Web servers with enabled SSL, which support server authentication and encryption
- WAP gateways with WTLS enabled, which support gateway authentication
- Services and devices, signing a content (software codes, documents etc.) on behalf of the organization
- VPN gateways
- Devices, services, applications, supporting authentication, integrity, and encryption of electronic data interchange (EDI), B2B, or B2C transactions

Among procedures enforced within applying organizations (before a certificate request is issued) are:

- An authority inside the organization should approve the certificate request.
- After that, an authorized person within the organization will submit a certificate application on behalf of the organization.
- The organizational certificate application will be submitted for authentication of the organizational identity.

Depending on the purpose of the certificate, a certificate issuer will try to authenticate the applying organization, which may include some but not all of the following steps, as in the example below:[2]

- Verify that the organization exists.
- Verify that the certificate applicant is the owner of the domain name that is the subject of the certificate.
- Verify employment of the certificate applicant and if the organization authorized the applicant to represent the organization.

There is always a correlation between the level of assurance provided by the certificate and the strength of the process of validation and authentication of the EE registering with PKI and obtaining that certificate.

92.2.2 How the Person, Acting on Behalf of the Subject, Authenticates Himself in the Process of Requesting Certificate (Case Study)

Individual certificates may serve different purposes, for example, for e-mail signing and encryption, for user authentication when they are connecting to servers (Web, directory, etc.), to obtain information, or for establishing a VPN encryption channel. These kinds of certificates, according to their policy, may be issued to anybody who is listed as a member of a group (for example, an employee of an organization) in the group's directory and who can authenticate himself. An additional authorization for an organizational person may or may not be required for PKI registration.

An individual who does not belong to any organization can register with some commercial certificate authorities with or without direct authentication and with or without presenting personal information. As a result, an individual receives his general use certificate.

Different cases are briefly described below.

92.2.2.1 Online Certificate Request without Explicit Authentication

As in the example with VeriSign certificate of Class 1, a CA can issue an individual certificate (a.k.a. digital ID) to any EE with an unambiguous name and e-mail address. In the process of submitting the certificate request to the CA, the keys are generated on the user's computer; and initial data for certificate request, entered by the user (user name and e-mail address) is encrypted with a newly generated private key. It is sent to the CA. Soon the user receives by e-mail his PIN and the URL of a secure Web page to enter that PIN to complete the process of issuing the user's certificate. As a consequence, the person's e-mail address and ability to log into this e-mail account may serve as indirect minimal proof of authenticity. However, nothing prevents person A from registering in the public Internet e-mail as person B and requesting, receiving, and using person B's certificate (see Exhibit 92.2).

92.2.2.2 Authentication of an Organizational Person

The ability of the EE to authenticate in the organization's network, (e.g., e-mail, domain) or with the organization's authentication database may provide an acceptable level of authentication for PKI registration. Even the person's organizational e-mail authentication is much stronger from a PKI registration perspective than authentication with public e-mail. In this case, a user authentication for PKI registration is basically delegated to e-mail or domain user authentication. In addition to corporate e-mail and domain controllers, an organization's HR database, directory servers, or databases can be used for the user's authentication and authorization for PKI registration. In each case an integration of the PKI registration process and the process of user authentication with corporate resources needs to be done (see Exhibit 92.3).

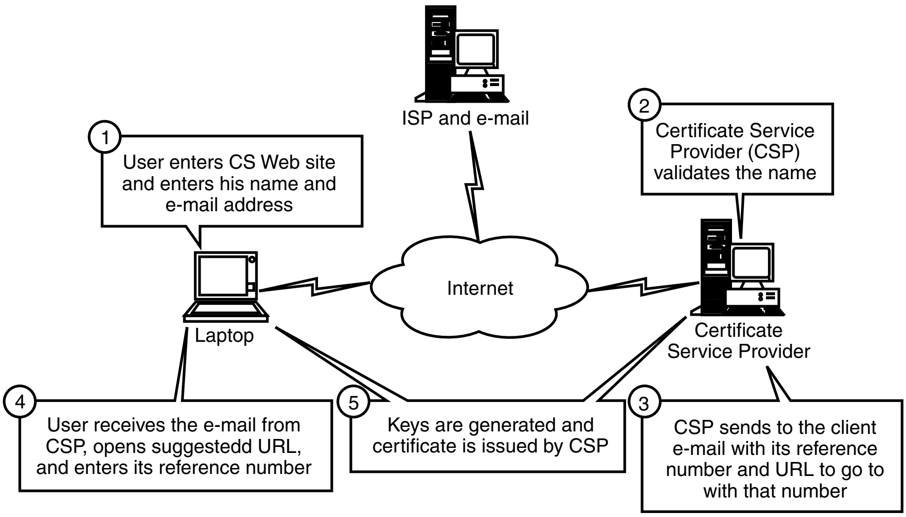
A simplified case occurs when a certificate request is initiated by a Registration Authority upon management authorization. In this case, no initial user authentication is involved.

92.2.3 Individual Authentication

In the broader case, a PKI registration will require a person to authenticate potentially with any authentication bases defined in accordance with CPS. For example, to obtain a purchasing certificate from the CA, which is integrated into a B2C system, a person will have to authenticate with financial institutions—which will secure the person's Internet purchasing transactions. In many cases, an authentication gateway or server will do it, using a user's credentials (see Exhibit 92.4).

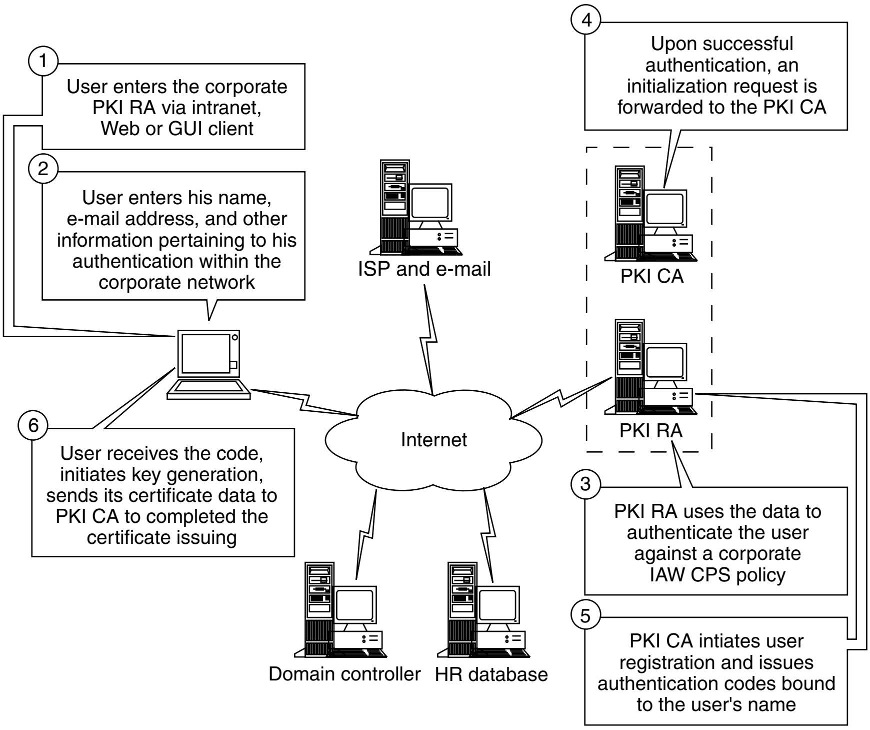
92.2.3.1 Dedicated Authentication Bases

In rare cases, when a PKI CPS requires a user authentication that cannot be satisfied by the existing authentication bases, a dedicated authentication base may be created to meet all CPS requirements.



ISP and e-mail
1
User enters CS Web site and enters his name and e-mail address
2
Certificate Service Provider (CSP) validates the name
Internet
Laptop
Certificate Service Provider
4
User receives the e-mail from CSP, opens suggestedd URL, and enters its reference number
5
Keys are generated and certificate is issued by CSP
3
CSP sends to the client e-mail with its reference number and URL to go to with that number

EXHIBIT 92.2 Certificate request via e-mail or Web with no authentication.



1
User enters the corporate PKI RA via intranet, Web or GUI client
2
User enters his name, e-mail address, and other information pertaining to his authentication within the corporate network
ISP and e-mail
4
Upon successful authentication, an initialization request is forwarded to the PKI CA
PKI CA
PKI RA
Internet
6
User receives the code, initiates key generation, sends its certificate data to PKI CA to completed the certificate issuing
3
PKI RA uses the data to authenticate the user against a corporate IAW CPS policy
5
PKI CA intiates user registration and issues authentication codes bound to the user's name
Domain controller
HR database

EXHIBIT 92.3 Certificate request via corporate e-mail or Web or GUI interface.

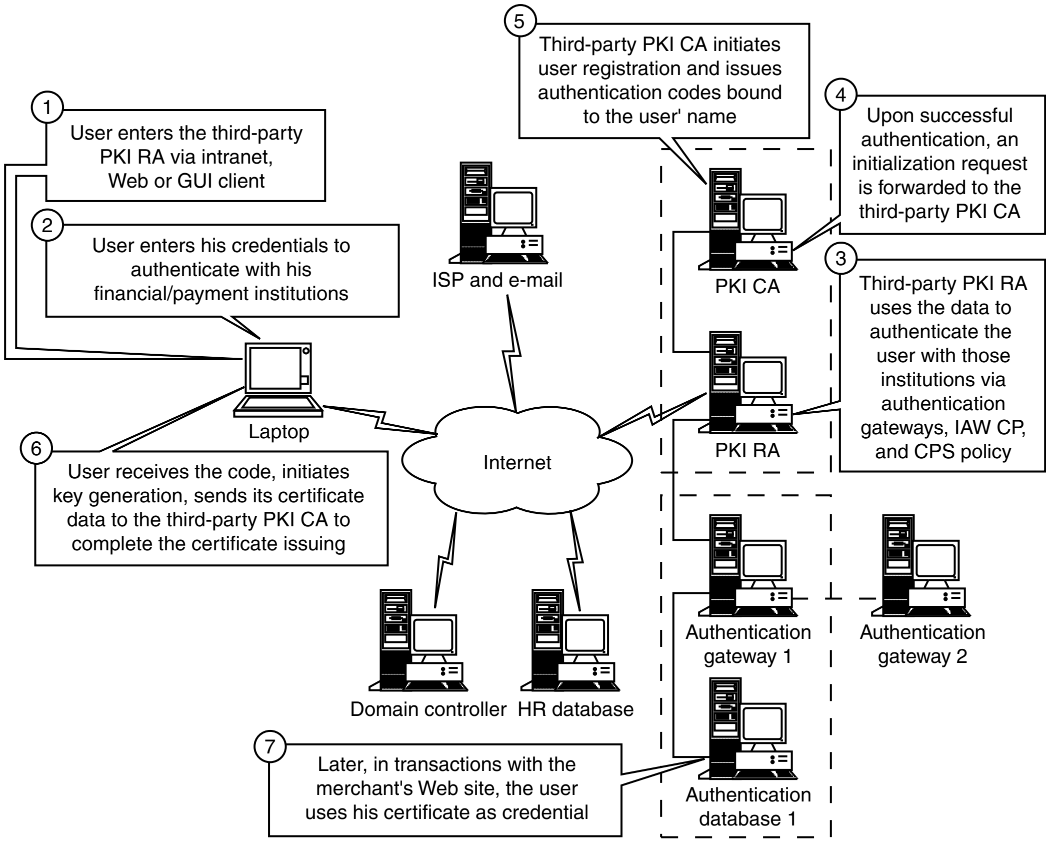
For example, for this purpose, a prepopulated PKI directory may be created, where each person eligible for PKI registration will be presented with a password and personal data attributes (favorite drink and color, car, etc.). Among possible authentication schemes with dedicated or existing authentication bases may be personal entropy, biometrics, and others.

92.2.3.2 Face-to-Face

The most reliable but most expensive method to authenticate an EE for PKI registration is face-to-face authentication. It is applied when the issued certificate will secure either high-risk and responsibility transactions (certificates for VPN gateways, CA and RA administrators) or transactions of high value, especially when the subscriber will authenticate and sign transactions on behalf of an organization. To obtain this type of certificate, the individual must be personally present and show a badge and other valid identification to the dedicated corporate registration security office and sign a document obliging use of the certificate only for assigned purposes. Another example is a healthcare application (e.g., Baltimore-based Healthcare eSignature Authority). All the procedures and sets of ID and documents that must be presented before an authentication authority are described in CPS.

92.3 Certificate Request Processing

So far we have looked at the process of EE authentication that may be required by CPS; but from the perspective of the PKI transactions, this process includes out-of-bound transactions. Whether the RA is contacting an authentication database online, or the EE is going through face-to-face authentication, there are still no PKI-specific messages. The RA only carries out the function of personal authentication of an EE before the true PKI registration of the EE can be initialized. This step can also be considered as



5
Third-party PKI CA initiates user registration and issues authentication codes bound to the user' name
1
User enters the third-party PKI RA via intranet, Web or GUI client
4
Upon successful authentication, an initialization request is forwarded to the third-party PKI CA
2
User enters his credentials to authenticate with his financial/payment institutions
ISP and e-mail
PKI CA
3
Third-party PKI RA uses the data to authenticate the user with those institutions via authentication gateways, IAW CP, and CPS policy
Laptop
Internet

EXHIBIT 92.4 Certificate request via gateway interfaces.

the first part of the process of initial registration with PKI. Another part of initial registration includes the step of EE initialization, when the EE is requesting information about the PKI-supported functions and acquiring CA public key. The EE is also making itself known to the CA, generating the EE key-pairs and creating a personal secure environment (PSE).

The initial PKI registration process, among other functions, should provide an assurance that the certificate request is really coming from the subject whose name is in the request, and that the subject holds private keys that are the counterparts to the public keys in the certificate request.

These and other PKI functions in many cases rely on PKI Certificate Management Protocols[3] and Certificate Request Management Format.[4]

PKIX–CMP establishes a framework for most of the aspects of PKI management. It is implemented as a message-handling system with a general message format as presented below:[3]

```
PKIMessage::= SEQUENCE {
header PKIHeader,
body PKIBody,
protection  [0]  PKIProtection OPTIONAL,
extraCerts  [1]  SEQUENCE SIZE (1..MAX) OF Certificate
OPTIONAL
}
```

EXHIBIT 92.5 Messages Used in Implementing PKI Management Functions

Source: RFC 2510.

The various messages used in implementing PKI management functions are presented in the PKI message body[3] (see Exhibit 92.5).

92.3.1 Initial Registration

In the PKIX–CMP framework, the first PKI message, related to the EE, may be considered as the start of the initial registration, provided that out-of-bound required EE authentication and CA public key installation have been successfully completed by this time. All the messages that are sent from PKI to the EE must be authenticated. The messages from the EE to PKI may or may not require authentication, depending on the implemented scheme, which includes the location of key generation and the requirements for confirmation messages.

- In the centralized scheme, initialization starts at the CA, and key-pair generation also occurs on the CA. Neither EE message authentication nor confirmation messages are required. Basically, the entire initial registration job is done on the CA, which may send to the EE a message containing the EE's PSE.
- In the basic scheme, initiation and key-pair generation start on the EE's site. As a consequence, its messages to RA and CA must be authenticated. This scheme also requires a confirmation message from the EE to RA/CA when the registration cycle is complete.

Issuing to the EE an authentication key or reference value facilitates authentication of any message from the EE to RA/CA. The EE will use the authentication key to encrypt its certificate request before sending it to the CA/RA.

92.3.2 Proof of Possession

A group of the key PKIX–CMP messages, sent by the EE in the process of initial registration, includes "ir," "cr," and "p10cr" messages (see the PKI message body above). The full structure of these messages is described in RFC 2511 and RSA Laboratories' Public-Key Cryptography Standards (PKCS). Certificate request messages, among other information, include "publicKey" and "subject" name attributes.

The EE has authenticated itself out-of-bound with RA on the initialization phase of initial registration (see above section on registration, identification, and authentication). Now an additional proof is required—that the EE, or the subject, is in possession of a private key, which is a counterpart of the public Key in the certificate request message. It is a proof of binding, or so-called proof of possession, or POP, which the EE submits to the RA.

Depending on the types of requested certificates and public/private key-pairs, different POP mechanisms may be implemented:

- For encryption certificates, the EE can simply provide a private key to the RA/CA, or the EE can be required to decrypt with its private key a value of the following data, which is sent back by RA/CA:
- In the direct method it will be a challenge value, generated and encrypted and sent to the EE by the RA. The EE is expected to decrypt and send the value back.
- In the indirect method, the CA will issue the certificate, encrypt it with the given public encryption key, and send it to the EE. The subsequent use of the certificate by the EE will demonstrate its ability to decrypt it, hence the possession of a private key.
- For signing certificates, the EE merely signs a value with its private key and sends it to the RA/CA.

Depending on implementation and policy, PKI parties may employ different schemes of PKIX–CMP message exchange in the process of initial registration (see Exhibit 92.6).

An initialization request ("ir") contains, as the PKIBody, a CertReqMessages data structure that specifies the requested certificate. This structure is represented in RFC 2511 (see Exhibit 92.7).

A registration/certification request ("cr") may also use as PKIBody a CertReqMessages data structure, or alternatively ("p10cr"), a CertificationRequest.[5]

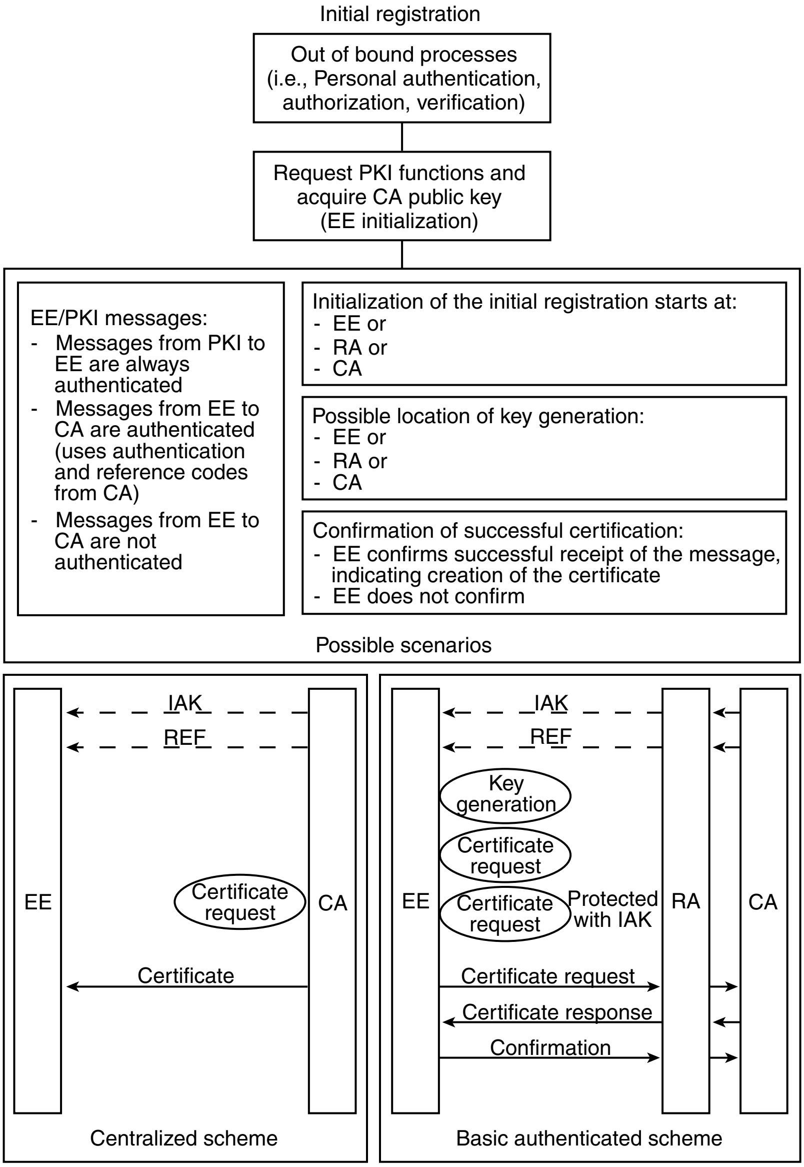
92.4 Administrative and Auto-Registration

As we saw above, the rich PKIX–CMP messaging framework supports the inbound initial certificate request and reply, message authentication, and POP. However, it does not support some important out-of-bound steps of PKI initial registration, such as:

- Authentication of an EE and binding its personal identification attributes with the name, which is a part of the registration request
- Administrative processes, such as managers' approval for PKI registration

To keep the PKIX–CMP framework functioning, the EE can generally communicate either directly with the CA or via the RA, depending on specific implementation. However, the CA cannot support the out-of-bound steps of initial registration. That is where the role of the RA is important. In addition to the two functions above, the RA also assumes some CA or EE functionality, such as initializing the whole process of initial registration and completing it by publishing a new certificate in the directory.

In the previous section on "Certificate Request Processing," we briefly mentioned several scenarios of user authentication. In the following analysis we will not consider the first scenario (online certificate request without explicit authentication) because certificates issued in this way have a very limited value.



Initial registration
Out of bound processes (i.e., Personal authentication, authorization, verification)
Request PKI functions and acquire CA public key (EE initialization)
EE/PKI messages:
- Messages from PKI to EE are always authenticated
- Messages from EE to CA are authenticated (uses authentication and reference codes from CA)
- Messages from EE to CA are not authenticated
Initialization of the initial registration starts at:
- EE or
- RA or
- CA
Possible location of key generation:
- EE or
- RA or
- CA
Confirmation of successful certification:
- EE confirms successful receipt of the message, indicating creation of the certificate
- EE does not confirm

EXHIBIT 92.6 Different schemes of PKIX–CMP message exchange.

92.4.1 Case Study

The following are examples of the initial registration, which requires explicit EE authentication.

92.4.1.1 Administrative Registration

1. An EE issues an out-of-bound request to become a PKI subscriber (either organizational or commercial third party).
2. An authorized administrator or commercial PKI clerk will authenticate EE and verify its request. Upon successful authentication and verification, an authorized administrator submits the request to the RA administrator.

EXHIBIT 92.7 Data Structure Specifying the Requested Certificate

```
CertReqMessages::=SEQUENCE SIZE (1..MAX) OF CertReqMsg
CertReqMsg::=SEQUENCE {
  certReqCertRequest,
  Pop  ProofOfPossession OPTIONAL,
---  content depends upon key type
  RegInfoSEQUENCE SIZE(1..MAX) OF AttributeTypeAndValue OPTIONAL}
CertRequest : : = SEQUENCE {
  certReqIdINTEGER,---  ID for matching request and reply
  certTemplateCertTemplate,---  Selected fields of cert to be issued

  controlsControls OPTIONAL}---  Attributes affecting issuance
CertTemplate : : =SEQUENCE {
  Version[0]  VersionOPTIONAL,
  serialNumber[1]  INTEGEROPTIONAL,
  SigningAlg[2]  AlgorithmIdentifierOPTIONAL,
  Issuer[3]  NameOPTIONAL,

  Subject[5]  NameOPTIONAL,
  publicKey[6]  SubjectPublicKeyInfoOPTIONAL,
  IssuerUID[7]  UniqueIdentifierOPTIONAL,
  SubjectUID[8]  UniqueIdentifierOPTIONAL,
  extensions[9]  Extensions OPTIONAL}
OptionalValidity : : = SEQUENCE {
  NotBefore[0]  Time OPTIONAL,
  NotAfter[1]  Time OPTIONAL}---at least one must be present
Time : : = CHOICE {
  utcTimeUTCTime,
  generalTimeGeneralizedTime}
```

3. The RA administrator enters the EE subject name and, optionally, additional attributes into the RA to pass it to the CA. The CA will verify if the subject name is not ambiguous and will issue a reference number (RN) to associate the forthcoming certificate request with the subject and an authentication code (AC) to encrypt forthcoming communications with EE.
4. The RA administrator sends the AC and RN in a secure out-of-bound way to the EE.
5. The EE generates a signing key-pair, and using AC and RN, establishes inbound “ir” PKIX–CMP exchange.
6. As a result, the EE’s verification and encryption certificates, along with signing and decryption keys, are placed in the EE PSE. The EE’s encryption certificate is also placed in the public directory.
7. If the keys are compromised or destroyed, the PKI administrator should start a recovery process, which quite closely repeats the steps of initial registration described here.

As we see, most of the out-of-bound steps in each individual case of administrative PKI registration are handled by administrators and clerks. Moreover, the out-of-bound distribution of AC/RN requires high confidentiality.

92.4.1.2 Auto-Registration

1. Optionally (depending on the policy), an EE may have to issue an out-of-bound application to become a PKI subscriber (either organizational or commercial third party). An authorized administrator or commercial PKI clerk will evaluate the request. Upon evaluation, the EE will be defined in the organizational or commercial database as a user, authorized to become a PKI subscriber.

2. The EE enters his authentication attributes online in the predefined GUI form.
3. The form processor (background process of the GUI form) checks if the EE is authorized to become a PKI subscriber and then tries to authenticate the EE based on the entered credentials.
4. Upon successful authentication of the EE, the subsequent registration steps are performed automatically, as well as the previous step.
5. As a result, the EE's verification and encryption certificates, along with signing and decryption keys, are placed in the EE PSE. The EE's encryption certificate is also placed in the public directory.
6. If the keys are compromised or destroyed, the EE can invoke via a GUI form a recovery process without any administrator's participation.

Comparing the two scenarios, we can see an obvious advantage to auto-registration. It is substantially a self-registration process. From an administration perspective, it requires simply to authorize the EE to become a PKI subscriber. After that, only exceptional situations may require a PKI administrator's intervention.

92.4.2 Authentication Is a Key Factor

We may assume that in both scenarios described above, all the inbound communications follow the same steps of the same protocol (PKIX–CMP). The difference is in the out-of-bound steps, and more specifically, in the user (EE) authentication. Generally, possible authentication scenarios are described in the section on "Registration, Identification, and Authentication." Most of those scenarios (except face-to-face scenarios) may be implemented either in the administrative or auto-registration stage. The form, sources, and quality of authentication data should be described in the CPS. The stronger the authentication criteria for PKI registration, the more trust the relying parties or applications can use. There may be explicit and implicit authentication factors.

In the administrative registration case above, authentication of the organizational user may be totally implicit, because his PKI subscription may have been authorized by his manager, and AC/RN data may have been delivered via organizational channels with good authentication mechanisms and access control. On the other hand, registration with a commercial PKI may require an EE to supply personal information (SSN, DOB, address, bank account, etc.), which may be verified by a clerk or administrator.

Auto-registration generally accommodates verification of all the pieces of the personal information. If it is implemented correctly, it may help to protect subscribers' privacy, because no personal information will be passed via clerks and administrators. In both the organizational and commercial PKI registration cases, it may even add additional authentication factors—the ability of the EE/user to authenticate himself online with his existing accounts using one or many authentication bases within one or many organizations.

92.5 Conclusion

For most common-use certificates, which do not assume a top fiscal or a highest legal responsibility, an automated process of PKI registration may be the best option, especially for large-scale PKI applications and for the geographically dispersed subscribers' base. Improvement of this technology in mitigating possible security risk, enlarging online authentication bases, methods of online authentication, and making the entire automated process more reliable, will allow the organization to rely on it when registering subscribers for more expensive certificates, which assume more responsibility.

For user registration for certificates carrying a very high responsibility and liability, the process will probably remain manual, with face-to face appearance of the applicant in front of the RA, with more than one proof of his identity. It will be complemented by application forms (from the applicant and his superior) and verification (both online an?d offline) with appropriate authorities. The number of certificates of this type is not high, and thus does not create a burden for the RA or another agency performing its role.

Implementing Kerberos in Distributed Systems

Joe Kovara

Ray Kaplan

Kerberos is a distributed security system that provides a wide range of security services for distributed environments. Those services include authentication and message protection, as well as providing the ability to securely carry authorization information needed by applications, operating systems, and networks. Kerberos also provides the facilities necessary for delegation, where limited-trust intermediaries perform operations on behalf of a client. Entering its second decade of use, Kerberos is arguably the best tested and most scrutinized distributed security system in widespread use today.

Kerberos differs from many other distributed security systems in its ability to incorporate a very wide range of security technologies and mechanisms. That flexibility allows a mixture of security technologies and mechanisms to be used, as narrowly or broadly as required, while still providing the economies of scale that come from a common, reusable, and technology-neutral Kerberos security infrastructure. Technologies and mechanisms that have been incorporated into Kerberos and that are in use today include certificate-based public key systems, smart cards, token cards, asymmetric-key cryptography, as well as the venerable user ID and password.

Kerberos' longevity and acceptance in the commercial market are testaments to its reliability, efficiency, cost of ownership, and its adaptability to security technologies past, present, and—we believe—future. Those factors have made Kerberos the *de facto* standard for distributed security in large, heterogeneous network environments. Kerberos has been in production on a large scale for years at a variety of commercial, government, and educational organizations, and for over a decade in one of the world's most challenging open systems environments: Project Athena[1] at MIT, where it protects campus users and services from what is possibly the security practitioner's worst nightmare.

93.1 History of Development

Many of the ideas for Kerberos originated in a discussion of how to use encryption for authentication in large networks that was published in 1978 by Roger Needham and Michael Schroeder.[2] Other early ideas can be attributed to continuing work by the security community, such as Dorothy Denning's and Giovanni Sacco's work on the use of time stamps in key distribution protocols.[3] Kerberos was designed and implemented in the mid-1980s as part of MIT's Project Athena. The original design and implementation of the first four versions of Kerberos were done by MIT Project Athena members Steve Miller (Digital Equipment Corp.) and Clifford Neuman, along with Jerome Salzer (Project Athena technical director) and Jeff Schiller (MIT campus network manager).

Kerberos versions 1 through 3 were internal development versions and, since its public release in 1989, version 4 of Kerberos has seen wide use in the Internet community. In 1990, John Kohl (Digital Equipment Corp.) and Clifford Neuman (University of Washington at that time and now with the Information Sciences Institute at the University of Southern California) presented a design for version 5 of the protocol based on input from many of those familiar with the limitations of version 4. Currently, Kerberos versions 4 and 5 are available from several sources, including freely distributed versions (subject to export restrictions) and fully supported commercial versions. Kerberos 4 is in rapid decline, and support for it is very limited. This discussion is limited to Kerberos 5.

[1] Project Athena is a model of "next-generation distributed computing" in the academic environment. It began in 1993 as an eight-year project with DEC and IBM as its major industrial) sponsors. Their pioneering model is based on client–server technology and it includes such innovations as authentication based on Kerberos and X Windows. An excellent reference—George Champine, MIT *Project Athena, A Model for Distributed Campus Computing*, Digital Press, 1991. Other definitive works on Kerberos include B. Clifford Neuman and Theodore Ts'o, Kerberos: an authentication service for computer networks, *IEEE Communications*, 32(9), 33–38. September 1994; available at http://gost.isi.edu/publications/kerberos-neuman-tso.html and http://nii.isi.edu/publications/kerberos-neuman-tso.html.

93.1.1 Current Development

Although there have been no fundamental changes to the Kerberos 5 protocol in recent years,[4] development and enhancement of Kerberos 5 continues today.[5] That development continues a history of incremental improvements to the protocol and implementations. Implementation improvements tend to be driven by commercial demands, lessons learned from large deployments, and the normal improvements in supporting technology and methodologies.

Standards efforts within the Internet Engineering Task Force (IETF) continue to play a predominant role in the Kerberos 5 protocol development, reflecting both the maturity of the protocol as well as the volatility of security technology. Protocol development is primarily driven by the emergence of new technologies, and standards efforts continue to provide an assurance of compatibility and interoperability between implementations as new capabilities and technologies are incorporated. Those efforts also ensure that new developments are vetted by the Internet community. Many additions to Kerberos take the form of separate standards, or IETF Request for Comments (RFCs).[6] Those standards make use of elements in the Kerberos protocol specifically intended to allow for extension and the addition and integration of new technologies. Some of those technologies and their integration into Kerberos are discussed in subsequent sections.

As of this writing, both Microsoft[7] and Sun[8] have committed to delivery of Kerberos 5 as a standard feature of their operating systems. Kerberos 5 has also been at the core of security for the Open Software Foundation's Distributed Computing Environment (OSF DCE) for many years.[9] Many application vendors have also implemented the ability to utilize Kerberos 5 in their products, either directly, or through the Generic Security Service Applications Programming Interface (GSS-API).

93.2 Standards and Implementations

When discussing any standard, care must be exercised in delineating the difference between what the standard defines, what is required for a solution, and what different vendors provide. As does any good protocol standard, the Kerberos 5 standard leaves as much freedom as possible to each implementation, and as little freedom as necessary to ensure interoperability. The basic Kerberos 5 protocol defines the syntax and semantics for authentication, secure messaging, limited syntax and semantics for authorization, and the application of various cryptographic algorithms within those elements.

The Kerberos 5 protocol implies, but does not define, the supporting infrastructure needed to build a solution that incorporates and makes useful all of the standard's elements. For example, the services that make up the logical grouping of the Kerberos security server are defined by the Kerberos 5 standard. The manifestation of those services—the underlying database that those services require, the supporting management tools, and the efficiency of the implementation—are not defined by the standard. Those elements make the difference between what is theoretically possible and what is real. That difference is a reflection of the state of technology, market demands, and vendor implementation abilities and priorities. In this discussion we have attempted to distinguish between the elements that make up the

Kerberos 5 protocol, the elements that are needed to build and deploy a solution, and the variations that can be expected in different implementations.

93.3 Perceptions and Technology

A review of perceptions about Kerberos will find many anecdotal and casual assertions about its poor usability, inferior performance, or lack of scalability. This appears to be inconsistent with the acceptance of Kerberos by major vendors and can be confusing to those tasked with evaluating security technologies. Much of that confusion is the result of the unqualified use of the term "Kerberos." Kerberos 4 and Kerberos 5 are very different, and any historical references must be qualified as to which version of Kerberos is the subject. As an early effort in distributed security, considerable study was devoted to the weaknesses, vulnerabilities, and limitations of Kerberos 4 and early drafts of the Kerberos 5 standard.[10] Modern implementations of Kerberos 5 address most, if not all, of those issues.

As a pioneering effort in distributed security, Kerberos exposed many new, and sometimes surprising, security issues. Many of those issues are endemic to distributed environments and are a reflection of organization and culture, and the changing face of security as organizations moved from a centralized to a distributed model. As a product of organization and culture, there is little if anything that technology alone can do to address most of those issues. Many of the resulting problems have been attributed to Kerberos, the vast majority of which are common to all distributed security systems, regardless of the technology used.

Various implementations of Kerberos have dealt with the broader organizational security issues in different ways, and with different degrees of success. The variability in the success of those implementations has also been a source of confusion. Enterprises that have a business need for distributed security and that understand the organizational, cultural, and security implications of distributed environments—or more accurately distributed business—tend to be most successful in deploying and applying Kerberos. Until very recently, organizations that fit that description have been in a small minority. Successes have also been achieved at other organizations, but those implementations tend to be narrowly focused on an application or a group within the organization. It should be no surprise that organizations that are in need of what Kerberos has to offer have been in the minority. Kerberos is a distributed security system. Distributed computing is still relatively young, and the technology and business paradigms are still far from convergence.

Outside of the minority of organizations with a business need for distributed security, attempts to implement broad-based distributed security systems such as Kerberos have generally failed. Horror stories of failed implementations tend to receive the most emphasis and are typically what an observer first encounters. Stories of successful implementations are more difficult to uncover. Those stories are rarely discussed outside of a small community of security practitioners or those directly involved, as there is generally little of interest to the broader community; "we're more secure than we were before" does not make for good press.

Whether drivers or indicators of change, the advent of the Internet and intranets bespeak a shift, as a greater number of enterprises move to more distributed organizational structures and business processes and discover a business need for solutions to distributed security problems. Those enterprises typically look first to the major vendors for solutions. Driven by customer business needs, those vendors have turned to Kerberos 5 as a key element in their security solutions.

93.3.1 Trust, Identity, and Cost

The vast majority of identity information used in organizations by computer systems and applications today is based on IDs and passwords, identity information that is bound to individuals. That is the result

[10] Bellovin, S. M. and Merritt, M. January 1991. Limitations of the Kerberos authentication system, *Proceedings of the Winter Usenix Conference.*

of years of evolution of our computer systems and applications. Any security based on that existing identity information is fundamentally limited by the trust placed in that information. In other words, security is limited by the level of trust we place in our current IDs and passwords as a means of identifying individuals.

Fundamentally increasing the level of trust placed in our identity information and the security of any system that uses those identities requires rebinding, or reverifying, individual identities. That is a very, very expensive proposition for all but the smallest organizations. In simple and extreme terms: any authentication technology purporting to improve the authenticity of individuals that is based on existing identity information is a waste of money; any authentication technology that is not based on existing identity information is too expensive to deploy on any but a small scale. This very simple but very fundamental equation limits all security technologies and the level of security that is practical and achievable.

We must use most of our existing identity information; the alternatives are not affordable. Although the situation appears bleak, it is far from hopeless; we must simply be realistic about what can be achieved, and at what cost. There is no "silver bullet." The best that any cost-effective solution can hope to do is establish the current level of trust in individual identities as a baseline and not allow further erosion of that trust. Once that baseline is established, measures can be taken to incrementally improve the situation as needed and as budgets allow. The cheaper those goals can be accomplished, the sooner we will start solving the problem and improving the level of trust we can place in our systems.

Kerberos provides the ability to stop further erosion of our trust in existing identities. Kerberos also allows that level of trust to be improved incrementally, by using technologies that are more secure than IDs and passwords. Kerberos allows both of those to be achieved at the lowest possible cost. The ability for Kerberos to effectively utilize what we have today, stop the erosion, and allow incremental improvement is one of the key factors in the success of Kerberos in real-world environments.

93.3.2 Technology Influences

Although technology continues to advance and provide us with the raw materials for improving Kerberos, many of the assumptions and influences that originally shaped Kerberos are still valid today. Although new security technologies may captivate audiences, the fundamentals have not changed. One fundamental of security that should never be forgotten is that a security system must be affordable and reliable if it is to achieve the goal of improving an organization's security.

An affordable and reliable security system makes the most of what exists, and does not require the use of new, expensive or unproven technologies as a prerequisite to improving security. A good security system such as Kerberos allows those newer technologies to be used but does not mandate them. With rapid advances in technology, single-technology solutions are also doomed to rapid obsolescence. Solutions that are predicated on new technologies will, by definition, see limited deployment until the cost and reliability of those solutions are acceptable to a broad range of organizations. The longer that evolution takes, the higher the probability that even newer technologies will render them, and any investment made in them, obsolete.

Moreover, history teaches us that time provides the only real validation of security. That is a difficult proposition for security practitioners when the norm in the information industry is a constant race of the latest and greatest. However, the historical landscape is littered with security technologies, most created by very smart people, that could not stand the test of time and the scrutiny of the security community. The technology influences that have shaped Kerberos have been based on simple and proven fundamentals that provide both a high degree of assurance and a continuing return on investment.

93.3.3 Protocol Placement

Kerberos is often described as an "application-layer protocol." Although that description is nominally correct, and most descriptions of Kerberos are from the perspective of the application, the unfortunate result is a perception that Kerberos requires modification of applications to be useful. Kerberos is not limited to use at the application layer, nor does Kerberos require modification of applications. Kerberos can be, and is, used very effectively at all layers of the network, as well as in middleware. Placing Kerberos authentication, integrity, confidentiality, and access control services below the application layer can provide significant improvements in security without the need to modify applications. The most obvious example of security "behind the scenes" is the use of Kerberos for authentication and key management in a virtual private network (VPN).

However, there are limits to what can be achieved without the cooperation and knowledge of an application. Those limits are a function of the application and apply to all security systems. Providing an authenticated and encrypted channel (e.g., using a VPN) may improve the security of access to the application and the security of information flowing between a client and the application. However, that alone does nothing to improve the usability of the application and does not take advantage of Kerberos' ability to provide secure single sign-on. For example, an application that insists on a local user ID for the users of that application will require mapping between the Kerberos identity and the application-specific user ID. An application that insists on a password will typically require some form of "password stuffing" to placate the application—even if the password is null. Some applications make life easier by providing hooks, call-outs, or exits that allow augmenting the application with alternative security mechanisms. Other applications that do not provide this flexibility require additional and complex infrastructure in order to provide the appearance of seamless operation. Note that these issues are a function of the applications, and not the security system. All security systems must deal with identical issues, and they will generally be forced to deal with those issues in similar ways.

Although we can formulate solutions to authentication, confidentiality, integrity, and access control that are useful and that are independent of a broad range of applications, the same cannot be said of delegation and authorization. In this context, the assertion that Kerberos requires modification of the application is correct. However, that requirement has little if any affect on the practical employment of Kerberos, because very few applications in use today need, or could make use of, those capabilities. Applications that can understand and make use of those capabilities are just starting to appear.

93.3.4 Passwords

One of the primary objectives of Kerberos has always been to provide security end-to-end. That is, all the way from an individual to a service, without the requirement to trust intermediaries. Kerberos can be, and is, also used to provide security for intermediate components such as computer systems, routers, and virtual private networks. However, humans present the most significant challenge for any security system, and Kerberos does an exemplary job of meeting that challenge.

The simple user ID and password are far and away the most common basis for identification and authentication used by humans and applications today. Whatever their faults, simple IDs and passwords predominate the security landscape and will likely do so for the foreseeable future. They are cheap, portable, and provide adequate security for many applications—virtually all applications in use today. Kerberos is exceptional in its ability to provide a high level of security with nothing more than those IDs and passwords. Kerberos allows more sophisticated identification and authentication mechanisms to be used, but does not mandate their use.

Kerberos is specifically designed to eliminate the transmission of passwords over the network. Passwords are not transmitted in any form as a part of the Kerberos authentication process. The only case in which a password or a derivation of the password (i.e., a key derived from the password) is transmitted is during a password-change operation—assuming, of course, that passwords are being used for authentication, and not an alternative technology such as smart cards. During a password-change operation, the password or its derivation is always protected using Kerberos confidentiality services.

93.3.5 Cryptography

The need to provide effective security using nothing more than very low-cost methods such as an ID and password has had a significant influence on the Kerberos protocol and its use of cryptography. In particular, using a password as the sole means for identification and authentication requires that the password is the basis of a shared secret between the user and the Kerberos security server. That also requires the use of symmetric-key cryptography. Although shared secrets and symmetric-key cryptography have been derided as "legacy" authentication technology, there are few if any alternatives to passwords if we want to provide an affordable and deployable solution sooner rather than later.

The efficiency of cryptographic methods has also had a significant influence on the protocol and its use of cryptography. Although Kerberos can incorporate asymmetric-key cryptography, such as elliptic curve cryptography (ECC) and RSA, Kerberos can provide all of the basic security services using shared secrets and symmetric-key cryptography. Because of the CPU-intensive nature of asymmetric-key cryptography, the ability to use symmetric-key cryptography is extremely important for environments or applications that are performance-sensitive, such as high-volume transaction-processing systems, where each transaction is individually authenticated.

93.3.6 Online Operation

In a distributed environment, individuals and services are scattered across many computer systems and are geographically dispersed. Whatever their physical distribution, those individuals and services operate within a collective enterprise. Typically, the association between an individual and his access to enterprise services is reestablished at the beginning of each workday, such as through a log-in. Day-to-day work in the distributed enterprise requires an individual to make use of many different services, and an individual typically establishes an association with a service, performs work, and then terminates the association. All of these functions occur online.

The association between individual and service may be very short-lived, such as for the duration of a single transaction. In other cases that association is long-lived and spans the workday. Whatever the duration of the association, the vast majority of work is performed online. That is, the individual and the service interact in real-time. Offline operation, which is sometimes necessary, is fast becoming a rarity. Notable exceptions are "road warriors," who must be capable of operating offline. However, that is a function of the limitations of connectivity, not of any desire to operate offline—as any road warrior will tell you.

The combined ability to provide both efficient and secure access to services, and the ability to serve as the basis for a collective security mechanism is one of Kerberos's major strengths. To deliver those capabilities, and deliver them efficiently, the Kerberos security server operates online. Extending that concept to an aggregate "enterprise security service" that incorporates Kerberos allows economies and efficiencies to be achieved across multiple security functions, including authentication, authorization, access control, and key management—all of which can be provided by, or built from, Kerberos. Although the concept of an aggregate enterprise security service is not native to Kerberos, the union of the two is very natural. Moreover, given the direction of technology and the composition and conduct of modern distributed enterprises, online security services are both required and desirable. These attributes have much to do with the adoption of Kerberos as the basis for providing enterprise security, as opposed to Internet security.

93.4 Organizational Model

There are many different approaches to distributed security, and each involves tradeoffs between scalability and resources. The only objective measure of a distributed security system is cost, as measured by the resources required to achieve a given level of security over a given scale. Resources include computational overhead, network bandwidth, and people. The resulting cost bounds the achievable security and the scalability of the system. The tradeoffs that must be made involve both the technology and the security model appropriate to an organization. The extremes of those organizational models are autocracy and anarchy.

93.4.1 Autocracy

All control flows from a central authority. That authority defines the association between itself and the individual and the level of trust it places in an individual. This model requires a level of control that is cost-prohibitive in today's distributed environments. The classic military or business models tend toward this end of the spectrum.

93.4.2 Anarchy

All authority flows from individuals. Each individual defines the association between himself and an enterprise and the level of trust they place in an enterprise. This model achieves no economies of scale or commonality. The Internet tends toward this end of the spectrum.

Where in that spectrum an enterprise lives depends on business practices and culture, and every enterprise is different. Within a single enterprise it is not unusual to find organizational units that span the entire spectrum. That variability places significant demands on a distributed security system, and in some cases those demands may conflict. Conflicting demands occur when multiple enterprises—or even different business units within the same enterprise—with very different business practices or cultures engage in a common activity, such as is typical in supplier and partner relationships. The extreme case of conflicting demands is most often seen when the enterprise meets the Internet. As enterprise boundaries continue to dissolve, the probability of conflicting demands increases, as does the need for security systems to cope with those conflicting demands.

Kerberos most naturally falls in the middle of the spectrum between the extremes of autocracy and anarchy. Depending on implementation and the technology that is incorporated, Kerberos can be applied to many points along that spectrum and can be used to bridge points along the spectrum. Kerberos' effectiveness drops as you approach the extreme ends of the spectrum. As a security system, Kerberos provides a means to express and enforce a common set of rules across a collective; by definition, that collective is not anarchy. As a distributed security system, Kerberos is designed to solve problems that result from autonomous (and hence untrusted) elements within the environment; by definition, that cannot be an autocracy. Note that "distributed" does not necessarily imply physically distributed. For example, if the LAN to which your computer is connected cannot ensure the confidentiality and integrity of data you send across it, then you are in a distributed security environment.

93.5 Trust Models

The level of trust that is required between entities in a distributed system is a distinguishing characteristic of all distributed security systems, and affects all other services that are built on the system, as well as the scalability of the system. A prerequisite to trust is authentication: knowing the identity of the person (or machine) you are dealing with. In Kerberos, the entities that authenticate with one another are referred to as "principals," as in "principals to a transaction."

93.5.1 Direct Trust

Historically, users and applications have established direct trust relationships with one another. For example, each user of each application requires a user ID and password to access that application; the user ID and password represents a direct trust relationship between the user and the application. As the

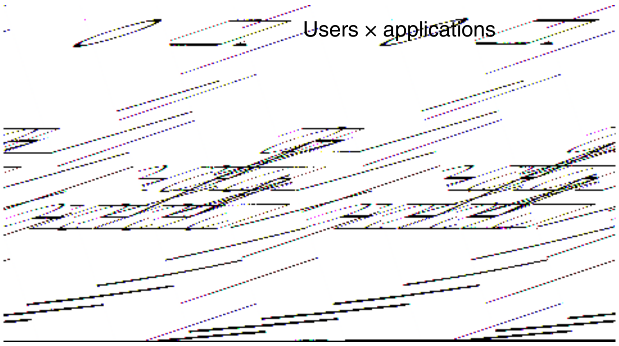

EXHIBIT 93.1 Direct trust relationships.

number of users and applications grows, the number of direct relationships, and the cost of establishing and managing those relationships, increases geometrically (Exhibit 93.1). A geometric increase in complexity and cost is obviously not sustainable and limits the scalability of such solutions to a small number of applications or users.

A secure authentication system does not, in and of itself, reduce the complexity of this problem. The increase in complexity is a function of the number of direct trust relationships and has nothing to do with the security of the user-to-application authentication mechanism. An example of this is seen in Web-based applications that use IDs and passwords for authentication through the SSL (Secure Sockets Layer) protocol. The SSL protocol can provide secure transmission of the ID and password from the client to the server. However, that alone does not reduce the number of IDs and passwords that users and servers must manage.

Mitigating the increasing cost and complexity of direct trust relationships in the form of many IDs and passwords is the same problem that single sign-on systems attempt to solve. One solution is to use the same user ID and password for all applications. However, this assumes that all applications a user has access to are secured to the level of the most demanding application or user. That is required because an application has the information required to assume the identity of any of its users, and a compromise of any application compromises all users of that application. In a distributed environment, ensuring that all applications, their host computer systems, and network connections are secured to the required level is cost-prohibitive. The extreme case occurs with applications that are outside the enterprise boundaries. This is a non-scalable trust model.

93.5.2 Indirect Trust

Achieving scalable and cost-effective trust requires an indirect trust model. Indirect trust uses a third party, or parties, to assist in the authentication process. In this model, users and applications have a very strong trust relationship with a common third party, either directly or indirectly. The users and applications, or principals, trust that third party for verification of another principal's identity. The introduction of a third party reduces the geometric increase in complexity (shown in the previous section) to a linear increase in complexity (Exhibit 93.2).

All scalable distributed security systems use a trusted third party. In the Kerberos system, the trusted third party is known as the Key Distribution Center (KDC). In public key systems, the trusted third party is referred to as a Certificate Authority (CA). In token card systems, the token card vendor's server acts as a trusted third party. Many other applications of third-party trust exist in the world, one of the most obvious being credit cards, where the bank acts as the trusted third party

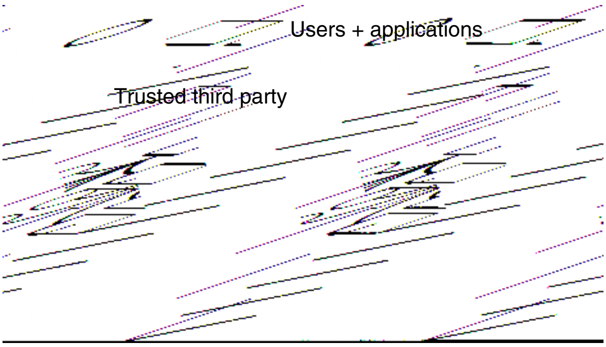

EXHIBIT 93.2 Indirect trust relationships.

between consumer and merchant. Neither consumer nor merchant shares a high degree of trust with each other, but both trust the credit card issuer. Note that without a credit card, each consumer would have to establish a direct trust relationship with each merchant (i.e., to obtain credit). Credit cards have made it much easier for consumers and merchants to do business, especially over long distances.

Much like credit cards, a trusted third-party authentication system makes it easier for principals to do business—the first step of which is to verify each other's identity. In practical terms, that makes applications, information, and services more accessible in a secure manner. That benefits both consumers and providers of applications, information, and services, and reduces the cost to the enterprise.

93.6 Security Model

The manner in which a trusted third party provides proof of a principal's identity is a distinguishing characteristic of trusted third party security systems. This has a significant effect on all other services provided by the security system, as well as the scalability of the system. Kerberos uses a credential-based mechanism as the basis for identification and authentication. Those same credentials may also be used to carry authorization information. Kerberos credentials are referred to as "tickets."

93.6.1 Credentials

Requiring interaction with the trusted third party every time verification of identity needs to be done would put an onerous burden on users, applications, the trusted third party, and network resources. In order to minimize that interaction, principals must carry proof of their identity. That proof takes the form of a credential that is issued by the trusted third party to a principal. The principal presents that credential as proof of identity when requested.

All scalable distributed security systems use credentials. The Kerberos credential, or ticket, is analogous to an X.509 certificate in a public key system. These electronic credentials are little different conceptually than physical credentials, such as a passport or driver's license, except that cryptography is used to make the electronic credentials resistant to forgery and tampering. As with physical credentials, an electronic credential is something you can "carry around with you," without the need for you to constantly go back to an authority to reassert and verify your identity, and without the need for services to go back to that authority to verify your identity or the authenticity of the credential. Note that the use of a trusted third party for authentication does not imply the use of credentials. Token card systems are an example of trusted third-party authentication without credentials. The result of the authentication using such a card is a simple yes–no answer, not a reusable credential, and every demand for authentication results in an interaction with both the user and the token card server.

The stronger a credential, the stronger the assurance that the principal's claimed identity is genuine. The strength of a credential is dependent on both technology and environmental factors. Because a credential is carried by each principal, the credential must be tamper-proof and not forgeable. A credential's resistance to tampering and forgery is contingent on the strength of the cryptography used. Assurance of identity is contingent on the diligence of the trusted third party in verifying the identity of the principal's identity prior to issuing the credential. Assurance of identity is also contingent on the secure management of the credential by the principal. As with physical credentials, electronic Kerberos credentials, and the information used to derive them must be protected, just as an individual's private key in a public key system must be protected.

As in the real world, all electronic credentials are not created equal. Simply possessing a credential does not imply universal acceptance or trust. As in the real world, the use and acceptance of a credential depends on the trust placed in the issuing authority, the integrity of the credential (resistance to forgery or tampering), and the purpose for which it is intended. For verification of identity, both passports and driver's licenses are widely accepted. A passport is typically trusted more than a driver's license, because the criteria for obtaining a passport are more stringent and a passport is more difficult to forge or alter. However, a passport says nothing about the holder's authorization or ability to operate a motor vehicle. A credential may also be single-purpose, such as a credit card. The issuing bank, as the trusted third party, provides protection to both the consumer and the merchant for a limited purpose: purchasing goods and services.

93.6.2 Credential Lifetime

As with physical credentials, the application and integrity of electronic credentials should limit the lifetime for which those credentials may be used. That lifetime may be measured in seconds or years, depending on the use of the credential. The strength of the cryptography that protects the integrity of the credential also effectively limits the lifetime of a credential. Credentials with longer lifetimes require stronger cryptography, because the credential is potentially exposed to attack for a longer period of time. However, cryptography is rarely the limiting factor in credential lifetime. Other issues, such as issuing cost and revocation cost, tend to be the determining factors for credential lifetime.

The distinguishing characteristic of credential-based systems is the lifetime of the credentials that they can feasibly accommodate. The longer the lifetime of a credential, the less often a new credential must be issued. However, the longer the life of a credential, the higher the probability that information embedded in the credential will change, or that the credential will be lost or stolen. The old "telephone book" revocation lists published by credit card companies is an example of the cost and complexity of revocation on a very large scale. Credit card companies have since moved to online authorization in order to lower costs and respond more rapidly.

Long-lived credentials reduce the credential-issuing cost but increase the credential-revocation cost. The shorter the lifetime of a credential, the more often a new credential must be issued. That increases the cost of the issuing process but reduces the cost of the revocation process. Credentials that are used only for authentication can have a relatively long lifetime. An individual's identity is not likely to change, and revocation would be necessary only if the credential was lost or stolen, or if the association between the individual and the issuing authority has been severed (e.g., such as when an employee leaves a company). Credentials that explicitly or implicitly carry authorization information generally require a shorter lifetime, because that information is more likely to change than identity information.

Different systems accommodate different lifetimes depending on the cost of issuing and revoking a credential and the intended use of the credential. While Kerberos credentials can have lifetimes of minutes or decades, they typically have lifetimes of hours or days. The process of constructing and issuing credentials is extremely efficient in Kerberos. That efficiency is key to Kerberos's ability to support authorization, capabilities, and delegation where new credentials may need to be issued frequently.

93.6.3 Capabilities

Credentials that carry authorization information are referred to as “capabilities,” as they imply certain capabilities, or rights, upon the carrier of the credential. Kerberos supports capabilities by allowing authorization information to be carried within a Kerberos credential. As with other credentials, it is imperative that capabilities be resistant to tampering and forgery. We most often think of authorization information as coming from a central authorization service that provides commonly used information to various services (e.g., group membership information) where that information defines the limit of an individual’s authorization. Kerberos supports this model by allowing authorization information from an authorization service to be embedded in a Kerberos credential when it is issued by the KDC; that authorization information is then available to services as a normal part of the Kerberos authentication process. Kerberos also supports a capability model based on “restricted proxies,” in which the authorization granted to intermediate services may be restricted by the client.[11]

93.6.4 Delegation

There are also situations in which an individual authorizes another person to act on his behalf, thereby delegating some authority to that person. This is analogous to a power of attorney. Consider the simple example of a client who wants to print a file on a file server using a print server. The client wants to ensure that the print server can *print* (read) only the requested file, and not *write* on the file, or read any other files. The file server wants to ensure that the client really requested that the file be printed (and thus that the print server needs read-access to the file) and that the print server did not forge the request. The client should also limit the time for which the print server has access to the file, otherwise the print server would have access to the file for an indefinite period of time.

The extreme case is when an individual delegates unrestricted use of his identity to another person. As with an unrestricted power of attorney, allowing unrestricted use of another’s identity can be extremely dangerous. (Obviously the authority that one individual can delegate to another must be limited by the authority of the delegating individual—we cannot allow an individual to grant authority they do not have, or the security of the entire system would crumble.) Unrestricted use of another’s identity can also make end-to-end auditing much more difficult in many applications. Kerberos allows delegation of a subset of an individual’s authority by allowing them to place authorization restrictions in a capability. The restricted proxy in Kerberos serves this function and is analogous to a restricted power of attorney. In the example above, the client would typically restrict the print server’s right to read only the file that is to be printed using a restricted proxy. When the print server presents the resulting capability to the file server, the file server has all the information needed to ensure that neither the print server nor the client can exceed its authority, either individually or in combination.

In modern networks and business processes, it is common to find situations such as the above. Three-tier applications are another example. Here, the middle tier acts on the client’s behalf for accessing back-end services. Delegation ensures the integrity and validity of the exchange and minimizes the amount of trust that must be placed in any intermediary. The need for delegation grows in significance as applications and services become more interconnected and as those connections become more dynamic. Without delegation, the identity and the rights of the originator, and the validity of a request, become difficult or impossible to determine with any degree of assurance. The alternative is to secure all intermediaries to the level required by the most sensitive application or user that makes use of the intermediary. This is cost-prohibitive on any but a very small scale.

[11] Clifford Neuman, B. May 1993. Proxy-based authorization and accounting for distributed systems, In *Proceedings of the 13th International Conference on Distributed Computing Systems*, Pittsburgh.

93.7 Security Services

Many component security services are required to provide a complete distributed security service. The effectiveness of a distributed security system can be gauged by the component services it provides,[12] the degree to which those components operate together to provide a complete distributed security service, and the efficiency with which it provides those services.

93.7.1 Authentication

An authentication service permits one principal to determine the identity of another principal. The strength of an authentication service is the level of assurance that a principal's claimed identity is genuine. Put another way, the strength depends on the ease with which an attacker may assume the identity of another principal. For example, sending a person's ID and password across a network in the clear provides a very weak authentication, because the information needed to assume the identity of that person is readily available to any eavesdropper. Kerberos provides strong authentication by providing a high level of assurance that a principal's claimed identity is genuine. Kerberos also provides mutual authentication so that the identity of both client and service can be assured.

The reason for authentication is to ensure the identity of each principal prior to their conversing. However, without continuing assurance that their conversation has not been subverted, the utility of authentication alone is questionable. The Kerberos authentication protocol implicitly provides the cryptographic material, or "session keys," needed for establishing a secure channel that continues to protect the principal's conversation after authentication has occurred.

93.7.2 Secure Channels

A secure channel provides integrity and confidentiality services to communicating principals. Kerberos provides these services either directly through the use of Kerberos protocol messages, or indirectly by providing the cryptographic material needed by other protocols or applications to implement their own form of a secure channel.

93.7.3 Integrity

An integrity service protects information against unauthorized modification and provides assurance to the receiver that the information was sent by the proper party. Kerberos provides message integrity through the use of signed message checksums or one-way hashes using a choice of algorithms. Each principal in a Kerberos message exchange separately derives a checksum or hash for the message. That checksum or hash is then protected using a choice of cryptographic algorithms. The session keys needed for integrity protection are a product of the Kerberos authentication process.

Integrity applies not only to a single message, but to a stream of messages. As applied to a stream of messages, integrity also requires the ability to detect replays of messages. Simple confidentiality protection does not necessarily accomplish this. For example, recording and then replaying an encrypted message such as "Credit $100 to account X" several hundred times may achieve an attacker's goal without the need to decrypt or tamper with the message contents. The Kerberos protocol provides the mechanisms necessary to thwart replay attacks for both authentication and data.

[12] In his treatise on distributed systems security, Morrie Gasser categorizes the security services that a distributed system can provide for its users and applications as: secure channels, authentication, confidentiality, integrity, access control, non-repudiation, and availability. Gasser, M. Security in distributed systems, In *Recent Developments in Telecommunications*, North-Holland, Amsterdam, The Netherlands, Elsevier Science Publishers, 1992.

93.7.4 Confidentiality

A confidentiality service protects information against unauthorized disclosure. Kerberos provides message confidentiality by encrypting messages using a choice of encryption algorithms. The session keys needed for confidentiality protection are a product of the Kerberos authentication process. Analysis based on message network addresses and traffic volume may also be used to infer information. An increase in the traffic between two business partners may predict a merger. Kerberos does not provide a defense against traffic analysis. Indeed, most don't since it is a very difficult problem.

93.7.5 Access Control

An access control service protects information from disclosure or modification in an unauthorized manner. Note that access control requires integrity and confidentiality services. Kerberos does not directly provide access control for persistent data, such as disk files. However, the Kerberos protocol provides for the inclusion and protection of authorization information needed by applications and operating systems in making access control decisions.

93.7.6 Authorization

An authorization service provides information that is used to make access control decisions. The secure transport of that authorization information is required in order to ensure that access control decisions are not subverted. Common mechanisms used to represent authorization information include access control lists (ACLs) and capabilities.

An ACL-based system uses access control lists to make access control decisions. An ACL-based system is built on top of other security services, including authentication, and integrity and confidentiality for distribution and management of ACLs. Kerberos does not provide an ACL-based authorization system but does provide all of the underlying services an ACL-based system requires.

Capability-based systems require the encapsulation of authorization information in a tamper-proof package that is bound to an identity. Capability-based authorization is a prerequisite to delegation in a distributed environment. Kerberos provides the facilities necessary for both capability-based authorization and delegation.

93.7.7 Non-Repudiation

Non-repudiation services provide assurance to senders and receivers that an exchange between the two cannot subsequently be repudiated by either. That assurance requires an arbitration authority that both parties agree to; presentation of sufficient and credible proof by the parties to the arbitrator; and evaluation of that proof by the arbitrator in order to settle the dispute. For example, in the case of an electronic funds transfer between two business entities, a court of law would be the arbitrator that adjudicates repudiation-based disputes that arise between the two businesses.

The technological strength of a non-repudiation service depends on the resistance to tampering or falsification of the information offered as proof and the arbitrator's ability to verify the validity of that information. Resistance to tampering or falsification must be sufficient to prevent modification of the proof for as long as a dispute might arise. Although Kerberos offers the basic authentication and integrity services from which a non-repudiation service could be built, the effectiveness of that service will depend on the required strength of the service, and it is dependent on what technologies are incorporated into a Kerberos implementation and the management of the implementation.

The symmetric-key cryptography as used by basic Kerberos implementations is generally not sufficient for non-repudiation, because two parties share a key. Since that key is the basis of any technical proof, either party in possession of that key can forge or alter the proof. If augmented with strict process controls and protection for the KDC, symmetric-key cryptography may be acceptable. However, that process control and protection can be quite expensive. (Note that banks face this issue with the use of PINs, which use symmetric-key cryptography; and the fact that two parties share that key—the consumer and the bank—is rarely an issue, because the bank provides sufficient process controls and protection for management of the PIN.) Kerberos does not offer the arbitration services that are required for the complete implementation of such a service.

93.7.8 Availability

Availability services provide an expected level of performance and availability such as error-free bandwidth. Perhaps the best example of an availability problem is a denial-of-service attack. Consider someone simply disconnecting the cable that connects a network segment to its router. Kerberos does not offer any services to deal with this set of problems. Distributed security systems generally do not offer availability services.

93.8 Functional Overview

The ultimate objective of any Kerberos user is to gain access to application services. The process by which that occurs involves several steps, the last step being the actual authentication between the user and the application service. A key part of that process involves the trusted third party in the Kerberos system, the Kerberos security server (KDC). Although descriptions of that process correctly focus on the interaction between users and the KDC, one of the key design elements of Kerberos is the ability for clients and services to securely interact, with little or no involvement of the KDC.

Kerberos is a trusted third-party, credentials-based authentication system. The KDC acts as the trusted third party for humans and services, or principals that operate on client or server computer systems. Kerberos principals authenticate with one another using Kerberos credentials, or tickets. These tickets are issued to principals by the KDC. A client principal authenticates to a service principal using a ticket. The Kerberos security server is not directly involved in that client–service authentication exchange. The result of an authentication exchange between a client and service is a shared session key that can be used to protect subsequent messages between the client and the service.

93.8.1 Components

The primary components of a Kerberos system are the client and server computer systems on which applications operate, and the Kerberos security server (KDC.) In addition to those physical components, there are a number of additional logical components and services that make up the Kerberos system, such as the authentication service and the principals that make use of Kerberos services.

93.8.1.1 KDC

The keystone of the Kerberos system is the Kerberos security server, generally referred to as the "KDC," or Key Distribution Center. Although the term KDC is not an accurate description of all the services provided, it has stuck. The KDC is the trusted third party in the Kerberos distributed security system. The KDC provides authentication services, as well as key distribution and management functions. There may be multiple KDCs, depending on the level of service and performance that is required. The KDC consists of a set of services and a database that contains information about principals.

93.8.1.2 Principal

The entities to which the KDC provides services are referred to as "principals." Principals share a very high degree of trust with the KDC. They may be human or may represent a service or a machine. Every principal has an identifier that is used by the KDC to uniquely identify a human or service and allow one principal to determine the identity of another during the Kerberos authentication process. Depending on the cryptographic mechanisms used, a principal may also share a secret key with the KDC, thus the high level of trust required between principals and the KDC.

The primary difference between human and service principals results from the available means for storing the password, or key, and the persistence of that key. A person can securely carry a password in his head, whereas services cannot. Services that use shared secrets for authentication require access to a key. Unlike keys that are used by humans—which are typically derived from a password—service keys are typically random bit strings. If unattended operation for services is required, that key must be kept in persistent storage that is accessible to the service. That key storage is referred to as a "key table" and is generally kept in a file on the host computer system on which the service operates. Key tables may contain keys for multiple services, or may be unique to a service. The security of key tables is dependent on the host computer system's security. This is identical to the problem of protecting private keys in public-key or asymmetric-key systems. More secure solutions for protection of key tables require tamper-proof hardware such as a smart card.

The most significant functional difference between a client and a service results from the difference in key persistence. Kerberos clients do not maintain the user's key in any form beyond a very short period of time during the initial authentication process. However, services always have ready access to their key in the key table. The result is that clients generally can only initiate communications, whereas services may either initiate or accept communications (i.e., a service may also act as a client).

93.8.1.3 Ticket

A ticket is part of a cryptographically sealed credential issued by the KDC to a client. A ticket, along with other confidential information, allows a client to prove their identity to a service, without the client and service having any preestablished relationship. A ticket is specific to a client–service pair. That is, a ticket specifies both a client principal and the service principal: the client principal to whom the ticket was issued, and the service principal for which it is intended. A client may reuse tickets. Once a client obtains a ticket for a service, subsequent authentication of the client to the service does not require involvement of the KDC.

93.8.1.4 Realm

The KDC logically consists of a set of services and a database that contains information about principals. In Kerberos that collective is referred to as a "realm," and the authentication service within the KDC is the trusted third party for all principals in the realm. Realms may be defined based on either security requirements in order to separate domains of trust, or as an administrative convenience for grouping principals. Some implementations allow a single KDC to serve multiple realms to reduce the number of physical systems needed. Principals in different realms can interact using "cross-realm" (sometimes referred to as "inter-realm") authentication. Cross-realm authentication generally requires prior agreement between the administrators of the different realms.

93.8.1.5 Principal Identifier

Kerberos defines several principal identifier forms, including a native Kerberos form, as well as an X.500 distinguished-name form. We describe only the native Kerberos name form here. Simple principal identifiers take the form name@REALM. Principal identifiers are case sensitive. By convention, the realm name is the DNS domain name in upper case. For example, hanley@Z.COM refers to the principal named hanley in domain z.com. Principal identifiers may also contain an instance. Instances are typically used only for service principals (discussed later in this chapter).

93.8.2 Authentication

The simplest and most basic form of the Kerberos protocol performs authentication using a shared secret and symmetric-key cryptography: the user and KDC share a secret key, and the service and KDC share a secret key. However, the user and service do not share a secret key. Providing the ability for a user and

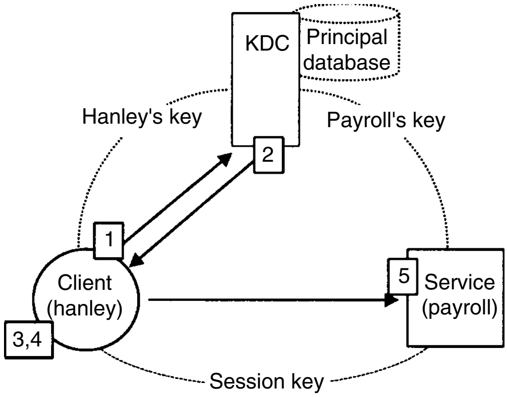

EXHIBIT 93.3 Basic Kerberos authentication.

service to authenticate, and establish a shared secret, where none previously existed, is the fundamental purpose of the Kerberos protocol.

For this basic form of Kerberos authentication to work, users and services must first share a secret key with the KDC. Methods for first establishing that shared secret vary. The steps of the basic authentication process are discussed below and shown in Exhibit 93.3.

1. A user, or more precisely, Kerberos client software on the user's work station acting on behalf of the user, prompts the user for his ID. The client then sends that ID to the KDC as an assertion of the user's identity, along with the name of a service that the client wishes to access (for example, "I'm Hanley and I want access to the payroll service").
2. The authentication service (AS) of the KDC receives that request, constructs a reply, and sends that reply to the client.
   - 2.1. The AS checks to ensure that the requesting client (Hanley) and service (payroll) principals exist in the principal database maintained by the KDC. Assuming they exist, the AS constructs a "service ticket" for the requested service (payroll) and places the user's principal name (Hanley) into that service ticket.
   - 2.2. The AS then generates a random key, referred to as the "session key."
   - 2.3. The AS then places the session key into the service ticket. The service ticket is then encrypted, or "sealed," using the service's key, obtained from the principal database. That service key is a secret key the (payroll) service shares with the KDC. That key is held in the principal database, as well as by the service.
   - 2.4. The AS constructs the client part of the reply and places the same session key (from step 2.2) into the client part of the reply. The client part of the reply is then encrypted using the user's key, obtained from the principal database. That is, the secret key (i.e., password) the user (Hanley) shares with the KDC. That key is held in the principal database, as well as by the user.
3. The client receives the reply from the AS, and prompts the user for his password. That password is then converted to a key, and that key is then used to decrypt, or "unseal," the client part of the reply from the AS (from step 2.4).

   If that decryption succeeds, then the password/key entered by the user is the same as the user's key held by the KDC (i.e., the key used to encrypt the client part of the reply). The decryption process also exposes the session key placed into the reply by the AS (from step 2.4). Note that the client cannot tamper with the service ticket in the reply, because it is encrypted, or "sealed," using the service's key, not the client's key.

   If the decryption does not succeed, then the password the user entered is incorrect, or the real AS did not issue the reply, or the user is not who he claims to be. In any case, the information in the

AS' reply is useless because it cannot be decrypted without the proper password/key, and the process ends.

The following steps assume that the decryption process succeeded. Note that the AS has no knowledge of whether or not the decryption process on the client succeeded.

4. When the client (Hanley) wishes to authenticate to the service (payroll), the client constructs a request to the service. That request contains the service ticket for the payroll service issued by the AS (from step 2.3).
5. The service receives the request from the client, and uses its service key to decrypt the ticket in the request, i.e., the key that is the shared secret between the (payroll) service and the KDC, and that was used to encrypt the service ticket by the AS (from step 2.3).

   If the decryption succeeds, the service's key and the key that the ticket is encrypted in are the same. Because the KDC is the only other entity that knows the service's key, the service knows that the ticket was issued by the KDC, and the information in the ticket can be trusted. Specifically, the client principal name placed into the ticket by the AS (from step 2.1) allows the service to authenticate the client's identity. The decryption process also exposes the session key placed into the service ticket by the AS (from step 2.3).

   If the decryption fails, then the ticket is not valid. It was either not issued by the real AS, or the user has tampered with the ticket. In any case, the ticket is useless because it cannot be decrypted, and the process ends.

At this point, the service (payroll) has proof of the client's identity (Hanley), and both the client and the service share a common key: the session key generated by the AS (from step 2.2), and successfully decrypted by the client (from step 3) and by the service (from step 5). That common session key can then be used for protecting subsequent messages between the client and the service. Note that once the ticket is issued to the client, there is no KDC involvement in the authentication exchange between the client and the service. Also note that the user's password/key is held on the work station, and thus exposed on the work station, only for the period of time required to decrypt the reply from the KDC.

A thief could eavesdrop on the transmission of the reply from the KDC to the client. However, without the user's key, that reply cannot be decrypted. A thief could also eavesdrop on the transmission of the service's ticket. However, without the service's key, that ticket cannot be decrypted. Without knowledge of the user's or service's keys, the attacker is left with encrypted blobs that are of no use. There are other more sophisticated attacks that can be mounted, such as a replay attack, and there are other countermeasures in Kerberos to help thwart those attacks; those attacks and countermeasures are discussed in subsequent sections.

93.8.3 Credentials Caching

The authentication exchange described above allows a client and service to securely authenticate and securely establish a shared secret—the session key—without requiring a preestablished secret between the client and service. While those are useful and necessary functions of any distributed authentication service, it requires that the user obtain a service ticket each time access is required to a service. It also requires that the user enter a password each time a service ticket is obtained in order to decrypt the ticket. This behavior would obviously not be a very efficient use of people's time or network bandwidth.

A simple additional step to cache credentials—that is, the service ticket and session key—would allow the reuse of credentials without having to constantly go back to the AS or requiring user involvement. A "credentials cache" on the client serves this purpose, and all Kerberos implementations provide a credentials cache. Thus, as the user collects service tickets during the day, they can be placed into the credentials cache and reused. This eliminates involvement between the user and the AS when the same service is accessed multiple times. Note that a client requires both a ticket and the ticket's associated session key (a credential) to make use of a ticket. Thus the term "credentials cache," and not "ticket cache."

Kerberos can also limit the usable life of credentials by placing an expiration time into the ticket when the AS constructs the ticket. The ticket expires after that time, and the user must go back to the AS to obtain another ticket. While Kerberos tickets can have virtually any lifetime, the typical lifetime of a Kerberos ticket is the average workday.

93.8.4 Ticket-Granting

Even with credentials caching, interaction between the user and the authentication service (AS) would still be required every time the user wants another ticket. For environments in which a user may access dozens of services during the day, this is unacceptable. One possible solution would be to cache the user's password in order to obtain service tickets without user interaction. However, that exposes the user's password to theft by rogue client software. Note that rogue software could also steal credentials from the credentials cache. However, those credentials will typically expire after a day or less. So, while a thief may have a day's fun with stolen credentials, at least the thief does not get indefinite use of the user's identity. Thus, we can limit the duration of such a compromise to the lifetime of the credentials. The ability to limit a compromise in both space and time is an extremely important attribute of a distributed security system. However, if the user's password is stolen, it is much more difficult to limit such a compromise.

The solution to this problem builds on the three parts that we already have: the authentication service (AS), which can issue tickets for services to clients; the credentials cache on the client that allows reuse of a ticket; and the ability to authenticate a user to a service using an existing credential. Using those components, we can then build a service that issues tickets for other services, much like the AS. However, our new service accepts a ticket issued by the AS, instead of requiring interaction with the user.

Our new service is known as the "ticket-granting service," or TGS. The TGS operates as part of the KDC along with the authentication service (AS) and has access to the same principal database as the AS. We have not dispensed with the AS, but the primary purpose of the AS is now to issue tickets for the TGS. A ticket issued by the AS for the TGS is known as a "ticket-granting ticket," or TGT. Using that ticket-granting ticket (TGT), a client can use the ticket-granting service (TGS) to obtain tickets for other services, or "service tickets." Thus, for example, instead of asking the authentication service (AS) for a ticket for the payroll service, the client first asks the AS for a ticket-granting ticket (TGT) for the ticket-granting service (TGS); then, using that TGT, asks the TGS for a service ticket for the payroll service. Although that introduces an additional exchange between the client and the KDC, it typically need be done only once at the beginning of the workday (see Exhibit 93.4).

By using the AS only once at the beginning of the day to obtain a TGT, and then using that TGT to obtain other service tickets from the TGS, we can make the entire operation invisible to the user and significantly improve the efficiency and security of the process. Thus, the behavior becomes:

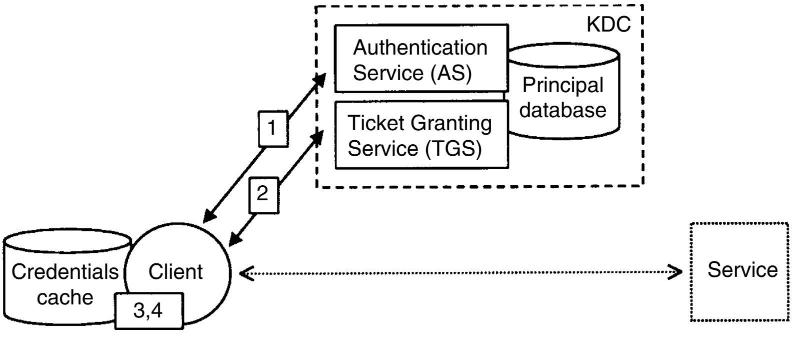

EXHIBIT 93.4 Authentication and ticket-granting services.

1. The first action of the day is to obtain a TGT from the AS as previously described (e.g., providing an ID and password). Only, instead of the user specifying the name of a service, the client automatically requests a ticket for the TGS on behalf of the user.
2. The TGT and session key returned by the AS from the prior step is placed into the credentials cache, along with the TGT's session key.
3. When a service ticket is needed, the client sends a request to the TGS (instead of to the AS). That request includes the TGT and the name of the service for which a ticket is needed. The TGS authenticates the client using the TGT just like any other service and, just like the AS, constructs a service ticket for the requested service and returns that ticket and session key to the client.
4. The service ticket and session key returned from the TGS is placed into the credentials cache for reuse. The client may then contact the service and authenticate to the service using that service ticket.

A TGT is identical to any other service ticket and is simply shorthand for "a ticket for the TGS." The AS and TGS are virtually identical, and both can issue tickets for any other service. The primary difference between the AS and TGS is that the TGS uses a TGT as proof of identity, whereas the AS can be used to issue the first, or "initial" ticket. The proof the AS requires before that initial ticket is issued to a user can involves forms that are not a Kerberos ticket, such as a token card, smart card, public key X.509 certificate, etc. Those various forms of proof are referred to as "preauthentication." Subsequent sections describe the AS and TGS exchanges, the client–service exchanges, and preauthentication in greater detail.

93.9 Functional Description

This section builds on the previous discussions and provides a description of both the Kerberos protocol and the interaction of various components in a Kerberos system. Application of the protocol to solve various distributed security problems is also used to illustrate concepts and applications of the protocol. This description is not definitive or complete, and there are many details that have been omitted for clarity and brevity. For a complete description of the protocol, the official standard, Internet RFC 1510, should be consulted.

93.9.1 Initial Authentication

The Kerberos initial authentication process is the point in time when an individual proves his identity to Kerberos and obtains a ticket-granting ticket (TGT). Typical implementations integrate the initial authentication process with the host OS log-in, providing a single point of authentication for the user each morning. A variety of technologies can be brought to bear at this point, depending on the level of assurance that is needed for an individual's identity. Once initial authentication is completed, the TGT obtained as a result of that initial authentication can be used to obtain service tickets from the ticket-granting service (TGS) for other services. Those service tickets are the basis for client–service authentication, as well as the establishment of the keys needed to subsequently protect client–service interactions.

The simplest form of initial authentication uses an ID and password, as previously described:

1. The client asserts its identity by sending a Kerberos principal name to the KDC. The client sends no proof of its identity at this time. To put it another way, the proof offered by the client at this time is null.
2. The KDC then constructs a TGT and a reply that is encrypted in the user's key. That key is derived from the user's password and is a shared secret between the user and the KDC.
3. The KDC then sends the (encrypted) reply with the TGT back to the client.
4. The client receives the reply from the KDC, then prompts the user for his password and converts the password to a key. That key is then used to decrypt the reply from the KDC.
5. If the reply from the KDC decrypts properly, the user has authenticated. If the reply does not decrypt properly, the password provided by the user is incorrect.

Note that authentication actually occurs on the client, and the KDC has no knowledge of whether or not the authentication was successful. The KDC can infer that the authentication was successful only if the client subsequently uses the TGT that is part of the reply to obtain a service ticket. The drawback of this approach is that anyone can make a request to the KDC asserting any identity, which allows an attacker to collect replies from the KDC, and subsequently mount an offline attack on those replies. The Kerberos preauthentication facility can be used to help thwart those attacks.

93.9.2 Preauthentication

The term "preauthentication" is used to describe an exchange in which the user sends some proof of his identity to the KDC as part of the initial authentication process. If that proof is unacceptable to the KDC, the KDC may demand more, or alternate, preauthentication information from the client, or may summarily reject or ignore the client. In essence, the client must authenticate prior to the KDC issuing a credential to the client; thus the term "preauthentication." The proof of identity used in preauthentication can take many forms and is how most technologies such as smart cards and tokens are integrated into the Kerberos initial authentication process.

What technologies are used depends on the level of assurance required for a user's identity and is typically associated with a user (or a role performed by a user). For example, Kerberos administrators might be required to use two-factor authentication, whereas a simple ID and password would suffice for other users. Implementations vary in the types of preauthentication they support. Preauthentication data may include a digital signature and an X.509 public key certificate; token card data; challenge-response; biometrics information; location information; or a combination of different types of those preauthentication data.

Preauthentication may require several messages between the client and KDC to complete the initial authentication process. For example, the challenge-response exchange used for some token cards may require additional messages for the challenge from the KDC and the response from the client. Only the simplest form of preauthentication is described here. The simplest form of preauthentication uses an ID and password, and an encrypted timestamp:

1. The client prompts the user for his principal ID and password, and converts the password to a key.
2. The client then obtains the current time and encrypts that (along with a random confounder), attaches its principal ID, and sends the request to the KDC.
3. If the KDC can decrypt the timestamp in the request from the client, it has some proof that the user is who he says he is. The KDC may also require that the timestamp be within certain limits.

After this point the process is the same as the simple (non-preauthentication) exchange. Note that this approach affords greater protection by making it more difficult for an attacker to obtain a TGT for other users or otherwise attack a captured TGT.[13] However, an offline attack may still be mounted against replies sent from the KDC to other users that are sniffed off of the network. Thus, good passwords are still as important as ever, and most Kerberos implementations provide facilities for password policy enforcement to minimize the risk of weak passwords.

93.9.3 KDC–Client Exchanges

The exchanges used for initial authentication with the AS and the subsequent exchanges used to obtain service tickets with the TGS, are both built from the same basic mechanism. In this section we also identify the message names that Kerberos uses for the various requests and replies.

1. The client sends an authentication request (AS–REQ) message to the authentication service. In that request, the client specifies that it wants a ticket for the TGS.

[13] Pato, J. December 1992. "Using Pre-Authentication to Avoid Password Guessing Attacks," Open Software Foundation DCE Request for Comments 26.

2. The AS sends a ticket-granting ticket (TGT) back to the client in an AS reply (AS–REP) message. That TGT is simply a service ticket for the TGS. The AS–REP contains both the TGT and the session key required in order for the client to use that TGT.
3. When the client wants a service ticket for another service, it requests a ticket from the TGS by placing the TGT into a TGS request (TGS–REQ) message. The TGS sends a service ticket for the requested service back to the client in a TGS reply (TGS–REP) message. The TGS–REP contains both the service ticket and the session key required for the client to use that service ticket.

Again, a TGT is functionally no different than any other ticket. Nor is the TGS conceptually any different than any other service. The only reason for using a special TGS–REQ message to talk to the TGS is to codify the conventions used by the ticket-granting service and optimize the protocol. However, if you look closely at the AS–REQ and TGS–REQ messages, they are very similar and are sometimes referred to collectively as a KDC request (KDC–REQ) message. The same is true of the AS–REP and TGS–REP messages, which are collectively referred to as a KDC reply (KDC–REP) message.

93.9.4 Initial Tickets

Although the primary purpose of the AS is to issue TGTs, the AS may issue tickets for any service, not just TGTs for the TGS. The only real difference between tickets issued by the AS and tickets issued by the TGS are that tickets obtained from the AS are marked as "initial" tickets; tickets obtained from the TGS (using a TGT) are not marked "initial." Initial tickets can be useful if an application wants to ensure that the user obtained the ticket from the AS (i.e., the client went through initial authentication to obtain the service ticket) and did not obtain the service ticket using a TGT. For example, the change-password service requires that the user obtain an initial ticket for the change-password service. This requires that the user enter his password to obtain a ticket that is marked initial (i.e., a ticket that the change-password service will accept). A ticket for the change-password service obtained from the TGS using a TGT will not be marked initial and will be rejected by the change-password service. This precludes the use of a stolen TGT to change a user's password, or someone using an unlocked work station to change the work station user's password using a cached TGT.

93.9.5 Ticket Construction

Every ticket adheres to the same basic format and contains the same basic information. That information includes the name of the client principal, the name of the service principal, the ticket expiration time, and a variety of other attributes and fields. When a client requests a ticket for a service, the reply from the KDC contains the service ticket, encrypted in the key of that service. Most of the information in the service ticket is also exposed to the client as part of the reply. That information is provided to the client so that the client can ensure that what it received is what the client requested.

The KDC may also provide defaults for various fields in the ticket, which the client did not specify, but which the client may need to know. For example, each ticket has a lifetime; the client may or may not specify the ticket lifetime in a request. If the client does not specify a lifetime, the KDC will provide a default value. The KDC may also enforce maximum values for various fields. For example, if the sitewide maximum ticket lifetime is eight hours, the KDC will not issue a ticket with a lifetime longer than eight hours, regardless of what the client requests. Knowing the lifetime of a ticket is important for a client so that if the ticket is expired, a new ticket can be requested automatically from the TGS without user involvement. For instance, long-running batch jobs.

Most implementations also allow each service to specify a maximum ticket lifetime, and the KDC will limit the lifetime of a ticket issued for a service to the service-defined maximum. Some services, such as the change-password service, typically have maximum ticket lifetimes that are very short (e.g., ten minutes), with the objective being to make those tickets "single use." Most password-change clients also do not cache such tickets, because holding on to them would be of no value.

93.9.6 Client–Service Exchanges

The authentication exchange that occurs between a client and a service is conceptually similar to the client–KDC exchanges. However, the messages used are different to accommodate specific needs of client–service authentication and to eliminate information that is required only for client–KDC exchanges. The messages used for client–service application authentication are collectively referred to as the application (AP) or client–server (CS), messages.

In the following example, we assume that the client already has a service ticket in its credentials cache and, if not, the client will obtain the required service ticket prior to beginning this exchange.

1. The client constructs an application request (AP–REQ) message and sends it to the service. The AP–REQ contains the service ticket as (previously issued by the KDC and stored in the credentials cache as part of a client–TGS exchange). The AP–REQ also contains an authenticator. The authenticator contains various information, including a time-stamp, and may be used by the service to ensure that the AP–REQ is not a replay. The client encrypts the authenticator, and some other information in the AP–REQ, with the session key that is associated with the service ticket (obtained originally from the KDC as part of the TGS–REP).
2. The service receives the AP–REQ and decrypts the ticket in the AP–REQ using its own service key. This exposes the information in the service ticket, including the client's identity, various flags, and the random session key generated by the KDC when the KDC issued the service ticket to the client. After this decryption process is completed, both the client and service are in possession of a common key: the random session key generated by the KDC when the service ticket was originally constructed and issued to the client by the KDC.
3. The session key obtained in the previous step is used to decrypt the authenticator. The authenticator contains information that allows the service to ensure that the AP–REQ message is not a replay. The authenticator may also contain a "subsession" key (see below).
4. If the client requests mutual authentication, the service is obliged to reply to the client with an application reply (AP–REP) message that is encrypted in either the session key from the ticket or a subsession key. The AP–REP allows the client to validate the identity of the service.

Other provisions of the AP–REQ and the AP–REP allow for the establishment of initial sequence numbers for data message sequencing, and the establishment of a new subsession key that is independent of the session key in the service ticket (which was generated by the KDC). Either the client or the service can generate a new subsession key. This allows a fresh session key, unknown to the KDC, to be used for every session between the client and the service.

93.9.6.1 Confidentiality and Integrity

Once the appropriate session keys are established, the Kerberos "safe" (SAFE) messages can be used for integrity protection, and "private" (PRIV) messages can be used for confidentiality protection. Those messages also provide for additional protection using sequence numbers, timestamps, and address restrictions (discussed later in this chapter). Alternatively, the application may choose to use its own form of integrity and confidentiality protection for data. For example, an IPSec (Internet Protocol Security) implementation could use the basic AP–REQ and AP–REP exchange to establish the keys for two end points, where the end points are network stacks or systems, instead of a human and a service.

93.9.7 TGS AP–REQ

Examination of the protocol will show that an AP–REQ is also used in the TGS request (TGS–REQ). The AP–REQ is the client's way of authenticating and securely communicating with a service, and the TGS is simply another service, albeit with special capabilities. The AP–REQ used to authenticate to the TGS contains the TGT (the service ticket for the TGS), just as any AP–REQ for any service. Because the TGS–REQ requires more than just an AP–REQ, the AP–REQ in the TGS–REQ is carried in a preauthentication element of the TGS–REQ.

93.9.8 Replay Protection

Replay protection ensures that an attacker cannot subvert the system by recording and replaying a previous message. As mentioned previously, confidentiality and integrity protection alone do not protect against replay attacks. Kerberos can use timestamps or a form of challenge response, to protect against replay attacks. The type of replay detection that is appropriate depends on whether a datagram-oriented protocol, such as UDP/IP, or a session-oriented protocol, such as TCP/IP, is used. Note that all protocols that provide replay protection will have mechanisms and requirements similar to those described here, regardless of the type of cryptography that is used.

93.9.8.1 Timestamps

Replay protection using timestamps is most suited to datagram- or transaction-oriented protocols and requires loosely synchronized clocks based on a secure time service and the use of a "replay cache" by the receiver. A replay cache is simply a cache of messages previously seen by the receiver, or more likely, a hash of each of those messages. The receiver must check each received message against the replay cache to determine if the message is a replay. Note that the replay cache must be maintained in persistent storage if replay detection is to survive a restart of the service.

Obviously, the replay cache could grow forever unless it is bounded in some manner. Timestamps help to limit the size of the replay cache. By defining a bounded window of time for the acceptance of messages, the replay cache can be limited to messages that are received within that window. A service will summarily reject any message with a timestamp outside of that window, and messages outside that window can be discarded from the cache. Thus, the replay cache must be checked only for messages that fall within that window, and the size of the replay cache can be limited to messages received within that window.

That window of time over which the replay cache must operate is referred to as the acceptable "clock skew." Clock skew represents the maximum difference that is allowable between the clocks of two different systems. If the systems' clocks differ by more than the clock skew, all messages will be rejected. A typical value for clock skew is five minutes. Smaller clock skew values require closer synchronization of system clocks but reduce the overhead of maintaining and checking the replay cache. Larger clock skew values allow looser synchronization of system clocks, but increase the overhead of maintaining and checking the replay cache.

Datagram- or transaction-based applications must deal with duplicate, dropped, and out-of-sequence messages as a normal network occurrence. Thus, well-behaved datagram- or transaction-based applications should already have mechanisms for replay detection within the application, regardless of security considerations. If those applications protect their messages using Kerberos confidentiality or integrity services, there is usually no need to use Kerberos replay protection for the application data. Although Kerberos can provide the necessary replay protection "out of the box" for those applications, the applications should be examined to ensure that the protection provided by Kerberos is not redundant and does not add unnecessary overhead.

93.9.8.2 Challenge-Response

Replay protection using a challenge-response exchange is most suited to session-oriented protocols, such as TCP/IP. The subsession key facility within the Kerberos AP–REQ and AP–REP messages provides a means to effect the challenge-response exchange. Challenge-response eliminates the requirement for clock synchronization between the client and the service, and the need for the service to maintain and check a replay cache. However, challenge-response adds an additional message from the service back to the client. Thus, challenge-response is typically suitable only for session-oriented communications where the cost of the messages can be amortized over an entire session, or where those messages can be piggybacked on the application's normal session-initiation messages. Individual messages within the session must then be protected using sequencing and confidentiality or integrity to ensure that the messages within the session are not subject to replay attacks. Mechanisms similar to what are described here can also be used to minimize the need for clock synchronization between clients and the KDC.

Making use of the subsession key facility within the AP–REQ and AP–REP messages requires mutual authentication. Challenge-response also requires that the service respond with a new random subsession key in the AP–REP for each AP–REQ. In effect, the new random subsession key in the AP–REP generated by the service is the challenge. The client's ability to subsequently decrypt the AP–REP, extract the new subsession key, and protect subsequent messages to the service using that subsession key provide proof that the AP–REQ was not a replay and serves as the client's response to the service's challenge.

Note that the service cannot verify that the client has passed the challenge until the service receives the first data message from the client to the service protected by the subsession key. Thus, the client is technically not authenticated to the service until the first data message from the client is successfully received and decrypted by the service. By the same token, the service is technically not authenticated to the client until the first data message from the service in reply to the client is received and decrypted by the client (the AP–REP from the service could be a replay to the client). Whether that technical issue is a security issue depends on the behavior of the client and server. If the client or service engage in a significant and irreversible act prior to the completion of authentication on both sides, damage could result. Generally however, the worst that can happen is a denial-of-service attack that is difficult to diagnose.

93.9.9 Session Keys

Tickets may be sniffed off the network by an attacker during client–KDC or client–service exchanges. Thus, a ticket alone is insufficient to prove the identity of the client principal name embedded in a ticket or the right of the holder to use that ticket. The session key associated with a ticket provides the additional information necessary for that proof. Every ticket issued by the KDC has a unique session key (unless a client specifically requests otherwise). A Kerberos credential is a ticket and the associated session key. The following sections review the role session keys play in the various exchanges.

93.9.9.1 Authentication Service

During the initial authentication exchange, the client uses the key derived from the user's password to decrypt the reply (the AS–REP message issued by the AS). That reply, as do all KDC replies, contains a ticket (in this case, the TGT returned by the AS). When the client decrypts that reply, the decryption exposes a session key. All requests and replies between the client and the TGS from that point onward are protected using that session key from the AS–REP. Using the session key that results from the initial AS exchange eliminates the need to store the user's key in any form on the work station. That is, once the initial authentication exchange between the client and the AS is completed, subsequent exchanges use the session key returned by that exchange and not the key derived from the user's password. The TGT, as with any ticket, is sealed with the service key of the service for which the ticket is intended, which in this case is the TGS. The client typically places the TGT and the TGT's session key into a credentials cache for future use.

93.9.9.2 Ticket-Granting Service

When the KDC builds a TGS reply (TGS–REP), it first constructs a ticket for the requested service. As part of that construction process, the KDC generates a random session key that is placed into the ticket. The KDC then encrypts that ticket in the service's key (the key it shares with the service.) That ticket is then placed into the reply (TGS–REP) to the client, with the ticket ultimately destined for the service. That same random session key is also placed into the reply destined for the client. The reply is then encrypted with the session key associated with the TGT in the client's request to the TGS (TGS–REQ). When the construction of the reply (TGS–REP) is completed by the KDC, we have: (1) a service ticket containing the session key; (2) that service ticket encrypted in the service's key; (3) a reply containing the same session key; and (4) that reply encrypted in the session key associated with the TGT.

When the reply is received and decrypted by the client—using the TGT's session key—one copy of the ticket's session key, along with other relevant information about the ticket, is exposed to the client.

The other copy of the session key, along with most of the same information exposed to the client, is still sealed in the service ticket. The content of that service ticket is not accessible to the client, because it is encrypted in the service's key (the key the service shares with the KDC), which is not known to the client. That prevents the client from tampering with the information in the ticket. The client typically places the ticket, along with the other ticket information, including the session key for that ticket, into a credentials cache for future use.

93.9.9.3 Client–Service Exchanges

Session keys play the same role in the client–service exchange as they do in the client–KDC exchanges. The authenticator constructed by the client as part of the application request (AP–REQ) message is encrypted using the session key associated with the service ticket. That same session key is accessible to the service when the service decrypts the service ticket using its own service key. That session key from the service ticket is then used to decrypt (and thus validate) the authenticator.

93.9.10 Cross-Real Authentication

A realm typically defines a collective trust, or common security domain. Obviously there are limits to the size of such a domain both in manageability and in the collective and common trust that domain represents. For example, collective or common trust usually drops precipitously at enterprise boundaries, and sometimes at organizational boundaries within an enterprise. However, it is often the case that those various domains, or realms, must still communicate securely.

Between realms, Kerberos provides cross-realm authentication services. Cross-realm authentication allows principals in one realm (e.g., clients) to authenticate with principals in another realm (e.g., services). Conceptually, cross-realm authentication treats each realm in the path between a client and a service as simply another service. The client's realm effectively issues a ticket for the ticket-granting service (TGS) in the service's realm; that ticket is referred to as a cross-realm or inter-realm TGT. For example, a client in realm X accessing a service in realm Y first goes to a KDC in realm X to obtain a cross-realm TGT for realm Y; that TGT is then presented to a KDC in realm Y in order to obtain a service ticket for the end, or "target" service.

Cross-realm authentication requires prior agreement between the administrators of the two realms in order to establish the keys on the respective KDCs. Those keys effectively allow one realm to issue cross-realm TGTs that will be honored by the other realm. As with other services, possession of a ticket does not ensure right of access; access is ultimately determined by the service and not the issuing realm or KDC. The trust established between realms for cross-realm authentication lies in the promise that the realms will not lie about the identity of their respective clients. The ability to issue a cross-realm TGT is not necessarily bilateral; this allows one-way cross-realm authentication, although this feature is rarely used.

The client may collect cross-realm TGTs obtained during cross-realm authentication, just as any other tickets, and hold them in its credential cache for reuse. Once the client obtains the cross-realm TGT for the target realm, the client can request tickets from the target realm's TGS directly, just as the client would request tickets directly from the TGS in its own realm. Once the client obtains the ticket for the target realm's TGS, the client–service authentication process is identical to the client–service authentication process within a single realm. Thus, cross-realm authentication between a client and any service in the other realm requires that the additional cross-realm authentication steps be performed only once. For example, given realms X and Y, where the realm administrators have previously established a cross-realm relationship, a client in realm X that wants to get to a service in realm Y must first obtain a cross-realm TGT from a KDC in realm X for realm Y. That cross-realm TGT may then be used to get a ticket from a KDC in realm Y for a service in realm Y and the KDC in realm X does not participate in the latter step.

Any number of realms can have a direct, or pair-wise, cross-realm relationship, in which case a client goes directly between those realms as described above. Where many realms are involved, direct relationships between every pair of realms can be a significant management overhead for establishing all of the necessary cross-realm keys. For example, with ten realms, a direct relationship between every pair of realms requires that each realm maintain nine pairs of cross-realm keys (a key pair assumes a bilateral relationship), for a total of 90 cross-realm key pairs. Although this is manageable for a relatively small number of realms, such as one might find within an enterprise, it becomes unmanageable for a large number of realms. Note that this is the geometric trust complexity problem discussed earlier.

To reduce the complexity of cross-realm key management, realms may also be arranged in transitive relationships. This reduces the number of direct relationships that must be managed but may require a client to traverse, or transit, intermediate realms in order to get to the realm of the end service. For example, given realms X, Y, and Z, where X–Y has a direct relationship, Y–Z has a direct relationship, but X–Z does not have a direct relationship. In this case, X–Z has a transitive relationship through Y. In order for a client in X to get to a service in Z, the client must transit Y, because X and Z do not have a direct relationship. The client first obtains a cross-realm TGT from realm X to realm Y. That cross-realm TGT is then used to obtain a cross-realm TGT from realm Y to realm Z. The cross-realm process may be extended to as many steps as are necessary for a client to reach the target realm of a service. Each step in that process is identical and results in a cross-realm TGT for a realm that is "closer" to the realm of the service.

Within a collective, realms are typically organized as a tree, or "realm hierarchy," where each realm has a direct relationship with one parent and potentially several children. To get from one realm to another, the client may have to climb up the tree toward the root, and then down the tree to get to the desired service's realm, collecting inter-realm TGTs along the way. The tradeoff between direct and transitive realm structures is the key management overhead required for direct relationships vs. the network overhead required to transit intermediate realms. Both direct and transitive relationships can be used in combination. For example, the majority of realms may be arranged using transitive cross-realm relationships, as in a realm hierarchy. Where performance or trust is an issue for specific realms, those realms can also have direct cross-realm relationships, allowing clients to go directly to the target realm, thereby "short circuiting" the need to transit intermediate realms in the realm hierarchy.

Tickets issued as a result of cross-realm authentication have within them the names of the realms transited by the client within them. The list of transited realms is referred to as the "transited realms list." This allows a service (or any intermediate realm) to ensure that all the realms in the path that participated in cross-realm authentication can be trusted not to lie about the client's identity. However, in general, a realm will either be trusted or not. A trusted realm will be part of a cross-realm collective. Untrusted realms will be excluded from that collective or will not be placed in the path between critical clients and services. If principals or services must avoid the use of a less trusted realm due to the sensitivity of their work, direct relationships can be established between those realms, bypassing those less trusted realms.

93.9.11 Ticket Restrictions

If the client sends a credential—that is, a ticket and the associated session key—to another principal, the recipient's use of the client's identity is limited solely by the ticket's implicit restrictions. The lifetime of a ticket is one obvious implicit restriction that defines the time during which a ticket may be used. Another implicit restriction is the service name in the ticket; that service name is an implicit restriction on the use of the ticket. If the service name in that ticket is the ticket-granting service (TGS), and hence the ticket is a TGT, then the holder may obtain any other tickets. Obviously, handing over your TGT (along with the TGT's session key) to another principal requires a very high level of trust in that principal.

In some cases, the implicit restrictions in a ticket may be sufficient. For example, consider a client that wishes to print a file on a file server using a print server. If the client sufficiently trusts the print server, the client can simply send a credential (ticket and session key) for the file server to the print server. The print server can then use that credential to access the file server in the client's name. The service ticket (for the file server) in that credential only allows the print server to access the file server using the client's identity; it does not allow the print server to access any other services using the client's identity. However, the client must trust the print server sufficiently to allow the print server unrestricted use of the client's identity when accessing the file server. If that trust is not warranted, authorization data can be used to further restrict the print server's use of the client's identity.

In many cases we would like to restrict certain common uses of a credential by another principal without having to first agree on the syntax or semantics of authorization data. There are several common forms of restrictions provided by Kerberos to deal with these cases. (Most if not all of these cases could use authorization data to restrict the ticket's use.) The codification of these restrictions by Kerberos is in large part recognition of common use. These restrictions also allow common constraints on ticket usage that are based on site policies that are enforced by the KDC.

93.9.11.1 Address Restrictions

A ticket's use may be limited to specific network addresses, such as the originating client work station. Those address restrictions may be used to help restrict the use of credentials sent to another principal and can also help to foil the use of stolen credentials. Multihomed systems (systems with more than one network address or interface) require special care to ensure that address restrictions include the appropriate addresses for the system. In some cases it may be appropriate to restrict use to a subset of the addresses or interfaces on the system (e.g., inbound or outbound interfaces on a firewall). In other cases there may be no control over, or any desire to control, which addresses or interfaces are used, such as on a high-performance server with many network interfaces. Address restrictions placed on a TGT are propagated to service tickets obtained with that TGT unless otherwise specified. Address restrictions may also be empty, in which case there are no restrictions on where a ticket may be used from. There are obvious security concerns with empty address restrictions. However, outside of a few uses, the use of address restrictions has fallen out of favor. This is due to the difficulty for clients and intermediaries to determine the addresses that a recipient may need.

Address restrictions provide the ability to restrict the use of credentials to a specific machine when those credentials are sent to an intermediary. It may also be desirable to restrict the intermediary's ability to propagate those credentials to other systems and services. (The term "propagation" used here means propagating the use of a credential; there is nothing that can be done to prohibit physical propagation of the ticket.) Ticket attributes known as "forwardable" and "proxiable" allow restricting the subsequent propagation of credentials by a recipient. Those restrictions are binary; they restrict further propagation of the credential by the recipient, or they do *not* restrict further propagation of the credential by the recipient. Finer-grained control must use restrictions in the authorization data. Sites may choose to limit the KDC's willingness to forward or proxy tickets. Similar indicators known as "forwarded" and "proxy" allow a service to determine if a ticket has been obtained in this manner. Services may modify their behavior based on the setting of those indicators. For example, a file server might choose to allow only read-access to certain files when presented with a ticket that has the proxy indicator set.

93.9.11.2 Proxiable

The proxiable attribute allows the holder of the ticket to ask the ticket-granting service (TGS) to modify the address or lifetime restrictions in the ticket. That results in another ticket with different address or lifetime restrictions. That resulting ticket always has the proxy attribute set. That proxy attribute may be checked by services to determine whether the ticket is from the original client or an intermediary. Proxiable tickets are used to restrict the use of a client's identity to a specific service; a proxiable ticket allows no changes to the ticket other than to the address restrictions. Sending a proxiable ticket to an intermediary allows that intermediary to propagate the ticket to other intermediaries.

For example, a client may provide an intermediary a service ticket for a file server where that ticket has the proxiable attribute set. This allows the intermediary to obtain another proxy or proxiable tickets for the file server and send that ticket to another intermediary, thus allowing other intermediaries access to the file server using the client's identity. Alternatively, the client may obtain a proxy ticket without the proxiable attribute set in the ticket. Lacking the proxiable attribute, that ticket can be used only by intermediaries that satisfy the address restrictions in the ticket. If there are no address restrictions in that ticket, there are effectively no restrictions on which intermediaries may use the ticket. However, what the ticket may be used for is still restricted implicitly by the ticket itself (e.g., the service name in the ticket). Client-specified authorization restrictions may further restrict the use of a credential (see below).

93.9.11.3 Forwardable

The forwardable attribute is similar to the proxiable attribute. The most significant difference is that the TGS will not issue another TGT based on a TGT with only the proxiable attribute set. A forwardable TGT effectively allows the holder (assuming they also have the TGT's session key) unrestricted use of the identity in the TGT: forwardable and forwarded tickets—including other TGTs—can be obtained by anyone holding such a TGT. A TGT that is only proxiable does not allow the holder to obtain another TGT.

A forwardable TGT is typically sent if unrestricted use of the client's identity is desirable. One of the few cases where this is desirable is when a user logs into another computer system using, e.g., telnet. In that case the use is effectively establishing the same identity on another remote system. Although we could require the user to go through an initial authentication process again on that remote system (to obtain a TGT), that would provide little additional security and simply irritate the user. The difference in application between forwardable and proxiable tickets can be subtle, but important. In essence, there are three attributes that determine what requests the TGS will honor based on the ticket presented to it: forwardable, proxiable, and whether or not the ticket is a TGT.

93.9.11.4 Lifetime

A ticket's lifetime is an implied restriction. A proxiable or forwardable ticket's lifetime may be decreased but never increased.

93.9.12 Proxy Services

A proxy service is a service that performs a function on behalf of the client and that uses another end service in order to perform that function on behalf of the client (for example, a client wishing to print files using a print server where the files reside on a file server). The print server acts as a proxy for the client in order to access the files on the file server. The basic form of a proxy provides only implicit restrictions on the use of the client's identity by the intermediate service. This may be sufficient for some clients and services. In the previous example, the client must first obtain a proxy ticket for the print server. That ticket will show the requesting client as the client principal name, and the file server as the service principal name. That proxy ticket may be based on an existing service ticket the client holds for the file service, or it may be obtained directly using a TGT.

1. The client obtains a proxy service ticket for the file server. If the client possesses a ticket for the file server with the proxiable attribute set, that ticket may be used to request a proxy ticket from the TGS. The client sends the file server service ticket in its possession to the TGS, requesting a proxy ticket along with new address restrictions, if any. The TGS returns a service ticket for the file server with new address restrictions. That service ticket will, by default, have the proxiable attribute cleared and will always have the proxy indicator set.

   If the client does not possess a proxiable ticket for the file server, the client must obtain a proxy ticket for the file server using a TGT. That TGT must have the proxiable attribute set. This process is similar to the one described above, only it follows more typical TGS semantics.
2. The client authenticates to the print server using a conventional client–service authentication exchange. The client then sends the proxy credential (ticket and session key) obtained in the previous step to the print server. A variety of means may be used to send those credentials; the Kerberos "credentials" (CREDS) message is intended specifically for this purpose and ensures that the session key associated with the ticket is protected during the transfer of those credentials.
3. The print server uses the file server credential obtained in the previous step to authenticate to the file server, and obtain access to the file server, using the client's identity.

Note that when presented with such a ticket, the file server has no way of knowing that it is not really the client, but the print server, that is requesting access—the client name shown in the ticket is the originating client, not the print server. The file server may infer some information from the fact that the proxy indicator is set in the credential, for example. While useful, this does not provide very granular control and requires that the client must have an fairly high level of trust in the print server. Unless the file server places additional restrictions on access to files based on the setting of the proxy indicator, the print server has full access to any of the client's files. More granular restrictions require the use of client-provided authorization restrictions.

93.9.13 Authorization

Kerberos defines the rules for packaging authorization data elements in tickets and the semantics for placing those elements into tickets. Kerberos does not define the interpretation of those authorization data elements. There are several points in time where authorization information may be provided or embedded into a ticket, ranging from the initial authentication exchange, to the client–service authentication exchange, and several points in between. There are also several possible sources of authorization information, including the client, as well as authorization services that may be a part of, or accessible to, the KDC. Authorization data provided by clients is referred to as restrictions, because the data restricts the authorized use of a client's identity. (Client-provided authorization data obviously should not be used to amplify the client's authorization, or clients could grant themselves any authority.)

Each authorization data element has a type associated with it. Kerberos defines the syntax of the type information, but does not generally define the interpretation of those types. Authorization data element types are application- or service-specific. Kerberos does not otherwise define the contents of the underlying authorization data elements, and KDCs generally do not interpret those elements, but treat them as opaque objects. Interpretation of authorization data elements is generally a function of each service. By convention or agreement, some elements may have meaning to a large number of services, and thus have a common syntax and interpretation for those services. In other cases, authorization data elements will be meaningful only to a single service, and thus the interpretation of those elements can be performed only by that service. Thus, the use of authorization data requires that the client and the end service (i.e., the applications) agree on the syntax and semantics of the authorization data.

In essence, Kerberos simply provides the ability to securely pass authorization data through intermediate services: the data is sealed (encrypted) in the ticket for the end service by the KDC using the end service's key; the data is unsealed (decrypted), by the end service using its service key. Because authorization data is sealed in a ticket, an intermediate service cannot tamper with that information. However, an intermediate service may be able to modify certain implicit restrictions or may add authorization information to the ticket, depending on ticket attributes.

During the initial authentication process between the client and the authentication service (AS), both the KDC and another authorization source may provide authorization data that is to be placed into the TGT. That data is generally propagated to all other tickets obtained using that TGT. That is, when the TGT is used to subsequently obtain a service ticket from the TGS, the authorization data in the TGT is copied to the service ticket as part of the service ticket construction by the TGS. KDC-supplied authorization data typically bounds the client's authorization. The authorization data placed into the TGT typically represents information that is widely applicable, and that would be of interest to most or all services. For example, KDC-supplied authorization data may include all of a client's group memberships.

The ticket-granting service (TGS) provides the same facilities as the AS for placing authorization data into a ticket. The KDC, or another authorization source, may provide authorization data that is to be placed into the service ticket. In addition, the client may also provide additional authorization data (i.e., restrictions) to be placed into the resulting ticket. That authorization data is in addition to the authorization data that is copied from the TGT used to obtain the service ticket. The authorization data placed into a service ticket as part of the TGS exchange typically represents information that is specific to a service; it may also represent information that is specific to a client–service pair.

Finally, the client–service authentication process provides an additional point at which the client can provide authorization data to the service. The client places additional authorization data into the authenticator that is part of the application request (AP–REQ) message. That authorization data represents restrictions that the client wishes to communicate to the service and that is specific to the session. Thus, at the point when a client authenticates to a service, the service has the sum of the authorization data and that is provided as part of the authenticator in the AP–REQ, the service ticket, and the TGT. That authorization data includes all client-specified restrictions.

Note that the AS does not define the ability for clients to specify authorization data (i.e., restrictions) in the authentication service request (AS–REQ) message, and thus place restrictions into the TGT. (The syntax of the AS–REQ allows this, but the semantics of the protocol preclude it, although it could be provided as preauthentication data if needed.) However, there is nothing that prevents a client from subsequently requesting a TGT from the TGS and placing restrictions into the resulting TGT at that time—for example, in the case of obtaining a proxy or forwarded TGT using an existing proxiable or forwardable TGT. The TGT is simply a ticket for the TGS, and there is nothing that precludes the TGS—or any service for that matter—from issuing a ticket for itself.

93.9.14 Capabilities and Delegation

A capability refers to a credential that has certain rights associated with its possession. Those rights may be both implicit in the fields of the associated ticket and explicit, using authorization data encapsulated in the ticket. A capability that has no address restrictions is sometimes referred to as a “bearer proxy,” because it may be used by anyone (client or service) who possesses the credential.[14]

Anyone who possesses a credential with a ticket that is forwardable or proxiable can change or remove address restrictions from the ticket. Anyone who possesses a credential with a ticket that is forwardable or proxiable can also add to the authorization data. That authorization information should never be additive and thus allow the holder to amplify his privileges, thus the use of the term “restrictions” to refer to client-provided authorization information in such tickets. That is, it is acceptable for any holder to further restrict authorization by adding to the authorization data to the ticket; it is not acceptable for any holder to further amplify authorization by adding authorization data to the ticket.

To illustrate the use of capabilities, we again use the example of the client, print server, and file server. The approach illustrated in this example must be used carefully to guard against unwarranted amplification of privileges by intermediate services. For this example, we define authorization data with semantics that are similar to what one might find in an ACL with the triplet:

$$<\text{id}=\text{principal}> <\text{object}=\text{name}> <\text{permissions}=\text{list}>$$

In this triplet, “user” specifies who (a principal identifier); “object” specifies the name of the object to be acted on; and “permissions” specifies the allowable actions by the user on the object. If “id” is empty, then the implied ID is the client name listed in the associated ticket. An authorization data element is thus a triplet as defined above.

Once again, the client wishes to print a file using a print server (the intermediate, or proxy, service), where the file is on a file server (the end service). However, the client does not place a tremendous amount of trust in this print server, and therefore wants to restrict the print server’s access. Specifically, the client wants to restrict the print server to read-access for a single file that is to be printed, and wants to restrict that access to a relatively short period of time. We assume that the client already has a service ticket for the print server and a proxiable service ticket for the file server.

1. The client requests a proxy ticket from the ticket-granting service (TGS) for the file server. In the TGS request, the client provides the proxiable service ticket for the file server that is already in the client’s possession; requests a lifetime of 30 minutes; specifies the proxy attribute; and has cleared

[14] See Reference 11.

the proxiable and forwardable attributes. If the client wishes to restrict the ticket to the use of a specific print server with a known network address, then the address restrictions in the TGS request specify only the print server's network address. The client could leave the address restrictions empty if the network address of the print server was unknown, or enumerate a list of addresses if the print server is multihomed, or if any one of a pool of networked printers might be used to satisfy the request.

The following element is specified in the authorization data field of the TGS request (or more accurately, the authorization data field of the AP–REQ that is part of the TGS request):

<id=> <object=/home/Hanley/thesis.ps> <permissions=read>

The interpretation of that triple is: id is null, and therefore interpreted as the client name in the ticket; object specifies the file "/home/Hanley/thesis.doc"; permissions specify read-access. The interpretation of that authorization is: "The client principal name specified in the ticket cannot perform any operation except to read the file '/home/Hanley/thesis.doc'."

2. The TGS constructs a new ticket and sends the new ticket back to the client. That new ticket is identical to the original proxiable service ticket for the file server (provided in the TGS request), except that the new ticket has the client-specified authorization data sealed within it; the proxy indicator set; the proxiable and forwardable attributes clear; and a lifetime of 30 minutes (the new ticket may also have different address restrictions). The new ticket also has a new session key.
3. The client authenticates to the print server using a client–service authentication exchange.
4. The client sends the proxy credential (ticket and session key) obtained in step 2 to the print server using a credentials (CREDS) message.
5. The print server authenticates to the file server using the proxy credential, obtained from the client in the previous step, using a conventional client–service authentication exchange. The print server is now communicating with the file server under the client's identity.
6. When the file server unseals the ticket received in the previous step, the authorization data in the ticket, placed there by the TGS in step 2, is exposed to the file server.

At this point, the print server and file server have authenticated, with the print server using the identity of the client. The file server has no knowledge of the fact that it is the print server actually acting on the client's behalf. However, the print server—through the authorization data in the ticket—knows that restrictions have been placed on the client's access and, we must assume, will enforce those restrictions. (If we cannot trust the file server to properly enforce access controls on its own files, then it is of questionable use for storing controlled information. We cannot solve that problem with Kerberos.) Also, because the ticket expires after 30 minutes, the print server will no longer be able to access the client's file on the print server after that time.

The conventions that control how authorization data is interpreted, the potential sources of that authorization data, and the ticket attributes used, are extremely important to ensure the integrity of this example. By convention, we have agreed that the presence of any authorization elements (i.e., authorization triples) in the authorization data implicitly restricts actions to those that are explicitly enumerated. While those enumerated elements are necessary, they are not sufficient for a complete and secure solution. If the ticket given to the print service had the proxiable or forwardable attribute set, the print service could go back to the TGS and obtain a new service ticket with different authorization. That would allow the print service to obtain access to any of the client's files. Note that this also implies that care should be exercised to ensure that no unwarranted authorization data is in the proxy ticket, as might be the case if the original (proxiable) ticket from which the proxy ticket was obtained had unwanted authorization information in it. Moreover, we cannot allow those tickets to be proxiable or forwardable, to eliminate the possibility of the print server amplifying its privileges by adding authorization data to a ticket.

Because the authorization data is created by the client, that authorization, while sufficient for the needs of the client, is not sufficient for the needs of the file server. The file server did not participate in the creation of the authorization data, and therefore should treat it as suspect. If the file server based all access control decisions only on the authorization data in the ticket, any client could grant itself any rights to any file. For example, there is nothing to stop the client from requesting a proxy with authorization data that specifies access to another user's files and using the resulting proxy ticket itself. This is one reason why proxiable and forwardable tickets should never be given out freely to untrusted intermediaries if authorization data could be used to amplify privileges.

If the file server blindly believed and obeyed the authorization data in the ticket, a client could use a proxy to gain access to any files. That would obviously not be very secure. Thus, this example is secure only if the file server has additional rules it applies to make authorization decisions, such as ACLs, to limit the authorization of the client. In other words, the file server must first check the authorization specified by its ACLs against the client's identity; with that as the authorized limits for the client, the file server can then determine if the authorization specified in the ticket is within those limits.

Note the temporal difference between capabilities and ACLs. To provide temporary, delegated access to a print server in an ACL-based system, the ACL on the file server would have to be modified temporarily to allow access by the file server. Constantly modifying ACLs could seriously degrade performance. However, there are practical limits to how much authorization data can be placed into a capability. This points to a need for both mechanisms: ACLs for long-lived and relatively static authorization information, and capabilities for more dynamic and context-specific information, as is found in delegation.

In the example above, the capability constructed by the client may be used by anyone who possesses the capability (subject to, for example, address restrictions). The client could also restrict the use of the capability to a specific principal using the "id" field in the authorization triplet. For example, by placing the print server's principal identifier into the ID field. This would require that the print server use two credentials to access the file server: the proxy credential provided by the client (showing the client identity in the ticket, and showing the print server's identity in the authorization data); and a credential for the print server itself (showing the print server's identity), to prove to the file server that the print server is the principal listed in the "id" field of the authorization triplet of the client proxy credential.

Identity-based restrictions, in conjunction with the other usage guidelines discussed above, would eliminate the possibility of the print server giving the client's proxy credential to another service, and of the other service subsequently using the credential to obtain unauthorized access to the client's files. This type of restriction would be preferable to address restrictions and also provides the ability for the file server to audit and control access based on the identity of both the client and the intermediate service. This would allow the file server to, for example, enforce additional restrictions based on the identity of the intermediate server. For example, the file server may choose to prohibit write-access to files by print servers, regardless of what permissions are specified in the authorization data. Another example is to restrict access to certain files by "public" printers, regardless of the file specified in the authorization data.

93.10 Management

Management, performance, and operation are all reflections of one another. A system that makes many demands on the environment will require more resources to meet and maintain those demands, whether those demands be disk storage, CPU, network bandwidth, users, or support personnel. A system that makes many assumptions about the environment will require more resources to meet and maintain those assumptions. Those assumptions are simply implied demands the system places on its environment. Those demands have a direct influence on the cost of achieving an acceptable level of performance and the ability of the implementation to perform its intended function. The greater the demands, the higher the cost of operating and managing the system, or the supporting elements that the system depends on. If those demands are not satisfied, a system's performance and usability will suffer. In the extreme case, performance becomes so poor that the system cannot carry out its intended function.

The cost of satisfying demands and assumptions can rise very rapidly in a distributed environment. The more distributed an environment, the less likely that demands will be satisfied over a given number of systems, and the higher the cost of satisfying those demands. Of special concern is the ability of a system to function effectively in the face of changes in the environment. The more distributed an environment, the higher the probability that changes to the environment will occur over a given unit of time and that intervention will be required to compensate for those changes. Thus, the cost of maintaining assumptions increases.

Those problems are magnified in distributed security. The greater the demands placed on the environment by the security system, the more likely it is that performance problems will result and that the security system will fail to carry out its assigned function. The more assumptions that are made about the environment, the more likely it is that intervention will be required to compensate for those changes. Intervention increases the probability of errors, which can lead to security problems.
